Three different theories of syntactic priming dominate current scientific discourse. One views priming as implicit learning, such that comprehending or producing particular structures (quasi-) permanently strengthens the knowledge of those structures, thereby resulting in repetition. Supporting this view are the observations that priming can be notably long-lived (surviving the comprehension and production of at least ten intervening neutral trials), is independent of explicit memory, and is evident in patients with anterograde amnesia. Another views priming as reflecting recent shorter-term activation of knowledge structures representing syntax. Supporting this is the observation that priming can be short-lived, especially when meaningful words are repeated from prime to target sentences. A third view is that priming is a force to coordinate knowledge structures among interlocutors in order to promote communicative success. Supporting this is the finding that priming is sensitive to conversational variables (such as the linguistic capabilities of the participants or whether participants are speakers, hearers, or side participants).

Earlier, syntactic priming was described as ill-fitting with respect to Garrett's framework. The reason is that priming operates similarly at both functional and positional processing. For example, the selection of an active rather than a passive sentence form – a sentence choice involving different assignments of grammatical functions – is influenced by priming in the same way as the selection of 'on the table is a book' versus 'the book is on the table' – a function-independent structure choice. Furthermore, to date, no aspect of priming has been revealed to dissociate along functional–positional lines (unlike accessibility effects, as noted earlier). Thus, though priming might affect the two separate processing stages identically, a more parsimonious proposal might be that the two stages should be collapsed into one.

The Separation of Words and Syntax

An area of active controversy in sentence production concerns the relationship between lexical and syntactic knowledge. At one extreme of a theoretical continuum, lexical knowledge could ground syntactic knowledge, such that the structure of a sentence is organized around the structures permitted by a particular verb, for example. These are termed lexically based theories. At the other extreme, lexical knowledge could be separate from syntactic knowledge, such that syntactic structures are constructed independently to obey communicative and grammatical constraints, and then words are slotted into those structures. These are termed frame-based theories. Between these are closed-class immanence accounts, whereby some words – closed-class or function words in particular, like 'the' and 'to' and 'by' – ground syntactic knowledge, with other words 'slotted in' as in the independent syntactic account.

Evidence from syntactic priming can be taken to support either extreme. Frame-based theories are supported by the fact that syntactic priming is observed even when no words are repeated between prime and target. Lexically based theories are supported by the fact that repeated words boost priming. Closed-class immanence accounts are supported especially by neuropsychological evidence showing that with breakdown of syntactic knowledge, speakers' use of function words is especially compromised.

From the Lab to the Wild

A current trend in sentence production work since the migration to the lab is toward evaluating issues of relevance to naturally produced sentences.

Corpora

The analysis of collections of natural speech, or language corpora, has a long tradition in sentence production research, with its current incarnation beginning with the publication of the famous Brown corpus in 1967. Ready access to greater computational power has allowed more-recent corpus work to take a considerable leap. Also, powerful statistical techniques such as mixed-effects modeling have allowed corpus researchers to isolate the influence of specific theoretically interesting factors while taking into account confounded uninteresting factors.

The Linguistic Data Consortium at the University of Pennsylvania is a useful source of corpus data.

Nonverbal Devices

Because of its laboratory tradition (and perhaps because of the emphasis on reading in sentence comprehension research), most investigations of sentence production have focused on issues relevant to 'idealized' utterances – sentences with an uninterrupted delivery characteristic of a prepared speech or words on a page. However, natural language is rife with disfluencies – violations of idealized delivery – including fillers like 'uh' and 'um,' backtracking, self-interruptions, and so forth. The lore was that such violations are nuisance factors, to be avoided or ignored. Recent work has challenged this assumption, instead identifying the performance factors that underlie disfluency. These performance factors seem to be metalinguistic, largely reflecting the state of mind of the speaker (e.g., an 'uh' and 'um' indicate that the speaker is having difficulty thinking of the material).

Gesture also sometimes conveys metalinguistic information. Some gesture simply accompanies the rhythm of a spoken sentence (what are sometimes called beat gestures). Other gesture conveys physical properties of the matter under discussion (e.g., 'The fish I caught was THAT big!'). Yet other gesture conveys information redundant with that in the speech signal, for example, the path along which an object is traveling. With the trend toward more naturalistic research, investigations of gesture are becoming more prominent.

Spoken sentence production has one other critical nonverbal property: because it is presented in a perceptually graded medium (sound), some of the acoustic properties of a sentence can vary independent of the lexical and syntactic properties (a situation that holds for signed languages as well). The higher-order structure of such acoustic properties is termed the prosody (e.g., rhythm and stress) of a sentence. Research suggests that these two levels of higher-order structure, syntactic and prosodic, are related but independent. Prosodic structure gets some of its characteristics from syntactic structure, but it is sensitive to its own pressures (including the facts that it must respect other acoustic properties of sentences that syntactic structure does not and that it represents a lower dimensionality of structure, without recursive properties).

Communicating Discourse Properties

Though sentences are the basic units of certain aspects of communication, they rarely occur in isolation. Rather, sentences are typically parts of discourses such as a story or conversation. Critically, devices within sentences help them cohere into discourses. This is sometimes termed the information structure of a sentence, referring to the linguistic devices that help convey the foreground and background status of referents in sentences. A systematic and universal example of a discourse device in sentence production is given–new ordering, whereby speakers tend to produce already described (given) information before newly introduced (new) information; accordingly, addressees can take early mention to indicate that they should already know a referent and later mention to indicate that they should add a referent to their discourse models. Note that such information–structure effects bear a tight relationship to the above-described accessibility effects. Indeed, it is reasonable to suppose that at least given–new ordering could emerge directly from accessibility if given items are more accessible than new.

The Neuroscience of Sentence Production

Thus far, this article has included little on the neuroscience of sentence production. Regarding traditional neuropsychology, this is because the range of work that has been done is extensive and detailed and involves its own set of phenomena and debates. A useful recent review is included in the recommended readings. An especially commendable characteristic of the primary literature on the neuropsychology of sentence production is that it has made very close contact with the core theories of normal sentence production outlined here.

Only a handful of studies have used techniques for assessing online neurological functioning (such as fMRI, PET, or EEG) to better understand mechanisms of sentence production. One major reason for this gap is (again) methodological: most techniques for assessing ongoing neural functioning are disrupted by head motion. It is difficult to investigate sentence production unless speakers actually produce sentences, and for spoken production, this requires the movement of the head and jaw. These challenges have begun to be overcome, however, and the cognitive neuroscience of sentence production promises to be an exciting avenue of research in the future.

Currently, debates in the cognitive neuroscience of sentence production have largely concerned the precise localization of general sentence production abilities. At this point, it is clear that brain regions within Brodmann areas 44 and 45 and adjacent regions are implicated in processes that combine words into grammatical sentences, as opposed to processes that just list words or simpler structures. Going forward, cognitive neuroscience investigations would (like

the traditional neuropsychological literature) gain by making greater contact with the rich and well-established range of theories on normal sentence production.

Serotonin (5-Hydroxtryptamine; 5-HT): Neurotransmission and Neuromodulation

A G Ramage, University College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Transmission

In this review the nature of 5-hydroxytryptamine (5-HT) transmission will be discussed with particular reference to the control of the cardiovascular system, micronutrition, the gut, and airways (autonomic nervous system) which most reviews fail to cover, concentrating on mood, cognition, perception, sleep, appetite, sex, and thermoregulation, to name but a few! There is direct evidence that 5-HT neurotransmission is involved in the central regulation of autonomic function as autonomic reflexes can be accurately measured and the underlying neuronal pathways have been fairly well delineated. Considering the relatively small number of 5-HT-containing neurons that are found in the brain, it is surprising that 5-HT is involved in so many functions; the total number of neurons in the mammalian brain is in the billions whereas the number of 5-HT-containing neurons is in the thousands. The majority of these 5-HT-containing neurons are located in the brain stem in the raphe nuclei, which are mainly located along the midline. These clusters of 5-HT-containing neurons have been labeled B1–B9. They send dense and divergent projections to all regions of the brain, as might be expected by their involvement in so many functions. Although some of these projections form classical synapses, many do not, indicating they may contribute to paracrine transmission, otherwise known as volume transmission (VT). VT would allow transmitter (information) to reach a variety of targets over a wide area, and thus it is more likely that 5-HT-containing neurons are involved in the modulation of a series of processes, such as rhythm generation. It should be noted that VT can also involve communication with glial cells. When 5-HT-containing neurons form classical synapses with their target neurons, which are sometimes referred to as 'private synapses,' the transmitter has only a very short distance to diffuse within such synapses, and so its action is rapid. Such fast transmission is referred to as 'wiring transmission' (WT). VT differs in that it can allow neuronal interaction via the transmitter and additional substances in the extracellular space. The ability of 5-HT to be involved in VT may explain the involvement of 5-HT neurons in such diverse functions. Data in support of this idea, that VT is occurring in a particular system, is the extrasynaptic localization of transmitter uptake transporters. In addition, the large number of receptor subtypes that 5-HT can interact with, which can have opposing actions, gives a vast repertoire of possible responses. For VT, the topographical organization of these different receptor subtypes would be important.

More recently, retrograde neural transmission has been demonstrated; however, whether this applies to 5-HT remains to be determined as presumably 5-HT-containing vesicles would be required in the postsynaptic specialization. The question arises as to whether 5-HT is the only transmitter released by 5-HT-containing neurons. In this respect, the term '5-hydroxytryptaminergic or serotoninergic' is often probably inappropriately used to indicate that these effects are mediated by such neurons using that one named transmitter. This is known as 'Dale's principle.' There is, however, much evidence that 5-HT-containing neurons release more than one transmitter and that cotransmission may be considered the norm. Normally cotransmission means the release of a peptide together with the main transmitter, which is usually associated with higher frequencies of neuronal firing. It is interesting to note that for 5-HT, there is also good evidence that glutamate may be co-released. In this respect, it has been suggested that where 5-HT-containing neurons form conventional synapses, that is, are involved in WT, glutamate only is released from these synapses, and at unconventional synapses (VT), 5-HT is released. This would in a sense be a return to Dale's principle in that each terminal (synapse) is releasing only one type of transmitter, although overall the neuron will release more than one type of transmitter depending on the synapse.

The Need for Multiple Receptors

The affinity of 5-HT for the different 5-HT receptor subtypes varies. For instance, the affinity that 5-HT has for 5-HT_1 receptor subtypes is higher than for most other subtypes, with 5-HT having the lowest affinity for the ligand-gated ion channel receptor, the 5-HT_3 receptor. This different affinity enables the target neuron or neurons to respond differentially to different amounts of 5-HT released, with lower concentrations favoring 5-HT_1 receptor activation. In addition, receptor desensitization rates vary; thus a slow and regular firing rate, a supposed characteristic of 5-HT-containing neurons, will mainly recruit 5-HT_1 and 5-HT_2 receptors. However, high firing rates would recruit 5-HT_3 and 5-HT_4 receptors.

All these receptors may undergo cycles of desensitization and recovery as firing patterns change. Thus changes in firing patterns would activate different receptors and in turn initiate temporal changes in the responsivity of the target neurons and so on to the next coding sequence. In addition, the fact that 5-HT receptors use a large repertoire of second messengers enables 5-HT neurons to have a large capacity to influence cellular events modulated by these second messengers. Thus it would be possible for neurons to have a 'memory' of the normal inputs they receive from 5-HT terminals. Overall, there are multiple ways that central 5-HT-containing neurons can modify transmission in other neurons. It should also be noted that 5-HT neurons can modulate their output of transmitter by using dendritic and somatodendritic autoreceptors.

Evidence that 5-HT Transmission Is Involved in Physiological Processes with Reference to Central Control of the Autonomic Nervous System

Central Cardiovascular Regulation

Brain stem 5-HT pathways are known to play important roles in cardiovascular regulation, although the precise role of each of the identified 5-HT receptor subtypes in this process remains to be determined. The main receptor subtypes that are known to be in this pathway are 5-HT_{1A}, 5-HT_3, and 5-HT_7. This has been determined using selective 5-HT receptor antagonists to interfere with defined reflex pathways, that is, inputs, which, when activated, give a well defined and characteristic output. In addition, studies depleting 5-HT have been carried out although it is very hard to know if all the 'functional' 5-HT has been removed in such studies. Nevertheless, data indicate that in rats with around only 6% of their total brain stem 5-HT, blood pressure is elevated and baroreceptor gain is attenuated. On the other hand, there is, at present, no evidence that 5-HT receptor antagonists can increase resting blood pressure in rats, suggesting that background tone in the resting condition is not mediated by 5-HT-containing neurons. In this respect, it has been suggested that 5-HT_7 receptors are involved in normalizing blood pressure after it has been destabilized by sensory input. This may have implications in cardiovascular changes induced by stress. The main types of receptors that have been identified in controlling sympathetic drive and thus the central maintenance of blood pressure are 5-HT_{1A} (sympathoinhibitory) and 5-HT_2 (sympathoexcitatory). Data suggest that it is the A subtype of the 5-HT_2 receptor that is primarily involved. However, blockade of either of these receptor subtypes has little effect on resting blood pressure. (It is interesting to note that it is these receptors which are also believed to be responsible for the hallucinogenic effects of LSD and related compounds.) It is somewhat surprising that 5-HT_{2A} receptor antagonists do not lower blood pressure, as activation of these receptors causes large central increases in sympathetic drive. However, this may be a problem with selectivity of the 5-HT_2 receptor antagonists used. Long-term block of 5-HT_2 receptors does prevent deoxycorticosterone acetate-salt hypertension, which probably reflects the importance of central 5-HT-containing neurons in the release of vasopressin (antidiuretic hormone). The release of vasopressin, though, involves the activation of 5-HT_{2A} receptors on a central angiotensinergic pathway. Overall, this implicates central 5-HT pathways in the control of blood volume, and in this respect, one of the characteristic unwanted effects of selective serotonin reuptake inhibitors is dilutional hyponatremia due to the release of vasopressin.

It is the role of central 5-HT neurotransmission in the control of vagal tone to the heart rather than sympathetic tone to the blood vessels that has been more thoroughly elucidated. The archetypical 5-HT_{1A} receptor agonist 8-OH-DPAT was observed to cause large increases in vagal drive to the heart. Vagal tone to the heart can also be increased by activation of a number of cardiovascular reflexes (cardiopulmonary and baroreceptor reflexes and the chemoreflex), and the afferents for these reflexes run in the IXth and Xth (vagus) cranial nerves and terminate along with other visceral afferents (e.g., gut) in the nucleus tractus solitarius (NTS). Of these reflexes, the cardiopulmonary has been identified in all species tested as involving 5-HT_{1A} receptor-mediated transmission. Those sensory nerve endings located in the pulmonary circulation and in the heart and coronary vessels have 5-HT_3 receptors located on them. The sites at which 5-HT transmission can modulate these reflexes in the central nervous system (CNS) are the NTS, the dorsal vagal motor nucleus, and the nucleus ambiguus. These latter two nuclei contain vagal (parasympathetic) preganglionic neurons. In the former, the neurons have unmyelinated axons mainly innervating parasympathetic ganglia (myenteric plexus) in the gut, while the latter have myelinated axons and mainly innervate parasympathetic ganglia in the heart and airways. Their activation could cause the heart to stop or cause severe bronchoconstriction. Central application of the archetypical 5-HT_{1A} receptor antagonist WAY-100635 attenuates the cardiopulmonary reflex vagal bradycardia, and this is believed to occur at the level of the nucleus ambiguus. As 5-HT_{1A} receptors are

usually inhibitory, this excitatory action is probably one of disinhibition (see Figure 1). It has thus been suggested that when NTS neurons activate cardiac vagal preganglionics in the ambiguus, this causes the release of 5-HT, which activates a 5-HT_{1A} receptor inhibiting a tonically active γ-aminobutyric acid (GABA)-ergic interneuron.

More recently, a 5-HT_7 receptor-mediated pathway has been shown to play a global role in the control of vagal tone by all these reflexes. 5-HT_7 receptors differ from 5-HT_{1A} receptors in that they are excitatory, increasing the levels of cyclic adenosine monophosphate. The site at which these receptors act is believed to be within the NTS as 5-HT_7 receptor blockade affects most of the components of these reflexes. It should be noted that there is overlap in the pharmacology of 5-HT_7 and 5-HT_{1A} receptors. In addition, at the level of the NTS, 5-HT_3 receptors are also involved in the vagal afferent excitation of NTS neurons. They do this indirectly by causing the release of glutamate, which has also been identified as a crucial transmitter in these reflex pathways. It is interesting to note that in dealing with the observations that blockade of 5-HT_7 receptors or glutamate receptors abolishes the baroreceptor reflex, the question arises as to why both transmitters are seemingly of equal importance. Furthermore, how 5-HT_3 receptors fit into such a system remains unclear. The importance of 5-HT_3 receptors in the control of these reflex pathways, although seemingly essential for transmission within the NTS, is at present not clear. It is thought that 5-HT_3 receptors may be located on glial cells, causing the release of glutamate from glial cells themselves. However, it is surprising that after vagotomy, there is considerable reduction in 5-HT_3 receptor density within the NTS, indicating that 5-HT_3 receptors are mainly located at the terminals of vagal afferents; see Figure 2 for a proposed functional 5-HT pathway within the NTS.

Thus 5-HT transmission plays an important role in cardiovascular afferent integration and in controlling vagal efferent output to the heart. Although 5-HT receptor activation can affect sympathetic outflow

Figure 1 A diagrammatic representation of involvement of pathways containing 5-hydroxytryptamine (5-HT) and receptors in the control of the activity of cardiac and bronchoconstrictor (airway) vagal preganglionic neurons. The 5-HT-containing neurons are in green whereas glutamate-containing neurons are in yellow. The vagal preganglionic neurons can be reflexly activated via the nucleus tractus solitarius (NTS) by the cardiopulmonary afferents that run in the vagus (see Figure 2 for fuller details of the role of 5-HT_3, 5-HT_7, glutamate, and glial cells in activating NTS neurons). It is proposed that the NTS neurons activate (1) a 5-HT-containing and (2) a glutamatergic pathway. The 5-HT pathway inhibits the γ-aminobutyric acid (GABA)-mediated (blue) 'brake,' allowing the glutamatergic pathway to fully excite the preganglionic vagal neurons, resulting in a bradycardia or bronchoconstriction. It should be noted that the 5-HT_{1A} receptors are located presynaptically, not postsynaptically. In addition, the diagram shows a 5-HT-containing pathway directly innervating vagal preganglionic neurons, which activates 5-HT_{2A} receptors to cause excitation. This pathway is not believed to be involved in the reflex activation of vagal preganglionic neurons; however, it is speculated that the putative 5-HT_{1A} receptors that mediate inhibition of vagal preganglionic neuronal activity could be located on the nerve terminals of this pathway and as such would function as autoreceptors. It should be noted that these inhibitory 5-HT_{1A} receptors could also be located on the terminals of the 5-HT-containing pathway, which inhibits the putative GABAergic brake. This could apply to all bronchial and bladder vagal preganglionic neurons in which 5-HT_{1A}-mediated transmission has been identified. NMDA, *N*-methyl-D-aspartate. Reproduced from Wang Y and Ramage AG (2001) The role of central 5-HT_{1A} receptors in the control of B-fibre cardiac and bronchoconstrictor vagal preganglionic neurons in anaesthetized cats. *Journal of Physiology* 536: 753–767, with permission from Blackwell publishing.

Figure 2 A diagrammatic representation of the interaction of vagal sensory afferents, involved in the cardiopulmonary reflex, and a 5-HT-containing projection from the raphe on a nucleus tractus solitarius (NTS) neuron. It is proposed that the vagal afferent can contain either 5-HT (green) or glutamate (GLU; yellow). It should be indicated that there is no reason why both transmitters cannot be contained in one afferent fiber. Further, these vagal afferent projections could just release either 5-HT or glutamate. However, for the present it is considered that they release both. In this respect, the 5-HT-containing afferents make apposition to the glial cell (the transmission here could be volume transmission (VT) or wiring transmission (WT); intuitively, VT is preferred). The released 5-HT activates 5-HT_3 receptors, which cause the release of glutamate from the glial cell and thus excitation of the NTS neuron via the activation of *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors. The other afferent releases glutamate directly to activate the NTS neuron. It is proposed that the 5-HT-containing raphe projection controls the 'gain' of this system via activation of 5-HT_3 receptors on the sensory afferent input and/or glial cell and 5-HT_7 receptors on the NTS neuron (this again could be a mixture of WT and VT). It should be noted that 5-HT terminal autoreceptors would be expected to be found in this system. This proposed system could apply to other afferent processing involving 5-HT.

to blood vessels, a role for 5-HT transmission in sympathetic (blood pressure) control is unclear, but 5-HT does seem to play a role in the regulation of blood volume by the CNS.

Airways

The predominant drive to airway smooth muscle is again the vagus, and again data indicate that 5-HT neurotransmission operating through 5-HT_{1A} and probably 5-HT_7 receptors is important for their regulation, increasing vagal drive. These bronchoconstrictor preganglionic neurons have a respiratory modulation effect opposite to that of cardiac neurons' being excited on inspiration. So the effects of 5-HT are unlikely to be due to an action on respiratory drive. Sadly, very little experimentation has been carried out on such neurons despite their ability to close down the airways.

Micturition – The Bladder

Storage and elimination of urine are performed by the bladder and urethra. This involves the sympathetic nervous system, which is considered important for storage, that is, increasing the compliance of the bladder, and the parasympathetic, which causes contraction of the bladder and thus voiding. The somatic nervous system is important in the control of the external urethral sphincter for the control of continence. The CNS seems to control micturition at two levels, one in the midbrain and the other at the sacral level of the spinal cord, where the preganglionic vagal neurons innervating the bladder are found. It has long been thought that 5-HT neurotransmission is inhibitory to micturition. As central regulation of micturition is very complex, it is not surprising that the majority of 5-HT receptors have been implicated; in order of known importance, they are: 5-HT_{1A}, 5-HT_7, 5-$HT_{2A/C}$, 5-HT_3, 5-HT_4, and 5-HT_{5A}. Again, what is surprising is that both 5-HT_{1A} and 5-HT_7 receptor antagonists inhibit micturition, indicating, as above, that although both have opposite effects on adenylyl cyclase, both play an excitatory role in this process, implying that 5-HT-containing pathways can be considered excitatory rather than inhibitory. The 5-HT pathway utilizing 5-HT_7 receptors operates only at the level of the brain stem whereas the 5-HT_{1A} pathway operates at both the brain stem and the sacral spinal cord regions involved in micturition.

A pathway mainly operating through 5-HT_{2C} receptors has also been strongly implicated in the control of micturition, and this pathway is proposed to be inhibitory. As this is an excitatory receptor, again disinhibition has been proposed for these actions, that is, activation of GABAergic interneurons. Indeed, administering selective 5-HT_{2C} receptor agonists does cause the inhibition of micturition, and this occurs at both brain stem and spinal cord levels. Nevertheless, the selective 5-HT_{2C} receptor antagonist SB 242084 did not affect the micturition reflex, indicating that these receptors have no physiological role. However, preliminary experiments suggest that there may be an excitatory role for 5-HT_{2A} receptors.

Recently the discovery of a high density of 5-HT_{5A} receptors in Onuf's nucleus, the site of somatic motor neurons controlling the external urethral sphincter, implies a role for 5-HT transmission in the control of this nucleus, which is also important for fecal continence.

Thus, the above data would suggest that depletion of brain 5-HT or destruction of 5-HT neurons would interfere with micturition. This has not been observed so far, although destruction of 5-HT neurons and terminals in the spinal cord by around 75% increased micturition volume, favoring an excitatory action of 5-HT.

Another question that arises from the above observations is, where are the 5-HT-containing neurons located that are involved in these actions? Further, do these neurons send axons all the way down to the sacral spinal cord? In the brain stem/pons area, the major structures involved in the control of micturition are the pontine micturition center, periaqueductal grey, and locus coeruleus. In this area of the brain is also located the dorsal raphe nucleus. This nucleus has very large numbers of 5-HT-containing neurons, which mainly project rostrally to the cortex. It is possible that the 5-HT-containing terminals, which presumably innervate these micturition areas, originate from this nucleus, probably operating by activating 5-HT_7 receptors to initiate micturition and/or switch from filling to voiding, that is, acting as a 'flip-flop switch.' Once more, 5-HT_{1A} receptors, as for cardiac vagal neurons, appear to switch off a tonic GABAergic input, a 'brake,' in the pontine micturition center so these neurons can then activate bladder parasympathetic preganglionic neurons to cause contraction of the bladder and voiding. This system could also act at the level of parasympathetic neurons in sacral spinal cord. However, the site these sacral 5-HT terminals come from remains to be determined. Yet again the role of 5-HT neurotransmission in controlling the sympathetic and sensory afferent side of this system remains to be fully determined.

Gut

5-HT is an important neurotransmitter and paracrine signaling molecule in the gut and is released from enterochromaffin cells by local stimulation of the intestinal mucosa. The released 5-HT activates 5-HT_3 and 5-HT_4 receptors on sensory afferents, initiating the peristaltic reflex. In this respect, treatment with a 5-HT_3 receptor antagonist slows down transit time through the gut. Another use of these antagonists is the treatment of vomiting and nausea. This action is believed to occur at two levels, at the level of the sensory nerves in the gut and in the area postrema (chemical triggers zone), sometimes referred to as the vomiting center and one of the circumventricular organs (allowing factors to 'circumvent' the blood–brain barrier). It also projects to the NTS, which is found just below it on the floor of the fourth ventricle. The area also receives vagal afferents and is rich in 5-HT_3 receptors, which again are mainly on vagal afferent nerve endings, as in the NTS (see above). The data suggest that these vagal afferents again release 5-HT; whether directly or indirectly remains to be determined.

Overview

The above data indicate that 5-HT neuronal transmission plays a vital role in the central control of the autonomic nervous system. How this 5-HT innervation integrates between the use of volume transmission and so-called tight private synapses to control these processes remains to be elucidated. In addition, the relationship between the different types of receptors involved also remains to be determined, and the site from which this 5-HT innervation arises is still unknown.

Serotonin (5-Hydroxytryptamine; 5-HT): Receptors

T P Blackburn, Helicon Therapeutics Inc., Farmingdale, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

During the past 50 years, since its discovery in 1948, studies of 5-hydroxytryptamine (5-HT; serotonin) have provided considerable insight into the metabolism and physiological functions of this monoaminergic neurotransmitter in the peripheral and central nervous system (CNS). Considerable interest in the biosynthesis, metabolism, and receptor pharmacology of 5-HT (Figure 1) has elevated this simple indolealkylamine into one of the most researched neurotransmitters of the twentieth century. The synthesis of 5-HT begins with the essential amino acid tryptophan, which can be found in foods such as bananas, turkey, and milk. The enzyme tryptophan hydroxylase hydroxylates tryptophan's benzene ring, to form 5-hydroxytryptophan. Aromatic amino acid decarboxylase then decarboxylates 5-hydroxytryptophan to produce 5-HT. 5-HT is formed in nerve terminals, where it is held in storage granules; when nerve impulses release 5-HT into the synaptic cleft, it acts on the postsynaptic neuron to affect the process of neurotransmission across the synapse. Released 5-HT is inactivated primarily by an active serotonin reuptake transporter (SERT) process that moves 5-HT back into the neuron. Once inside the 5-HT neuron, the neurotransmitter is either repackaged into storage granules or degraded metabolically by monoamine oxidase (MAO). Pre- and postsynaptic 5-HT receptors exist on the 5-HT nerve terminals and cell bodies. Activation of these receptors leads to a disruption in the synthesis and release of serotonin. The role of the presynaptic autoreceptor is to modulate the concentration of serotonin in the synaptic cleft, thereby reducing further release and synthesis of 5-HT (see the sections 'The 5-$HT_{1A(Gi/Go)}$ receptor' and 'The 5-$HT_{1B(Gi/Go)}$ receptor').

It is probable that early work on the synthesis, neurochemistry, and distribution of 5-HT stimulated the expectation that 5-HT might be important in anxiety, depression, and schizophrenia. It is quite remarkable, and a far cry from those early days, that the total sales of drugs modulating central and peripheral 5-HT activity exceeded $20 billion (US) in 2006. This is undoubtedly due to an increasing awareness of the 5-HT receptor subtypes associated with the multitude of disorders treated by drugs modulating 5-HT function; migraine, chemotherapy-induced emesis, depression, anxiety, schizophrenia, and irritable bowel syndrome are examples of such disorders. The promise of further therapeutic opportunities emerging awaits the development of more selective agents (combination agents) and the possibility of discovery of further novel 5-HT receptor subtypes.

Evidence for Multiple Serotonin Receptor Genes

The classification and nomenclature of 5-HT receptors in the past 10 years has emerged from criteria established by the International Union of Basic and Clinical Pharmacology (IUPHAR) Subcommittee for the Classification and Nomenclature of 5-HT receptors Guide to Receptors and Channels (GRAC) 2007 (Figure 2; Tables 1–5). To date, 13 distinct subtypes of human serotonin receptor are recognized on the basis of structural, transductional, and operational characteristics. A fourteenth purported receptor subtype (5-ht_{5B}) has been identified in rodents only.

The various subtypes are subdivided into seven different classes (5-$HT_{1–7}$), based on gene encoding, and in some cases only one gene product has been identified. These gene products are referred to by use of lower case (e.g., 5-ht_{1E}, 5-ht_{1F}) and will only be accepted into the 5-HT family and given 'upper-case' status when there is unequivocal evidence that the receptor exists as an operational endogenous, physiologically relevant receptor.

G-Protein-Coupled 5-$HT_{(1–7)}$ Receptor Family

5-HT_1 serotonin receptors are expressed in a variety of neurons in the peripheral and central nervous systems. The 5-HT_1 receptor family – 5-HT_{1A}, 5-HT_{1B} (formerly termed 5-$HT_{1D\beta}$), 5-HT_{1D} (formerly 5-$HT_{1D\alpha}$), 5-ht_{1E}, and 5-ht_{1F} – are all seven-transmembrane (7TM) G-protein-coupled receptors (via G_i or G_o; see nomenclature in Figure 2). They are all encoded by intronless genes (of approximately 365–421 amino acids) and are negatively coupled to adenylyl cyclase, and principally cause hyperpolarization.

The 5-$HT_{1A(Gi/Go)}$ Receptor

The most studied of the 5-HT_1 receptor family is the 5-HT_{1A} receptor, located on human chromosome HTR1/5q11.2–q13, which encodes 421 amino acids.

The receptor is found largely on neuronal soma and dendrites and epithelial cells, where it is found on both apical and basolateral membranes. Release of 5-HT in the CNS is under the control of a 5-HT_{1A} autoreceptor (and 5-HT_{1B} autoreceptors, see later). These autoreceptors fall into two categories: cell body autoreceptors and terminal autoreceptors. The former inhibit 5-HT release through inhibition of cell firing; the latter act through direct inhibition of release at the terminal. Cell body (or somatodendritic) autoreceptors belong to the 5-HT_{1A} receptor subtype in all species studied so far. *In vivo* immunocytochemical experiments have clearly demonstrated that, in striatal medium spiny neurons, the 5-HT_{1A} receptor is restricted to the somatodendritic level, while 5-HT_{1B} receptors are shipped exclusively toward axon terminals. In all systems examined to date, there appears to be a differential sorting of the 5-HT_{1A} and 5-HT_{1B} receptors. This observation is largely based on an *in vivo* transgenic system and appears to represent the only model that reconstitutes proper sorting of these receptors.

5-HT_{1A} receptors in the raphe nuclei act as somatodendritic autoreceptors and have little effect on extraneuronal 5-HT levels alone, but potentiate the increase seen after selective serotonin reuptake inhibitor (SSRI) administration. It is this effect that has been purported to be the mechanism of action of SSRIs, whereby desensitization of the 5-HT_{1A} autoreceptors may underlie the ability of chronic, but not acute, SSRI administration to increase synaptic cleft levels of 5-HT.

Evidence from *in vivo* studies indicates that activation of the postsynaptic 5-HT_{1A} receptor in the rat results in a characteristic 5-HT syndrome consisting of flat body posture, forepaw treading and head weaving, hypothermia, and adrenocorticotropic hormone (ACTH) release. Stimulation of postsynaptic 5-HT_{1A} receptors may also cause anxiogenic-like responses. In contrast, activation of presynaptic 5-HT_{1A} receptors induces both hyperphagia and anxiolytic-like effects in rats and hence may account for the clinical anxiolytic efficacy of the 5-HT_{1A} receptor agonists, buspirone and gepirone. 5-HT_{1A} receptor agonists are also active in animal models of depression, such as the rat forced swimming and mouse tail suspension tests, consistent with their purported antidepressant efficacy.

Several agonists show selectivity for the 5-HT_{1A} receptor, particularly *R*(+)-8-hydroxy-(di-*n*-propylamino) tetralin (8-OH-DPAT; Table 1), U92016A, and *R*(+)-UH301, which act as high-efficacy agonists in most systems. In contrast, the nonbenzodiazepine anxiolytics (buspirone and gepirone) and other ligands (such as MDL72832) have been shown to be partial agonists (low efficacy) at the 5-HT_{1A} receptor. Several apparent antagonists have also been characterized, such as NAN190, BMY7387, MDL 73005EF, WAY100135, *S*(−)-UH301, *S*(−)-pindolol, spiroxatrine, spiperone, SDZ216525, and NAD299 (robalzotan). However, all have demonstrated partial agonist properties in studies of somatodendritic autoreceptor function, perhaps due to the much larger receptor reserve associated with these, as opposed to postsynaptic receptors. To date, two selective high-affinity silent antagonists at this receptor have been identified; WAY100635 (pK_B 8.7; Table 1) and lecozotan (SRA-333; K_i 1.6 nM). The latter compound is currently in phase I studies for mild to moderate symptoms of Alzheimer's disease.

The 5-HT_{1A} receptor remains an enigma; however, continued great interest in this receptor persists, based on the ability of azapirone partial agonists (e.g., gepirone, isapirone, and zalospirone) to modify 5-HT function by an action on the 5-HT autoreceptor. 5-HT_{1A} agonists in this class include GR127935 and WAY163426, which are reported to

[a]Overview (see also **Tables 2–5**) of 5-HT receptors. Modified nomenclature as agreed by the Nomenclature Committee of the International Union of Basic and Clinical Pharmacology (IUPHAR), subcommittee on 5-HT receptors; receptors and subsequently revised types are, with the exception of the ionotropic 5-HT_3 class, seven-transmembrane receptors, for which the endogenous agonist is 5-HT. The diversity of 5-HT receptors is increased by alternative splicing that produces isoforms of the 5-HT_{2A} (nonfunctional), 5-HT_{2C} (nonfunctional), 5-HT_4, and 5-HT_7 receptors. RNA editing produces 5-HT_{2C} receptor isoforms that differ in function, such as in efficiency and specificity of coupling to $G_{q/11}$.The 5-HT_3 receptor exists as a pentamer of 4TM subunits that form an intrinsic cation selective channel. Three 5-HT_3 receptor subunits (5-HT_{3A}, 5-HT_{3B}, and 5-HT_{3C}) have been cloned, but only homo-oligomeric assemblies of 5-HT_{3A} and hetero-oligometric assemblies of 5-HT_{3A} and 5-HT_{3B} subunits have been characterized in detail. Putative HTR3D and HTR3E genes have also been described but there is no evidence to date that they encode functional subunits. Also, a hetero-oligometric receptor that contains two copies of the 5-HT_{3A} subunit and three copies of the 5-HT_{3B} subunit has been described. The 5-HT_{3B} subunit has distinctive biophysical properties upon hetero-oligomeric versus homo-oligomeric (5-HT_{3A}) recombinant receptors but generally has little effect upon the apparent affinity of agonists and antagonists. However, homo- and hetero-oliogomeric 5-HT_3 receptors have been reported to differ in their allosteric regulation by some general anesthetic agents. The diversity of 5-HT_3 receptors is also further increased by alternative splicing of the 5-HT_{3A} subunit. Evidence to date, indicates that the 5-HT_{3A} subunit appears to be essential for 5-HT_3 operational characteristics.
Tabulated K_D values refer to binding to human 5-HT receptors, with the exception of SB207710 (piglet) and RP62203 (rat). The nomenclature of 5-HT_{1B}/5-HT_{1D} receptors has been revised. Only the nonrodent form of the receptor was previously called 5-HT_{1Db}: the human 5-HT_{1B} receptor (tabulated) displays a pharmacology different from that of the rodent forms of the receptor, due to Thr335 of the human sequence being replaced by Asn in rodent receptors. NAS-181 is a selective antagonist of the rodent 5-HT_{1B} receptor. Fananserin binds with high affinity to dopamine D4, in addition to 5-HT_{2A}receptors. The human 5-ht_{5A} receptor has been claimed to couple to several signal transduction pathways when stably expressed in C6 glioma cells. The human ortholog of the mouse 5-ht_{5B} receptor is nonfunctional due to interruption of the gene by stop codons. In addition to the receptors listed in the table, an 'orphan' receptor, unofficially termed 5-HT1P, has been described in the literature. Abbreviations here and for **Tables 2–4** (subtype-selective 5-HT compounds): **BIMU8**, (endo-*N*-8-methyl-8-azabicyclo[3.2.1]oct-3-yl)-2,3-dihydro-3-isopropyl-2-oxo-1*H*-benzimidazol-1-carboxamide hydrochloride; **BRL15572**, 3-[4-(3-chlorophenyl)piperazin-1-yl]-1,1,-diphenyl-2-propanol; **BW723C86**, 1-[5(2-thienylmethoxy)-1*H*-3-indolyl]propan-2-amine hydrochloride; **5-CT**, 5-carboxamidotryptamine; **8-OH-DPAT**, 8-hydroxy-2-(di-*n*-propylamino)tetralin; **EGIS-7625**, 1-benzyl-4-[(2-nitro-4-methyl-5-amino)-phenyl]-piperazine; **GR55562**, 3-[3-(dimethylamino)propyl]-4-hydroxy-*N*-[4-(4-pyridinyl)phenyl] benzamide; **GR113808**, [1–2[(methylsulfonyl)amino]ethyl]-4-piperidinyl]methyl-1-methyl-1*H*-indole-3-carboxylate; **GR125743**, *n*-[4-methoxy-3-(4-methyl-1-piperizinyl)phenyl]-3-methyl-4-(4-pyrindinyl)benzamide; **CP 93,129** ([3-(1,2,5,6-tetrahydropyr-id-4-yl)pyrrolo[3,2-b]pyrid-5-one]), **CP-122,288** (5-methyl-aminosulfonylmethyl-3-(N-methylpyrrolidin-2R-yl-methyl)-1H-indole), **GTI**, [^{125}I]5-hydroxytryptamine-5-O-carboxymethylglycyltyrosinamide, **GR65630**-(5-methyl-1*H*-imidazol-4-yl)-1-(1-methyl-*H*-indol-3-yl)-1-propanone, **LY278584**, 1 methyl-N-(8-methyl-8-azabicyclo[3.2.1]oct-3-yl)-1H-indazole-3-carboxamide, **TMB-8**, 8-(diethylamine)octyl-3,4,5-trimethoxybenzoate; **GTI**, 5-*O*-carboxamidomethylglycyl[^{125}I]tyrosinamide-tryptamine; **PNU109291**, (*S*)-3,4-dihydro-1-[2-[4-(4-methoxyphenyl)-1-piperazinyl] ethyl]-*N*-methyl-1*H*-2-benzopyran-6-carboximide; **Ro 60–0175**, (*S*)-2-(6-chloro-5-fluroindol-1-yl)-1-methyethylamine; **Ro 63–0563**, 4-amino-*N*-[2,6-bis(methylamino)pyridin-4-yl]benzenesulfonamide; **RP62203**, 2-[3-(4-(4-fluorophenyl)-piperazinyl)propyl]naphto[1,8-ca] isothiazole-1,1-dioxide; **RS127445**, (2-amino-4-(4-fluoronaphthyl-1-yl)-6-isopropylpyrimidine); **RS57639**, 4-amino-5-chloro-2-methoxybenzoic acid 1-(3-[2,3-dihydrobenzo[1,4]dioxin-6yl)-propyl]-piperidin-4yl methyl ester; **RS100235**, 1-(8-amino-7-chloro-1,4-benzodioxan-5-yl)-5-((3-(3,4-dimethoxyphenyl)prop-1-yl)piperidin-4-yl)propan-1-one; **RS102221**, 8-[5-(5-amino 2,4-dimethoxyphenyl) 5-oxopentyl]-1,3,8-triazaspiro[4,5]decane-2,4-dione; **SB204070**, 1-butyl-4-piperidinylmethyl-8-amino-7-chloro-1–4-benzoioxan-5-carboxylate; **SB207710**, 1-butyl-4-piperidinylmethyl-8-amino-7-iodo-1,4-benzodioxan-5-carboxylate; **SB224289**, 10-methyl-5[((20-methyl-40-)5-methyl-1,2,4-oxadiazol-3-yl)biphenyl-4-yl]carbonyl-2,3,6,-7-tetrahydrospiro[furo[2,3-f]indole-3,40-piperidine]oxalate; **SB236057**, 10-ethyl-5-(20-methyl-40-(5-methyl-1,3,4-oxadiazol-2-yl)biphenyl-4-carbonyl)-2,3,6,7-tetrahydrospiro[furo[2,3-f]indol3–3,40-piperidine; **SB242084**, 6-chloro-5-methyl-1-[2-(2-methylpyridyl-3-oxy)-pyrid-5-yl-carbamoyl] indoline; **SB258585**, 4-iodo-*N*-[4-methoxy-3-(4-methylpiperazin-1-yl)-phenyl]-benzenesulfonamide; **SB258719**, (*R*)-3,*N*-dimethyl-*N*-[1-methyl-3-(4-methylpiperidin-1-yl)propyl]benzene sulfonamide; **SB269970**, (*R*)-3-(2-(2-(4-methylpiperidin-1-yl)ethyl)pyrrolidine-1-sulfonyl)phenol; **SB271046**, 5-chloro-*N*-(4-methoxy-3-piperazin-1-yl-phenyl)-3-methyl-2-benzothiophenesulfonamide; **SB357134**, *N*-(2,5-dibromo-3-fluorophenyl)-4-methoxy-3-piperazin-1-yl-benzenesulfonamide; **SB656104**, 6-((*R*)-2-[2-[4-(4-chlorophenoxy)-piperidin-1-yl]-ethyl]-pyrrolidine-1-sulfonyl)-1*H*-indole hydrochloride; **SB699551**, 3-cyclopentyl-*N*-[2-(dimethylamino)ethyl]-*N*-[(40-{[(2-phenylethyl)amino]methyl}-4-biphenylyl)methyl]propanamide dihydrochloride; **SB714786**, 2-methyl-5-({2-[4-(8-quinolinylmethyl)-1-piperazinyl]ethyl}oxy)quinoline; **SR57227**, 4-amino-(6-chloro-2-pyridyl)-1-piperidine hydrochloride; **UH301**, 5-fluoro-8-hydroxy-2-(dipropylamino) tetralin; **U92016A**, ()-(*R*)-2-cyano-*N*,*N*-dipropyl-8-amino-6,7,8,9-tetrahydro-3*H*-benz[e]indole; **WAY100635**, *N*-(2-(4-(2-methoxyphenyl)-1-piperazinyl)ethyl)-*N*-(2-pyridyl)-cyclohexanecarboxamide trichloride.

raise serotonin levels more rapidly than occurs with an SSRI, and which exhibit activity in chronic models of depression that are consistent with a more rapid onset. Two compounds, VPI-013 and PRX-00023, are also adding to the renewed interest in this area; although they have mixed 5-HT_{1A} receptor antagonist and sigma agonist properties, they are reported to be in phase II studies for depression.

The 5-$HT_{1B(Gi/Go)}$ Receptor

5-HT_{1B} receptors are expressed throughout the mammalian central nervous system. These receptors are located on the axon terminals of both serotonergic and nonserotonergic neurons, where they act as inhibitory autoreceptors or heteroreceptors, respectively. 5-HT_{1B} receptors inhibit the release of a range of neurotransmitters, including serotonin, noradrenaline, γ-aminobutyric acid (GABA), acetylcholine, and glutamate. In rats and mice, the terminal autoreceptor is known to be a 5-HT_{1B} receptor, whereas in humans, pigs, rabbits, and guinea pigs, the terminal autoreceptor is thought to belong to the 5-HT_{1D} receptor subtype (see later). The 5-HT_{1B} receptor is located on human chromosome HTR1/6q13 and the receptor gene is largely concentrated in the basal ganglia, striatum, and frontal cortex. The receptor was originally defined by its pharmacology and also because of species differences in the binding affinity of key ligands, such as the β-adrenoceptor antagonist, cyanopindolol, which was thought to exist only in rodents. More recently, the amino acid sequence of the receptor has been characterized (humans, 390 amino acids; rodents, 386 amino acids) and found to be 93% identical overall and 96% identical with the transmembrane domains of the 5-$HT_{1D\beta}$ receptor, a close homolog found in higher species. This has a distribution and function similar to that of the 5HT_{1B} receptor. Indeed, the differences in the pharmacology of these two homologs are now attributed to the mutation of a single amino acid. Only the nonrodent form of the receptor was previously called 5-HT_{1D}: the human 5-HT_{1B} receptor displays a pharmacology different from that of the rodent forms of the receptor due to Thr335 of the human sequence being replaced by Asn in rodent receptors in the transmembrane-spanning region. In the rodent it is possible to differentiate between the pharmacology of the 5-HT_{1B} and 5-HT_{1D} receptors, as the 5-HT ortholog in these species exhibits a different pharmacology due to an Asp123/Arg123 switch in the rodent receptor. Thus, it has recently been agreed to classify the receptors as species homologs of the same receptor, termed h5-HT_{1B} (formerly 5-$HT_{1D\beta}$) and r5-HT_{1B}, with the h and r prefixes referring to the human and rat species, respectively.

Highly selective agonists and antagonists (Table 1) have now been identified to facilitate characterization of this receptor. There has been accumulating evidence, however, that 5-HT_{1B} receptors modulate drug reinforcement, stress sensitivity, mood, anxiety, and aggression. The general results of a number of studies and human genetics suggest that reduced 5-HT_{1B} heteroreceptor activity may increase impulsive behaviors, whereas reduced 5-HT_{1B} autoreceptor activity may have an antidepressant-like effect.

A large number of studies have established the 5-HT_{1B} terminal autoreceptor in controlling 5-HT release in rats, guinea pigs, and humans. The notion that a selective 5-HT_{1B} antagonist might prevent 5-HT negative feedback via this site, thereby increasing extraneuronal 5-HT and mimicking SSRI antidepressants, awaits clinical efficacy studies.

RU24969 was the first reported full agonist at the 5-HT_{1B} receptor, but, in binding studies, it is only fivefold selective over the 5-HT_{1A} and 5-HT_{1D} receptors. Since the first reports, several other compounds with dubious selectivity have emerged, at best having five-to tenfold selectivity in binding and functional assays (CGS 12066B, anpirtoline trifluoromethylphenylpiperasine (TFM), *m*-cholorophenylpiperazine (mCPP), MK 464, BW311C90, KSF99101H, and GR46611). The most potent agonist reported is L694247 (pK_D 10.0). None of these, however, differentiates between the 5-HT_{1B} and the 5-HT_{1D} receptor subtypes. More recently, selective 5-HT_{1B} receptor agonists (L694247) and antagonists (GR55562, pK_B 7.4; SB224289, pK_B 8.5; SB236657, pK_B8.9; SB236057, pK_B8.9) have been reported, generating further excitement around this receptor subtype and promising to shed light on the therapeutic utility of such agents.

The first potent and selective 5-$HT_{1B/1D}$ antagonist to be reported, GR127935 (pK_D 9.9), decreased extraneuronal 5-HT in the brain when administered systemically to guinea pigs. This may be due to its partial agonist activity at the 5-HT_{1B} receptor or to the presence of 5-HT_{1D} receptors on the raphe acting as somatodendritic autoreceptors, at which GR127935 also has agonist properties. This interpretation is supported by the failure of the recently characterized selective silent 5-HT_{1B} antagonist, SB224289 (pK_B 8.5, >60-fold selective over 5-HT_{1D} and other receptors; Table 1), to increase 5-HT release in the frontal cortex. NAS-181 has been reported to be the only selective antagonist of the rodent 5-HT_{1B} receptor and it may add to our knowledge of the operational characteristics of the rat receptor subtype.

Complementary studies in 5-HT_{1B} null mutant ('knockout') mice have proved unhelpful in understanding the pharmacology of the 5-HT_{1B} receptor, as it has been suggested that a compensatory adaptation to the constitutive loss of 5-HT_{1B} receptors becomes an important determinant of the altered response of 5-HT_{1B} knockout mice to a variety of pharmacological challenges. Altered expression and functions of serotonin 5-HT_{1A} and 5-HT_{1B} receptors in knockout mice lacking the 5-HT transporter (SERT knockout mice) have also been reported.

Although the effects on 5-HT release are unclear from 5-HT_{1B} knockout mice, *in vivo* studies have shown that stimulation of central postsynaptic 5-HT_{1B} receptors in mice, but not rats, causes hyperlocomotion, and penile erection and hypophagia in rats are also reportedly 5-HT_{1B} receptor mediated. Postsynaptic 5-HT_{1B} receptor activation in another species, the guinea pig, is reported to induce hypothermia, while the hypothermic response to 5-HT_{1B} agonists in the rat remains to be fully characterized. The putative 5-HT_{1B} receptor agonist, anpirtoline, has analgesic, cognitive, and antidepressant-like properties in rodents and it is of interest that mutant mice lacking the 5-HT_{1B} receptor are reported to be both highly aggressive and have an increased preference for alcohol.

Great interest in 5-HT_{1B} receptor agonists has been largely generated by the highly successful antimigraine drug sumatriptan, a nonselective 5-HT_{1D} and 5-HT_{1B} receptor agonist with low selectivity for other receptors in functional studies (Table 1). This compound may act either via constriction-mediating 5-HT_{1B} receptors on cerebral arteries or by blocking neurogenic inflammation and nociceptive activity with trigeminovascular afferents. This latter action has been argued to be 5-HT_{1B} receptor mediated, as protein extravasation induced by trigeminal ganglion stimulation is blocked by sumatriptan, the nonselective 5-HT_{1B} receptor agonist, by CP-93129 (>100-fold selectivity over 5-HT_{1A}, 5-HT_{1B}, and 5-HT_2 receptors; Tables 1 and 2), and by the close structural analog of sumatriptan, CP-122288, in wild-type, but not mutant, mice lacking the 5-HT_{1B} receptor. However, while 5-HT_{1B} receptor mRNA has been detected in rats, only 5-HT_{1D} mRNA has been detected in the guinea pig and human trigeminal ganglia. Thus, in humans, the antimigraine properties of sumatriptan may be either 5-HT_{1B} or 5-HT_{1D} receptor mediated. It is therefore abundantly clear that our understanding of the operational and physiological consequences of the 5-HT_{1B} activation across species is still largely in its infancy.

The 5-$HT_{1D(Gi/Go)}$ Receptor

The 5-HT_{1D} receptor has 63% overall structural homology with the 5-HT_{1B} receptor (formerly 5-$HT_{1D\beta}$) and a 77% amino acid sequence homology in the seven-transmembrane domains. The receptor is located on human chromosome HR1D/1p34.3–p36.3 and contains 377 and 374 amino acids for the human and rodent gene, respectively. Low levels of the 5-HT_{1D} receptor mRNA are found in the rat brain, predominantly in the caudate putamen, nucleus accumbens, hippocampus, and cortex, but also in the dorsal raphe and locus coeruleus.

It has been proposed that neurogenic inflammation and nociceptive activity within the trigeminovascular afferents may be 5-HT_{1D} receptor mediated due to the presence of 5-HT_{1D}, but not 5-HT_{1B}, receptor mRNA in the guinea pig and human trigeminal ganglia. Thus antagonism of plasma extravasation, induced by electrical stimulation of the trigeminal nerves, is observed with the antimigraine 5-$HT_{1B/1D}$ receptor agonists sumatriptan, naratriptan, rizatriptan, and zolmitriptan. Some advocates, however, claim that this is a 5-HT_{1D} receptor-mediated response. Several other pharmacological nonselective tool 5-$HT_{1B/1D}$ ligands have been used extensively to characterize the 5-HT_{1D} receptor. These include sumatriptan, PU109291, L694247 (pK_D 10.0), CP-122288, MK 464, and BW311C90, and the more brain penetrant agonists SKF 99101H, GR46611, and GR125743.

The location of 5-HT_{1D} receptor mRNA in the raphe suggests that, like the 5-HT_{1B} receptor, it too may function as a 5-HT autoreceptor. Indeed, there is electrophysiological, release, and voltammetric evidence to this effect. These data are further substantiated by the use of ketanserin and ritanserin, which, in addition their high affinity for the 5-HT_{2A} site, also have high affinity for the 5-HT_{1D}, but not for the 5-HT_{1B}, site (Table 1). The antagonist SB714786 (pK_D 9.1) and BRL-15572 (pK_D 7.9) 5-$HT_{1B/D}$ ligands mediate their effects at autoreceptors involved in the local inhibitory control of 5-HT release and may play a role in the pathogenesis of major depressive disorder (MDD) and in the antidepressant effects of the SSRIs in patients. A number of compounds in this class – including GR125743, SB224289, and L694247; AZD8129, a 5-HT_{1B} receptor antagonist; and CP-448187, a 5-$HT_{1B/1D}$ receptor antagonist – are in phase II studies for depression, and the outcome of these studies is eagerly awaited.

The 5-$HT_{1E(Gi/Go)}$ Receptor

The 5-HT_{1E} receptor was first characterized in humans as a [^{3}H]-5-HT binding site in the presence of 5-carboxyamidotryptamine (5-CT) that blocked binding to the 5-HT_{1A} and 5-HT_{1D} receptors. Human brain binding studies have reported that 5-HT_{1E} receptors (representing up to 60% of 5-HT_1 receptor binding) are concentrated in the caudate putamen,

with lower levels in the amygdala, frontal cortex, and globus pallidus. This is consistent with the observed distribution of 5-HT_{1E} mRNA. The receptor has been mapped to human chromosome HTR1E/6q14–q15, and the gene encodes a 365-amino-acid protein (Table 1). There are no reported selective or high-affinity ligands for this receptor (except for 5-HT) and its function is currently unknown. However, based on its distribution, one could argue that the amygdala is regarded as the 'emotional engine,' and dysfunction of the amygdala (and caudate putamen) has been associated with numerous psychiatric and neurological disorders, ranging from epilepsy to anxiety disorders, attention-deficit/hyperactivity disorder (ADHD), and social phobia, to Alzheimer's disease. Some schools of thought have even proposed that the amygdala is involved in sociopathic and criminal behaviors. Only time will tell, with the development of selective agents for the 5-HT_{1E} receptor.

The 5-$HT_{1F(Gi/Go)}$ Receptor

This receptor subtype is most closely related to the 5-HT_{1E} receptor, with 70% sequence homology across the 7TM domains. The gene is located on chromosome HTR1F/3p11, encoding 366 amino acids across human and rodent species. The mRNA coding for the receptor is concentrated in the dorsal raphe, hippocampus, and cortex of the rat and also in the striatum, thalamus, and hypothalamus of the mouse. 5-HT_{1F} receptor mRNA has been detected in human brain and is also present in the mesentery and uterus. Sumatriptan has almost equal affinity for the 5-HT_{1F} (pK_i 7.6) and 5-$HT_{1B/1D}$ receptors (pK_i 8.4 and 8.1, respectively; Table 1). Thus, it has been hypothesized that the 5-HT_{1F} receptor might be a target for drugs with antimigraine properties. 5-HT_{1F} mRNA has been detected in the trigeminal ganglia, the stimulation of which leads to plasma extravasation in the dura, a component of neurogenic inflammation that is thought to be a possible cause of migraine. The first 5-HT_{1F} receptor selective agonist, LY334370 (pK_D 9.4; see Table 2), with >100-fold separation over the 5-$HT_{1B/1D}$ receptors, has been claimed to block the effects of trigeminal nerve stimulation, as does sumatriptan, naratriptan, rizatriptan, and zolmitriptan . LY334370 has also been used successfully as a radioligand (K_D 0.5 nM) and demonstrated a reasonable correlation between the receptor protein and mRNA distribution, with the highest binding in the cortical areas, striatum, hippocampus, and olfactory bulb.

The 5-$HT_{2(Gq11)}$ Receptor Family

5-HT_2 receptors are characterized by having a relatively lower affinity for indolealkylamines, including 5-HT, and are linked to the G_q/phospholipase C pathway of signal transduction. The structural organization of the 5-HT_2 receptor has largely been determined by mutagenesis analyses that have identified a number of primary binding residues located mainly on TMs 3, 5, and 6, which are believed to constitute the purported binding pocket. Other residues identified on TMs 2, 3, 6, and 7 have been implicated in receptor activation and G-protein coupling. The 5-HT_2 receptor family mediates a large array of physiological and behavioral functions in humans via three distinct subtypes: 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}. While selective 5-HT_{2A} receptor antagonists have been known for some time, knowledge of the precise effects of 5-HT_{2C} and 5-HT_{2B} receptor antagonists has been hampered by the existence of only mixed receptor antagonists for 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}. However, selective 5-HT_{2A}, 5-HT_{2C}, and 5-HT_{2B} receptor antagonists have emerged over the past 5–10 years. Indeed, several structural classes belonging to the various pharmacophores have been reported.

The 5-HT_{2A} Receptor Subtype

The 5-HT_{2A} receptor subtype refers to the classical 'D' 5-HT_2 receptor as defined by the neuroleptic [^{3}H]spiperone in rat brain frontal cortex. Much of the early pharmacology of the 5-HT_{2A} receptor was pioneered using the selective ligand, [^{3}H]ketanserin, which made an important contribution to the characterization and localization of 5-HT_{2A} receptors. Since the early ligand binding studies, only a few compounds have shown over all selectivity for the 5-HT_{2A} site. Of these compounds, MDL100097 possesses subnanomolar affinity for the 5-HT_{2A} receptor (pK_B 9.4), with a minimum 300-fold selectivity for the 5-HT_{2A} site (pK_B 8.5–9.5) over other receptors examined, including the 5-HT_{2C} receptor. Other less selective compounds include ICI 169369, ICI 170809, RP62203 (fananserin), and SR46349B (20- to 30-fold selective). The recent introduction of more selective 5-HT_{2A} receptor antagonists (e.g., APD-125) will greatly accelerate the clinic potential of this receptor subtype. However, as yet, no selective agonists exist to provide a more precise classification of this receptor. Only α-methyl-5-HT has been shown to be a useful selective agonist for identifying 5-$HT_{2A/2C/2B}$ receptors (Table 2) Other (nonselective) compounds with agonist properties at 5-HT_2 receptors include 1-(2,5-dimethoxy-4-methylphenyl)-2-amino propane (DOM) and its 4-bromophenyl (DOB) and 4-iodophenyl (DOI) congeners. DOI is the preferred radioligand, albeit that it is relatively nonselective.

The actions elicited via 5-HT_{2A} receptors comprise mostly those previously considered to be mediated by postsynaptic 'D' receptor and include vascular

smooth muscle contraction in several preparations (e.g., rabbit aorta, rat caudal artery, dog gastrosplenic vein); contraction of bronchial, uterine, bladder, and some gastrointestinal smooth muscle; platelet aggregation; increased capillary permeability; and some behavioral syndromes in rodents, such as head twitch, forepaw treading, and coarse body tremors induced by 5-HT agonists. In humans, hallucinations and vivid dreams have been reported to be induced by 5-HT_{2A} receptor stimulation. The contribution of 5-HT neurotoxins in understanding the role of 5-HT_{2A} receptors and the mechanisms of action of hallucinogenic amphetamine analogs such as 3,4-methylenedioxymethamphetamine (MDMA) have implicated the 5-$HT_{2A/2C}$ receptors in psychiatric disorders. Several nonselective 5-HT_{2A}/5-HT_{2C} antagonists under investigation have failed to show any clinical utility for the treatment of several psychiatric disorders, including schizophrenia, anxiety, neurotic depression, migraine, sleep disorders, and drug abuse. However, a number of compounds have been shown to have therapeutic potential in cardiovascular disorders and migraine prophylaxis.

As considered earlier, the striking similarities between 5-HT_{2A} and 5-HT_{2C} receptors with respect to amino acid sequence (70% in 7TM domains) holds true for the signal transduction mechanism, as both receptors stimulate phosphatidylinositol (PI) turnover. However, the receptors have distinct chromosomal localizations (HTR2A/13q14–q21 and HTR2C/Xq24). The characterization of the 5-HT_{2A} receptor-coupled signal transduction system was first studied in human platelets. It is likely that the biochemical events mediated by the 5-HT_{2A} receptor are important for both the shape change and the aggregation of human platelets. Controversy still exists, but a few studies have reported 5-HT-induced platelet aggregation in patients with peripheral cerebrovascular disease. Peripheral arterial vasospasms subsequent to platelet activation appear to be mediated in part by 5-HT and can be effectively reduced by ketanserin. In animal studies, postthrombotic peripheral collateral circulation can be significantly restored by treatment with ketanserin (pK_D 8.5–9.5) and MDL100907 (pK_D 9.4), and 5-HT-induced reduction of blood supply through the collateral system can be effectively counteracted by pretreatment with ketanserin. In *ex vivo* human platelet studies, the 5-HT_{2A}/5-HT_{2C}/5-HT_{2B} receptor antagonist ICI 170809 significantly inhibited 5-HT-induced aggregation (minimum effective dose, 0.1 mg kg^{-1} per os), thus lending support for the potential therapeutic role of 5-HT_{2A} receptor antagonists in modulating the vasospastic effects of 5-HT released from platelets during vascular trauma. The clinical significance of selective 5-HT_{2A} (see also discussions of 5-HT_{2B} and 5-HT_{2C}) receptor antagonists in this vascular disorder and various psychiatric disorders still awaits further conclusive evidence of clinical efficacy with selective agents. In psychiatric disorder studies, two recent 5-HT_{2A} receptor antagonists have shown significant clinical efficacy in schizophrenia. Pimavanserin (ACP-103) significantly improved efficacy scores (positive and negative syndrome scale; PANSS), showing a faster onset and improved side-effect profile, following co-therapy with risperidone. Fananserin, which binds with high affinity to dopamine D_4, in addition to 5-HT_{2A} receptors, also showed good clinically efficacy in schizophrenia, with an improved side-effect profile. This therapeutic opportunity is currently been actively pursued by several pharmaceutical companies, and several compounds acting at 5-HT_{2A} and dopamine D_2 receptors, are at various stages of clinical development (e.g., asenapine, blonanserin, eplivanserin, pruvanserin, paliperidone, uoperidone, and vabicaserin). Another selective 5-HT_{2A} receptor antagonist, APD-125, is currently being assessed in the clinic for insomnia and sleep maintenance.

The 5-$HT_{2B(Gq11)}$ Receptor

The 5-HT_{2B} mRNA transcript has been now been identified in human and nonvertebrates and the receptor has been mapped to human chromosome HTR2B/2q36.3–2q37.1, with the human gene encoding 481 amino acids (Table 2). It was first identified in the stomach of the rat and in the small intestine, kidney, heart, and cerebellum in the mouse. The presence of the transcript in the rat stomach and the pharmacology of the cloned 5-HT_{2B} receptor have led ultimately to defining the rat stomach fundus receptor. In Gaddum and Picarelli's first classical attempt at subdivision of 5-HT receptors, the D subtype (5-HT_{2A}) preceded the first descriptions of the rat stomach fundus 5-HT receptor by only a few pages in the same issue of the *British Journal of Pharmacology*, whereas the 5-HT_{2C} receptor was not identified until some 28 years later.

The 5-HT_{2B} receptor represents the second member of the 5-HT_2 family, but it is still unclear how the clone relates pharmacologically to that 5-HT receptor which mediates contraction of the rat stomach fundus. Evidence indicates that the 5-HT_{2B} contractile receptor in the rat stomach fundus is coupled to calcium influx through voltage-dependent calcium channels, intracellular calcium release, and activation of protein kinase C (PKC). These actions may reflect a novel coupling mechanism unrelated to increases in PI hydrolysis, unlike the other 5-HT_2 receptors.

In the 1990s a series of potent, selective 5-HT_{2B} receptor antagonists were identified, of which

SB204741 (pK_i 7.8) has proved to be an important tool for characterizing this receptor, along with the less selective 5-HT_{2B} receptor agonists BW723C86 and α-Me-5-HT. Recent additions to the 5-HT_{2B} tool-kit have been the introduction of two highly selective 5-HT_{2B} receptor antagonists, RS127445 (pK_i 9.5) and EGIS-7625 (pK_i 9.0).

The clinical potential of compounds selective for the 5-HT_{2B} receptor site has pointed to an alternative target for initiation of migraine and may account for the continued use of methysergide, pizotifen, and cyproheptadine for migraine prophylaxis. More selective compounds have been developed for this indication, but to date no selective 5-HT_{2B} compound has shown clinical efficacy for migraine. Moreover, the only 5-HT_{2B} compound in current clinical development for the treatment of pulmonary hypertension is PRX-08066, which is surprising, considering the critical importance of the 5-HT_{2B} receptor in mammalian heart development.

The 5-$HT_{2C(Gq11)}$ Receptor

The human 5-HT_{2C} receptor gene HTR2C/Xq24 encodes 377 amino acid residues with seven hydrophobic domains of 20–30 residues (Table 2). The rat and mouse sequences suggest the presence of an eighth transmembrane region not seen in the human receptor. The rat and human sequences are otherwise very similar, with a 90% overall homology. They are also positively coupled to phosphoinositide hydrolysis, providing a common secondary messenger system for 5-HT_{2C} and 5-HT_{2A} receptors. It is well established that 5-HT_{2C} receptors display a high degree of constitutive activity, and consequently inverse agonists have a large effect when they bind to the 5-HT_{2C} receptor. Furthermore, the mRNA for the 5-HT_{2C} receptor undergoes mRNA editing, which results in the expression of multiple 5-HT_{2C} receptor isoforms. Correspondingly, INI (unedited) and VSV (a fully edited version) isoforms are abundant in rat brain. The VSV isoform lacks the high-affinity recognition site for 5-HT, which may be caused by low-efficiency coupling to G-proteins. These edited isoforms appear to have reduced constitutive activity and reduced capacity to couple to G_{q11} signaling proteins. This suggests that the INI isoform of the 5-HT_{2C} receptor is pharmacologically similar to the VSV form of the 5-HT_{2C} receptor, but that it couples more efficiently to G-proteins. Importantly, the capacity of some cells in the brain to edit the 5-HT_{2C} mRNA is reduced. It has been suggested that this may well be the underlying pathophysiology in schizophrenic patients and that this reduced capacity is evident in brains of patients who had committed suicide. Changes in the RNA-editing capacity of the brain will result in altered patterns of expression of the edited 5-HT_{2C} isoforms and perhaps in altered responses to drugs. Consequently, it is important to understand the signaling characteristics and mechanism of the edited 5-HT_{2C} receptor isoforms in various psychiatric and neurological conditions, and selective agents are allowing this work to progress.

The pharmacological characteristics of the 5-HT_{2A} and 5-HT_{2C} (formally named 5-HT_{1C}) receptors are remarkably similar, with many of the 'classical' 5-HT receptor antagonists showing high affinity for both sites. Furthermore, some compounds may have different affinities for human as opposed to rat receptors. The first 5-HT_{2C} selective antagonist SB200646A (50-fold) was reported in the early 1990s; however, few truly selective 5-HT_{2C} receptor agonists have been identified. MK 212 (30-fold) is the most selective CNS active agonist, but is also a 5-HT_{2A} agonist, while α-methyl-5-HT has equal affinity for all 5-HT_2 receptor subtypes. Of the various 5-HT_2 receptor agonists, (+)-DOB and *m*-chlorophenylpiperazine (mCPP) possess approximately tenfold selectivity over other binding sites in the rat but not in humans. However, mCPP is of particular interest because of its use as a clinical probe in the 1990s to study human 5-HT_{2C} receptor function.

mCPP is commonly observed to induce anxiety and panic attacks in humans. This mCPP-induced anxiogenesis is inhibited by the 5-HT_{2C} and 5-HT_{2A} receptor antagonist ritanserin, which is consistent with 5-HT_{2C} receptor mediation. If 5-HT_{2C} receptor activation is anxiogenic, the blockade of this receptor might induce anxiolysis, provided the receptors are tonically innervated. This argument is supported by the anxiolytic properties of SB243213, a selective 5-HT_{2C} antagonist, in rat models of anxiety with quite different motivational and aversive bases (the rat social interaction and Geller–Seifter tests). To date this hypothesis awaits clinical testing.

In support of this hypothesis, the selective 5-HT reuptake inhibitors (SSRIs) paroxetine, fluoxetine, clomipramine, sertraline, and citalopram, on chronic administration, have all been observed to desensitize behavioral responses to mCPP. The monoamine oxidase inhibitors phenelzine and nialamide, which also raise extraneuronal 5-HT levels, have a similar effect after chronic treatment. These results suggest that SSRIs and MAO inhibition antidepressant treatments may desensitize the 5-HT_{2C} receptor, although there is no direct evidence from receptor binding, mRNA, or secondary messenger systems as yet. Furthermore, unlike other SSRIs, fluoxetine and its metabolite norfluoxetine have weak affinity for the 5-HT_{2C} receptor and are therefore likely to accumulate and directly block 5-HT_{2C} sites.

Paradoxically, there is an emerging rationale and literature for the use of selective 5-HT_{2C} receptor agonists in psychiatric and eating disorders that has been driven by recently reported compounds that have shown greater selectivity for the 5-HT_{2C} receptor than has mCPP. Early studies with mCPP pointed the way to far more selective agonists in eating and psychiatric disorders. Several reports suggest that the 5-HT_{2C} receptor agonists VER-2692 and WAY16909 are potent and selective agonists, and these are currently being evaluated as antiobesity agents.

Early clinical studies with mCPP in bulimic patients induced migraine-like headaches 8–12 h later. This response was correlated with plasma levels of mCPP and was more pronounced in patients with a personal or family history of migraine. Conversely, the nonselective 5-HT_{2C}/5-HT_{2A} receptor antagonists pizotifen, cyproheptadine, and methysergide are all clinically effective as migraine prophylactics. ICI 169369 and sergolexole, which have high affinity for 5-HT_{2C} and 5-HT_{2A} receptors, but little affinity for other sites, have subsequently been found to have modest antimigraine efficacy in an early trial. As these drugs only share a high affinity for the 5-HT_{2C} and 5-HT_{2A} receptors, and as the selective 5-HT_{2A} receptor antagonist ketanserin is ineffective as a migraine prophylactic, it was proposed that blockade of 5-HT_{2C} receptors mediated this effect (although this has recently been challenged on the basis of their affinity for the 5-HT_{2B} receptor). Furthermore, downregulation of 5-HT_{2C} receptors may mediate the antimigraine properties of the antidepressants amitriptyline and fluoxetine; alternatively, the latter compounds may act by direct antagonism of vascular 5-HT_{2C} receptor sites. Other possible therapeutic targets for drugs acting at 5-HT_{2C} receptors include eating disorders, sexual dysfunction, and head trauma, based on the actions of nonselective 5-$HT_{2C/2A}$ agonists and antagonists.

It is highly likely that the 5-HT_2 family will continue to grow. There is already considerable evidence for a number of other 'orphan' receptors which may be adopted into the family. Several orphans are thought to exist, one of which is the endothelial 5-HT receptor, which is present in rabbit and rat jugular vein and pig pulmonary artery and vena cava. The rat jugular vein is now known to represent a 5-HT_{2B} receptor. More recently, a site identified in choroid plexus has been shown to bind the 5-HT_2-selective ligand RP62203 with high affinity, but does not possess identity with any of the three established 5-HT_2 receptors. However, it would appear that the endothelial receptors do not represent a pharmacologically homogeneous class. While possessing many of the characteristics of 5-HT_{2C} and 5-HT_{2B} receptors, subtle yet robust differences render any explicit affiliation impossible. These problems are confounded by the need, in many instances, to make comparisons across species. The potential for substantial species differences in pharmacology is highlighted on pharmacological comparison of mouse and rat homologs of the cloned 5-HT_{2B} receptor. Thus the eventual classification of the orphan endothelial 5-HT receptor awaits robust interspecies comparison of 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptors. In this regard, in rat jugular vein, the endothelial receptor, which was previously classified as 5-HT_{2C}-like, has now been shown to be more like 5-HT_{2B} receptors, using ligands which discriminate the rodent (rat) 5-HT_2 receptor subtypes.

Another therapeutic area that has gained prominence recently arose from observations in humans that mCPP reduces total sleep time, sleep efficiency, slow-wave sleep (SWS), and rapid eye movement sleep (REMS). The actions of 5-$HT_{2A/2C}$ receptor antagonists on sleep architecture have since been widely studied. Thus ritanserin has been reported to increase SWS, reduce sleep onset latency, and improve subjective sleep quality in volunteers, while REMS is reduced in some, but not all, studies. Ritanserin has also been observed to be of therapeutic use in insomniacs and in patients suffering from dysthymia. These effects were maintained with chronic treatment. Other nonselective 5-HT_{2A}/5-HT_{2C} receptor antagonists such as mianserin, cyproheptadine, and pizotifen have similar effects. In rats, ritanserin generally increases SWS and reduces REMS, although some studies report that the deepest phase of SWS (SWS2) is increased but total SWS is unaffected. Studies with three other 5-HT_{2A}/5-HT_{2C} receptor antagonists, ICI 169369 and ICI 170809 and SR46349B, report reduced REMS, but little effect on undifferentiated SWS. These results, therefore, suggest that a 5-HT_{2C} receptor antagonist may improve sleep quality (see also agomelatine).

Of great interest to pharmaceutical companies is the role of the 5-HT_{2C} receptor in anxiety and depression. Two 5-HT_{2C} receptor inverse agonists, SB243213 and WAY163909, have been reported to be in development for the treatment of depression. The fact that both compounds show a similar pharmacology in several animal models of depression reflects the ability of the 5-HT_{2C} receptor agonists and antagonists/inverse agonists to desensitize the 5-HT_{2C} receptor, as observed following chronic SSRI treatment. Another drug that has recently gained European regulatory approval is agomelatine, which is a melatonergic, MT1 and MT2 receptor agonist/5-HT_{2C} antagonist with

antidepressant properties and which may be acting through a similar mechanism. It is reported to improve disrupted sleep patterns in depressed patients (which also is likely, due to its 5-HT_{2C} receptor antagonist properties), without affecting daytime vigilance. The reported lack of effect on sexual function, tolerability problems, or discontinuation symptoms offers several advantages over current therapy for the treatment of depression.

It is clearly evident that therapeutic opportunities are still to be realized in the 5-HT_2 receptor family and will undoubtedly follow with clinical evaluation of selective, nonselective, and combination agents.

The Ligand-Gated 5-HT_3 Receptor

The original naming of the 'M' receptor by Gaddum and Picarelli was based on the ability of morphine to antagonize the serotonin receptor which mediates depolarization of cholinergic nerves in the guinea pig ileum. Morphine was the first pharmacological tool to help characterize this receptor, now referred to as the 5-HT_3 receptor. Since the time of these early observations, 5-HT_3 receptors have been reported to be present on postganglionic autonomic neurons in the peripheral sympathetic and parasympathetic nervous systems, on enteric neurons, and on sensory neurons in various tissues.

The 5-HT_3 receptor is a member of the Cys-Cys loop ligand-gated ion channel superfamily and as such is composed of multiple subunits, containing 478 amino acids. Five human genes have been identified on chromosome HTR3/11, which encodes the 5-HT_3 subunit (5-$HT_{3A–E}$) (Table 3). To date, conflicting reports as to the existence of central 5-HT_{3B} subunits have been reported. However, immunohistochemical studies using sections of human temporal lobe demonstrated both 5-HT_{3A} and 5-HT_{3B} immunoreactivity associated with pyramidal neurons within all CA fields of the hippocampus, as well as with large neurons within the hilus. The expression of both h5-HT_{3A} and h5-HT_{3B} subunit mRNAs in human hippocampus would therefore support the presence of both homomeric h5-HT_{3A} and heteromeric h-5-$HT_{3A/3B}$ receptors in human hippocampus.

The pathophysiological relevance of central h5-HT_{3A} and h5-HT_{3B} receptors remains to be fully evaluated with selective receptor antagonists in preclinical and clinical studies. The pioneering animal studies in the 1980s with the nonselective antagonist ondansetron clearly point to a role for 5-HT_3 receptors in anxiety, depression, and schizophrenia. However, this was not substantiated in human studies with several 5-HT_3 receptor antagonists, including, ondansetron, granisetron, BRL46470, and dolasetron.

5-HT is found in both the brain and the gut, but it is now widely understood that 95% of the serotonin in the body resides in the gut. The two leading 5-HT_3 receptor antagonists, ondansetron and granisetron, have proved to be highly successful antiemetic agents, and they are widely used in the prophylactic treatment of chemotherapy-induced nausea and vomiting. This discovery arose from carefully reasoned experimental research. It was shown in animal studies that chemotherapeutic agents such as cisplatin released 5-HT in the gut in vast quantities, activating 5-HT_3 receptors in this region. Activation of 5-HT_3 receptors resulted in the firing of a vagally mediated response resulting in emesis. The discovery of the antiemetic properties of these 5-HT_3 receptor antagonists, along with several others that followed, opened the way for this class of compounds to become the gold standard in the clinical treatment of chemotherapy-induced nausea and emesis.

A second non-CNS therapeutic target that has gained prominence in recent years has been irritable bowel syndrome (IBS) and its association with the 5-HT_3 receptor and 5-HT_4 receptor. 5-HT_3 receptor antagonists were predicted to be effective in diarrhea-predominant IBS based on animal studies. Clinical studies with ondansetron and granisetron showed a reversal in rectal hypersensitivity in IBS, and the longer acting agent alosetron showed significant clinical improvement in IBS symptoms. However, alosetron has had a checkered clinical existence following early withdrawal after reports of rare serious gastrointestinal adverse events among patients taking the drug. Similar drugs (i.e., cilansetron, ramosetron, and DDP-733) are also in clinical studies for IBS, with the hope that these side effects are not class related. The latter compound is a partial agonist that has recently been reported to be active in a phase II IBS study.

The complex symptomatology in IBS may be attributed to activation of other 5-HT receptor subtypes in the gastrointestinal tract. It was the identification of 5-HT_4 receptors that led many pharmaceutical companies to believe that agents acting as 5-HT_4 receptors would be useful in the treatment of this condition (see discussion of the 5-HT_4 receptor and Table 4).

The 5-$HT_{4(Gs)}$ Receptor

The 5-HT_4 receptor was originally identified in primary cell cultures of mouse embryo colliculli, where later it was found to have a broad tissue distribution and to be positively coupled to adenylate cyclase. In early functional assays studies the 5-HT_4 receptor was identified in the rat esophageal muscularis mucosae and guinea pig colon, where activation resulted in

relaxation and contraction, respectively. The cloned human and rodent receptor was shown to consist of 388 and 406 amino acids, respectively. Various isoforms of the 5-HT_4 receptor have now been identified (5-$HT_{4b,c}$ and 5-HT_{4d}), encoded by a gene located on chromosome HTR4/5q31–q33 (Table 4).

In the brain, 5-HT_4 receptors appear to be located on neurons, whereas in the peripheral nervous system they are reported to facilitate the release of acetylcholine in smooth muscle of the intestinal tract. It was these observations on the gastrointestinal tract that led to the notion that 5-HT_4 receptors may have a role in the pathophysiology of irritable bowel syndrome and gastroesophageal reflux disease (GERD).

The complex symptomatology and pharmacology of IBS led to the development of several highly selective 5-HT_4 receptor agonists and antagonists that are now established in clinical practice for this indication. Tegaserod (HTF-919) and purcalopride (R93877) are 5-HT_4 receptor partial agonists, and piboserod (SB207266) is an antagonist. All of these medications are reported to relieve the symptoms of constipation, the notion being that the 5-$HT_{3/4}$ agonists are intended to have prokinetic activity, like the mixed 5-HT_4 receptor agonist/5-HT_3 receptor agonist, cisapride. Such agents would therefore be beneficial for constipation-predominant IBS. Conversely, the antagonist piboserod would be indicated for diarrhea-predominant IBS. However, the therapeutic potential of piboserod was noted to be limited to a decrease in rectal sensitivity, and the compound was not advanced in further clinical studies. The disappointment with this class of drugs has been their lack of efficacy in IBS-related pain. However, other 5-HT_3 agonists (pumosetrag) and 5-HT_4 agonists (TD-2749 and TD-5108) are also being evaluated in IBS, which may address this important, unmet medical need.

The potential CNS efficacy of 5-HT_4 receptor antagonists is less well developed, though the 5-HT_4 partial agonist SL65.0155 (5-(8-amino-7-chloro-2,3dihydro-1,4-benzodioxin-5yl)-3-[1-(2-phenylethyl)-4-piperidinyl]1,3,4-oxadiazol-2(3*H*)-one-monohydro chloride) has been reported to show cognitive enhancing effects in animal models. The high density of 5-HT_4 receptors in the nucleus accumbens has suggested that these receptors may be involved in reward mechanisms and may influence self-administration. Recent studies with GR113808 and its effects on reducing alcohol intake in rats would concur with this suggestion.

The clinical benefit of selective agents for the 5-HT_4 receptors in medical practice and the promise of more developments clearly represent one of many success stories of 5-HT drug development.

The 5-ht_5 Receptor (G-Protein Coupling, None Identified)

The 5-HT_5 receptor is highly localized in the rodent CNS; its distribution in the hippocampus (CA1, CA3, dentate gyrus), cortex, cerebellum (granular layer), olfactory bulb, habenula, and spinal cord would suggest a role in the pathophysiology of psychiatric and neurological disorders. A human 5-HT_{5A}, but not a 5-ht_{5B}, receptor has been identified; the human 5-HT_{5A} receptor gene, like the rodent gene, contains two codon exons separated by a single large intron. In the case of the human and rodent 5-HT_{5A} receptor, the gene contains the same number of amino acids (357); similarly, the rodent $5ht_{5b}$ gene contains 387. To elucidate the pathophysiology of the 5-HT_5 gene, chromosomal localization studies have identified the receptor on HTR5A/7q36, whereas the $5ht_{5b}$ gene is localized on htr5b/2q11–q13. The signal transduction mechanism for the 5-HT_5 receptor is still a matter for conjecture, as some suggest it may utilize a novel (perhaps ion channel) second-messenger system (Table 4).

The physiological function of the 5-HT_{5A} receptor is poorly understood. 5-HT_{5A} null mutant mouse studies suggest a role in exploratory behavior, but the lack of selective pharmacological tools has hampered progress. Localization studies have revealed that 5-HT_{5A} receptors have widespread distribution in the CNS. It has been speculated that, on the basis of their localization, the receptors may be involved in motor control, learning and memory consolidation, and anxiety and depression.

Recently a selective 5-HT_{5A} receptor antagonist, SB699551A, has been identified. This compound has been reported to attenuate 5-carboxyamidotryptamine-induced inhibition of raphe neuronal cell firing *in vitro* and to increase 5-HT levels in prefrontal cortex *in vivo*, suggesting a role for the 5-HT_{5A} receptor in the modulation of raphe 5-HT neuronal activity. This is another pharmacological opportunity whereby 'tool' compounds will expose the receptor subtype operational and functional characteristics in native tissue, as it has been suggested that many of the operational characteristics of the 5-HT_{1D} receptor may be attributed to the 5-HT_{5A} receptor.

The 5-$HT_{6(Gs)}$ Receptor

5-HT_6 receptors have been identified in areas of the rat and human brain associated with learning and memory: hippocampus, CA1, CA3, dentate gyrus, olfactory tubercles, cerebral cortex, nucleus accumbens, and striatum. The 5-HT_6 gene is localized on chromosome HTR6/1p35–p36, and studies to

determine its linkage to several CNS disorders (memory dysfunction and schizophrenia) are actively being pursued (Table 4). However, the potential of 5-HT_6 receptor antagonists in the treatment of cognitive disorders has been an actively researched topic in recent years, and the availability of numerous tool compounds for this receptor, some of which are currently in clinical trial, will advance our understanding of the role of this receptor in cognitive process.

The notion that several atypical antipsychotic agents such as clozapine, quetiapine, and olanzapine possess high affinity for the 5-HT_6 receptor adds translational creditability to this approach. The leading pharmacophores are indole-related compounds, of which several have emerged, including the recently described aryl sulfonamide indole chemotype, SB271046 (pK_i 8.6), with excellent CNS bioavailability and *in vivo* efficacy, compared to several earlier compounds.

More recently, 5-HT_6 receptors have been demonstrated to regulate central cholinergic neurotransmission. In this regard, administration of the 5-HT_6 receptor-selective antagonist Ro 04–6790 reversed scopolamine-induced rotation in 6-hydroxydopamine-lesioned rats. Additionally, 5-HT_6 receptor antisense oligonucleotides or 5-HT_6 receptor-selective inhibitors enhanced retention by rats of the learned platform position in the Morris water maze. These data suggest that 5-HT_6 receptor antagonists might boost cholinergic neurotransmission and reduce the cognitive impairments experienced by patients with dementia or schizophrenia. Intriguingly, it has recently been determined that the 267C allele of the 5-HT_6 receptor is a significant risk factor for Alzheimer's disease. Taken together, these findings indicate that 5-HT_6 antagonists might prove useful in treating a number of common illnesses, including dementia and schizophrenia.

A major concern in drug discovery is that the cloned mouse receptor is significantly different in rat and human 5-HT_6 receptors. In addition to species differences in the binding of drugs to 5-HT_6 receptors, differences in the regional expression of 5-HT_6 receptors are also apparent. Furthermore, quantitative polymerase chain reaction studies have demonstrated that the mouse 5-HT_6 receptor mRNA is at least tenfold less abundant than are the rat and human 5-HT_6 receptor mRNAs, in every brain region examined. Surprisingly, whereas 5-HT_6 receptor mRNA and radioligand binding activity is enriched in the basal ganglia of rat and human brain, there is no such enrichment in the mouse brain.

Finally, using a combination of site-directed mutagenesis and molecular modeling studies, it has been shown that the peculiar mouse 5-HT_6 pharmacology is attributable to two amino acids – Tyr188 (in helix 5, which is Phe188 in rats and humans) and Ser290 (in helix 6, which is Asn290 in rats and humans) – and these account for the bulk of the differences in pharmacology. These findings are a cautionary note but may have important implications for drug discovery.

The 5-$HT_{7(Gs)}$ Receptor

Since the identification of the 5-HT_7 receptor in the early 1990s, evidence has accumulated supporting a role for 5-HT_7 receptors in various physiological functions, including sleep disorders, circadian rhythms, cognition, mood, and sleep (see Table 5). A number of splice variants of the 5-HT_7 receptor have been identified and exhibit overlapping mRNA distributions, and all couple to G_s, though no differences in operational characteristics have been shown, which may have led to differentiation of behavioral phenotypes. Work is still ongoing to elucidate the pathophysiology of these splice variants, and chromosomal localization studies have identified the receptor on HTR5A/7q36, encoding 445 and 488 amino acids for the human and rodent receptor, respectively (Table 5). The finding that several drugs used in clinical psychiatric practice had high affinity for 5-HT_7 receptor binding sites in the brain initiated an ongoing interest in evaluating the involvement of neuropsychiatric disorders. The distribution of 5-HT_7 receptors in areas of the brain associated with neuropsychiatric disorders – hippocampus (CA_1, CA_2), hypothalamus, thalamus, raphe nuclei, and superior colliculus – supported this notion. In concordance with its distribution in the hippocampus, the selective 5-HT_7 receptor antagonist SB269700-Z was shown to attenuate phencyclidine (PCP)-induced cognition dysfunction associated with schizophrenia.

The strongest case has been made for the importance of the 5-HT_7 receptor in depression. Inactivation or blockade of the receptor leads to an 'antidepressant' state in behavioral models of depression. Furthermore, 5-HT_7 receptor downregulation following chronic administration of antidepressants in animal studies points to a possible molecular mechanism of action. This hypothesis is supported by recent animal experiments using 5-HT_7 receptor knockout mice that clearly show an antidepressant-like profile in the rat forced swim test and mouse tail suspension test. Selective antagonist tool compounds SB258717, SB269970, and SB656104-A have all been shown to exhibit antidepressant-like properties in animal studies and to modulate REM sleep in rats, results that concur with this line of investigation. Several lines

of evidence have shown that 5-HT-induced hypothermia is mediated by the 5-HT_7 receptor, as defined with selective antagonists and in 5-HT_7 knockout mice studies. What is interesting, however, is recent work with the endogenous fatty acid oleamide that suggests it may act through an independent mechanism as well as at an allosteric 5-HT_7 receptor site to regulate body temperature and perhaps circadian rhythms. Clinical progress in this area has been limited by suboptimal clinical candidates, and clinical efficacy data for selective agents are still awaited.

The Future of 5-HT Research

It is now over 50 years since Gaddum first suggested "that a drug with a specific antagonistic action to 5-HT – might be used in therapeutics." Clearly, drugs acting at the 5-HT receptor subtypes have revolutionized therapeutics during the intervening years. However, it is only now that selective agents are appearing to differentiate many operational and physiological characteristics of 5-HT actions on the various receptor subtypes currently identified. The future therapeutic potential of drugs acting at these 5-HT subtypes and isoforms or in combination with other neurotransmitter receptors will open up next generation of novel serotonergic therapeutic agents.

Serotonin (5-Hydroxytryptamine; 5-HT): CNS Pathways and Neurophysiology

G Aghajanian and R-J Liu, Yale School of Medicine, New Haven, CT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Serotonin (5-hydroxytryptamine; 5-HT), a biogenic indoleamine derived metabolically from the dietary amino acid tryptophan, was first discovered in peripheral tissues and subsequently found in brain. Shortly afterward, in the early 1950s, a structural relationship was noted between serotonin and *d*-lysergic acid diethylamide (LSD), the most potent of all known hallucinogenic drugs. Subsequently, it was recognized that a wide range of psychedelic hallucinogens, both indoleamines such as *N*,*N*-dimethyltryptame (DMT) and phenethyamines such as mescaline, had structural similarities to LSD (Figure 1). This relationship to powerful psychotropic drugs sparked interest in the idea that serotonin might function as a central 'neurohumoral' substance with a profound influence on behavior. However, it was not obvious how to investigate this idea directly until the mid-1960s, when, through the use of a new histochemical method (the Falck–Hillarp method), it was discovered that serotonin was highly concentrated in specific sets of neurons located almost exclusively in the raphe nuclei of the brain stem. Histochemical maps showed that serotonergic projections emanating from the raphe nuclei innervate, to varying degrees, virtually all other parts of the central nervous system, ranging from the cerebral cortex to the spinal cord. Based on these maps, it became possible to study the properties of identified serotonergic neurons and their postsynaptic targets.

Although it was its link to hallucinogenic drugs that first brought it to prominence, serotonin has now been implicated in almost every conceivable physiological or behavioral function – affect, aggression, appetite, cognition, emesis, endocrine function, gastrointestinal function, motor function, neurotrophism, perception, sensory function, sex, sleep, respiration, and vascular function. Moreover, many drugs that are currently used for the treatment of psychiatric disorders (e.g., depression, mania, schizophrenia, autism, obsessive–compulsive disorder, anxiety disorders) are thought to act, at least partially, through serotonergic mechanisms.

How is it possible for serotonin to be involved in so many different processes? One answer lies in the anatomy of the serotonergic system, where small clusters of serotoninergic cell bodies located in the brain stem raphe nuclei are positioned through their vast projections to influence all regions of the neuraxis. Another answer lies in the molecular diversity and differential cellular distribution of the many serotonin receptor subtypes that are expressed differentially in brain and other tissues. For example, the effects of hallucinogenics are mediated via the 5-HT_{2A} subtype of serotonin receptor, which is expressed extensively in the cerebral cortex. In contrast, antidepressant effects are thought to involve members of the 5-HT_1 family of receptors located in the brain stem raphe as well as in certain postsynaptic regions. Given this diversity, it is useful to approach serotonin neurophysiology within the context of the neuroanatomical and cellular distribution of serotonin receptor subtypes and their associated transduction pathways.

Serotonergic Neuronal Pathways

Serotonergic neurons are clustered in a series of midline nuclei, labeled B1–B9, extending from the midbrain to the medulla oblongata. The dorsal and median raphe nuclei (B7 and B8) comprise the largest of these groupings of brain serotonergic neurons, and together they provide the major serotonergic input to the forebrain; the lower brain stem raphe nuclei supply the main serotonergic projections to the spinal cord. A single serotonergic neuron projects to large numbers of postsynaptic cells and does so in an overlapping fashion with other serotonergic neurons. While the density of this input varies widely, both regionally and between different cell types within a given region, virtually no corner of the CNS is lacking a serotonergic input despite the fact that serotonergic neurons represent far less than 1% of all the neurons in the brain. Given these anatomical considerations, the serotonergic system is well positioned to provide a broad modulatory influence upon diverse functions rather than the precise point-to-point transmission characteristic of traditional sensory, motor, or associational pathways.

In view of its widespread projections arising from a relative handful of neurons, is it possible to assign an overarching function to the serotonergic system? An answer to this question may come from the fact that serotonergic neurons display a pattern of firing that is dependent upon behavioral state: they fire most rapidly during alert waking, decelerate considerably during slow-wave sleep, and become almost entirely silent during dream – or rapid-eye-movement

Figure 1 The structural formulas of serotonin and three related hallucinogenic drugs: LSD, DMT, and mescaline. Note that serotonin, LSD, and DMT have in common an indolethylamine moiety. While it is not an indolethylamine, mescaline shares with LSD a phenethylamine moiety. The structures are drawn so as to emphasize these shared structural features. Provided by GK Aghajanian.

Figure 2 Schematic diagram showing norepinephrine (NE), hypocretin/orexin (hcrt/orexin), and γ-aminobutryic acid (GABA) inputs to a 5-HT cell in the brain stem raphe. The NE input originates from nearby sites in the brain stem while the hcrt/orexin input is hypothalamic in origin; both of these are excitatory (+). Also depicted is a 5-HT collateral input to the 5-HT cell; this input is inhibitory (−) via somatodendritic 5-HT_{1A} autoreceptors. Finally, an inhibitory input (−) from a local GABA interneuron is shown; the GABA cell itself receives 5-HT collaterals, which can be excitatory (via 5-HT_{2A} receptors) or inhibitory (via 5-HT_{1A}) receptors. Provided by GK Aghajanian.

(REM) – sleep. Thus, in a broad sense, one can view serotonergic neurons as constituting a 'wake-on' system. In this context, many of the electrophysiological effects of serotonin in postsynaptic regions can be seen as facilitating motor, sensory, and cognitive functions characteristic of the waking state. All of this would be reversed when serotonergic neurons become quiescent during sleep states, when there is an emergence of sleep- and dream-related systems. Such a broad, state-related function for serotonin has been likened to the peripheral sympathetic system where small clusters of noradrenergic neurons project to a myriad of organs including the heart, gut, and skin to influence their function in a concerted manner. Interestingly, a central counterpart to the sympathetic system exists in the brain stem where small clusters of noradrenergic neurons (e.g., in the locus coeruleus) parallel the broad projections of the serotonergic system and similarly have a broad influence on a wide range of wake-related functions.

Regulation of Serotonergic Neuronal Activity

Ultimately, the electrophysiological effects of serotonin depend upon the activity of the serotonergic cells of origin in the raphe nuclei. In various mammalian species, serotonergic neurons in waking states have been found to have a slow, tonic pattern of firing ($\sim$1–4 spikes s^{-1}). During slow-wave sleep, there is a deceleration of firing rate, and during REM (or dream) sleep, nearly a total cessation of activity. Thus, serotonergic neurons can be seen as being 'wake-on' cells. The maintenance of rhythmic firing during the waking state has suggested that serotonergic neurons possess regulated tonic pacemaker mechanisms. Intracellular and whole cell recordings from dorsal raphe neurons show that spikes arise from gradual depolarizing ramps (pacemaker potentials) rather than synaptic potentials. The regular pacemaker rhythm of serotonergic neurons is shaped by a complex interplay of intrinsic ionic currents; these include a voltage-dependent transient outward potassium current, a low-threshold inward calcium current, and a large calcium-activated outward potassium current. However, the drive behind the pacemaker activity mainly comes from extrinsic excitatory inputs, including brain stem noradrenergic inputs and hypothalamic hypocretin (orexin) inputs (Figure 2). The hypocretin system is essential for maintaining the normal waking state and loss of this system leads to the condition of narcolepsy, characterized by excessive somnolence. Both norepinephrine (via α_1-adrenoceptors) and the peptide hypocretin/orexin

Figure 3 Activation of pacemaker activity in a serotonergic neuron by norepinephrine (NE) or hypocretin in brain slice. Whole cell recording from a serotonergic neuron located in the dorsal raphe nucleus of a midbrain slice. As is typical of serotonergic neurons in brain slice where excitatory afferents are disconnected, this cell shows no basal spiking activity. When NE (top traces) or hypocretin/orexin (hcrt; bottom traces) is applied, there is a slow depolarization leading to tonic pacemaker activity. The expanded traces to the right show the gradual depolarizing ramps leading up to the onset of spiking activity. NE and hcrt/orexin can be seen as restoring the tonic pacemaker activity that is typical of serotonergic neurons *in vivo*. Provided by R-J Liu and GK Aghajanian.

(via hypocretin receptors 1 and 2), by closing potassium channels and opening nonselective cation channels, accelerate pacemaker activity of serotonergic neurons by inducing a slow depolarization (Figure 3). In addition to neurotransmitter inputs, elevated levels of CO_2 also have a strong activating effect on serotonergic as well as noradrenergic neurons. This would provide an alerting signal in response to states of respiratory insufficiency.

Serotonergic pacemaker activity is negatively modulated by the autoinhibitory action of serotonin, acting via somatodendritic 5-HT_{1A} autoreceptors. The maintenance of tonic 5-HT_{1A} autoinhibition depends upon the rate of serotonins synthesis, which in turn depends on availability of the initial serotonin precursor L-tryptophan. The activity of tryptophan hydroxylase, the limiting step in serotonin synthesis, is highly regulated by the tryptophan hydroxylase-activating kinases calcium/calmodulin protein kinase II (CaMKII) and protein kinase A (PKA). Increased calcium influx at higher firing rates, by activating tryptophan hydroxylase via CaMKII and PKA, can work together with tryptophan to enhance negative feedback control of the output of the serotonergic system.

Electrophysiology of Serotonin Receptor Subtypes

The electrophysiological actions of serotonin are a function of the receptor subtype(s) expressed by a given cell. The G_i/G_o-coupled 5-HT_1 receptors generally mediate inhibitory effects on neuronal firing through an opening of potassium channels or a closing of calcium channels. Inhibitions mediated by 5-HT_{1A} and other 5-HT_1 receptor subtypes have been observed in postsynaptic neurons located in many regions of the central nervous system. Presynaptic 5-HT_{1A} receptors, located at the somatodendritic region of serotonergic neurons, have been termed 'autoreceptors,' mediating negative feedback inhibition via the cell's own transmitter. The 5-HT_{2A} receptors mediate slow excitatory effects through a decrease in potassium conductance or an increase in nonselective cation conductance. These are merely a few examples of how serotonin, with its widespread projections and large array of receptor subtypes/transduction pathways, is able to modulate neuronal excitability in a complex fashion throughout the neuraxis.

While the electrophysiological actions of serotonin may seem quite varied, there is considerable uniformity within each of the major receptor families. Because of their common G-protein coupling, all members of the 5-HT_1 receptor family tend to have inhibitory actions either pre- or postsynaptically. Similarly, all members of the 5-HT_2 family tend to have excitatory actions. Therefore, the discussion of serotonin electrophysiology in selected regions of brain will be organized according to receptor families and their transduction pathways (Figure 4).

5-HT_1 Receptors

Members of the 5-HT_1 receptor family are coupled via G_i/G_o G proteins and produce their effects through opening of inwardly rectifying K^+ channels or closing of Ca^{2+} channels. Particularly high levels of 5-HT_{1A} receptors are found in certain regions,

Figure 4 The four major groupings of serotonin receptor families and their transduction pathways. Three of the four groups are coupled through G-proteins: 5-HT_1-G_i/G_o, 5-HT_2-G_q, and 5-$HT_{4,6,7}$-G_s. The remaining receptor is 5-HT_3, which is a ligand-gated channel and is not coupled through a G protein. cAMP, adenosine 3′,5′-cyclic monophosphate; DAG, diacylglycerol; PKC, protein kinase C; sAHP, slow after hyperpolarization; PLC, phospholipase C. Provided by GK Aghajanian.

including the dorsal raphe nucleus, hippocampus, lateral septum, and certain layers of the cerebral cortex. Studies in these regions and other regions have been useful in delineating the physiological role of this receptor.

Raphe nuclei Serotonergic neurons of the raphe nuclei are inhibited by the local (microiontophoretic) application of serotonin to their cell body region. Thus, the receptor mediating this effect has been termed a somatodendritic autoreceptor (as opposed to the prejunctional autoreceptor). Functionally, the somatodendritic serotonin autoreceptor has been shown to mediate collateral inhibition. The ionic basis for the autoreceptor-mediated inhibition, either by serotonin or LSD, is an opening of K^+ channels to produce a hyperpolarization; these channels are characterized by their inwardly rectifying properties. Patch clamp recordings in the cell-attached and outside-out configuration from such acutely isolated dorsal raphe neurons show that the increase in K^+ current results from a greater probability of opening of unitary K^+ channel activity.

The somatodendritic autoreceptors of serotonergic neurons in both the dorsal raphe and other raphe nuclei appear to be predominantly of the 5-HT_{1A} subtype, as a variety of drugs with 5-HT_{1A} selectivity (e.g., 8-OH-DPAT) share the ability to potently inhibit raphe cell firing in a dose-dependent manner. Highly selective 5-HT_{1A} antagonists (e.g., WAY 100635) have been found which potently block the direct inhibition of dorsal raphe serotonergic neurons both by serotonin and selective 5-HT_{1A} agonists. As described above, the somatodendritic 5-HT_{1A} autoreceptor is importantly involved in the negative feedback regulation of sertonergic cell activity through the release of endogenous serotonin.

Other subcortical regions Inhibitory or hyperpolarizing responses to serotonin have been reported in a wide variety of neurons in the spinal cord, brain stem, and diencephalon. In general, such responses have been attributed to mediation by 5-HT_1 receptors. In the nucleus prepositus hypoglossi, focal electrical stimulation evokes inhibitory postsynaptic potentials (IPSPs) that are mediated by 5-HT_{1A} receptors to activate an inwardly rectifying K^+ conductance and a novel outwardly rectifying K^+ conductance. In the midbrain periaqueductal gray, a region known to be involved in pain modulation and fear responses, approximately half the cells are inhibited/hyperpolarized by 8-OH-DPAT, suggesting mediation by 5-HT_{1A} receptors. In the ventromedial hypothalamus and lateral septum, serotonin and 5-HT_{1A} agonists produce inhibitory effects also by activating a potassium conductance. In addition to these postsynaptic effects, serotonin has been shown to suppress glutamatergic synaptic transmission via presynaptic 5-HT_{1B} receptors in various regions including the hypoglossal nucleus and the nucleus accumbens.

In the rat laterodorsal tegmental nucleus (LDT), bursting cholinergic neurons are hyperpolarized by serotonin via 5-HT_1 receptors. In freely behaving rats, the direct injecton of serotonin into the LDT was found to suppress REM sleep. In unanesthetized cats, a corresponding population of neurons that are active selectively during REM states (REM-on neurons) in the LDT are inhibited by direct application of the 5-HT_{1A} agonist 8-OH-DPAT. It has been proposed that during REM sleep, the removal of a tonic inhibitory serotonin influence from these cholinergic neurons may be responsible for the emergence of an activated EEG during this behavioral state (see later).

Hippocampus Pyramidal cells of the CA1 region express high levels of 5-HT_{1A} receptor mRNA and 5-HT_{1A} receptor binding. Serotonin-induced inhibition in both CA1 and CA3 pyramidal cells is mediated

by the activation of receptors of the 5-HT_{1A} subtype coupled to an opening of K^+ channels. In addition to the above direct effects on pyramidal cells, serotonin has been shown to depress both excitatory and inhibitory synaptic potentials in the hippocampus. Relatively high concentrations of serotonin cause a reduction in electrically evoked excitatory postsynaptic potentials (EPSPs) in CA1 pyramidal cells, an effect that is mimicked by 8-OH-DPAT, suggesting mediation by 5-HT_{1A} receptors. Indirect measures indicate that serotonin acts presynaptically to reduce Ca^{2+} entry and thereby gluamatergic synaptic transmission. In addition, there is a 5-HT_{1A}-mediated inhibitory effect on putative inhibitory interneurons of the hippocampus. Functionally, the 5-HT_{1A}-mediated inhibition of GABAergic interneurons in the hippocampus leads to a disinhibition of pyramidal cells in CA1. Clearly, the effects of serotonin in the hippocampus are highly complex, involving both pre- and postsynaptic actions which may, to varying degrees, be inhibitory or disinhibitory, facilitatory or disfacilitatory.

Cerebral cortex 5-HT_{1A}-induced hyperpolarizing/inhibitory responses in pyramidal cells of the cerebral cortex have been described in a number of studies. In entorhinal cortex, where there is an especially high density of 5-HT_{1A} receptors (and a low density of 5-HT_{2A} receptors), unopposed 5-HT_{1A} receptor-mediated hyperpolarizing responses are seen. However, cortical neurons in most other regions typically display mixed inhibitory and excitatory responses to serotonin due to the expression by the same pyramidal cells of multiple serotonin receptor subtypes (e.g., 5-HT_{1A}, and 5-$HT_{2/2C}$). Hyperpolarizing responses mediated by 5-HT_{1A} receptors are often unmasked or enhanced in the presence of 5-HT_2 antagonists, consistent with the idea that there is an interaction between 5-HT_{1A} and 5-HT_{2A} receptors at an individual neuronal level. In addition to these postsynaptic effects, there are various presynaptic effects mediated by 5-HT_1 receptors in the cerebral cortex. In cingulate cortex, serotonin, acting upon presynaptic 5-HT_{1B} receptors, reduces the amplitude of electrically evoked EPSPs, including both *N*-methyl-D-aspartate (NMDA) and non-NMDA components. Similar modulations of EPSPs, mediated by 5-HT_{1A} or 5-HT_{1B} receptors, have been reported for several cortical regions including medial prefrontal and entorhinal cortex.

5-HT_2 Receptors

Members of the 5-HT_2 family of receptors are coupled through Gq-type G proteins and have excitatory effects through closing of K^+ channels or opening nonselective cation channels. High concentrations of 5-HT_2 are expressed in certain regions of the forebrain such as the neocortex, piriform cortex, claustrum, and olfactory tubercle. With few notable exceptions (e.g., motor nuclei and the nucleus tractus solitarius), relatively low concentrations of 5-HT_2 receptors or mRNA expression are found in the brain stem and spinal cord. Studies aimed at examining the physiological role of 5-HT_2 receptors in several of these regions are described in the following sections.

Motoneurons In spinal cord and brain stem motor nuclei, motoneurons have a high density of 5-HT_2 receptor binding sites. Early studies *in vivo* showed that serotonin applied microiontophoretically does not by itself induce firing in the normally quiescent facial motoneurons but does facilitate the subthreshold and threshold excitatory effects of glutamate. Intracellular recordings from facial motoneurons *in vivo* or in brain slices *in vitro* show that serotonin induces a slow, subthreshold depolarization associated with an increase in input resistance, indicating a decrease in a resting K^+ conductance. Selective 5-HT_2 antagonists are able to selectively block the excitatory effects of serotonin in facial motoneurons. The facilitation of motoneuron excitability contributes to the role of serotonin as a 'wake-on' system to promote activity during the waking state (see later).

Other subcortical regions In brain slices of the medial pontine reticular formation, serotonin induces depolarizing responses that have a 5-HT_2 pharmacology and are associated with a decrease in membrane conductance resulting from a decrease in an outward K^+ current. In brain slices of the substantia nigra pars reticulata, a majority of neurons are excited by serotonin via 5-HT_2 receptors, possibly of the 5-HT_{2C} rather than 5-HT_{2A} subtype. Neurons in the inferior olivary nucleus are excited by serotonin via 5-HT_{2A} receptors, thereby altering the oscillatory frequency of input to cerebellar Purkinje cells. In the nucleus accumbens, the great majority of neurons are depolarized by serotonin, inducing them to fire. This depolarization is associated with an increase in input resistance due to a reduction in an inward rectifier K^+ conductance. In addition, GABAergic neurons within a number of regions (e.g., dorsal raphe nucleus, medial septal nucleus, hippocampus, cerebral cortex) are also excited by serotonin via 5-HT_2 receptors, suggesting that in multiple locations within the CNS there are subpopulations of interneurons that are excited by serotonin via 5-HT_2 receptors, giving rise to indirect inhibitory effects.

Cerebral cortex The electrophysiological effects of serotonin have been studied in several cortical-regions. *In vitro* studies in the brain slice preparation have shown that pyramidal cells in various cortical regions respond to serotonin by either a small hyperpolarization, depolarization, or no change in potential. Depending on the region of cortex under study, as described below, the depolarizations appear to be mediated by 5-HT_{2A} or 5-HT_{2C} receptors. In addition to these postsynaptic effects, serotonin induces an increase in 'spontaneous' (nonelectrically evoked) postsynaptic potentials or currents (PSPs/PSCs) recorded in brain slices from various cortical regions. These may originate from the activation of intracortical pathways or through interactions with subcortical inputs such as the thalamus. Activation of 5-HT_{2A} receptors also enhances late components of evoked responses in cerebral cortex (Figure 5). These late responses (also termed UP states) are generated by sustained recurrent network activity. It has recently been shown that UP states rely on glutamate spillover onto extrasynaptic NMDA receptors. Interestingly, these UP states are characteristic of alert waking and are enhanced by psychedelic hallucinogens which are known to be 5-$HT_{2A/2C}$ partial agonists. It has been proposed that the hallucinogenic drugs produce their characteristic aberrations in perception, cognition, and affect by driving cortical UP states beyond normal limits. It is significant that the facilitation of UP states by 5-HT_{2A} receptors is opposed by 5-HT_{1A} receptors which tend to suppress UP states. This damping effect of 5-HT_{1A} receptors on UP states may explain why selective 5-HT_{2A} agonists are hallucinogenic, whereas serotonin, the natural transmitter, is not. This example further illustrates how serotonin, rather than having a monolithic action, exercises numerous checks and balances at a cellular and systems level via its diverse receptor subtypes.

Figure 5 Enhancement of electrically evoked recurrent network activity (prolonged late excitatory postsynaptic current (EPSC) or UP state) in prefrontal brain slice by the hallucinogen LSD. Under basal conditions (top traces), note the fast EPSC, which occurs within a few milliseconds of a local electrical stimulus applied to the brain slice; following the fast EPSC, a low-amplitude late EPSC can be seen. After the application of a low concentration of LSD in the bath, the late EPSC or UP state is greatly enhanced both in amplitude and duration. Whole cell recording from a layer V pyramidal cell in rat prefrontal cortex. Provided by GK Aghajanian.

5-HT_3 Receptors

Excitatory responses to serotonin have been found in various central neurons that have a rapid onset of action and rapid desensitization, features that are typical of ligand-gated ion channels rather than G-protein-coupled receptor responses. The cloned 5-HT_3 receptor homologous with the nicotinic acetylcholine receptor and the β_1 subunit of the $GABA_A$ receptor indicate that it is a member of the ligand-gated ion channel superfamily. Typically members of this superfamily are comprised of multiple subunits; however, only one 5-HT_3 receptor subunit and an alternatively spliced variant has been cloned to date.

In hippocampal slices, serotonin has been reported to increase spontaneous GABAergic IPSPs, most likely through a 5-HT_3 receptor-mediated excitation of inhibitory interneurons; these responses also show fading with time. A similar induction of 5-HT_3 receptor-mediated induction of inhibitory postsynaptic currents (IPSCs) has been reported in the neocortex. While fast, rapidly inactivating excitation has generally become accepted as characteristic of 5-HT_3 receptors, non-desensitizing responses have also been reported. In dorsal root ganglion cells, a relatively rapid but non-inactivating depolarizing response has been described that has a 5-HT_3 pharmacological profile. In neurons of the nucleus tractus solitarius brain slices, there is a postsynaptic depolarizing response to 5-HT_3 agonists that is not rapidly desensitizing.

5-HT_4, 5-HT_6, 5-HT_7

There are three known G_s-coupled serotonin receptors: 5-HT_4, 5-HT_6, and 5-HT_7, all mediating positive coupling of serotonin responses to adenylyl cyclase. The resulting increase in cyclic AMP can produce its electrophysiological effects through interacting directly with ion channels or through the activation of the PKA signal transduction pathway, which can interact

with a myriad of ion channels, transporters, and other kinases. At this time, electrophysiological studies are available only for the 5-HT_4 and 5-HT_7 receptors, as described below.

5-HT_4 receptors Binding studies using a selective 5-HT_4 ligand indicate that 5-HT_4 receptors are present in several discrete regions of the mammalian brain including the striatum, substantia nigra, olfactory tubercle, and hippocampus. As these regions also express 5-HT_4 receptor mRNA, it appears likely that these receptors function postsynaptically to mediate certain actions of serotonin. The best studied of these regions is the hippocampus where both biochemical and electrophysiological studies have provided detailed picture of the actions of serotonin at 5-HT_4 receptors. Electrophysiological studies show that 5-HT_4 receptors mediate an inhibition of a calcium-activated potassium current, which is responsible for the generation of a slow afterhyperpolarization (AHP) in hippocampal pyramidal cells of the CA1 region. A suppression of the AHP would enhance the ability of these cells to respond to excitatory inputs with robust spike activity.

5-HT_7 receptors The 5-HT_7 receptor is positively coupled to adenylate cyclase and can mediate electrophysiological actions through the cyclic AMP pathway. One such effect is through a cyclic nucleotide enhancement of the hyperpolarizing-activated nonselective cationic current I_h. An increase in I_h tends to prevent excessive hyperpolarization and increase neuronal excitability. 5-HT_7 receptors can also influence neuronal excitability through cyclic AMP-activated PKAs, leading to suppression of slow AHPs. This occurs in the midline/intralaminar nuclei of the thalamus where the highest expression of 5-HT_7 receptors in the brain occurs. As the thalamocortical pathway projecting from the midline/intralaminar nuclei is the final link in the ascending arousal pathway, this is one way that serotonin exerts its effects as a wake-on system to promote alertness and attention (see later).

Behavioral and Clinical Correlations

The diversity of receptors and transduction pathways underlying the varied electrophysiological actions of serotonin, together with the differential expression of these receptors in different neuronal populations, helps explain how one transmitter can be involved in such a large array of behaviors, clinical conditions, and drug actions. Alterations in serotonin function have been linked to affective disorders, anxiety states, schizophrenia, obsessive–compulsive disorder, eating disorders, migraine, and sleep disorders, including sleep apnea. Drugs that modify serotonergic transmission include antidepressants, atypical antipsychotics, antiemetics, hallucinogens, antimigraine drugs, and appetite suppressants. For example, the most commonly used antidepressant drugs act by blocking serotonin reuptake, which results in increased synaptic availability of this transmitter. Antagonism of 5-HT_{2A} receptors has been proposed as contributing to the favorable clinical profile of atypical antipsychotic drugs. Conversely, an agonist action of psychedelic hallucinogens at 5-HT_{2A} receptors is thought to mediate the psychotomimetic effects of these drugs. Because of its ubiquitous distribution and diverse actions in the central nervous system, it is likely that future research will continue to uncover an involvement of serotonin in many pathological as well as normal behavioral processes.

It has been hypothesized that activation of serotonin neurons works in concert with other components of the ascending arousal system projecting to the forebrain. For example, noradrenergic neurons, which also constitute a wake-on system, directly activate serotonergic neurons. A further linkage is seen by the fact that both noradrenergic and serotonergic neurons are activated by inputs from hcrt/orexin neurons, which are essential for normal wakefulness. A concerted action is also seen upstream, by the excitatory/facilitatory effects of both serotonin and hcrt upon the relay neurons of the midline/intralaminar nuclei which project to prefrontal cortex. This prefrontal input, which represents the final synapse in the ascending arousal system, is essential for awareness and attention. Within the cortex itself, 5-HT_{2A} receptors enhance UP states, which are closely associated with the alert waking state. However, excessive stimulation of 5-HT_{2A} receptors by hallucinogenic drugs can be pathological by leading to uncontrolled UP states.

In conclusion, through its effects on neuronal excitability in diverse regions of the brain and spinal cord, the serotonergic system is positioned to coordinate complex sensory and motor patterns during different behavioral states. More specifically, since the activity of serotonergic neurons is greatest during periods of active waking, reduced during slow-wave sleep, and almost completely absent during REM (dream) sleep, the serotonin system can be seen as promoting neuronal activity in support of the waking state while concomitantly suppressing neuronal activity underlying sleep and dream states.

The Suprachiasmatic Nucleus Regulates Mammalian Circadian Rhythms

Organisms from plants to humans have developed a self-sustaining clocklike mechanism that coordinates biological functions both with one another and with specific times of the day or night. In mammals, the hypothalamic suprachiasmatic nucleus (SCN) is the primary circadian oscillator responsible for the generation of circadian rhythms in physiology, behavior, and metabolism. The SCN is an autonomous and self-sustaining circadian oscillator generating an oscillation of neural activity with a period of approximately 24 h (the term circadian is derived from the Latin *circa* 'about' and *dies* 'day'). Environmental time cues, the most potent being the day/night cycle, entrain the SCN circadian oscillation of neural activity to the 24-h day/night cycle. Entrainment is achieved by light-induced signals that are generated in the retina and conveyed to the SCN by axons of the retinohypothalamic tract (RHT) traveling via the optic nerve.

Anatomical Organization of the SCN

The SCN in mammals is located in the anterior hypothalamus adjacent to the midline third ventricle and situated just dorsal to the optic chiasm from which the RHT emerges. The SCN is composed of a heterogeneous group of about 10 000 small neurons within a complex neuropil. The dendritic arbors of SCN neurons are relatively simple, with most cells having only two or three dendrites that branch very little. Most SCN neurons are γ-aminobutyric acid (GABA) ergic and are capable of generating a circadian oscillation in their action potential firing rate. SCN GABAergic projection neurons also possess local collaterals that innervate other neurons within the nucleus, thus forming a complex intra-SCN network. The intra-SCN GABAergic network is important for the functional coordination of the unitary output of SCN circadian oscillations that are derived from a large number of oscillating clock cells.

SCN Divisions

Several different neuroactive peptides have been localized within the SCN. Based primarily on the nonhomogeneous distribution of these peptidergic neurons within the SCN, the nucleus has been subdivided into two somewhat imprecise divisions – a ventrolateral region rich in vasoactive intestinal polypeptide (VIP) neurons and a dorsomedial region containing vasopressin (VP) neurons, although as noted earlier, most, if not all, of these neurons also use GABA as a neurotransmitter. Whether these two regions defined by their peptidergic phenotype represent distinct functional units within the SCN remains to be firmly established. It has been suggested by some, based primarily on the distribution of peptidergic neurons in the rat SCN, that the VIP neuron-containing region represents a receptive core that receives both retinal and serotonergic afferents and is surrounded by a shell region containing VP neurons and receiving afferents from nonvisual cortical and subcortical regions. However, significant species variations in the core/shell organizational plan suggest that this may be an oversimplification of the complex organization of the mammalian SCN.

Afferent Fiber Inputs to the SCN

The SCN receives many afferent fiber inputs arising from neurons located in several regions of the brain. The RHT arising from retinal ganglion cells (RGCs) and afferent fibers arising from serotonergic neurons located in the midbrain median raphe nucleus have received significant attention and are perhaps the best-understood afferent fiber systems innervating the SCN.

The Retinohypothalamic Tract

The retinal input to the SCN is bilateral and retinal fibers are found distributed throughout much of the SCN except typically for a medial crescent-shaped region that is almost devoid of retinal input. The RGCs that give rise to the RHT represent 1–2% of the total RGC population, and these cells were recently discovered to be intrinsically photosensitive due to their expression of a novel mammalian opsin, melanopsin. Melanopsin-expressing intrinsically photosensitive retinal ganglion cells (ipRGCs) depolarize in response to light and send environmental irradiance information to the SCN. Melanopsin ipRGCs removed from the retina and maintained in culture retain their photosensitivity, although *in situ* the ipRGCs also receive input in the conventional manner: rod/cone photoreceptor → bipolar/amacrine → RGC. The ipRGCs use glutamate as a neurotransmitter, and these cells also synthesize pituitary adenylate cyclase-activating polypeptide (PACAP), which may

be co-released with glutamate in the SCN. In addition to the SCN, ipRGCs send axons to the thalamic intergeniculate leaflet (IGL), olivary pretectal nucleus (OPN), ventral subparaventricular zone of the hypothalamus, and ventrolateral preoptic (VLPO) nucleus, suggesting that these cells may play a broad role in nonvisual photoreception.

The primary role of the RHT input to the SCN is to convey light/dark information (i.e., level of ambient illumination), thereby entraining the intrinsic SCN circadian oscillation to the environmental 24 h day/night cycle. Entrainment is accomplished by a daily resetting of the SCN such that the light-induced phase shift is equal in magnitude to the difference between the free-running circadian period of the endogenous SCN oscillation and the 24 h period of the day/night cycle. This light-induced resetting process is described experimentally by the response of animals free running under constant dark (DD) conditions and exposed briefly to light at different phases of the circadian cycle. The response of the SCN to brief light pulses is phase dependent: light exposure early in the subjective night produces phase delays in circadian rhythms, while light exposure late in the subjective night results in phase advances. In contrast, light exposure during the subjective day has no effect on the phase of the free-running circadian rhythm. The effects of drugs on light-induced behavioral phase shifts have often been used to explore the neuropharmacology of the SCN circadian system.

Figure 1 Representation of the retinohypothalamic tract (RHT) and serotonin (5-hydroxytryptamine; 5-HT) terminal fields in the mouse suprachiasmatic nucleus (SCN). The region of the SCN containing the heaviest concentration of retinal fibers is shown in green and the region of densest 5-HT fibers is depicted in red; the yellow region represents the area where the terminal fields are co-extensive.

Serotonergic Afferents

The SCN has long been known to receive one of the densest serotonergic innervations in the brain. This monoaminergic input to the SCN arises from ascending projections of serotonin (5-hydroxytryptamine; 5-HT) neurons in the midbrain median raphe nucleus. 5-HT fibers are distributed throughout much of the SCN, but they are most heavily concentrated in the ventral aspect of the nucleus, forming a curved, shaped terminal plexus that is co-extensive to a considerable degree with the RHT terminal field (Figure 1). In this region of overlap between the two afferent fiber systems, 5-HT fibers preferentially make axo-dendritic and axo-somatic synaptic contacts with VIP neurons that also receive retinal synapses. Ultrastructural analyses have also shown that 5-HT varicosities in the SCN are very often apposed to retinal and GABA terminals; these 5-HT axo-axonic interfaces represent additional important sites for serotonergic modulation of SCN activity.

Early on it was demonstrated that the 5-HT input to the SCN was not essential for the expression of circadian behavior. However, removal of the serotonergic input to the SCN following ablation of the median raphe nucleus does produce an increased sensitivity to photic input in the SCN and an alteration in the phase angle of entrainment of the circadian activity rhythm to the light/dark cycle. These findings are consistent with the generally accepted theme that 5-HT neurons do not play an essential role in physiological and behavioral processes but rather exert tonic modulatory influences on their targets.

Serotonin receptor subtypes in the SCN A family of seven serotonin receptor subtypes (5-HT_{1-7}) with at least 14 members mediates the diverse modulatory effects of serotonin in the central nervous system. Using a variety of techniques, including radioligand binding, *in situ* hybridization for 5-HT receptor mRNA, and immunocytochemical localization for 5-HT receptor proteins at both the light and electron microscopic level of examination, six 5-HT receptor subtypes have been identified in the SCN: 5-HT_{1A}, 5-HT_{1B}, 5-HT_{2A}, 5-HT_{2C}, 5-HT_{5A}, and 5-HT_7. *In situ* hybridization and binding studies typically lack the resolution to provide detailed information on subcellular localization. Electron microscopic immunocytochemical procedures have been used to describe the subcellular distribution for the 5-HT_{1B} and 5-HT_7 receptors in the SCN. 5-HT_{1B} receptor immunostaining is associated primarily with the membrane of axon terminals, many of which are of retinal origin. These 5-HT_{1B} presynaptic receptors are synthesized by RGCs and are transported via the RHT to the SCN, where they are then inserted into the terminal membrane, but almost never at the synaptic active

zone. 5-HT_7 receptors are synthesized by SCN neurons, and 5-HT_7 immunoreactivity is often associated with the dendrites of SCN GABAergic neurons as a postsynaptic receptor.

Effects of Serotonergic Compounds on Retinal Input to the SCN

To determine if the serotonergic innervation of the SCN modulates retinal input, several different approaches have been used. *In vivo* studies have utilized systemic administration of serotonergic drugs to evaluate their effect on light-induced responses of the SCN. Although relatively easy to perform, these studies lack the ability to determine the precise site of action of the drugs administered. For example, the dorsal raphe nucleus provides serotonergic input to the retinorecipient IGL. The IGL sends to the SCN afferent fibers that modulate SCN responses to light. Thus, compounds administered systemically may alter SCN-mediated responses indirectly. Direct microinjection of drugs into the region of the SCN via an indwelling guide cannula provides better assurance that the drugs are acting locally on the SCN, but these types of studies are more difficult to conduct and also require *post hoc* analyses to confirm the precise location of the injection site in the region of the SCN. *In vitro* studies using electrophysiological recording from SCN neurons in a hypothalamic slice preparation provide cellular detail, but the natural stimulus pathway (i.e., light-induced activation of the RHT) is unavailable and electrical stimulation of the optic nerve must be used to simulate photic input to the SCN. Taken together, these different approaches have firmly established that serotonergic afferents modulate photic responses of the SCN.

5-HT Modulation of the SCN Response to Light

Based on the intimate anatomical relationship between 5-HT afferent fibers and RHT afferent fibers in the SCN, it is not surprising that 5-HT has been shown to alter the response of the SCN to light. Single-unit activity recorded from the SCN *in vivo* was initially used to examine the effects of 5-HT agonists on photically responsive cells. Intravenous application of the nonselective 5-HT agonist quipazine was shown to inhibit light-induced responses in the SCN. With the development of more selective serotonergic compounds, it became possible to identify the involvement of specific serotonin receptor subtypes in mediating the effects of 5-HT on photic responses.

5-HT_{1B} receptor-mediated presynaptic inhibition of retinal input 5-HT modulates the sensitivity of the SCN to light by acting on 5-HT_{1B} presynaptic receptors located on retinal terminals and by inhibiting glutamate release. 5-HT_{1B} receptor agonists, including *m*-trifluoromethylphenylpiperazine (TFMPP), CGS-12066A, and CP-94253, injected peripherally inhibit light-induced phase shifts of rodent circadian activity rhythms in a dose-dependent manner. Similarly, 5-HT_{1B} receptor agonists inhibit light-induced expression of the immediate-early gene c-*fos* in the SCN as well as light-induced expression of VIP mRNA in the SCN. 5-HT_{1B} receptor agonists have also been shown to inhibit the light-induced suppression of pineal melatonin during the night. TFMPP injected directly into the SCN has been shown to inhibit light-induced behavioral phase shifts. TFMPP is a well-characterized 5-HT_{1B} receptor agonist, although it also has a relatively high affinity for 5-HT_{1A} and 5-HT_{2C} receptors. However, TFMPP has no effect on light-induced behavioral phase shifts in 5-HT_{1B} receptor knockout mice, which lack functional 5-HT_{1B} receptors, indicating that its effect in wild-type (WT) mice is mediated via 5-HT_{1B} receptors.

Although the studies described here are consistent with the interpretation that the 5-HT agonists act at 5-HT_{1B} receptors located presynaptically on retinal terminals in the SCN, the data do not exclude the possibility that they act at receptors located postsynaptically on the soma or dendrites of SCN neurons. Support for a presynaptic effect has been provided using whole-cell patch clamp recording from SCN neurons in a slice preparation (Figure 2). 5-HT_{1B} receptor agonists decreased reversibly the amplitude of the optic nerve-evoked excitatory postsynaptic current (EPSC) but had no effect on glutamate-evoked whole-cell currents, indicating that the drug effect was due to activation of receptors located presynaptically to the recorded neuron (Figure 3).

5-HT_7 receptor-mediated inhibition of retinal input The mixed 5-$HT_{1A/7}$ receptor agonist 8-hydroxy-2-(di-*n*-propylamino)tetralin (8-OH-DPAT) administered *in vivo* inhibits light-induced behavioral phase shifts and light-induced gene expression in the SCN. 8-OH-DPAT *in vitro* also inhibits optic nerve stimulation-evoked field potentials and optic nerve stimulation-evoked EPSCs in the SCN slice preparation. The effect of 8-OH-DPAT in the latter case is minimally attenuated by a highly selective 5-HT_{1A} antagonist, WAY 100635, but is reversibly and significantly reduced in the presence of ritanserin, a 5-$HT_{2/7}$ antagonist. Although the site of action of 8-OH-DPAT within the SCN has not been addressed directly, 5-HT_7 receptors are postsynaptic in the SCN and have been described on VIP cells that receive retinal synapses.

Figure 2 Composite figure of a horizontal slice of the ventral hypothalamus, illustrating recording configuration for examining retinohypothalamic input to the suprachiasmatic nucleus (SCN). To illustrate bilateral retinal innervation of the SCN, retinal fibers were labeled after monocular injection of horseradish peroxidase into the vitreous body of the eye. Horseradish peroxidase-labeled optic fibers are visible in this dark-field image in the optic nerve (CN II) of the injected eye, crossing in the optic chiasm, and terminating bilaterally in the SCN just posterior to the optic chiasm (OC). Whole-cell patch clamp recordings of evoked excitatory postsynaptic currents in SCN neurons after optic nerve stimulation were conducted to examine the effect of serotonergic compounds on retinal input. Adapted from Pickard GE, Smith BN, Belenky M, et al. (1999) 5-HT_{1B} receptor-mediated presynaptic inhibition of retinal input to the suprachiasmatic nucleus. *Journal of Neuroscience* 19: 4034–4045, copyright 1999 by the society for Neuroscience.

5-HT Alterations in Circadian Phase

Alterations in the phase of the SCN clock generated by stimuli other than light (e.g., arousal, neuropeptides, and 5-HT agonists) fall into the general category of nonphotic phase shifts. Such phase shifts typically are largest during the subjective day, when light has little effect on the SCN. 8-OH-DPAT administered systemically during the subjective night does not alter the phase of the circadian activity rhythm, whereas it produces phase advances with maximal effects observed in the midsubjective day. These effects may be due to 8-OH-DPAT acting on somtatodendritic 5-HT_{1A} autoreceptors in the raphe nucleus, resulting in a decrease in 5-HT firing and subsequent decrease in 5-HT release in the SCN. The disinhibition of SCN unit activity may be responsible for the phase shift. It is thought that the 5-HT_{1A} agonist MKC-242 potentiates the effects of light on the SCN by such an effect on median raphe activity. The inability of 8-OH-DPAT to elicit phase shifts when injected into the SCN supports a site of action outside the nucleus. However, it is unclear how much these data can be generalized, as there appears to be significant species differences in the susceptibility of the circadian system to modulation by systemically delivered serotonergics.

Effects of Serotonergic Compounds on SCN Rhythms *In Vitro*

Circadian rhythms may be monitored *in vitro* by isolating the SCN in a brain slice preparation and observing changes in the rhythms of spontaneous unit firing. These rhythms readily survive outside the animal, generating distinct peaks near the midpoint of the light phase and repeating this pattern at roughly 24 h intervals. Peaks occur at the same time of day in tissue obtained from both nocturnal and diurnal species, suggesting that the ecological preference for daytime or nighttime activity is downstream of the oscillator. Shifts in the occurrence of the peak, either in a phase advance or phase delay direction, can be accomplished by briefly incubating the slices with fixed concentrations of drug to yield both concentration-response and phase-response curves. Presumably the magnitude and direction of the shift observed as such *in vitro* form the basis of the shifts revealed in awake, behaving animals. That this is not the case, based on extensive research in the past few years, hints at the complexity of the pharmacology and our crude understanding of it.

Roles for 5-HT_{1A}, 5-HT_{5A}, and 5-HT_7 Receptors

Early *in vitro* studies with 8-OH-DPAT (at the time believed to be a selective 5-HTIA receptor agonist), when given at midday or ZT6 (zeitgeber time, with ZT0 defined as 'lights on'), demonstrated robust phase advances. Such shifts were attributed to this receptor subtype, a tentative finding in the absence of confirmatory experiments with 5-HT antagonists. When the latter approach was undertaken, a somewhat surprising interpretation surfaced with a significantly greater role for 5-HT_7 receptor activation. Specifically, pretreatment with antagonists selective for the 5-HT_{1A} subtype failed to block the 8-OH-DPAT-induced advances; pretreatment with those counting 5-HT_7 antagonism among their activities were considerably more effective. Although the density of 5-HT_7 sites within the SCN certainly gave credence to this interpretation, it left the somewhat more potent activity of 8-OH-DPAT at the 5-HT_{1A}

Figure 3 *m*-Trifluoromethylphenylpiperazine (TFMPP) reduces the amplitude of evoked excitatory postsynaptic currents (EPSCs) but has no effect on the inward current evoked by direct application of glutamate. (a) TFMPP reversibly reduced the amplitude of the optic nerve-evoked EPSC. The average of eight events is shown. (b) In the same neuron, direct application of glutamate (20 mM) to the surface of the slice evoked an inward current that was not reduced by TFMPP. (c) The effect of 100 μM TFMPP on the optic nerve-evoked EPSC and on the glutamate-evoked inward current in several neurons is shown. The number of neurons examined is indicated above each column set. Adapted from Pickard GE, Smith BN, Belenky M, et al. (1999) 5-HT_{1B} receptor-mediated presynaptic inhibition of retinal input to the suprachiasmatic nucleus. *Journal of Neuroscience* 19: 4034–4045, copyright 1999 by the Society for Neuroscience.

subtype (and its relative abundance) without an apparent role. At least, an immediate role was not apparent, although this was to change in due time.

What was true for 8-OH-DPAT would surely be true for 5-HT itself and initial studies did confirm very similar phase-response curves for both the time of dosing for the peak effect and the relative magnitude of the response (Figure 4). When co-incubated with 5-HT_7 antagonists, however, a surprising pattern emerged: the phase advances elicited by 5-HT at ZT6 were apparently reduced by one 5-HT_7 antagonist, ritanserin, but not by another, mesulergine. Subsequent receptor binding studies demonstrated a 25-fold greater affinity of ritanserin for 5-HT_{5A} sites compared to mesulergine, an observation suggestive of a 5-HT_{5A} mechanism for 5-HT and consistent with earlier observations of robust labeling of 5-HT_{5A} sites in the SCN. The Rp diastereomer of adenosine 3′,5′-cyclic monophosphothioate (Rp-cAMPS), a cAMP antagonist, failed to block the phase shifts elicited by 5-HT at a concentration previously shown to be effective against 8-OH-DPAT-induced phase shifts, in keeping with the proposed negative coupling of 5-HT_{5A} receptors to cAMP production and the positive coupling assigned to 5-HT_7. While these data were internally consistent, the broader picture grew considerably more complicated: similar phase advances by an exogenous agonist and an endogenous neurotransmitter that were mediated by two distinct 5-HT receptor subtypes.

Efforts to simplify this story only served to add to its complexity. The development of a 5-HT_7 knockout (KO) mouse promised a quick confirmation of earlier findings – the loss of phase advances following incubations with 8-OH-DPAT and the continuing presence of these when 5-HT was used – as a receptor mechanism functioning exclusively through 5-HT_{5A} receptors should not be affected. The results were again surprising, this time in two ways. In slices obtained from 5-HT_7 KO animals, bath application of 8-OH-DPAT produced a phase advance in neuronal firing when applied one circadian cycle earlier at ZT6, but the mean phase advance was no different in slices prepared from KO or matched WT animals. Co-application of 8-OH-DPAT with a highly selective 5-HT_{1A} antagonist significantly reduced the phase advance, both in experiments with WT and KO

Figure 4 Phase-shifting effects of 5-hydroxytryptamine in rat suprachiasmatic nucleus slices maintained *in vitro*. 5-Hydroxytryptamine (0.5 μM) was added in a 1-h static bath application at ZT6 (zeitgeber time) nominally on the preparatory day. One circadian cycle later, on the experimental day, firing rates of single units were derived from neuronal recordings in sequential electrode passes. An impartial observer determined peak activity visually. In this example, 5-hydroxytryptamine pretreatment shifted the peak to an earlier time point, a phase advance, 3.0 h before that noted in vehicle-treated slices (mean of nine experiments at dashed line) and similar to that obtained with 8-hydroxy-2-(di-*n*-propylamino) tetralin (10 μM). (Zeitgeber time is a 24-h notation of the phase in an entrained circadian cycle; ZT0 indicates the beginning of day, or the light phase, and ZT12 is the beginning of night, or the dark phase.) Adapted from Sprouse JS, Reynolds L, Braselton J, and Schmidt A (2004) Serotonin-induced phase advances of SCN neuronal firing *in vitro*: A possible role for 5-HT5A receptors? *Synapse* 54: 111–118, copyright 2004 John Wiley & Sons, Inc.

mice, suggesting the greater importance of this serotonin subtype independent of genetic modification. 5-HT at ZT6 also yielded phase advances that were indistinguishable in slices prepared from WT and KO mice and that were also sensitive to 5-HT_{1A} antagonism. Unlike the pattern with 8-OH-DPAT, however, the 5-HT-induced phase advances were blocked by ritanserin, in this paradigm useful as a 5-HT_{5A} antagonist (in addition to its more typical role as a 5-$HT_{2A/2C/7}$ antagonist). In sum, these results highlight the importance of the species used in establishing receptor mechanism, a rather well-worn observation. More provocatively, they support the involvement of multiple 5-HT receptors (5-HT_{1A} and 5-HT_{5A}, as well as 5-HT_7) in shifting the phase of circadian rhythms at ZT6.

Actions of SSRIs

Taking a step back from the goal of role-assigning for specific receptor subtype, other efforts have investigated the utility of selective serotonin reuptake inhibitors (SSRIs) in modulating rhythmicity, and in doing so modulating affective state. Fluoxetine, perhaps the prototypical SSRI, when added to SCN slices, has no effect on the timing of phasic activity. While initially puzzling, it was reasoned that the fluoxetine-induced phase shifts would be dependent on existing 5-HT in the slices, likely at a minimum after multiple hours in culture. L-Tryptophan, the amino acid precursor of 5-HT, when applied at ZT6, was subsequently found to produce phase advances similar to those observed with 5-HT agonists; co-incubation of a subthreshold concentration of this 5-HT synthesis-boosting agent with fluoxetine yielded the expected phase advances.

What is to be made of fluoxetine-induced phase advance of SCN neuronal firing? In terms of a clinical dosing strategy, patients receiving their total daily dose of fluoxetine in the morning versus in the evening differed little in their depression scores, and there have been no reported changes in circadian rhythm measurements that might track with symptom improvement. In all of these studies, however, dosing was performed in the morning or in the evening and did not include a midday time point. This is typical strategy in which drugs that tend to sedate are given before bedtime and those that more likely would stimulate are given at the start of the day. A comparison of optimal dosing times utilizing a noontime dose, in this case using chlomipramine, did establish it as being the most effective in a single clinical study, superior to morning or evening doses or to three equally divided doses. More work needs to be done; it is hoped that a greater appreciation of what might be accomplished will spur such activities. In making the considerable leap to the clinical setting, several other factors are of concern – the magnitude of the shift, the direction of the shift, the effect of chronic dosing – and it is clear that further laboratory experimentation, complemented by its clinical counterpart, is the key to greater understanding.

Circadian Rhythms and Mood Disorders

Over the years, evidence has accumulated suggesting that mood disorders such as major depressive disorder and bipolar disorder may be related to alterations in circadian clock functioning. In recent years there has been considerable effort to correlate mood regulation with the activity of individual clock genes. Moreover, some treatments for mood disorders such as seasonal affective disorder (SAD) successfully employ bright light therapy as a means of shifting or resetting the circadian clock; the magnitude of advance phase shifts correlates with the extent of mood improvement.

5-HT_{1B} Receptors and SAD

Seasonal affective disorder is a subtype of major depression most often characterized by autumn onset

of depressive symptoms that worsen throughout the winter and then dissipate as summer approaches. Patients suffering from SAD typically have a phase-delayed circadian system. Morning light therapy, especially if timed to maximize the corrective phase advance, has proved to be an effective treatment for SAD. The mechanisms underlying the pathophysiology of this subtype of depression are poorly understood, although it has been suggested that 5-HT plays a key role.

Very recently, it has been shown that p11 (S100A10), a member of the S100 protein family, interacts with 5-HT_{1B} receptors and p11 is decreased in brain tissue from depressed patients. p11 appears to participate in the translocation of proteins to the cell surface of neurons and in particular plays a role in the localization of the 5-HT_{1B} receptor to the presynaptic terminal membrane. p11 KO mice have reduced 5-HT_{1B} receptor function and exhibit a depression-like phenotype.

Although it is clear that activation of 5-HT_{1B} presynaptic receptors on RHT terminals reduces glutamate release, paradoxically, the SCN of 5-HT_{1B} receptor KO mice is less sensitive to light. This is probably due to an increase in GABAergic tone in the SCN resulting from the concomitant loss of 5-HT_{1B} receptors on GABA terminals and a reduction in 5-HT_{1B} receptor-mediated presynaptic inhibition of GABA release. Elimination of 5-HT_{1B} receptor function in the KO mouse results in an alteration in entrainment to the day/night cycle. When 5-HT_{1B} KO mice are maintained under short day (winterlike) photoperiod conditions, their circadian activity rhythm is significantly phase delayed compared to WT mice. The phase-delayed pattern of entrainment in mice lacking functional 5-HT_{1B} receptors under short day condition is similar to patients with SAD, and thus the 5-HT_{1B} receptor KO mouse may be a valuable model to study the relationship between circadian rhythms, 5-HT, and depression.

Chronopharmacology

Chronopharmacology, the strategy of exploiting in pharmacological terms what the clock has set in motion, is well accepted, as it is tied to the cyclical nature of biological phenomena and the rationale for pacing the delivery of drugs to optimize patient benefit. Remarkable success has been achieved in the timing of chemotherapy and the treatment of cardiovascular disease, and more widespread utility may be in the offing as the importance of peripheral circadian oscillators residing in various organ systems gains greater acceptance. The results presented here focus on a simple logical extension of this argument, the notion that the administration of drugs to directly alter SCN function might be of great importance. In doing so, two highly desirable outcomes might be obtained: an improvement in general timekeeping and, as a consequence, a facilitation of psychotherapeutic efficacy.

Historical Introduction

Hallucinogen use by humans dates back at least two millennia and continues in virtually all cultures today. The vast majority of human experience with these compounds derives from the ingestion of plant materials; only recently have the chemical constituents of these plants been identified, synthesized, and ultimately modified and elaborated. Traditional uses of hallucinogens were typically characterized by sacramental ritual uses appropriate to the particular culture. With the advent of modern chemistry, potent hallucinogenic compounds are more widely available and used in more diverse ways. Although several chemical classes are now understood to be represented among the large family of hallucinogenic agents, the present focus is on those whose primary mechanism of action is believed to be mediated by actions on serotonergic neuronal systems.

Defining Phenomenology

Fundamentally, the category of hallucinogens is defined only by the subjective reports by humans of various distortions of perception and affect. Specifically, serotonergic hallucinogens such as lysergic acid *N*, *N*-diethylamide (LSD), mescaline, ayahuasca, and psilocybin increase the intensity and lability of affective responses and produce profound distortions of perceptual processes encompassing visual, auditory, somesthetic, and olfactory modalities. Hallucinogens produce profound changes in mood, thought, intuition, and sensory perception, including changes in the experience of time, space, and self that are otherwise rarely experienced except in dreams. Depending upon person and circumstance, the same hallucinogen may, on the one hand, produce a loss of ego boundaries including heightened mood ranging from pleasure to bliss, and feelings of oneness with the universe, or may, on the other hand, lead to more psychotic ego dissolution, including fear and paranoid ideation associated with experiences of split ego. In these states, perceptual hypersensitivity, illusions, and elementary hallucinations are common. In general, the intensity of these alterations of consciousness is dose dependent, so that hallucinations involving cognitive impairment or disorientation in person, place, and time rarely, if at all, occur with low to medium doses.

Altered States of Consciousness

According to the work of Dittrich, the common nucleus of hallucinogen-induced altered states of consciousness (ASCs) can be described and assessed by three primary dimensions: (1) 'oceanic boundlessness' (OB), referring to positively experienced ego dissolution; (2) 'anxious ego dissolution' (AED), including thought disorder and loss of self-control; and (3) 'visionary restructuralization' (VR), referring to perceptual alterations and altered meaning of percepts. Recent brain imaging studies demonstrate that the degree to which each of these key dimensions of ASCs is expressed across individuals correlates with functional alterations in segregated neuronal networks, including prefrontal, temporal, and parietal cortical regions as well as the basal ganglia and thalamus.

Chemical Structures

For the classical serotonergic hallucinogens, which presumably exert their psychedelic actions predominantly through a 5-HT_{2A} receptor mechanism, molecules are comprised of a basic amino group, separated by two carbon atoms from an aromatic system. This motif reflects the fact that serotonin and the other monoamine neurotransmitters arise through biosynthesis from tryptophan and tyrosine. Thus, the hallucinogens embody the same carbon framework as the natural transmitters. There are two major classes of serotonergic hallucinogens: the phenethylamines and the tryptamines. The tryptamines can further be divided into the simple tryptamines and the tetracyclic ergolines that include LSD and related lysergic acid amides.

Phenethylamines

The simplest phenethylamine hallucinogen is mescaline, which occurs naturally in the peyote cactus, *Lophophora williamsii*. Apparently the only naturally occurring phenethylamine hallucinogen, the potency of mescaline is low, requiring a dose on the order of 250–500 mg for a full effect lasting 8–10 h. Despite its low potency, however, mescaline has served as a molecular template for the chemical synthesis of hundreds of structural modifications that have been made and tested.

Early modifications involved adding an alkyl group to the side chain, to provide TMA, which is about

Figure 1 Mescaline and related phenethylamine hallucinogens.

twice as potent as mescaline. Transposing one of the distal methoxy groups to an *ortho*-position gave TMA-2, which was an order of magnitude more potent than mescaline. These alpha-methyl-substituted compounds are often referred to as 'hallucinogenic amphetamines.' Finally, replacing the 4-alkoxy of TMA-2 with alkyl, alkylthio, or halogen groups gives the most potent phenethylamine-type compounds, some of which are two orders of magnitude more potent than mescaline itself. The introduction of the alpha-methyl group to provide the hallucinogenic 'amphetamines' also introduces a center of chirality. It is known that the *R*-(–) isomer, as shown in Figure 1, is the more potent one. This *R* stereochemistry is opposite to psychostimulant amphetamines, where the *S*-(+) 'dextro' isomers are more potent. In general, substituted amphetamines that are substrates for and inhibitors of monoamine transporters have stereochemistry like *S*-(+)-amphetamine. Because the target of the hallucinogenic amphetamines is a postsynaptic receptor, the different stereochemistry is not surprising.

A variety of 'designer' phenethylamines that lack the alpha-methyl group have appeared on the illicit market. Except for the 2,4,5-trimethoxy compound itself, virtually everything that has a more hydrophobic group at the 4-position has been found to possess oral activity. For example, as shown in Figure 2, several 2C-T compounds have been reported, where the 4-position is an *S*-alkylthio compound. Another example that made frequent appearance on the illicit market was the 4-bromo analog, known as 2C-B (Figure 1). Generally, these phenethylamines are somewhat less potent than the corresponding amphetamine, and of shorter duration of action. They do not, however, produce qualitatively the same type of pharmacology as their amphetamine counterparts.

The most extensive studies of structure–activity relationships of the phenethylamine-type hallucinogens have involved variations in aromatic ring substituents.

Figure 2 Phenethylamine hallucinogens that lack the alpha-methyl group.

Figure 3 Phenethylamine hallucinogens of the benzofurano type.

Methoxy groups at the 2- and 5-positions of the aromatic ring are optimal. Extension of either methoxy group by one carbon, to an ethoxy group, markedly reduces or abolishes activity. The one caveat to this conclusion is that the methoxy groups can be incorporated into heterocyclic oxygen rings. Indeed, the benzofurano-type compounds shown in Figure 3 are the most potent phenethylamine hallucinogens reported to date, with the fully aromatic compounds having K_i values at cloned human 5-HT_{2A} receptors of <0.10 nM. Human data for many phenethylamines have been reported by the Shulgins and also on some Internet sites. In contrast to the relatively low potency of mescaline, many phenethylamines have effective dosages between 1 and 10 mg, with most being orally active and having durations of action ranging from a few hours to as much as 24 h or more.

As illustrated in Figure 1, a large variety of different substituents can be placed at the R position. Of the simple halogens, bromine (DOB) and iodine (DOI) are the most potent, whereas the highly electronegative

MDMA

Figure 4 3,4-Methylenedioxymethamphetamine (MDMA; 'ecstasy').

group CF_3 is even more potent. Alkylthio groups also have given very potent and interesting compounds.

Although 3,4-methylenedioxymethamphetamine (MDMA; ecstasy) is not properly classified as a hallucinogen, it is relevant here because it is a substituted phenethylamine derivative and is in the same legal class as the hallucinogens (Figure 4). In contrast to the hallucinogenic amphetamines, however, which have a direct receptor agonist action, MDMA is an indirect-acting agent that causes release of endogenous serotonin, dopamine, and norepinephrine from neuron terminals. The mechanism appears to be similar to amphetamine itself, and is believed to be related to a reverse transport of the monoamine uptake transporter, leading to drug-induced efflux of monoamine from the neuron. Although the primary behavioral effects of MDMA are attributable to the release of presynaptic serotonin and consequent activation of 5-HT_{1B} receptors, it is clear that the release of dopamine also contributes. There has been very little study of the role of norepinephrine, but it is also robustly released by MDMA.

The mechanism of action for MDMA clearly differs from that of the hallucinogenic amphetamines. That conclusion is evident initially from a chemical perspective. First of all, in the hallucinogenic amphetamines, the isomer with the *R* configuration in the side chain is most active. By contrast, it is the *S* enantiomer (shown) of MDMA that is more active, the same stereochemistry that is most active in the psychostimulants amphetamine and methamphetamine. Second, when an *N*-methyl is attached to the amine of a hallucinogenic amphetamine, there is a dramatic and near-total loss of activity. Yet MDMA possesses this feature, and retains about half the potency of the primary amine analog MDA. Finally, if the alpha-methyl group in the side chain of the hallucinogenic amphetamines is lengthened by one carbon atom to an ethyl group, hallucinogenic activity is completely abolished. If the alpha-methyl of MDMA is changed to an ethyl group, however, about 70% of the potency of MDMA is retained.

Tryptamines

The tryptamines bear the closest resemblance to the neurotransmitter serotonin, as seen in Figure 5.

Figure 5 Serotonin and the major tryptamine-based hallucinogens.

A number of these substances are found in nature. The simplest is *N,N*-dimethyltryptamine (DMT), which is found in a number of plant species, and also has been detected in human cerebrospinal fluid. It is not active orally, being degraded by monoamine oxidase (MAO) in the liver, and is usually smoked or injected, where doses of 50–75 mg would be typical, with transient effects. There is an orally active preparation of DMT known as ayahuasca, or yagé, which has been used by Indians of the Amazonian basin in Brazil. Ayahuasca is a decoction made from two different plants, *Banisteriopsis capii*, a source of beta-carboline alkaloids, and DMT-containing species such as *Psychotria viridis*. The beta-carbolines include harmine, harmaline, and tetrahydroharmine, and are reversible MAO-A inhibitors. It is thought therefore, that ayahuasca has pharmacological activity because the harmala alkaloids inhibit the MAO in the liver that would normally deaminate the DMT following oral ingestion.

Another tryptamine that occurs in nature is 5-methoxy-*N,N*-dimethyltryptamine (5-MeO-DMT). Like DMT, it is not orally active. It occurs naturally in a number of species of *Virola* that grow in central and South America. The red exudate from the inner surface of bark off these trees is dried and finely ground to produce a powerful snuff called epená. The effects of both DMT and 5-MeO-DMT generally last less than 30 min.

In contrast to DMT and 5-MeO-DMT, psilocybin is orally active in the 6–20 mg range, with a duration of action of 4–6 h. Psilocybin itself serves as a prodrug, as serum phosphatases cleave the *O*-phosphate to give psilocin, the active moiety. Although there are

a few other substituted tryptamines that are known to be hallucinogenic, for example α-methyltryptamine (AMT), in general there is little information available on their human psychopharmacological properties, metabolism, etc. A number of anecdotal human reports have been presented by Shulgin and Shulgin.

LSD and Other Ergolines

The tetracyclic ergoline *N,N*-diethyllysergamide (LSD; LSD-25) is the most potent of the known hallucinogens and is shown in Figure 6. A typical clinically effective oral dose of the tartrate salt is 0.10 mg, with effects lasting for 8–10 h. LSD is a semisynthetic material, prepared by the condensation of (+)-lysergic acid with diethylamine. Lysergic acid is obtained by basic hydrolysis of ergot alkaloids (e.g., ergotamine), which are obtained from any of a variety of *Claviceps* (ergot) species.

The stereochemistry illustrated here is critical for activity, and if the chirality at either the 5- or the 8-position is reversed, activity is lost. In contrast to the phenethylamine hallucinogens, the structural requirements for activity in the ergolines are narrowly restricted. No other amide group, other than diethyl, has the potency of LSD. Isosteric groups such as methyl-isopropyl, or methyl-propyl, or heterocyclic rings such as pyrrolidine, all fail to provide compounds with more than about 10% of the potency of LSD, at least in humans. An isomeric series of azetidines, four-membered nitrogen-containing heterocyclic rings with two methyl groups attached, has been used to show that the diethyl group must adopt a very specific stereochemical orientation when LSD binds to its receptors. This knowledge, coupled with examination of homology models for the 5-HT_{2A} receptor, suggests that there is a very specific amino acid motif in the area where the diethylamide binds. This topographically defined region apparently has steric and spatial requirements that are uniquely complementary to the diethylamide of LSD.

LSD

Psychopharmacology in Animals

Serotonin Receptor Mechanisms

Studies in the 1950s indicated that hallucinogens had profound effects on serotonin in the brain. The recognition that both LSD and serotonin were built on the same tryptamine scaffold led to early hypotheses that LSD was affecting brain serotonin neurotransmission. It was only after radioligand binding techniques were developed in the 1970s that it was discovered that hallucinogens bound with high affinity to specific serotonin receptor subtypes and subsequently that all the chemical classes of hallucinogens activate serotonin 5-HT_{2A} receptors, a member of the Gαq-coupled family of G-protein-coupled receptors.

The earliest mechanistic evidence for a serotonergic action of psychedelics came from George Aghajanian's laboratory, where it was found that LSD and tryptamine hallucinogens suppressed firing of serotonergic cells in the dorsal raphe nucleus. The correlation between raphe cell firing and general level of vigilance, and the cessation of firing during rapid-eye-movement (REM) sleep, were intriguing phenomena that seemed to identify raphe cells as likely targets for hallucinogens. Subsequent studies indicating that some ligands that suppressed raphe firing were not hallucinogenic led to the abandonment of this hypothesis. When subtype-selective serotonin receptor ligands were finally developed, it was found that suppression of raphe cell firing was mediated by somatodendritic serotonin 5-HT_{1A} receptors. Ideas then moved to a focus on other serotonin receptor subtypes and other brain areas. Of greatest interest currently are the 5-HT_{2A} receptors in multiple regions such as the thalamus and frontal cortex. Nevertheless, several experimental studies in animals indicate that LSD and other tryptamines may have some subtle psychopharmacological properties that could be attributed to their agonist actions on 5-HT_{1A} receptors. Unfortunately, the well-controlled clinical studies employing specific 5-HT_{1A} receptor ligands necessary to elucidate these issues in humans have not been conducted.

Behavioral Effects in Animals

Given the complexity, variety, and variability of the effects of psychedelics in humans, it has been difficult to define animal behavior tests for hallucinogenic activity. In animals, psychedelics (1) potentiate neophobia and other anxiety-related behaviors, (2) increase responsiveness to sensory stimulation, (3) retard habituation in a variety of input modalities and

response output systems, and (4) induce a variety of abnormal behaviors such as ear scratches and head twitches. Using various behavioral paradigms in rodents, researchers have identified the 5-HT_{2A} subtype of serotonin receptors as being responsible for the major psychological effects of the classical hallucinogens. These behavioral paradigms included measures based on abnormal behaviors induced by hallucinogens, alterations within the normal range of unconditioned behaviors such as locomotor activity or habituation to sensory stimuli, changes in simple forms of classical or instrumental learning, and assessments of the discriminative stimulus properties of psychoactive drugs. Despite their limitations, animal models of the effects of hallucinogens enabled the evaluation of several hypotheses regarding their neurochemical substrates of action. Indeed, the major contributions of $5HT_{2A}$ receptor agonism to the behavioral effects of hallucinogens and the contrasting importance of serotonin release to MDMA effects were first demonstrated using animal behavioral models and more recently confirmed by studies in humans. Thus, clinical studies demonstrated that – as was originally discovered in animal studies – the selective 5-HT_{2A} receptor antagonist ketanserin, but not serotonin reuptake inhibitors, blocks the psychopharmacological effects of the hallucinogen psilocybin in human volunteers. Similarly, confirming the earlier studies of locomotor activity in rats and mice, serotonin reuptake blockers such as citalopram block the psychological effects of MDMA in humans, whereas 5-HT_{2A} receptor antagonists have minimal effects. These results are the most compelling and conclusive proof of 5-HT_{2A} receptor mediation of the effects of hallucinogens.

Interactions with Other Systems

Although 5-HT_{2A} receptors appear to be the most important, the activation of 5-HT_{1A} receptors also has been shown to influence many of the same behavioral end points and often contribute to and/or interact with the impact of hallucinogens on 5-HT_{2A} receptors. The contributions of activation of 5-HT_{2C} receptors have not been assessed adequately in the absence of a hallucinogen that has selective effects at the 5-HT_{2A} receptor, relative to the 5-HT_{2C} receptor. Possible contributions of the 5-HT_4, 5-HT_5, 5-HT_6, or 5-HT_7 receptors also await additional study. Nevertheless, one could make the argument that activation of the 5-HT_{2A} receptor is a necessary, but not sufficient, condition for producing hallucinogenic effects, especially with regard to the mechanism of action of phenethylamine and simple tryptamine hallucinogens. It should be noted, however, that the pharmacology of LSD may be more complex. Although LSD is known to have affinity for the majority of serotonin receptor subtypes, the receptor affinities and intrinsic activity of LSD are unremarkable. In particular, the receptor affinity of LSD for the 5-HT_{2A} and 5-HT_{2C} receptor is essentially identical to that of simple phenethylamines such as DOB or DOI. Furthermore, the intrinsic activity of these phenethylamines is on the order of about 80%, whereas that of LSD is less than 50%. Yet, LSD is more than an order of magnitude more potent than these phenethylamines. Therefore, the question "why is LSD so potent?" has often been asked. There has been no definitive answer as yet, but it should be noted that LSD has relatively high affinities and intrinsic activities for the dopamine D_2-like family of receptors.

Psychopharmacology in Humans

In addition to the defining aspects of the effects of serotonergic hallucinogens discussed above, experimental neurophysiological and neuropsychological studies confirm that hallucinogens produce dose-dependent cognitive impairments in healthy subjects, including deficits in attention, working memory, and associative learning, while leaving executive functions almost unaffected. Serotonergic hallucinogens also impair high-level but not low-level motion perception and reduce binocular rivalry rate and rhythmicity in a manner reflecting subjective changes in conscious state alterations that also have been reported in bipolar disorder and schizophrenia.

Relevance of Psychedelics to Clinical Pharmacotherapeutics

Studies of the mechanisms responsible for the psychotomimetic aspects of serotonergic hallucinogens have provided important insights into the neurobiology of schizophrenia and related psychotic disorders. Indeed, recent research into hallucinogenic drug action has revitalized alternative hypotheses to the classic dopamine hyperactivity model of schizophrenia. Historically, the serotonin hypothesis of schizophrenia derived from the early studies of the pharmacology of LSD and its structural relationship to serotonin. This hypothesis has received renewed support because indoleamine hallucinogens produce their psychological effects predominantly via activation of 5-HT_{2A} receptors, 5-HT_{2A} receptors are abnormal in the brains of schizophrenic patients, and 5-HT_{2A} receptor antagonism appears to contribute substantially to the therapeutic effects of atypical antipsychotics such as clozapine.

Figure 7 (a,b) The effects of a 5-HT_{2A} agonist, psilocybin, in healthy human volunteers as measured by changes of cerebral blood flow (CBF) using H_2O-PET (positron emission tomography). Red is a relative increase as indexed by H_2O-PET (CBF); blue is a relative decrease in brain activity. Psilocybin alters neuronal activity in key components of limbic cortico-striato-thalamic pathways (CSTC loops), which are important for gating or filtering of extrinsic and intrinsic information flow to the cortex. Disruption of the functional integrity of CSTC loops and subsequently reduced thalamic gating may explain at least in part the sensory flooding and psychotic symptom formation reported by individuals during psilocybin-induced altered states. Marked increases in regional activity were found in areas that are important for both cognitive and affective processes such as the frontomedial cortex extending into the anterior cingulate (1,2), the dorsolateral (3), insula (4), and temporal cortices (5), as well as the left posterior cingulate (6). In comparison, decreased cerebral blood flow was found in brain areas that are important for gating or integrating cortical information processing such as bilateral thalamus (7), right globus pallidus (8), bilateral pons (9), and in cerebellum (10). Finally, psilocybin also reduced neuronal activity in components responsible for higher-order visuospatial processing such as precuneus (12) and angular gyrus (11), as well as in supplementary eye fields of the premotor area (13). In combination, psilocybin alters brain activation in such a way as to increase cognitive and affective processing in the context of reduced gating and reduced focus on external stimulus processing. Unpublished data from FX Vollenweider.

Several authors have argued that hallucinogen-induced ASCs share multiple phenomenological features with early acute stages of schizophrenia and may provide useful models to elucidate the neuronal basis of productive symptoms and cognitive deficits of schizophrenic pathophysiology. Recent theories about the neurobiology of ASCs suggest that deficits in basic information processing may be elaborated into the diverse psychotic symptoms and cognitive disturbances seen in both drug-induced model psychoses and naturally occurring psychoses such as schizophrenia. For example, one fundamental feature of information processing dysfunction in both hallucinogen-induced states and schizophrenia-spectrum disorders is the inability of these subjects to inhibit, filter, or gate extraneous stimuli and to attend selectively to important features of the environment. Extensive neurobiological studies have identified cortico-striato-thalamic pathways (CSTC loops) that subserve major aspects of gating functions in mammals. As shown in Figure 7, acute treatment with psilocybin alters cerebral blood flow within the CSTC gating circuits in healthy human volunteers. Gating deficits may cause both psychedelic-treated and schizophrenia subjects to become overloaded with excessive exteroceptive and interoceptive stimuli and subsequently disrupt normal cognitive integrity. Impaired gating and loosening of ego boundaries could lead to positive symptoms such as delusions, hallucinations, thought disturbances, persecution, and the loss of a coherent ego experience. In addition, various negative symptoms, such as emotional and social withdrawal, could reflect efforts to protect the individual from input overload. Nevertheless, despite the number of similarities between hallucinogen-induced models of psychoses, substantial differences also are apparent in the limited human studies. One of the most striking of these differences involves the essentially lifelong nature of schizophrenia disorders, which contrasts with the rapidity with which tolerance develops to the psychological effects of serotonergic hallucinogens.

Possible Therapeutic Applications of Psychedelics

In the 1950s and early 1960s, LSD was hailed as an important new technology that had the potential to revolutionize psychiatry. Parallels were often drawn between the discovery of LSD and the discovery of atomic energy. Thus, there were more than a thousand published clinical studies of over 40 000 subjects. Unfortunately, the unbridled enthusiasm for the value of LSD most often meant that clinical studies were

poorly designed, poorly controlled, and poorly analyzed, with inadequate posttreatment follow-up. As a result, the widespread impression remains that LSD was found to lack any therapeutic value.

In the absence of well-designed studies, the only conclusion that can safely be drawn is that we really do not know what medical value LSD or other hallucinogens might have. Like any new technology, and here we might usefully employ the analogy to atomic energy, it may take some time to discover how best to use it. Certainly, the use of radium to produce luminescent watch and clock dials was a trivial one and did not reflect the great potential that the atom represented. Similarly, we might speculate that LSD might have important medical uses if the time and effort were spent to investigate its potential.

What leaves us curious are the many anecdotal reports of individuals who used LSD and experienced profound sorts of unexpected healing, from a variety of disorders. Many alcoholics claim to have stopped drinking, and individuals with substance abuse problems have reported losing their desire to continue their substance use. These reports fail to meet the test as science, because they were case reports, or personal essays, and either were not replicated or could not be replicated.

The most well-documented value of hallucinogens as therapeutics was in the treatment of dying cancer patients. Starting with the work of Chicago internist Eric Kast and ending in several studies at the Baltimore State Hospital, LSD treatment in a program that included only a modest amount of counseling produced some degree of benefit in 60–70% of patients, measured as a reduced need for pain medication and improved mood. The patients who had the most profound LSD experiences gained the most therapeutic benefit. The overall conclusion is that the LSD treatment program appeared to have led to a reduced fear of death, and thus a reduction in the anxiety normally caused by impending death. Recently, a small number of new clinical studies have begun to reexamine the possible clinical benefits of serotonergic hallucinogens. With modern clinical designs and appropriate controls, there is a need to assess whether or not hallucinogens do represent useful tools for psychiatry. This chapter of history has not been closed, and hopefully future clinicians will make the efforts necessary to gain the answers to this question once and for all.

In another context, explored primarily in Europe, hallucinogens have been suggested to be useful tools in so-called psycholytic or hallucinogen-aided psychotherapy, given that they have the potential to improve the patient–therapist relationship, to free the patient from autistic fixation and isolation, and to call up forgotten and repressed unconscious material. Under the effects of hallucinogens, repressed memory traces, even those going back to early childhood and which may often contribute to psychiatric disorders, can enter vividly into consciousness. In the context of psychodynamic concepts, the performance of psycholytic therapy is similar to the imaginative techniques, such as guided affective imagery, in terms of setting, the interaction between the patient and therapist, and the clinically relevant phenomena. Nevertheless, without clinical supervision, patients and nonpatients should not experiment with substances having such deep and profound effects on mind and body, for many of the effects, their intensity, duration, and potential after effects, can in no way be foreseen. From a therapeutic perspective, such uncontrolled use of hallucinogens is dangerous.

Conclusions

Serotonergic hallucinogens, the classical psychedelic compounds, have profound effects on human consciousness. These substances have been used ceremonially for many centuries in many cultures. Neurochemists and behavioral neuroscientists have identified agonist actions at specific subtypes of serotonin receptors, primarily the 5-HT_{2A} receptors, as being the primary mechanism of action for the behavioral effects of psychedelics. More recent clinical studies of human volunteers have confirmed that the psychedelic effects of hallucinogens such as psilocybin are largely attributable to the activation of 5-HT_{2A} receptors. The study of serotonergic hallucinogens has been informative as to the neurobiological substrates of ASCs and likely mechanisms contributing to some psychiatric disorders such as schizophrenia. Further research in this area could lead to the identification of novel pharmacotherapeutics, potentially including therapeutic effects of the hallucinogens themselves in certain conditions.

Female Behavior

The most prominent, biologically crucial, strongly sexually differentiated behavior in mammals is lordosis behavior (Figure 1), the vertebral dorsiflexion response by which female quadrupeds permit reproduction. Lordosis is governed by a limbic–hypothalamic system of estrogen-binding neurons (Figure 2), a system proven to be universal among mammals. Lordosis depends on a spino–midbrain–spinal neural circuit (Figure 3), which explains the physiology of the behaviorally adequate sensory stimulation and the production of the motor response of lordosis.

Later immunocytochemical analyses identified the contributions of two different gene products: those due to the estrogen receptor (ER)-α gene and those due to the ER-β gene. In the ventromedial hypothalamus, a cell group containing neurons crucial for lordosis behavior, the number of ER-α-expressing neurons far exceeds that expressing ER-β.

Because estrogen receptors are ligand-activated transcription factors, estrogen actions in the hypothalamic neurons that govern lordosis could be used to generate a list of genes that have two properties: Their transcript levels are elevated by estrogens, and their gene products foster lordosis behavior (Figure 4). It can be seen from Figure 4 that these genes encode many different kinds of biochemicals: growth-related products, another transcription factor (the progesterone receptor), neurotransmitter receptors, neuropeptides, and their receptors. Nevertheless, we have argued that the genes identified so far encode products that participate in functional modules ensuring the biological adaptiveness of reproductive behaviors.

Overall, the lordosis behavior neural circuit – the first worked out for a mammalian behavior – and the corresponding molecular mechanisms prove that specific biochemical reactions in specific parts of the mammalian brain produce a specific, biologically important behavior.

Membrane-Initiated Hormone Actions Potentiate Genomic Actions

Historically, biochemical and physiological actions of steroid hormones were laid exclusively to effects in the cell nucleus on gene transcription. However, it has become clear that some steroid hormone effects on electrical activity of neurons occur too rapidly to be dependent on genomic actions. In the past, scientists argued that either the rapid, membrane-initiated actions or the slow nuclear actions were most important. Vasudevan resolved this argument by showing that rapid, membrane-initiated effects of estrogens actually potentiate the cell nuclear actions of estrogens on gene transcription. Thus, there now exists a unified theory of steroid hormone actions on neurons.

What might this mean for the facilitation of lordosis behavior? In the ventromedial nucleus of the hypothalamus (Figure 2), which is crucial for facilitating lordosis, estrogens have at least three ways to rapidly (within seconds or minutes) increase electrical activity: increasing inward, excitatory ionic currents; decreasing outward, inhibitory ionic currents; and amplifying excitatory responses to arousal-related neurotransmitters such as histamine and glutamate. The signal transduction pathways potentially involved in these various rapid actions of estrogens and important for lordosis behavior are partially known (Table 1).

In summary, estrogens rapidly heighten electrical activity in nerve cells crucial for lordosis and amplify gene transcription actions of estrogens. Therefore, it must be concluded that rapid, membrane-initiated effects of estrogens cooperate with slower genomic effects in order to facilitate lordosis behavior.

Reverse Engineering the Lordosis Behavior Circuit

Having worked out the major mechanisms that produce lordosis behavior (hormonal, neuronal, and genomic), we can now look back on these mechanisms and ask what engineering design principles they manifest. 'Reverse engineering' asks the following question: Why was that particular set of neuronal connections (or, for example, that particular action of a hormone on a gene's transcription) evolved that way, with the eventual effect of producing biologically adaptive, well-regulated mating behaviors?

In the small laboratory animals in which lordosis mechanisms have been worked out, mating behaviors (which may involve exposure to predators as well as the expenditure of metabolic energy) should only occur when the female is about to ovulate so that the mating will produce the young animals of the next generation. Years ago, we found that the neuropeptide gonadotropic-releasing hormone (GnRH, or leutinizing hormone-releasing hormone), whose main job is to trigger ovulation, also facilitates lordosis behavior; thus the 'unity of the body' – the physiology of peripheral reproductive organs coordinated with the brain's control of mating behavior. Furthermore,

Figure 1 Lordosis behavior (bottom) as performed by female rats. In all female quadrupeds, the vertebral dorsiflexion by the female permits fertilization by the male and thus controls reproduction. Adapted from Becker et al. (1992).

the sex steroid hormones emanating from the ovaries and circulating in the blood to the brain signal that the ovaries are doing their job and are ready to ovulate. From a reverse engineering standpoint, the genomic actions of estrogens in hypothalamic neurons (Figure 4) provide the hormone dependence required for whole-body management of reproduction and its associated behaviors.

Ventromedial hypothalamic neurons that govern lordosis project to the midbrain central gray (Figure 3), where a transformation takes place in the temporal dynamics of neuronal controls. Hypothalamic neurons are slow. Genomic actions of hormones there take hours, neuronal responses are sluggish, and resting discharge rates are low. Yet, in the real world of mating behavior, the female's courtship and lordosis behaviors are fast. Nerve cells in the central gray of the midbrain take the gradually fluctuating inputs from the hypothalamus and translate them into response biases that are important for the postural, behavioral, and autonomic controls managed by the hindbrain. These central gray neurons project to the medullary and pontine reticular formation.

The reticulospinal cells projecting from the medullary and pontine reticular formation, as well as the vestibulospinal neurons projecting from the lateral vestibular nucleus (also important for lordosis behavior; Figure 3), are responsible for managing the coordinated actions of all the segments of the spinal cord that receive the somatosensory inputs from the mounting by the male and that execute the vertebral dorsiflexion (Figure 1) of lordosis behavior. Finally, the descending signals from reticulospinal and vestibulospinal neurons are integrated, at each individual spinal level, with the relevant somatosensory inputs from the male's mounting so that local spinal reflexes executed by motor neurons in the ventromedial corner of the ventral horns bilaterally can stimulate the necessary activation of the deep back muscles, whose contractions up and down the spinal column constitute lordosis.

Usually when we think of design principles during engineering exercises, we are searching for negative and positive feedback. In the controls over mating behaviors, some of these are most prominent in the endocrine dynamics involved. The hypothalamus tells the pituitary gland to send protein hormones, 'gonadotropic hormones,' to the ovaries and testes so that those gonadal organs will produce and release steroidal hormones such as estradiol and testosterone. When those steroidal hormones reach the brain and pituitary, they reduce the hypothalamic/pituitary action and thereby keep hormone levels within a prescribed physiological range. Thus, this process results in negative feedback. However, on the day of ovulation in the female, a temporary but powerful positive feedback mechanism kicks in. For a brief period of time in the late afternoon, higher estrogen levels, supplemented by progesterone, increase gonadotropic hormone release such that a massive amount of gonadotropic hormones in the blood circulates from the pituitary to the ovary and causes ovulation. As noted previously, we believe that the coordinated actions by GnRH, the neuropeptide in charge of the ovulatory surge of hormones causing both behavioral and endocrine changes, provide the neurochemical mechanism for behavior to be rendered consonant with the physiology of the rest of the body.

Male Behavior

Analyses of male mating behaviors have not proceeded as quickly as those of female mating behavior for at least two reasons. First, the steroid chemistry involved is more complicated. Rather than simply depend on testosterone, the peripheral and central physiological changes required for normal male sexual performance depend on testosterone plus its metabolites estradiol and dihydrotestosterone. Second, the behavior is more complicated. Compared to the simple vertebral dorsiflexion that constitutes lordosis behavior (Figure 1), male mating behaviors in laboratory animals involve locomotion and highly coordinated balancing actions during mounting. Nevertheless, in 2002 Hull et al. summarized an impressive body of data on the neuroanatomy and neurochemistry that underlie male behaviors.

A male must chase the female, mount the female, thrust his hindquarters against her so as to achieve

Figure 2 Two sagittal sections through the rat brain looking at it from the left side. Black dots indicate locations of cells expressing estrogen receptors as proven by the binding and retention of tritiated estradiol. The limbic–hypothalamic system revealed in this experiment with rat brain was found to be universal among vertebrate brains. Adapted from Pfaff D and Keiner M (1973) Atlas of estradiol-concentrating cells in the central nervous system of the female rat. *Journal of Comparative Neurology* 151: 121–157.

intravaginal penile insertion ('intromission'), and, after multiple intromissions, ejaculate. Preoptic area neurons, especially those in the medial preoptic area, are essential for the performance of these male sexual behaviors in every vertebrate animal studied. Axonal projections from these neurons reach, among other places, the central gray of the midbrain. The most important axonal termination sites in the central gray are among those neurons that project in turn to the nucleus paragigantocellularis in the medullary reticular formation. These neurons send reticulospinal axons down to the spinal cord, where they excite motor neurons responsible for penile erection and ejaculation.

Although the preoptic area is the brain region most obviously controlling male behaviors, several other forebrain regions contribute. For example, lesions of the corticomedial nuclei of the amygdala reduce male copulatory behaviors, perhaps because they interrupt olfactory signaling from the olfactory and accessory olfactory bulbs to the preoptic area.

Among neurotransmitter inputs to the preoptic area, dopamine acting through D1 receptors seems to be the most involved. In contrast, D2 receptor agonists tend to reduce male copulatory behavior. There is a similar split among receptor subtypes for serotonin. 5-HT-1a agonists increase male sex behaviors, whereas 5-HT-1b agonists decrease them. The inhibitory transmitter GABA working in the preoptic area through $GABA_A$ receptors, as expected, inhibits male mating. A gaseous transmitter, nitric oxide, supports erection but not necessarily through mechanisms located in the forebrain. For example, systemic

Figure 3 Neural circuit for the production of lordosis behavior. A spinal–midbrain–spinal circuit is regulated by estrogen-modulated neurons in the ventromedial nucleus of the hypothalamus. Adapted from Pfaff D (1980) *Estrogens and Brain Function*. New York: Springer.

inhibition of nitric oxide synthase enzymatic activities will reduce the capacity for erection and, thus, normal male mating behavior.

Neuropeptides emanating from forebrain neurons are also important. For example, oxytocin, a nine-amino-acid peptide associated with affiliative, friendly behaviors and with parental behaviors, can increase spontaneous erections when administered through the cerebral ventricles. Furthermore, GnRH tends to decrease latencies and increase frequencies of male mating responses.

Kevin McKenna and colleagues reported that temporally coordinated sympathetic and parasympathetic autonomic nervous system influences must be integrated with somatosensory inputs from the penile surface to manage erection and then ejaculation. William deGroat charted the sympathetic nervous system connections through the pelvic and pudendal nerves and the parasympathetic nervous system connections through the superior hypogastric and pelvic plexuses. How sympathetic, parasympathetic, and somatosensory influences interact at various stages of the male's mating behaviors is still debated. Nevertheless, the old stereotype of sympathetic 'versus' parasympathetic influence is not correct. Instead, the two autonomic influences must be viewed as a team, not identical or correlated with each other but, rather, coordinated in a biologically adaptive manner.

Generalized Central Nervous System Arousal

Underlying all motivated behaviors in animals and in humans is a set of functions identified as 'generalized

Figure 4 Genes that have two properties: Their transcript levels are elevated by estrogens (E) following binding to an estrogen receptor (ER) and their products foster female reproductive behaviors. The exception is the expression of prostaglandin D synthase in the preoptic area, which works through an estrogen-triggered disinhibition. central nervous system (CNS) arousal.' Its operational definition states that a more aroused animal or human (1) is more responsive to sensory stimuli in all sensory modalities, (2) emits more voluntary motor activity, and (3) is more reactive emotionally. In our laboratory, we use an automated assay of all three components to examine the functional genomics of generalized arousal in mice. At least five major ascending systems in the CNS and at least four major descending systems participate in heightening

generalized CNS arousal. More than 120 genes are involved with the receptors, the transporters, and the chemical synthesis and regulated breakdown of the relevant neurotransmitters and neuropeptides. However, what does this mean for mating behaviors of males and females?

Generalized Arousal Fuels Sexual Arousal, Which Fuels Sex Behaviors

In neuroanatomical terms, ascending systems that signal generalized arousal send axons that terminate in the ventromedial nucleus of the hypothalamus (necessary for female sex behavior) and the preoptic area (necessary for male sex behavior). These are so-called 'nonspecific' arousal systems. Among the most important of these are noradrenergic signals (from the locus coeruleus), cholinergic signals (likely from the dorsomedial nucleus of the tegmentum), dopaminergic signals (from the ventral tegmental area), serotonergic signals (from the raphe nuclei of the midbrain), and histaminergic signals (from the tuberomammillary nucleus of the hypothalamus). These arousal-related transmitters have the capacity to potentiate a wide variety of behavioral responses, including mating behaviors (Table 2).

In electrophysiological terms, noradrenergic, cholinergic, and histaminergic transmitters turn on the electrical activity of ventromedial hypothalamic neurons crucial for lordosis behavior in the female. Correspondingly, dopamine, acting through D1 receptors in the preoptic area, facilitates male sex behavior. Thus, heightened electrical activity in these hypothalamic and preoptic neurons is the neurophysiologic equivalent of sexual arousal in the female and male, respectively.

In behavioral terms, sexual arousal is occasioned by heightened muscular tone throughout the body and by courtship behaviors designed to bring reproductively competent males and females into contact. In the female rat, extreme axial muscle tension and rapid darting movements that attract the male are easily noticed. In the male, searching and following the female are obvious. These are accomplished not only by heightened electrical activity in the ventromedial hypothalamic and medial preoptic neurons but also by the generalized CNS arousal mechanisms referred to previously (Table 2).

Logically, therefore, it must be concluded that generalized arousal is required for heightened sexual arousal, which in turn is required for the normal performance of both male and female sexual behaviors. This field of work offers the possibility of linking well-understood, concrete mechanisms for specific biologically important behaviors to a generalized CNS function crucial for the potentiation of all mammalian behaviors.

Sexual Differentiation of the Brain

D G Zuloaga, C L Jordan, and S M Breedlove, Michigan State University, East Lansing, MI, USA

© 2009 Published by Elsevier Ltd.

Men and women differ not only in their anatomy and reproductive functions but also in cognitive and affective behaviors. On an average, men are generally better at tasks involving the mental rotation of objects, whereas females are superior at memory tasks in which they are asked to recall objects in a spatial array. There are also sex differences in the prevalence of mental disorders, with males more commonly diagnosed with schizophrenia, autism, and attention deficit hyperactivity disorder. Females, on the other hand, are more likely to suffer from disorders of depression and anxiety. During the past several decades, scientists have uncovered sexual dimorphisms in the central nervous system (CNS) of mammals that may contribute to the etiology of these sex differences. Studies on rodents suggest that many sexual dimorphisms in the CNS result from exposure to hormones at approximately the time of birth, lending credence to the idea that the masculinizing or feminizing seed is planted early in life. However, some areas of the brain remain vulnerable to hormones after this critical period and can incur morphological changes during adolescence and in adulthood. This article discusses instances of each in the mammalian CNS, the mechanisms that underlie these sexual dimorphisms, and examples of sexual differentiation of the human brain and behavior.

The sex of a mammal is determined at the time of conception when sperm from the male penetrates the egg and either contributes an X or a Y chromosome to the genetic makeup. If the sperm donates a Y chromosome, the offspring will be a male, and if it donates an X chromosome, the offspring will be a female. The sex-determining region Y (SRY) gene on the Y chromosome of the male is responsible for the formation of the testes, and in the absence of this gene, ovaries form. In males, it is the formation of the testes and the subsequent secretion of testicular hormones that masculinize the body. One of these hormones, anti-Müllerian hormone (AMH), suppresses the development of the female reproductive organs (e.g., the fallopian tubes and uterus), whereas another, the steroidal androgen testosterone (T), induces the formation of the male reproductive system (including the seminal vesicles and prostate) and external genitalia. In females, T and AMH are nearly absent, so male genitalia and internal sex organs fail to form and sex organs develop a feminine phenotype. Gonadal hormones can only influence genital phenotype during specific developmental periods; T in adulthood does not result in further development of male genitalia.

Testicular androgens such as T are primarily responsible for masculinization of the brain. In 1959, Phoenix and colleagues discovered that prenatal administration of T to female guinea pigs resulted in a defeminization of female sexual behavior. As adults, these early T-treated females (when administered estrogen and progesterone (E + P) to stimulate female sexual behavior) displayed little or no lordosis, the female rodent posture of sexual receptivity. However, these same females responded to testosterone in T, showing increased pelvic thrusting (typical of male mounting behavior). Similarly, adult males that were castrated immediately after birth showed increased lordosis after E + P administration as adults and decreased pelvic thrusting after T treatment. This outcome suggested that perinatal androgens are necessary for masculinization (promoting male-typical behaviors such as pelvic thrusting) and defeminization (interfering with female-typical behaviors such as lordosis) in male rodents. Females treated with T only in adulthood show little or no difference in sexual behavior, implying that rodents need 'androgen priming' in early development in order for adult testosterone to 'activate' behavior. This series of experiments laid the foundation for the organizational hypothesis, which postulates that behavioral sex differences result from (1) exposure to different hormones that act in early development to organize the neural machinery underlying behaviors and (2) exposure to different sex hormones in adulthood that activate the previously organized neural machinery. This conceptual framework has been amply confirmed in studies of nonhuman mammals.

Sexual Differentiation of the CNS

Exposure to steroid hormones at approximately the time of birth can also result in permanent morphological changes in the CNS, which may explain the lasting effects of early hormone exposure on adult behavior. In rodents, there are structural sex differences in several areas of the brain, one of the most robust of which is the sexually dimorphic nucleus of the preoptic area (SDN-POA). The volume of the SDN-POA is several times greater in males than in females, a difference which results from T exposure at approximately the time of birth. Castration of

newborn male rats decreases the size of the SDN-POA in adulthood, whereas T treatment of female rats just before and after birth increases adult SDN-POA volume. In the SDN-POA, masculinization results not from the direct activation of androgen receptors (ARs) by T or its metabolite dihydrotestosterone, as it does in the genitalia. Rather, T is converted to estrogens such as estradiol by the enzyme aromatase within the brain, and this brain-produced estrogen activates estrogen receptors (ERs) to masculinize the SDN-POA. The effect of activating ERs is to keep neurons in the SDN-POA from dying during the course of neuronal development. In turn, this rescuing of neurons from death by estradiol results in a greater SDN-POA volume in males than in females (**Figures 1(a)** and **1(b)**).

In another sexually dimorphic brain region, the anteroventral periventricular nucleus (AVPV), which is involved in regulating ovulatory cycles by influencing secretion of the luteinizing hormone, regional volume is greater in female rats and mice than in males. This sex difference is also due to the binding of aromatized metabolites of T to ERs. However, in the AVPV, ER activation promotes cell death, contributing to a larger female nucleus.

The spinal nucleus of the bulbocavernosus (SNB) provides another example of a sexually differentiated structure in the CNS in which gonadal hormones play a decisive role. The SNB is a sexually dimorphic group of motor neurons located in the lower lumbar spinal cord which innervates muscles involved in male copulatory behavior: the bulbocavernosus and

Figure 1 The sexually dimorphic nucleus of the preoptic area (SDN-POA) and the posterodorsal portion of the medial amygdala (MePD) are larger in males (left) than in females (right). There are also more motor neurons in the spinal nucleus of the bulbocavernosus (SNB) of males (left) than of females (right). SCN, suprachiasmatic nucleus.

levator ani perineal muscles. SNB motor neurons and the muscles they innervate are present at approximately the time of birth in both sexes, but they die in females postnatally while surviving in males. The SNB system is spared from death by early exposure to T in males (Figures 1(e) and 1(f)). Neonatal castration of males causes the SNB system to die, whereas T treatment of females spares the system. However, unlike the SDN-POA, SNB cells are spared from apoptosis (cell death) by the action of androgens upon ARs and not ERs. Genetic male rats with a defective AR fail to develop a masculine SNB. It is also known that androgens do not act directly on SNB motor neurons to spare them from death. Rather, androgens first act in the periphery to spare the muscles that are innervated by the SNB, and this action secondarily spares SNB motor neurons from death.

Sexual Differentiation during Adolescence

The maturation of the reproductive system during adolescence is marked by a period of elevated gonadal hormones. It is likely that these gonadal hormones also play a role in molding both the male and the female adolescent brain, and emerging evidence in rodents suggests that pubertal hormones indeed organize brain morphology and behavior. For example, some sex differences in the brain develop during the course of adolescent development, as in the locus coeruleus (LC) and AVPV, where volume is greater in females, and in the primary visual cortex, where volume is greater in male rats. Both the LC and the AVPV enlarge in females during adolescence, although the mechanisms that underlie these increases in volume are not known (neurogenesis, increased migration, or cell differentiation?). There is evidence that sex differences in the primary visual cortex are the result of ovarian hormones that induce cell death in females during adolescence, suggesting that female gonadal hormones can also drive brain organization. Ovariectomy of female rats prior to puberty results in an increased number of neurons in the primary visual cortex compared to females with intact ovaries. The visual cortex of ovariectomized females becomes similar to males in both neuron number and volume.

Changes in synaptic organization also occur during adolescence, a process that has been best studied in the medial amygdala (MeA). The MeA is a brain region that receives input from olfactory and pheromonal systems by way of the olfactory bulbs, and it has been implicated in male sexual behavior. The MeA is approximately 150% larger in adult male rats than in females. A significant amount of remodeling, involving the pruning of dendrites as well as changes in dendritic spine density in the MeA, accompanies adolescent development in hamsters and may serve to organize aspects of cognition and behavior.

Studies of the Syrian hamster further indicate that adolescence is a second critical period for behavioral development. T during puberty is necessary for the full masculinization of male hamster sexual behavior since prepubertal castration decreases mounts and intromissions when the hamster is exposed to a receptive female in adulthood. Similarly, pubertal hormones appear to masculinize male agonistic behavior since castration prior to puberty decreases aggressive attacks and increases submissive behavior compared to animals that received T during puberty.

Sexual Differentiation in Adulthood

In certain areas of the CNS, sexual differentiation occurs in adulthood and is similarly dependent on gonadal hormones. In rats, portions of the MeA remain sensitive to circulating androgens into adulthood because castration of adult males causes some areas within the MeA to shrink to a size typical of females, whereas T treatment of adult females causes the same area to grow to a male-typical volume. The size of the posterodorsal medial amygdala (MePD; Figures 1(c) and 1(d), which receives olfactory and pheromonal information and is important for some aspects of male sexual behavior, appears to be solely dependent on adult hormones. MePD volume is 1.5 times greater in male compared to female rats and mice, but this sex difference can be abolished by castration of males or administration of T to females. Structural plasticity in the MePD is mediated in adulthood through activation of both ARs and ERs, and the overall amygdala also appears to grow at puberty in boys, but not girls, suggesting that it is sensitive to androgens in humans as well as in rodents.

Another brain sexual dimorphism, arginine vasopressin (AVP) fiber innervation of the septal area in rodents, depends on T in both early development and adulthood for full masculinization. Septal AVP innervation is greater in males and plays a role in pair bonding, parental, and aggressive behavior. Castration of adult males decreases septal vasopressin innervation, although AVP depletion following neonatal castration is more extensive than the reduction following adult castration. The sex difference in septal vasopressin in adulthood is primarily dependent on aromatized metabolites of T that act on ERs, although the AR also contributes to some degree to the perinatal organization of this system.

The SNB system, like septal AVP innervation, is influenced by hormones in both development

and adulthood. Castration of adult males causes widespread regression throughout the system: The muscles, the motor neurons, and their synapses all regress after castration in adulthood. These morphological changes are accompanied by a reduction in spinal reflexes of the penis that are necessary for male sexual behavior. Interestingly, although both SNB somas and dendrites shrink after castration, each appear to be regulated by distinct mechanisms. In rats, androgens act directly through ARs in SNB motor neurons to regulate soma size while acting indirectly, through AR in the target muscles, to regulate the length of SNB dendrites.

Hormonal Site of Action and Downstream Regulation

Although the particular hormones and receptors involved in sexual differentiation of brain and spinal cord structures are becoming clear, little is known about the location and cell types that these hormones act upon and the downstream genes regulated to masculinize the CNS. In the SDN-POA, T acts to prevent apoptosis; however, it is not known whether it is acting directly on neurons in the SDN-POA or in some other area that indirectly spares these neurons. In the SNB system, motor neuron survival results, secondarily, from the sparing of target musculature that provides SNB motor neurons with a signal that keeps them alive. Thus, it is possible that sexual differentiation of the SDN-POA and AVPV results from T acting on distant target cells. However, although it is known that T acts on the target musculature to spare SNB motor neurons, it is not known what cell types in the muscle (muscle fibers, fibroblasts, or Schwann cells) are involved. Similarly, in the SDN-POA and the AVPV, it is not known which cell type (neurons, astroctyes, or oligodendrocytes) provides the site(s) of action for T. The only morphological sex difference in rodents for which the cellular target of T is known is in the regulation of SNB soma size. In female rats heterozygous for the testicular feminization mutation, a mutation that renders the AR protein nonfunctional, testosterone treatment in adulthood increased soma size only in SNB neurons with functional ARs. This suggests that T acts directly via the AR in SNB motor neurons to regulate soma size.

Researchers are also just beginning to uncover the genes acting downstream from T. Evidence suggests that T may modulate the Bcl2 family of genes that are involved in regulating apoptosis in the SNB, AVPV, and the central division of the medial preoptic nucleus (which comprises a significant portion of the SDN-POA). Deletion of a member of the Bcl2 family, the Bax gene, which signals downstream regulators of cell death, decreases sex differences in neuron number in both the SNB and the AVPV by decreasing the amount of cell death. Likewise, sex differences are reduced in the SNB and AVPV in transgenic mice that overexpress the anti-apoptotic Bcl2 gene. Interestingly, T promotes cell death in the AVPV while preventing it in SNB and SDN-POA. In both cases, T appears to affect expression of Bcl2 family genes in such a way that it can spare cells in some areas and condemn them in others.

Neurotrophic factors, as mediators of hormone effects, also appear to play a role in the sexual differentiation of the CNS. In the SNB system, T-dependent signaling through the ciliary neurotrophic factor receptor α (CNTFRα) is necessary for the development of a sex difference. CNTFRα is highly expressed in SNB motor neurons and administration of CNTF to female rats rescues SNB motor neurons from death. Similarly, male mice lacking CNTFRα fail to develop a masculine SNB system. Evidence from our laboratory suggests that another neurotrophic factor, brain-derived neurotrophic factor (BDNF), plays a role in the arborization of SNB dendrites in adulthood. Castration of adult rats, which results in decreased SNB dendritic length, is paralleled by a decrease in BDNF signal in SNB motor neurons and their dendrites, whereas BDNF signal is unaltered in androgen-insensitive motor neurons of the nearby retrodorsolateral nucleus.

In the POA, T induces the formation of prostaglandin E_2 (PGE_2), which is involved in dendritic spine development. The proliferation of dendritic spines in the POA appears to be important in the organization of male sexual behavior. Pharmacological blockade of PGE_2 in male newborns inhibits the formation of dendritic spines, whereas administration of PGE_2 to newborn females increases spine formation. Neither manipulation of PGE_2 has an effect on SDN-POA volume, suggesting that T may regulate the expression of different genes to promote dendritic spine formation in the POA, on the one hand, and increase volume of the SDN-POA on the other hand. For other areas of the CNS where sex differences have been located, little is known about the genes acting downstream from T, primarily because not enough is known about the target cells that respond directly to T or its metabolites.

Sexual Differentiation of the Human Brain and Behavior

The role of gonadal steroid hormones in the masculinization of the human brain and behavior is not as clear as in rodents, partially because human

behavior is very complex. Humans are so dramatically influenced by social cues that it is difficult to decipher whether a particular behavior is the result of T exposure or a byproduct of the milieu in which they were raised. Many sex differences in behavior may simply reflect the fact that boys have a penis and girls have a vagina, because from the moment of birth something as simple as genital development will radically shape the child's social environment.

Much of what we have learned about the role of hormones in the development of human behavior has come from studies of people who have been exposed to unique cascades of hormonal development. One such example is found in genetic males (XY) with complete androgen insensitivity syndrome (CAIS), a disorder characterized by a mutation in the AR gene. In people with CAIS, the testes develop and release T, but in the absence of functional AR, T fails to masculinize the periphery, resulting in a female phenotype. These individuals are generally raised as girls, and as adults they self-identify as women. They do not differ from genetic (XX) females in sexual orientation, are just as likely to be married, and as children were involved in female-typical play. Since people with CAIS have ample T and functional ER, this suggests either that, unlike rodents, the aromatization of T to estrogen and subsequent activation of ERs is not responsible for the masculinization of behavior (and thus AR may be necessary), or that the social context in which these individuals are raised and continue to live outweighs any influence of gonadal hormones.

Studies of women with congenital adrenal hyperplasia (CAH), who are exposed to T in fetal development because their adrenal glands overproduce androgens, suggest that androgens may play a role in masculinizing the female brain. Females with CAH are more likely to engage in male-typical activities and are less interested in female-typical activities throughout life. In addition, although most women with CAH are self-reported heterosexuals, they are more likely to be homosexual than are other women. Women with CAH also show male-typical spatial performance, suggesting that androgens play a role in the masculinization of behavior in humans. However, the genitalia of these women are also slightly masculinized, which could affect the way these women are perceived either by their parents or by themselves.

Another strategy that has been used to study the effects of early androgen exposure on human behavior is through the examination of somatic markers that are affected by prenatal androgen exposure. These somatic markers of androgen exposure, including finger length measurements (ratio between second and fourth digit lengths (2D:4D)), otoacoustic emissions, eyeblink patterns, and limb measurements, can be co-varied across measures of sexual orientation, cognitive abilities, and sex-biased affective and mood disorders. Using these somatic markers, links have been made between an increased exposure to prenatal T and homosexuality in women. A relationship between somatic markers of T in male homosexuality is less clear. Examination of finger length ratios in males suggests that levels of prenatal testosterone may be related to some affective and mood disorders. Boys with autism and attention deficit hyperactivity disorder, which are more common in males, tend to have hypermasculine finger length ratios (smaller 2D:4D; increased prenatal testosterone), whereas boys with anxiety disorders have more feminine ratios (larger 2D:4D; decreased prenatal testosterone).

Differences in hormone exposure may contribute to structural sex differences in the human CNS, including the corpus callosum, anterior commissure, third interstitial nucleus of the anterior thalamus (INAH3), bed nucleus of the stria terminalis, Onuf's nucleus, and suprachiasmatic nucleus (SCN). There is also a sex difference in overall brain weight favoring men, although women have a greater cortical surface area. These sexual dimorphisms in brain morphology may contribute to gender differences in behavior and the prevalence of some mental illnesses. Very little is known about how sex differences in the human brain may be related to differences in behavior, although the sizes of two hypothalamic nuclei have been correlated to sexual orientation in men. Inspired by the dramatic sex difference in the SDN-POA of rats, in 1991 Simon LeVay compared nuclei within the preoptic area of heterosexual men and women and discovered that one of these nuclei, INAH3, was larger in heterosexual men than in women, and that homosexual men had a feminine-sized nucleus. On the other hand, the vasopressinergic subnucleus of the SCN was found to be larger in volume and contained twice as many cells in homosexual men compared to heterosexual men. In this instance, the nucleus of homosexual men was not feminized. Together, these findings indicate that the brains of homosexual men may be feminized in some areas but not in others. However, it is important to note that it is unclear whether these morphological differences in the brains of homosexual men are the result of androgen exposure or arise as a result of differences in experience and behavior.

In some areas of the brain, sex differences in morphology may exist as a means to minimize sex differences in behavior. Differences in gonadal hormone levels between men and women could potentially contribute to maladaptive sex differences in behavior,

with alterations in brain structure compensating for these differences. An example of such a phenomenon has been suggested in the prairie vole, in which the male and female both contribute to the care of their offspring. In females, changes in hormones that accompany pregnancy and childbirth prime maternal behavior. Males, on the other hand, are not exposed to these hormones and their parental behavior appears to rely on sexually differentiated vasopressin innervation. This more extensive vasopressin innervation of the septal area in males may then compensate for the lack of maternal hormone exposure and make male prairie voles more effective fathers. It is also possible that hormones *per se* are not the sole contributor to the sexual differentiation of brain and behavior. Evidence suggests that in some songbirds and perhaps in mice, the expression of sex chromosome genes within cells may exert some influence on sexual differentiation of the brain and behavior independently of gonadal steroids. However, gonadal hormones are the primary instigators of sex differences in neural structure.

In many ways, hormone exposure during critical periods of development affects us, partially because these hormones have made us look like a male or a female, and also because these hormones have influenced the development of our brain and subsequently our behavior. Hormones may also continue to act throughout our lives to influence behavior; decreases in gonadal hormones with aging are often associated with depression, anxiety, debilitated memory, and general unhappiness. Lifelong plasticity in areas such as the MePD and the SNB demonstrates how these changes in behavior may also be accompanied by changes in structure. It is likely that there are many additional sex differences in the CNS waiting to be revealed. As we discover more of these dimorphisms and uncover how these sex differences emerge, we gain a better understanding about the influence of hormones and why, in many ways, men and women are really not the same.

Sexual Differentiation of the Central Nervous System

R B Simerly, Childrens Hospital Los Angeles, Los Angeles, CA, USA

© 2009 Published by Elsevier Ltd.

Introduction

Despite a wide variety of behaviors that are shared between male and female members of vertebrate species, certain traits are strongly associated with a single sex. Such behaviors are said to exist in two forms and are therefore dimorphic. Behaviors that are characteristic of males are designated as masculine and those that are characteristic of females as feminine. Sexually dimorphic behaviors are widespread among vertebrate species because nearly all reproduce sexually. Accordingly, dimorphic phenotypic traits have developed to support these sex-specific behaviors and the physiological processes that accompany them. Thus, males and females display distinct copulatory behaviors and neuroendocrine physiological responses. The importance of these sex-specific functions to vertebrate species is reflected in their widespread occurrence and in the reliability of developmental mechanisms that have evolved to ensure their unambiguous display. Sexually dimorphic behavior extends beyond reproduction and maternal behavior, although such differences can be more subtle and at times less reproducible.

Chromosomal Sex and the Developing Gonad

Masculinization of the body begins with a genetically controlled process termed sex determination that leads to the sex-specific differentiation of the gonad. The genetic sex of mammals is specified by the presence of either paired X chromosomes (females) or single X and Y chromosomes (males). The paternally derived Y chromosome contains the Sry (sex-determining region of the Y) gene, which encodes a transcription factor that causes the undifferentiated gonads to develop into testes; the absence of Sry expression leads to development of ovaries. Hormones secreted by the testes act on various tissues to masculinize the body, and it is testosterone secreted by Leydig cells in the testes that is responsible for masculinization of the central nervous system (CNS). In males, levels of testosterone are elevated significantly at approximately the time of birth (perinatal) and pass through the blood to the CNS, where they have free access to developing neurons and glia. Although all of the evidence to date supports a defining role for testosterone in sexual differentiation of the brain, it would be surprising if genes located on the Y chromosome, and therefore only present in males, did not influence masculinization of the CNS in some manner. Genetic studies in mice suggest that chromosomal sex does appear to impact certain behaviors, but these effects are relatively subtle compared with the robust changes caused by sex steroid hormones.

Major Principles and Model Systems

The developing brain is considered to be bipotential with respect to sexual differentiation, and in the absence of testosterone it develops phenotypic traits that are characteristic of females. For example, the ability of males to mount receptive females and the ability of females to display lordosis are dependent on the perinatal hormone environment. Similarly, whether the brain can induce a surge in secretion of gonadotropins from the pituitary gland, and thereby cause ovulation, is also determined by perinatal exposure to testosterone. Sex steroids also regulate expression of reproductive behavior and associated neuroendocrine events throughout life in response to what are described as activational influences of steroid hormones. The more permanent, developmental actions of testosterone are viewed as having an organizational action on the CNS and tend to be restricted to discrete periods of development. Thus, treating a female rat with testosterone during the first few days of life will permanently masculinize copulatory behavior and eliminate ovulation, but applying a similar treatment in adulthood does not. However, in adulthood, sex steroids regulate sexually dimorphic behavior and these activational actions are required for full expression of behavior (Figure 1).

The ability of perinatal testosterone to permanently alter neural structure and function is primarily due its action on brain development. The neural circuits controlling sexually dimorphic functions are thought to be specified during a developmental critical period occurring at or near the time of birth. For example, injecting female rats with testosterone during the first week of life generally increases the size of the sexually dimorphic nuclei, but treatments later on do not. However, sex steroid hormones continue to affect the structure and function of the CNS throughout life, but to a more limited degree than during the perinatal period. Gonadal hormones can alter patterns of connectivity, change expression of neurotransmitters and their receptors, and influence electrophysiological properties of neurons in adults. These effects can be very rapid (seconds to minutes) or can occur over extended periods (days to weeks). Thus, it is the combined action of sex steroid

Figure 1 Sexual differentiation and hormonal activation. Sex determination is specified by the complement of sex chromosomes (X and Y). Expression of the Sry gene on the Y chromosome in males causes formation of the testes, which in rodents secrete testosterone at high levels during the neonatal period (the first few days of life). During this period, testosterone acts on the brain to 'organize' the structure of regions that mediate sexually dimorphic functions. During adulthood, sex steroid hormones such as testosterone (T) and estrogen (E) act on the brain to 'activate' expression of copulatory behavior, mounting in males and lordosis or arching of the back in females, as well as sex-specific patterns of luteinizing hormone (LH) secretion from the pituitary gland, which causes ovulation. Castration of male newborn mice, or treating females with testosterone, on the day of birth (P0) reverses expression of these sexually dimorphic functions.

hormones, acting during discrete periods of sensitivity during development, together with the more short-term activational actions of these hormones later in life, that determines display of sexually dimorphic behaviors and physiological responses. However, it is important to remember that levels of circulating hormones in adult animals are different in males and females, which may influence expression of phenotypic traits independent of the developmental actions of testosterone. Surprisingly, it is estrogen that effects many of the masculinizing developmental actions of testosterone in the brain through intracellular conversion of testosterone to estradiol (a form of estrogen) by the enzyme aromatase. Once formed in the cell, the estradiol binds to estrogen receptors, which function as ligand-activated transcription factors to control gene expression. By regulating expression of genes involved in multiple aspects of cell function and development, estrogen directs the formation of sexually dimorphic neural circuits that are presumably responsible for expression of sexually dimorphic behaviors and physiological responses.

Because of its prominent role in regulating reproductive function, the hypothalamus has been the focus of many studies on sexual dimorphism in the brain, and most sexually dimorphic nuclei have been found within the hypothalamus or in limbic regions that innervate it. Nuclei in the preoptic region of the hypothalamus are known to control copulatory behavior and ovulation, and generally these regions contain high densities of neurons that express receptors for testosterone and estrogen. In a variety of mammalian species, preoptic nuclei involved in these functions contain different numbers of neurons in males and females, as well as having sexually dimorphic patterns of connectivity. The medial preoptic nucleus of the hypothalamus (MPN) contains distinct components that are larger in males and contain more neurons. These cellular components were included within a region designated as the sexually dimorphic nucleus of the preoptic area (SDN-POA) by Roger Gorski and co-workers. This region is so dimorphic as to be identifiable in stained tissue sections without magnification. Treatment of females with either testosterone or estrogen increases the size of the SDN-POA to that characteristic of males, and removal of the gonads from newborn male rats reduces the size of the region. Most morphological sex differences follow this pattern of hormonally specified male dominance, but the pattern is reversed in another preoptic nucleus, the anteroventral periventricular nucleus (AVPV). The AVPV plays a critical role in the control of ovulation and is larger in females. Exposure to testosterone during perinatal life reduces the size of the AVPV and permanently alters numbers of distinct subpopulations of neurons in a cell-type-specific manner. For example, treatment of female rats with testosterone decreases the number of dopaminergic neurons in the AVPV but increases numbers of neurons that express the opioid peptide dynorphin in the same nucleus. In humans, the rostral hypothalamus contains several distinct cell groups, termed the interstitial nuclei of the anterior hypothalamus, and at least two of these nuclei have been reported to be sexually dimorphic. Although these findings are controversial, and present difficulties for functional interpretation, it seems clear that structural sex differences are not restricted to nonhuman species.

The MPN and AVPV receive inputs conveying a variety of sensory modalities, but the most direct are those than transmit olfactory signals. The medial nucleus of the amygdala and principal nucleus of the bed nuclei of the stria terminalis (BSTp) are sexually dimorphic nuclei (larger in males) that are key components of the pathway from the accessory olfactory bulb to the hypothalamus. Androgen receptors may play a more prominent role in regulating the development of these telencephalic nuclei than they do in the hypothalamus, and these regions appear to remain relatively sensitive to the effects of testosterone manipulations in adulthood. Breedlove and colleagues showed that castration of adult males decreased, and treatment of adult females increased, the size of the posterodorsal part of the medial amygdala. Concurrent changes in the hormone-treated animals in their responses to airborne cues from receptive females suggest that hormonal regulation of nuclear volume may underlie changes in the function of this sexually dimorphic olfactory pathway.

The most thoroughly studied sexually dimorphic motor pathway is the spinal nucleus of the bulbocavernosus (SNB), which innervates striated muscles of the perineum (Figure 2). The motor neurons of the SNB are present before birth in both sexes and innervate the muscles, but the muscles regress and the neurons die soon after birth in females unless they are exposed to testosterone. In contrast to the sexual differentiation of the preoptic region, which is largely mediated by estrogen receptors, the action of testosterone on the SNB relies solely on androgen receptors.

Figure 2 The spinal nucleus of the bulbocavernus (SNB). The SNB is found in the lumbar region of the spinal cord in rats. There are 3 times as many motor neurons in the SNB (arrows) of male rats as there are in females. Adapted from Breedlove SM, Jordan CL, and Kelley DB (2002) What neuromuscular systems tell us about hormones and behavior. In: Pfaff D, Arnold A, Etgen A, Fahrbach S, and Rubin R (eds.) *Hormones, Brain and Behavior*, pp. 192–222. San Diego, CA: Academic Press.

However, testosterone does not act directly on the SNB to influence neuron number but, rather, acts on the perineal muscles and then secondarily affects the motor neurons of the SNB. Such target-dependent control of development is a common feature of neuromuscular systems. However, hormones can also act at multiple levels and at multiple times during development of neuromuscular systems. For example, in the frog vocal control neuromuscular system studied by Darcy Kelley and colleagues, both muscle cells and motor neurons express androgen receptors and appear to represent direct targets for hormone action on sexual differentiation of this system.

The avian song control system presents yet another pattern of steroid action. Male zebra finches sing more than females, and the system of nuclei responsible for song production is sexually dimorphic. Treatment of newly hatched female finches with estrogen masculinizes both the pattern of singing and the size of sexually dimorphic song system nuclei. Surprisingly, neither castration of young birds nor blockade of steroid receptors prevents sexual differentiation of these brain nuclei. *In vitro* studies of isolated brain slices provide a possible explanation: the active hormone (estrogen) is produced by forebrain neurons, which then directs sexual differentiation locally. However, even in identical culture conditions the slices derived from the brains of male birds produced more estrogen than those derived from females, suggesting that the male genotype may cause a higher level of hormone production in the male brain, independent of hormone levels produced by the gonad. Evidence from mammalian systems also supports a possible role for genetic signals in sexual differentiation of the CNS. Dispersed cultures of midbrain dopaminergic neurons derived from male and female mice placed *in vitro* on embryonic day 14, a time that precedes the normal increase in testosterone levels, nevertheless develop differently: the cultures derived from males end up with significantly more neurons. Moreover, similar embryonic cultures derived from mice lacking the Sry gene, and therefore lacking testicular testosterone secretion, have a greater number of dopaminergic neurons when derived from male embryos compared to those derived from females. The laboratory of Arthur Arnold used transgenic mice, engineered to display gonadal sex independent of chromosomal sex, to study correlations between Y chromosomal genes and sex differences in behavior and brain chemistry. Together, these findings suggest that multiple cell types may be masculinized by genetic signals. However, it should be noted that the overwhelming majority of sexually dimorphic traits evaluated in this transgenic paradigm support a dominant role for sex steroids in the control of sexual differentiation.

Neurobiology of Sexual Differentiation

Few studies have provided definitive proof that individual sexual dimorphisms are responsible for specific aspects of functional sex differences. In large part this is due to the fact that the study of sexual dimorphisms proceeded well ahead of our understanding of the functional neural systems that mediate sexually dimorphic behavior and physiology. However, an emerging perspective is that sexually dimorphic aspects of neural circuits conveying or decoding sensory information, or that control motor output systems, function differently in males and females because of structural differences in their organization. Alternatively, there may be differences in the way these pathways respond to changes in hormone levels acutely. Brain function is dependent on the numbers, organization, and patterns of connections that constitute functional neural systems, so it follows that developmental events that alter these parameters of neural circuits will impact their function. Numerous regions in the mammalian forebrain have been identified as sexually dimorphic, and their normal development is dependent on testosterone exposure during the perinatal period. For hypothalamic regions, conversion of testosterone to estradiol and activation of either or both estrogen receptors (ER-α and ER-β) are initial events in the process. These hormone receptors impact development through changes in gene expression that ultimately cause changes in cell number, morphology, neurochemistry, and connectivity among a wide variety of sexually dimorphic neural circuits.

Sex Steroids Regulate Programmed Cell Death

Assembly of neural circuits involves generation and differentiation of component populations of neurons, migration of neurons to resident sites, and establishment of functional connections with other parts of the nervous system. Hormonal regulation of neurogenesis does not appear to play a major role in specifying sexually dimorphic numbers of neurons in the CNS; however, estrogen appears to influence neurogenesis in mature animals. Nor does formation of sexually dimorphic nuclei appear to be influenced significantly by hormonal regulation of neuronal migration patterns; however, it is possible that experimental limitations are largely responsible for a lack of definitive information on migration. The cumulative evidence indicates that the major way in which sex steroid hormones alter neuronal number in sexually dimorphic regions of the CNS is by influencing cell death. Testosterone decreases cell death in the MPN, BSTp, and SNB, all of which have more neurons in males. In contrast, testosterone exposure increases cell death in the AVPV, where cell number is greater in females. In each of these regions, dying neurons display the morphological features of an apoptotic cell death mechanism, including DNA fragmentation. Moreover, cell loss in the AVPV appears to depend on activation of caspases, enzymes that mediate key aspects of the apoptotic cell death cascade. Although the evidence for cell death as a mechanism underlying sexual differentiation of neuronal number is most thoroughly documented for these nuclei, there is compelling support for cell death as a major determinant in several sexually dimorphic nuclei, in a variety of vertebrate model systems, indicating that hormonally induced control of cell number is a widespread neurobiological mechanism. Less clear is how sex steroid hormones bring about cell death. One possibility is that testosterone regulates expression of antiapoptotic genes such as members of the Bcl2 family, and overexpression of Bcl2 appears to function in a neuroprotective way. The laboratory of Nancy Forger showed that overexpression of Bcl2 in mice reduces the magnitude of sex differences in the SNB and AVPV, suggesting that testosterone regulates cell death in these nuclei through a Bcl2-dependent mechanism. Sex differences were eliminated in mice in which the proapoptotic gene Bax was deleted, demonstrating that Bax is required for sexual differentiation of these nuclei. However, it is a mistake to assume that all sexually dimorphic populations of neurons are regulated through differential control of such proapoptotic or antiapoptotic genes. For example, dopamine neurons in the AVPV are resistant to the developmental effects of manipulating Bcl2 expression or deletion of Bax, despite the overall effects on cell number in the AVPV, indicating that the reduction in dopaminergic neurons seen following exposure to testosterone is caused by a cell death program that is independent of Bcl2 family proteins. In addition to regulation of cell death, testosterone acting early in development may cause lasting changes in neurotransmitter phenotype. In the BST of the rat, perinatal steroids appear to specify a subset of galanin-containing neurons to co-express vasopressin, consistent with the notion that hormones acting perinatally may induce marked and lasting changes in gene expression that lead to sex-specific patterns of neuronal differentiation.

Sex Steroids Specify Patterns of Connectivity

Axon guidance The assembly of functional neural circuits requires neurons to establish polarity, undergo dendritic morphogenesis, and extend axons that traverse significant distances in the CNS guided to their

targets by a complex array of molecular guidance cues. Estrogen is capable of exerting a direct trophic action on neural tissue, especially if the neurons express estrogen receptors. For example, hypothalamic explants extend a profusion of neurites in response to estrogen treatment, suggesting that sex steroids can promote axonal growth. Two sexually dimorphic nuclei in the zebra finch song control system, designated the higher vocal center (HVC) and the robust nucleus of the archistriatum (RA), play important roles in the motor control of song production. A massive projection from the HVC to the RA is required for expression of song in adulthood, and this pathway forms in male but not female finches. Formation of this pathway can be induced in female finches by exposure to exogenous estrogen, which *in vivo* appears to be derived locally rather than from the gonad. In contrast, neurons in the preoptic region of the quail hypothalamus provide sexually dimorphic projections to the midbrain periaqueductal gray. These neurons contain aromatase and convert gonadally derived testosterone to estrogen during development. The homologous pathway in rats shows a similar sex difference, with more preoptic neurons innervating the periaqueductal gray in males than in females. The most dimorphic pathway in the mammalian forebrain appears to be a projection from the BSTp to the AVPV (Figure 3). The intensity of this limbic–hypothalamic pathway is at least an order of magnitude greater in males relative to the homologous pathway in females, and it appears to develop through a directed mechanism rather than forming in both sexes and then regressing in females. The molecular mechanisms directing development of the BSTp-to-AVPV pathway remain unknown, but it is clear that testosterone acts on the AVPV target cells to promote innervation by BSTp neurons. Because the BSTp is larger in males, it is not surprising that it provides a more robust projection to its targets in males. However, the density of projections from the BSTp to the AVPV in male rats is much greater than would be predicted simply on the basis of the greater number of neurons in the BSTp. Numbers of projection neurons are often influenced by the size of their targets, but the AVPV contains fewer neurons in males relative to females, which would argue for a weaker input in males if target size were controlling the number of afferents from the BSTp. Thus, exposure to sex steroids during the perinatal period decreases the number of cells in the AVPV while increasing the innervation of the remaining cells, resulting in a hormonally directed increase in the convergence of BSTp inputs onto AVPV neurons in males. Because the BSTp conveys olfactory information to the hypothalamus, the hormonally directed differentiation of the BSTp-to-AVPV pathway means that sensory information will impact certain hypothalamic circuits differently in males and females. Innervation of perineal muscles by the SNB is also regulated by target-derived factors. In this system, testosterone acts on the muscles to induce endogenous factors, which then act on SNB motor neurons to mediate

Figure 3 Sexually dimorphic limbic–hypothalamic pathway. The principal nucleus of the bed nuclei of the stria terminalis (BSTp) innervates the anteroventral periventricular nucleus (AVPV) of the hypothalamus. The axonal tracer PHAL was used to label neural projections from the BSTp to the AVPV in male (a), female (b), and testosterone-treated female (c) rats. Treatment of newborn females with testosterone induces innervation of the AVPV by BSTp neurons, thereby changing this pathway from the female to the male pattern. och, optic chiasm; V3, third ventricle. Adapted from Gu G, Cornea A, and Simerly RB (2003) Sexual differentiation of projections from the principal nucleus of the bed nuclei of the stria terminalis. *Journal of Comparative Neurology* 460: 542–562.

sexual differentiation of the SNB. One such factor has been identified as the ciliary neurotrophic factor, but other factors that influence growth and maintenance of neuromuscular junctions may also play a role in specifying innervation of perineal musculature by SNB neurons. The brain-derived neurotrophic factor (BDNF) is important for development of the avian song control nuclei, but in contrast to the SNB system, BDNF appears to act through both retrograde and nonretrograde signaling mechanisms.

Synaptogenesis Sex steroid hormones also appear to be involved in regulation of dendritic structure and synapse formation in sexually dimorphic regions. *In vitro* experiments document the ability of estrogen to promote dendritic length and branching in embryonic limbic and hypothalamic neurons. Estrogen specifies sexually dimorphic patterns of dendritic morphology in the hypothalamus of postnatal rats, and glial cells appear to play a determinant role in this process. Sexually dimorphic patterns of synapses on hypothalamic neurons have been identified that are determined by exposure to testosterone during perinatal life. In the arcuate nucleus of the hypothalamus, synapses on both dendrites and cell bodies of neurons are more abundant in females. In contrast, there is a different synaptic pattern in the ventromedial hypothalamic nucleus, in which the density of synapses is greater in males, indicating that there is considerable regional variation in sexually dimorphic patterns of synaptogenesis. Whether these different patterns of synaptology are due to differential innervation by regions with varying numbers of afferent neurons or are locally specified by postsynaptic mechanisms is unknown. The arcuate nucleus is innervated by the AVPV, which contains more neurons in females and provides more robust innervation of the arcuate nucleus. Similarly, several regions that have greater numbers of neurons in males innervate the ventromedial nucleus. However, inputs to the ventromedial nucleus from the BSTp are similar in males and females, even though the BSTp provides a sexually dimorphic projection to the AVPV, indicating that at least for the BSTp, hypothalamic targets play an important role in specifying patterns of innervation. Thus, in addition to regulating the numbers of neurons that reside in sexually dimorphic nuclei, perinatal testosterone specifies patterns of connectivity in multiple neural networks. The functional consequence of these sex differences is that the input–output relationships of neurons comprising key components of both sensory and motor pathways are different in males and females, which means that information is processed in unique ways, leading to expression of sex-specific behaviors.

The Role of Receptors for Estrogen and Testosterone

A key developmental factor in the regulation of sexual differentiation of the brain is expression of receptors for estrogen and testosterone by neurons in sexually dimorphic nuclei (**Figure 4**). All of the major sexually dimorphic nuclei in the mammalian brain contain high densities of neurons that express ER-α, AR, or ER-β during the perinatal period, when testosterone exerts its greatest effect on brain development. These receptor proteins function primarily as ligand-activated transcription factors that regulate cell development through regulation of gene expression. However, sex steroids can also influence the activity of neurons through what appear to be membrane-associated receptors. Because neural activity has a profound influence on neuronal differentiation and formation of connectivity, such membrane receptor-mediated effects of sex steroids may alter development of regions that do not express the nuclear steroid receptors in abundance. In the rodent, estrogen receptors are responsible for regulation of sexual differentiation of the hypothalamus, whereas the AR appears to mediate most of the sex-specific developmental events in telencephalic regions. This regional specification of receptor function may underlie the enhanced role of the AR in sexual differentiation of behavior in primate species, in which telencephalic regions play a more dominant role in controlling behavior.

The signaling events underlying the developmental actions of sex steroid hormones appear to interact at several levels with neurotrophin signal transduction pathways. For example, estrogen can activate the mitogen-activated protein kinase cascade in postnatal neurons as well as regulate the activity of transcription factors such as c-fos and the cAMP-regulated enhancer binding protein (CREB). These cellular signals in turn play an important role in coupling neurotrophin signaling to the nucleus. Work from the laboratory of Margaret McCarthy has directly implicated CREB in sexual differentiation of copulatory behavior. Few downstream targets of these hormonally activated signaling pathways have been identified, but similarities between some of the morphological effects of estrogen and molecules such as BDNF suggest there is a convergence of neurotrophin and sex steroid signaling on common pathways impacting development. These signaling pathways are commonly activated by a variety of environmental factors and are sensitive to the overall effects of experience. It is therefore intriguing to speculate that the observed interactions between developmental

Sexual Selection and the Evolution of Animal Signals

Introduction

Darwin defined sexual selection in *On the Origin of Species* as a mechanism that "depends, not on a struggle for existence, but on a struggle between the males for possession of the females; the result is not death to the unsuccessful competitor, but few or no offspring." Thus sexual selection is a form of selection in which variation in fitness is caused by variation in mating success, and which favors traits associated with enhanced mating success. Darwin's initial description of sexual selection – "a struggle between the males for possession of the females" – implies that he had in mind only aggressive competition among males, but the paragraphs that followed make it clear that Darwin recognized that the struggle "is often of a more peaceful character," with males competing through displays to attract females for mating. Darwin later expanded on these themes in *The Descent of Man, and Selection in Relation to Sex*, treating at length both of the major components of sexual selection: intrasexual selection through aggressive competition and intersexual selection through mate choice. Here we concentrate on the intersexual, mate choice component and its effects on animal communication.

Darwin thought that it was almost universally true that males are more eager to mate than are females and that as a consequence, females are the sex that exercises mate choice. This pattern is still considered the rule, though exceptions are now recognized, both cases in which males and females are almost equally selective and cases in which male choice of mates predominates. Theory successfully explains both the rule and the exceptions, either on the basis of the relative parental investment made by the two sexes or, almost equivalently, on the basis of maximal rates of reproduction. In brief, the sex that makes the greater investment in producing and rearing offspring, or that has the lower maximal rate of reproduction, limits reproduction in the other sex; consequently, the limited sex competes to mate, while the limiting sex exercises choice. Females typically provide greater parental investment than males do, whether in taxa in which both sexes invest only in gametes or in groups such as mammals and birds, with extensive parental care. Largely as a result of these parental investment patterns, females typically have lower maximal rates of reproduction. Thus sexual biases in both parental investment and maximal rates of reproduction predict the predominance of female choice.

Many of the greats of evolutionary biology who followed Darwin were skeptical of the importance of female choice as a selective mechanism. Alfred Russel Wallace, for example, thought "it almost inconceivable that female preference could have been effective in the way suggested," that is, in bringing about the evolution of male displays. Such skepticism may be attributed in part to unwary references by Darwin to an "aesthetic capacity" in female animals, allowing them "an appreciation of the beautiful in sound, colour or form. . . ." Attribution of an esthetic sense to animals, or even of simple choice, implied a higher level of cognition than many scientists were willing to accede to birds of paradise and peafowl, let alone to crickets and moths. Nowadays, however, evolutionary biologists realize that the kinds of mating preferences observed in many animals do not actually call for much in the way of cognitive ability. The words 'choice' and 'preference' currently are used to describe biases in the probability that females will mate with males having certain traits, without regard to whether these biases require cognitive processing. From an evolutionary perspective, what matters most is whether female mating behavior is biased in a way that affects male mating success, not the mechanism – cognitive or otherwise – that underlies the bias. Moreover, it is now realized that, though we may be tempted to label the preferences of nonhuman animals as esthetic, these preferences do not necessarily mesh with our own sense of what is beautiful, as should be conceded by anyone who observes such preferences as that of female common grackles for the songs of their own species.

Another reason for Wallace's skepticism about female choice was the lack of empirical evidence for the hypothesized preferences. One could in theory explain the evolution of the extravagant song of a nightingale or the brilliant coloration of a coral reef fish by positing the appropriate female preferences, but there was no evidence that the required preferences actually existed. Since Wallace's day, however, and in particular during the past 30 years, a great deal of evidence has supported the existence of female preferences in various animal groups. More often than

not, the female preference is for a male trait that we would label as a signal, and which is therefore an element of animal communication.

Evidence of Female Preferences Based on Male Signals

An excellent illustration of female preferences based on male signal characteristics is provided by the work of Michael Greenfield and colleagues on female choice in the lesser wax moth (*Achroia grisella*). Lesser wax moths are obligate symbionts of honeybees (*Apis mellifera*), feeding as larvae on honeycomb and other materials found in honeybee colonies. As adults, male lesser wax moths aggregate in the vicinity of a honeybee colony and produce sexual displays to attract females for mating. The primary display is an ultrasonic acoustic signal produced by fanning the wings. The sound-producing organs are a pair of tymbals located at the base of the forewings; these are hardened, platelike structures that produce sound when they buckle either in or out. A single stroke of the wings produces a pair of sound pulses, one from the left tymbal and one from the right, slightly offset in time (**Figure 1(a)**). Pairs of pulses are produced by both the downstroke and the upstroke of the wings. Males also release pheromones in conjunction with wing fanning, but playback of the sound from a loudspeaker is as effective in attracting females as is a live signaling male, indicating that the ultrasonic signal is the only cue essential for mate attraction.

Female lesser wax moths have been tested in the laboratory for preferences based on acoustic properties of male sounds, using phonotaxis to a loudspeaker playing a signal as a measure of preference for that signal. In each test, a female was given a choice between a standard stimulus, one having the average properties of a male signal, and a stimulus artificially modified along one dimension. Tested this way, females show a preference based on call amplitude, preferring louder calls across the entire range of amplitudes presented (**Figure 1(b)**). This preference should generate directional selection on males to produce signals of higher amplitude. Females also show a preference based on call rates, but here the shape of the preference function is different: instead of always preferring more-extreme signals, females most prefer signals of an intermediate rate, with response falling away for higher as well as lower rates (**Figure 1(c)**). The most preferred rate is higher than the mean rate in the male population (**Figure 1(c)**), however, so this preference should also impose directional selection, in this case for higher signal rates. Finally, females show a preference based on 'asynchrony interval,' the time interval between the onsets of the two pulses in a pair. This preference function shows yet another shape, with females discriminating against signals with very short asynchrony intervals but treating all signals with higher intervals equivalently (**Figure 1(d)**).

Further experiments confirmed these preferences under more naturalistic conditions. Series of females were allowed to choose between sets of four males confined in separate cages. Approach was again assumed to indicate choice. Partial regression coefficients indicate that the number of females attracted by a male is significantly positively related to each of the three signal characteristics mentioned above: call amplitude, call rate, and asynchrony interval.

These results from lesser wax moths are typical of a large body of evidence from insects and anurans showing female preferences for male displays that have greater acoustic energy. In a review of results on several dozen species of frogs and insects, Gerhardt and Huber found that females prefer higher male call rates over lower in the great majority of the studied species. Similarly, females typically prefer male calls of longer duration to shorter ones. By contrast, preferences based on the rate of pulses within a call or on carrier frequency are most often stabilizing, with calls of average properties preferred over either extreme. Exceptions to all these generalizations have been found; in particular, females in several species of frogs show preferences for male calls of lower frequency than the population mean.

In birds, female preferences based on vocalization rates are again observed quite commonly, with females consistently preferring males that sing at higher rates. A second common preference in female birds is for local songs over foreign ones. An example is provided by our work on geographic preferences in female song sparrows (*Melospiza melodia*). We tested for preferences using the solicitation display assay, in which captive females are first treated with estradiol and then exposed to playback of male songs. Subjects respond to conspecific songs with a species-typical precopulation display, and the magnitude of this response is used to infer preferences. We tested females from a site in Pennsylvania for discrimination between a sample of local songs and songs recorded at various points along a transect leading away from the local site. Females showed no discrimination between local songs and songs from the first foreign site (at 18 km) but gave significantly more displays for local songs than for songs from the second foreign site, located 34 km from the start of the transect (**Figure 2(a)**). Females preferred local songs to songs from all sites

Figure 1 The shape of female preference functions for male ultrasonic signals in lesser wax moths (*Achroia grisella*), as measured by female orientation in two-speaker playback tests. (a) Oscillogram showing the temporal sequence of pulses produced by male wax moths. One pair of pulses is produced by each downstroke of the wings and the subsequent pair by the following upstroke. (b) Preferences of females for male calls differing in amplitude. Bars indicate the proportion of subjects choosing calls of specific amplitudes over a standard call in two speaker choice tests. The arrow indicates the amplitude of the standard call. (c) On the left is the frequency distribution of call rates in 529 calls of 33 males. Rate is the reciprocal of the time between one downstroke and the next. On the right are the preferences of females for calls differing in rate. Bars indicate the proportion of subjects choosing calls of specific rates over a standard rate. The arrow indicates the standard rate. Note that the most preferred call rate is well above the population mean. (d) On the left is the frequency distribution of asynchrony intervals in 1057 measurements of calls from 33 males. Asynchrony interval is the time between the beginning of the first pulse in a pair and the beginning of the second. On the right are the preferences of females for calls differing in asynchrony intervals. Bars indicate the proportion of subjects choosing specific intervals over a standard interval. The arrow indicates the standard interval. * indicates a significant preference ($p < 0.25$) for or against the indicated signal without correction for multiple tests. ** indicates a significant preference ($p < 0.05$) for or against the indicated signal after correction for multiple tests. Note that the only significant preferences are against especially short asynchrony intervals. farther away than 34 km, and in general the strength of their preferences increased with increasing distance to the foreign site.

A third preference common in female birds is for more-complex song or more-complex song repertoires. Song sparrows again provide an illustration. Male song sparrows possess repertoires of 5–13 song types, each of which is a discretely different version of the species song. Female song sparrows tested in captivity perform more courtship for 32 songs of four types than for

Figure 2 Female preferences based on song in song sparrows (*Melospiza melodia*). (a) Preferences based on geographic origin of song. Preference is measured as the number of courtship displays given by females in response to songs from their local site, as a proportion of the total given to songs from the local site plus the foreign site. An asterisk denotes a significant preference for the local songs over the foreign. Error bars indicate standard errors. Data are from Searcy WA, Nowicki S, Hughes M, and Peters S (2002) Geographic song discrimination in relation to dispersal distances in song sparrows. *American Naturalist* 159: 221–230. (b) Female preferences based on numbers of song types. Preferences are measured using display scores that combine the number and intensity of displays. Females were tested in single-speaker playbacks with (from left to right) 32 songs of one or four types; 64 songs of four or eight types; and 64 songs of eight or 16 types. Females in each test showed significantly higher response to the greater number of song types. Data are from Searcy WA (1984) Song repertoire size and female preferences in song sparrows. *Behavioral Ecology and Sociobiology* 14: 281–286; and Searcy WA and Marler P (1981) A test for responsiveness to song structure and programming in female sparrows. *Science* 213: 926–928. (c) Field measures of female preferences for males with larger repertoires in song sparrows. On the left, a male's residual probability of mating in his first year, after controlling for territory size and population sex ratio, increases with his repertoire size. On the right, a first-year male's residual laying date, after controlling for between-year variation in the timing of breeding, decreases as his repertoire size increases. Thus first-year males with large repertoires are more likely to mate and mate earlier than males with small repertoires. (c) Reproduced from Reid JM, Arcese P, Cassidy ALEV, et al., (2004) Song repertoire size predicts initial mating success in male song sparrows, *Melospiza melodia. Animal Behaviour* 68: 1055–1063, with permission from Elsevier.

32 songs of one type. Similarly, holding the number of songs constant, females perform more courtship for eight song types than for four, and more for 16 types than for eight (Figure 2(b)). In the field, Jane Reid and colleagues have shown that for male song sparrows holding territories for the first time, the probability of attracting a mate increases with repertoire size, holding the yearly sex ratio constant (Figure 2(c)). Among the males that do breed, laying date decreases as repertoire size increases, indicating that males with large repertoires are chosen before males with smaller repertoires (Figure 2(c)).

Female preferences can, of course, be based on signals other than acoustic ones. Preferences based

on color are common in both birds and fishes. In sticklebacks (*Gasterosteus aculeatus*), females prefer to lay eggs in the nest of males with red ventral coloration over males lacking red. Females show the same preference when the red is added experimentally as when the color is natural. Similarly, male house finches (*Carpodacus mexicanus*) are more likely to find a mate the redder their natural coloration, and their chances of being chosen by a female can be altered by manipulating their red coloration in either direction. Other visual ornaments known to be important to female preferences in birds include the exaggerated trains or tails of male common peafowl (*Pavo cristatus*), long-tailed widowbirds (*Euplectes progne*), and barn swallows (*Hirundo rustica*). In satin bowerbirds (*Ptilonorhynchus violaceus*), males decorate individual mating arenas ('bowers') with objects such as blue and yellow flowers, and the number of these external ornaments affects the likelihood that females will mate with a bower's owner.

In some animals, female preferences are based on olfactory signals rather than on visual or acoustic displays. In house mice (*Mus musculus*), females show preferences for the odors of healthy males over those of males experimentally infected with viral or protozoan parasites. Female house mice also show preferences for males whose major histocompatibility complex genotypes are dissimilar to their own, and these preferences are again thought to be based on odor. In Iberian rock lizards (*Lacerta monticola*), females prefer to associate with the odors of older males over those of younger males, and with the odors of males in good body condition over those of males in poor condition. In field crickets (*Gryllus integer*), females exhibit preferences based on male acoustic signals, but they also show preferences based on male odors, preferring odors of dominant males to odors of subordinates. Conversely, female cockroaches prefer the mix of pheromones produced by subordinate males to the mix produced by dominants.

Evolution of Female Preferences: Theory

If we accept the evidence for female preferences favoring such traits as the exaggerated tails of peacocks and the ultrasonic displays of male wax moths, we can explain the evolution of these traits in males; however, we have solved one difficulty only at the cost of creating another – explaining the evolution of female preferences. RA Fisher was the first to grapple with this problem, remarking that "the tastes of organisms, like their organs and faculties, must be regarded as the product of evolutionary change, governed by the relative advantage which such tastes may confer. . . ." In other words, a female preference is a trait that must have itself evolved, presumably in most cases in response to selection in one form or another. Understanding how selection works in such cases turns out to present considerable difficulties. Fisher stated his own solution concisely, perhaps too concisely given the subtlety of his proposal. Suppose females express a preference based on a male trait in a species in which female preferences have a considerable effect on the reproductive success of males. If the male trait has an initial selective advantage, for example, in promoting male survival, then the preference will begin to spread among the females because of the effect it has on the fitness of their sons. The increase in the preference among females then gives an additional advantage to the preferred trait in males, through increased mating success. As long as the sons of females exercising the preference have a net advantage, due to the combination of the initial natural selective advantage and the subsequent sexual selective advantage, the intensity of the preference will continue to increase. In this way, the male trait can be exaggerated past the point at which its initial natural selective advantage has been lost. The core idea expressed by Fisher – that the exaggeration of a female preference for a male trait leads to stronger selection on both the trait and the preference, leading to a further exaggeration of the preference and the preferred trait – is now termed the 'Fisher' or 'runaway' mechanism.

The Fisher mechanism may seem hopelessly circular, but its logic has been confirmed repeatedly during the past quarter century by mathematical models of various types. The gist of these models can be summarized as follows. We start with a female preference already existing at some low frequency, perhaps due to an initial advantage from securing mates of high viability. Females with the preference mate with males with the preferred trait, and their offspring therefore inherit both the genes for the preference and the genes for the male ornament. This creates a genetic correlation between trait and preference. Consequently, when sexual selection favors the male trait because of its advantage in mating, the preference is favored indirectly, because of the genetic correlation. As the preference increases, sexual selection in favor of the ornament strengthens, which in turn strengthens selection for the preference, and so on. Under certain conditions, such as weak genetic covariance between trait and preference, evolution proceeds toward a line of equilibria, at which the degree of exaggeration of the male trait balances the degree of strength of the preference. Under other conditions, such as stronger genetic covariance, the process can run away toward ever increasing levels of trait and preference. Even in the latter case, the process is

expected to stabilize eventually as the preferred trait becomes increasingly costly under natural selection. The benefit of increased mating success conferred by a bird's long tail, for example, may be outweighed at some point by the cost of poorer flight capabilities associated with having a long tail or the physiological cost of producing a long tail in the first place.

The Fisher mechanism is classified as an indirect selection hypothesis because selection acts on the preference only indirectly, through its genetic correlation with the preferred trait. A second indirect selection hypothesis is provided by the 'good genes' mechanism. Here the male ornamental trait is thought to serve as an 'indicator' of male viability because, for example, only males in good condition are able to develop the ornament fully. Mating between females with the preference and males with the preferred trait creates a genetic correlation between preference, preferred trait, and viability. Natural selection always favors high viability, and the preference and ornamental trait are consequently favored indirectly because of their genetic correlation with viability. A general problem with the good genes hypothesis is that it requires viability to be heritable; this is a problem because natural selection always favors high viability and thus tends to exhaust additive genetic variance for traits contributing to viability. Among several hypotheses for escaping this dilemma, the best known is that of William Hamilton and Marlene Zuk, who suggested that coevolutionary cycles between parasites and hosts ought to maintain additive genetic variance for resistance in hosts and thus the heritability of viability. A preference for males with good genes would then often manifest itself as a preference for males resistant to parasites.

Some theoreticians have considered the good genes mechanism to be a distinct alternative to the Fisher process – and a more parsimonious alternative by virtue of being both less circular and less arbitrary. Those taking this view have assumed that the fitness of offspring of preferred males is a test of these alternatives: under the good genes hypothesis, preferred males should have sons and daughters of superior viability, whereas under the Fisher hypothesis, only sons of preferred males would have an advantage, and the advantage would stem only from superior mating success. Recently, however, others have argued that Fisher effects – those in which sexual selection acts indirectly on the preference – are inevitable in a good genes process and that therefore the two mechanisms cannot be disentangled.

It is also possible for selection to act directly on a preference, because the preference affects the fitness of the female expressing the preference rather than the fitness of her offspring. Direct selection will occur if the preference affects the quality of material benefits provided by the male; such benefits might include nuptial gifts of food, a breeding territory, or resources passed to the offspring in parental care. If a female can observe something about a male, such as his size or vigor, that allows her to assess directly his potential for providing material benefits, then communication does not need to be invoked. If instead a female assesses a male through a signal that correlates with his ability to provide material benefits, then communication is involved. The signal can again be considered an 'indicator' of male quality, albeit of direct material benefits instead of indirect genetic benefits.

Another possibility is for the preference to affect the costs of mate choice to the female; for example, if searching for a mate exposes the female to predation risk, an appropriate preference shortens the search and thus reduces risk. Yet another possibility is that mating with preferred males may be harmful to females, as for example when male seminal fluids contain substances toxic to females, as occurs in *Drosophila*. In this case, females may evolve resistance to the preferred male display, in the sense of an increased threshold for response, which paradoxically may lead to selection for exaggeration of the display in order to overcome resistance.

A final possibility is for a preference to be the consequence of properties of the sensory or neural systems of the female that have evolved in contexts having nothing to do with mating. The preference is then said to represent a 'sensory bias,' and the evolution of a male signal in response to the preference is said to represent 'sensory exploitation.' Sensory bias is sometimes considered to fall in the category of direct selection hypotheses, as natural selection has presumably acted directly on the relevant sensory or neural properties in some other context, such as predator avoidance or food finding. Alternatively, sensory bias can be considered to be a case of no selection, because the mating preference *per se* has not affected either the female's fitness or that of her offspring and thus has not been acted on by selection.

Evolution of Female Preferences: Evidence

To a layperson, the simplest explanation of female preferences might seem to be the good genes hypothesis: a female prefers a male whose displays advertise his health and vigor, and she benefits when he passes those traits to her offspring. To a population geneticist, however, this explanation may seem the least parsimonious of the possibilities, depending as it does on a series of genetic correlations and heritabilities that are all likely to be low. Nevertheless, there is

evidence in some instances that females benefit from their preferences in ways predicted by the good genes hypothesis. In great reed warblers *(Acrocephalus arundinaceus*), for example, females prefer males with larger syllable repertoires, and such males sire offspring that have superior postfledging survival. Similarly, peafowl females prefer males with larger trains, and those males sire offspring that experience higher survival. In gray treefrogs (*Hyla versicolor*), females prefer calls of long duration, and males that give such calls sire offspring that grow at a faster rate and complete development in a shorter interval than the offspring of males giving shorter calls. This advantage, however, is seen only at low densities; at high densities, offspring of males of short call duration complete development faster. Similarly, in the lesser wax moths described above, the offspring of males with attractive ultrasonic signals develop faster under favorable environmental conditions but slower under unfavorable conditions. Thus support for the good genes mechanism must be considered equivocal for gray treefrogs and lesser wax moths.

A crucial prediction of the Fisher mechanism for the evolution of female preferences is that a genetic correlation ought to exist between the preference and the preferred trait. This prediction has been verified in several cases using two methods. In one, artificial selection is imposed on the preferred trait only; a genetic correlation between the two is demonstrated if the preference changes along with the preferred trait. In stalked-eyed flies (*Cyrtodiopsis dalmanni*), for example, females normally prefer males with long eye spans. When males were selected for shorter eye spans for 13 generations, eye stalk length responded, and female preferences also changed, such that females in the selected population came to prefer males with short rather than long eye stalks. Similarly, when artificial selection was imposed on male guppies for greater or lesser area of orange, females in the selected lines also diverged in the strength of their preference for orange males. The second way to demonstrate a genetic correlation is by measuring the covariance of the trait and preference in genetic relatives, such as full sibs, half sibs, or parent and offspring. Using this method, a genetic correlation has been demonstrated in the field cricket *Gryllus texensis* between pulse rate in male calls and female preference for pulse rates, and in sticklebacks between area of red in males and female preference for red in their mates.

A second prediction of the Fisher mechanism is that the traits that make males attractive are heritable, so that attractive fathers produce attractive, or 'sexy,' sons. The predicted heritability has been demonstrated for pulse rate of male calls in the field cricket *G. texensis* mentioned above and for all three of the male call traits contributing to attractiveness in lesser wax moths. The prediction has been verified more directly in the lekking sandfly *Lutzomyia longipalpis*, through evidence of a positive relationship between mating success of fathers and mating success of sons. Pheromones are thought to mediate male attractiveness in this case. The most direct evidence confirming the prediction comes from guppies, in which it has been shown (through the resemblance of half-sibs) that male color pattern is heritable and that there is a genetic correlation between male color pattern and male attractiveness to females. Thus, a female choosing a male based on his attractive color pattern will acquire genes for her sons that enhance their attractiveness.

Although the good genes and Fisher mechanisms receive support in some cases, it is thought that the most parsimonious explanations for the evolution of female preferences are ones in which selection acts directly on a preference. In variable field crickets (*Gryllus lineaticeps*), for example, females prefer males producing calling songs with higher chirp rates and longer chirp durations. Among females maintained on a restricted diet, longevity was positively associated with the chirp duration of the male to which they were mated, while the number of fertile eggs produced was positively associated with male chirp rate. Both effects seem likely to be due to nutrients passed in the seminal fluid, since neither effect occurred in females maintained on a better diet. Both aspects of the preference, for call rate and call duration, affect the female's own fitness, and thus selection acts directly on these preferences. Even in guppies, in which such a good case can be made that females benefit indirectly from mating with preferred males through the enhanced mating success of sons, it may be more important that the preferred males – those with a greater area of orange – have larger sperm stores and deliver more sperm to the female.

Sensory bias proposes that mating preferences are a consequence of properties of a female's sensory or neural systems that have evolved due to selection in some context other than mating. The hypothesis thus predicts that the preference existed before the preferred trait evolved, a prediction not made by other hypotheses for the evolution of preferences. Evidence supporting this prediction comes from the neotropical frog *Physalaemus pustulosus*. Here males produce calls consisting of a low-frequency whine plus one or more high-frequency chucks, and females prefer calls with chucks to calls without them. Females of a related species, *P. coloradorum*, also prefer conspecific calls to which chucks are added, even though males of this species never produce chucks. The preference can be explained by the organization of the anuran ear, which has two papillae, one tuned to low frequencies

and thus stimulated by a whine, and the other tuned to higher frequencies and thus stimulated by chucks. Phylogenetic analysis indicates that both the tuning properties of the ear and the preference for the chuck probably existed in an ancestor that lacked the preference; thus the preference seems to have evolved before the preferred trait. The same pattern of auditory tuning, however, also exists in another *Physalaemus* species that lacks the preference, arguing that the preference is not solely determined by the tuning pattern. Support for a sensory bias explanation has also been found in analyses of female preferences for swords in swordtail fish and for water vibrations in water mites.

Conclusions

Initial skepticism about the plausibility of female choice as a mechanism of sexual selection has given way in the face of overwhelming evidence that preferences for male traits do bias female mating patterns. The male traits on which female preferences act are most often male signal characteristics, and thus sexual selection plays a large role in shaping animal communication. Understanding why sexual selection shapes communication the way it does requires understanding the evolution of female preferences. Various theories have been elaborated on how and why female preferences evolve, including the Fisher mechanism, the good genes hypothesis, sensory bias, and various direct selection explanations. These hypotheses are not mutually exclusive, so it is not surprising that empirical support exists for multiple hypotheses, not only with respect to separate preferences in different species, but even with respect to a single preference in a single species.

Shape Representation in Inferotemporal Cortex

L Woloszyn and D L Sheinberg, Brown University, Providence, RI, USA

© 2009 Elsevier Ltd. All rights reserved.

The macaque visual system is commonly divided into two parallel processing streams. The dorsal pathway travels from the occipital lobe into the parietal lobe and is thought to be responsible for analyzing the spatial layout and movement of objects. The ventral pathway, which follows the inferior longitudinal fasciculus, extends from the occipital lobe into the anterior and ventral portions of the temporal lobe; unlike the dorsal pathway, it is thought to be primarily responsible for representing those aspects of visual information critical for encoding object identity. Anatomical and physiological evidence indicates that the flow of visual information in the ventral pathway proceeds in a hierarchical fashion through several distinct functional areas. In nonhuman primates, a collection of visual areas that comprises the most anterior and ventral portions of this pathway are generally referred to as the inferotemporal (IT) cortex. As the name implies, this large region of cortex is located on the ventrolateral surface of the central and anterior temporal lobe. A major source of feed-forward input into the IT cortex is area V4, a retinotopically organized visual area that responds to visual information of intermediate complexity, such as oriented contours. Individual neurons within IT, because of their large receptive fields and lack of retinotopic arrangement, integrate this incoming information into even more elaborate representations. Many experiments have shown that single IT neurons respond selectively to the presentation of faces, animals, cars, fruits, and a myriad of other complex images. Coupled with the IT cortex's position in the visual hierarchy, these observations have led researchers to speculate that the IT cortex underlies the perception and representation of complete visual objects.

Selectivity, Invariance, and Tuning Functions

The tuning profiles of individual IT neurons reveal considerable individual variation, ranging from broadly tuned neurons that respond to the presentation of many objects to narrowly tuned neurons that respond extremely selectively to only one test stimulus. The breadth of observed response selectivities is consistent with the remarkable ability of the visual system to simultaneously mediate two seemingly antagonistic processes required for successful visual object recognition. On one hand, the visual system must be able to identify the same visual object regardless of its size, position, angle, and other factors that affect its appearance but not what it is. On the other hand, the visual system must also be capable of making fine discriminations between very similar yet different objects. This interplay between invariance and selectivity is illustrated in Figure 1. Ever since the pioneering studies of Gross and colleagues, in which it was shown that single IT neurons can display extraordinary selectivity for individual visual objects, a major focus of research has been to identify the particular attributes that determine neuronal selectivity.

Shape Selectivity

Implicit in the idea that visual recognition capacities are directly linked to the activity of cells in IT cortex is the notion that those features critical for judging identity will be reflected in individual cell response profiles. Consistent with this suggestion is the observation that IT neurons respond to a given shape independent of the cue used to construct that shape. For example, a bright square patch against a dark background or a square patch of upward-moving dots against a background of downward-moving dots can both indicate the shape of a square. An IT neuron selective for a square will give a vigorous response to both the luminance- and the motion-defined shapes. This finding has led some to propose that shape is the fundamental visual attribute that the IT cortex represents. Support for the shape hypothesis, however, is complicated by the wide array of complex visual images that are used to explore the selectivity of IT neurons. Whereas some labs use images of real objects, other labs decompose these objects into their constituent parts or employ completely arbitrary shapes. Because the concept of shape has been so operationalized, results from one study are difficult, if not impossible, to interpret in the context of another study. Notwithstanding these difficulties, numerous efforts have been undertaken to systematically analyze shape representation in IT cortex. One such approach has been to record from IT neurons while monkeys view a parameterized set of shapes.

What is a parameterized set of shapes? A shape's quantitative description lies in several dimensions. Some simple and concrete examples of these dimensions are the length, position, orientation, and curvature of the line segments that compose a particular shape. Different values along the dimensions lead to

Figure 1 Location of inferotemporal (IT) cortex and the response properties of individual IT neurons. (a) Lateral view of the macaque cortex with the anatomical location of IT shaded in yellow. IT is part of the ventral visual stream, which descends from the posterior pole

different shapes. It is possible that IT neurons explicitly represent these dimensions, but using real-world objects to assess this is difficult because two different real-world objects will differ along several dimensions at a time. This makes it hard to interpret to which dimension a neuron is sensitive. Parameterized shapes overcome this problem because their distinguishing characteristics vary along a known number and identity of dimensions. Hence, a set of parameterized shapes can hold constant all but a few dimensions, allowing for a better understanding of what it is that an individual IT neuron represents. This sort of approach has shown that IT neurons have the capability to encode simple dimensions of shapes. For instance, an IT neuron selective for a triangle's height will systematically increase or decrease its firing rate as a function of the triangle's height. A separate neuron selective for how curved the triangle is will similarly increase or decrease its firing rate as a function of the triangle's curvature. It is interesting that single neurons can be sensitive to changes along more than one dimension. When both dimensions change simultaneously, the neuron's response can be predicted on the basis of its response to the individual changes, implying that the dimensions can be encoded independently.

In most situations, the dimensions that define a shape are numerous and complex. It would seem to be an ineffective and inefficient strategy to represent each of these dimensions separately and independently. So how can such shapes be represented systematically at the neural level? Given a set of complex shapes, some of them are naturally judged to be more similar than others. If the stimuli have been parameterized properly, the perceptual similarities can be plotted in an arbitrary low-dimensional space (e.g., a two-dimensional plane). The larger the distance between a pair of points in this space, the less perceptually similar the two shapes are. It has been shown that IT neurons have tuning functions consistent with the representation of such low-dimensional arrangements of parameterized shapes. Specifically, an IT neuron that has a preferred shape will decrease its response to the other shapes, and the magnitude of the decrease corresponds to the magnitude of the perceived dissimilarity. This coding scheme, depicted in Figure 2, suggests that a clever neural code for representing stimuli is one that constructs arbitrary dimensions which capture most of the variations in a set of shapes.

Parameter Invariance

The ability of IT neurons to detect subtle differences between shapes supports the claim that this population of cells allows observers to make fine discriminations between visual objects. This selectivity, however, must be balanced by an equally important aspect of shape representation: invariance. Any two particular instances of a shape are unlikely to be exactly the same. A shape's size, position, or orientation on the retina will never be exactly the same. The visual system faces the difficult task of identifying shapes independent of these (contextually) irrelevant variations. To couch this in the adopted terminology, IT neurons, in addition to their sensitivity to one set of parameters, must also be insensitive to another set of parameters. What are some of the neural correlates of invariance?

At its anterior location in the ventral visual processing pathway, IT cells have receptive field sizes that are significantly larger than those of cells in more posterior visual areas. Receptive fields as large as 30–50° in diameter and spanning both the contra- and ipsilateral visual fields are encountered routinely during recordings. This size allows individual IT neurons to integrate sensory information from a substantial portion of the visual scene. As such, IT neurons can maintain their relative selectivity for a given shape over large changes in its location. Even though the absolute responses to shapes may well be affected by changes in eccentricity (almost always being reduced with increasing distance from the fovea), the shape selectivity is generally preserved. Likewise, this relative selectivity is preserved across variations in the shape's size. It is intriguing to note that there does appear to be a trade-off in the ability of IT neurons to be very selective for one or a small number of shapes and the ability of IT neurons to demonstrate invariance in the face of image transformations. That is, the responses of narrowly tuned neurons are more likely

of the occipital lobe into the anterior portions of the temporal lobe. The main visual areas comprising the ventral visual stream are indicated: V1, V2, V4, TEO, and TE. CS, central sulcus; LS, lateral sulcus; STS, superior temporal sulcus. (b) The response profile of a narrowly tuned IT neuron, showing high selectivity. This neuron responds selectively to the presentation of the pacifier. None of the other images in the set produce a reliable response. (c) The response profile of a different, broadly tuned IT neuron. The presentation of any kind of butterfly wing elicits a consistent response from this neuron. This neuron's response is somewhat invariant to different instances of a butterfly wing. For each panel in (b) and (c), the visual stimulus is placed above its corresponding raster and spike density function. Each row in the raster (top) is one trial; the black bars indicate individual action potentials for that trial (each trial is marked by the aligned horizontal red ticks). The spike density function (below) is the averaged data for all trials with a particular image. The *x*-axis is time in milliseconds. The green line in the middle of each panel designates time of stimulus onset. Mruczek and Sheinberg (unpublished data).

Figure 2 Low-dimensional configurations of parameterized shapes. (a) A set of eight parameterized shapes used to explore the representational scheme in inferotemporal (IT) cortex. Parameter space configuration: The eight shapes varied systematically along two radial frequency components. The shape in the top left has low amplitude values for both components. The shapes in the top right and bottom left have high amplitude values for one or the other component. The shape in the bottom right has high amplitude values for both components. (b) Perceived similarities: monkeys judged a pair of these stimuli (for all possible pairs) as same or different. By means of a technique known as multidimensional scaling, the perceived similarities of the monkey were plotted in a low number of arbitrary dimensions. The low-dimensional configuration of perceived similarities has a squarelike arrangement very similar to the actual parameter space configuration. Neuron-based similarities: multidimensional scaling can also be applied to the neuronal responses obtained while the monkey passively views the shapes. The correspondence between the low-dimensional configuration of the neuron-based similarities and the perceived similarities is readily apparent. (c) The response profile of a single IT neuron to the eight shapes. The inside part of the figure is a polar plot which shows the normalized response of the neuron to each of the eight shapes. On the outside of the polar plot are the spike density functions used to generate the polar plot. This neuron is most responsive to the presentation of stimulus 6. Shapes perceived by the monkey to be the least similar to shape 6 caused the largest decrease in the response of this neuron. From Op de Beeck H, Wagemans J, and Vogels R (2001) Inferotemporal neurons represent low-dimensional configurations of parameterized shapes. *Nature Neuroscience* 4: 1244–1252.

to be affected by changes in size and position than are those of broadly tuned neurons, possibly suggesting that distinct populations of neurons within IT cortex mediate selectivity and invariance.

Bell-Shaped versus Monotonic Response Functions

From studies using parameterized shape stimuli has emerged the hypothesis that IT neurons have monotonic tuning functions. In order to explain this coding scheme, it is easiest to contrast it with an alternative, bell-shaped tuning. Bell-shaped tuning refers to tuning functions whereby each neuron has some optimal stimulus to which it will respond, and any deviations from this stimulus will cause a decrease in the response. The most obvious example of this kind of tuning is seen in V1 with respect to orientation. A V1 neuron maximally responsive to a 180°-oriented bar will respond less to 150°- and 210°-oriented bars and even less than that to 120°- and 240°-oriented bars. It has always been implicitly assumed (and largely observed) that IT neural tuning would be similar to these bell-shaped curves of V1. An IT neuron sensitive to variations in a shape dimension would have a preferred value along this dimension (e.g., some particular height of the triangle which it liked the most), and any departures from this value would elicit a smaller response. Different neurons would have different preferred values, and the collection of preferred values would span the whole range of values that the dimension could take.

Unlike cells in V1, studies using parameterized shapes have suggested that IT neurons often respond maximally to those stimuli which attain the least or most extreme value of the dimension under investigation, such as the shortest or tallest triangle. Hence, there exist only two preferred values along the whole span of the dimension, and individual IT neurons are required to adopt one or the other extreme. This observation is inconsistent with bell-shaped tuning because the bell-shaped tuning account would predict a comparable number of neurons maximally responsive to the intermediate values. It is worth noting that the concept of 'most' extreme is operationally defined because dimensions can attain values higher than those tested in a particular experiment. IT neurons, however, cannot increase their response magnitude forever. Is there a way around this dilemma?

Two general solutions are possible. First, it could be the case that at the more extreme values, the neural response does start to decrease. This would support somewhat broad bell-shaped tuning functions. Second, at some point the higher-dimension value could

cause a sharp and distinct transition in the shape itself. To provide a concrete example, imagine a trapezoid whose two parallel sides are of very different length. As the lengths of these two parallel sides are made more and more equal, eventually this trapezoid will become a rectangle (if the endpoints of the parallel side are the same). It has been shown that an IT neuron selective for the trapezoid will maintain its response to the trapezoid over a rather wide range of the relative lengths of the two parallel sides but that the response will abruptly cease if the trapezoid is converted into a rectangle. This observation suggests that IT neurons show enhanced sensitivity to qualitative, as opposed to quantitative, differences in shapes. Figure 3 depicts how qualitative shape differences are able to modulate the responses of individual IT neurons more significantly than are equally large quantitative differences.

Prototype Shapes and Combination Encoding

A large but finite set of such qualitatively different 'prototype' shapes could be used to construct an almost infinite number of new shapes. Any new and arbitrary shape would simply be some unique combination of the already existing prototype shapes. In essence, the prototype shapes can be thought of as parts that are used to make a whole, complete object. It is plausible that IT cortex contains cells with sensitivities spanning a complete set of prototype shapes. Such a representational scheme demands that for any object to be accurately represented, it has to be decomposed into its individual parts.

Binding Problem

This decomposition raises the question of how the parts are eventually bound together to form a coherent percept of one complete visual object. When there is only one object in the environment, all the parts are assumed to belong to that one object (though their configuration is not specified). In most circumstances, however, biological vision systems have to deal with multiple objects simultaneously. Suppose there are two multipart objects present, a triangle on top of a square and a circle on top of a pentagon. A simple decomposition would result in several separate parts: triangle, square, circle, and pentagon. How does the visual system know to put the triangle with the square and not the pentagon or the circle?

Most current theories on how this binding process is carried out posit a substantial role for attention. Attention refers to enhanced sensory processing at those locations in the visual field that are attended to. How might attentional processes be related to binding? Prior to the allocation of attention to particular spatial locations, one is aware only of individual parts; at this point, misbinding is likely to occur at the unattended locations. However, subsequent to the deployment of attention, the parts at the attended locations get bound together and, as a result, complete object representations materialize. The specific mechanism through which attentional effects are manifested at the neural level remains a topic of debate. One interesting possibility is that attention synchronizes the neurons that are representing different parts of the same object. To be precise, each object is represented through an ensemble of neurons, and each ensemble contains neurons that are firing in concert. Synchronization prevents parts belonging to different objects from being falsely associated because these parts are embedded in different ensembles of neurons.

Spatial Configurations

Another implicit assumption in the prototype-based scheme is the ability of IT neurons to encode the spatial relationships between the individual parts. For example, it must be made explicit that the triangle goes on top of the circle, not off to the side or underneath it. A study that used a large battery of two-dimensional silhouette shapes showed that IT neurons can represent not only the particular parts comprising a shape but also the spatial arrangement of the object components. A separate experiment found that keeping the identities of the parts constant but varying their spatial arrangement causes a considerable decrease in the response of a subset of IT neurons. It seems then that the IT cortex is able to integrate simpler information from more posterior visual areas into something more closely resembling a complete object representation.

Dynamics of Shape Encoding

Despite the intuitive appeal and biological plausibility of prototype shapes and the electrophysiological evidence supporting such a scheme, the existence of a fixed set of structural primitives is incongruent with the phenomenon of visual experience. That is, prototype shapes are building blocks that can be arranged in any arbitrary fashion to describe something completely new and previously unseen. As such, the difference between the representation of novel and familiar shapes should be minimal as all the shapes are constructed in essentially the same manner. Yet we have all had the experience of encountering a new environment and being astounded by the novelty and complexity of the visual objects therein. Over time, as we become more and more familiar with our surroundings, we are able to more efficiently and accurately identify all

Figure 3 Qualitative vs. quantitative shape changes. (a) Responses of three example neurons to a basic shape (middle column), a qualitatively different shape (left column) and a quantitatively different shape (right column). The neuron in the top row maintained its response to the curved triangle as the curvature of the main axis was increased. However, when the triangle was made upright, the response was markedly reduced. For the neuron in the middle row, neither of the trapezoids elicited a reliable response, but the rectangle did. For the neuron in the bottom row, a change from a slightly oval rectangle to a more oval rectangle caused no significant change in the firing rate whereas a change to a rigid rectangle produced a substantial increase in the response. The changes between the basic shape and the qualitatively different shape were equal in magnitude (as measured through Euclidian distance) to the changes between the basic shape and the quantitatively different shape. (b) Across the whole population of neurons, qualitatively different shapes caused more modulation in the responses of inferotemporal neurons than did quantitatively different shapes. Spk, spikes. From Kayaert G, Biederman I, and Vogels R (2003) Shape tuning in macaque inferior temporal cortex. *Journal of Neuroscience* 23: 3016–3027.

the objects and shapes that are present in this setting. This is presumably the result of some changes that are taking place at the neural level. The concept of prototype shapes, therefore, needs to be complemented by a neural representational scheme that is better equipped to take into account visual experience.

Long-Term Plasticity

In contrast to primary visual cortex, plasticity in IT cortex appears to be prevalent throughout adulthood. Studies have shown that repeated visual experience may lead to an increased proportion of neurons responsive to the previously seen stimuli. More interesting, individual IT neurons show greater response differences to well-known stimuli. The existence of neurons that respond selectively to familiar objects presumably aids the identification and discrimination process. Recent observations suggest that changes caused by visual experience are also present in the local field potential, which is thought to reflect the integrated synaptic activity of thousands of neurons. These modifications alone, however, seem insufficient to underlie all the different forms of visual experience.

In real-world situations, different objects (especially of the same class) often share the same overall global shape. The proper representation of these shapes requires that the observer makes use of those local features that are informative while disregarding the irrelevant ones. Bird experts, for example, learn that in some situations the shape of the wings can identify a bird whereas in other situations the shape of the beak may be more critical. A plausible neural mechanism underlying this perceptual phenomenon might be for individual IT neurons to be sensitive to changes in the diagnostic features but insensitive to changes in the uninformative features. This hypothesis has in fact received supporting evidence. In a recent study, monkeys were trained to categorize stimuli as belonging to one of two arbitrary classes. Even though the stimuli had four different local features (e.g., dorsal fin, tail, ventral fin, mouth), only two local features (e.g., dorsal fin and tail) were informative with regard to performing the categorization. Physiological recordings indicated that only changes in the relevant feature dimensions modulated the responses

of individual IT neurons. Thus behavioral experience can bias to which aspects of a shape individual IT neurons devote their processing and selectivity.

For certain classes of shapes, individual local features are inadequate for correct identification. A classic example is that of faces; all faces have two eyes, a nose, a mouth, and so forth. While any of the features alone is enough to signal the presence of a face, it provides little information as to the identity of the face. To recognize a face requires a more holistic approach, a process whereby the spatial configurations of the features are given more weight. How does one go about exploring the possible neural mechanisms underlying holistic processing?

Monkeys can be trained to discriminate between objects composed of the same parts presented in unique combinations of parts (Figure 4). As in the classic XOR problem, this is achieved by creating two-part objects in such a way that the identity of any one part is ambiguous with respect to the identity of the object; both parts must be seen together in order to perform this task correctly. IT neurons demonstrate several changes in their tuning profiles following extensive experience with this task. Notable among these is nonlinear integration: neural responses to wholes that cannot be predicted from the responses to the individual parts. Such holistic responses allow for a more efficient representation of well-known, multipart stimuli.

The presence of neurons that develop such extraordinary selectivity for whole and complete shapes indicates the existence of a sparse representational code within the IT cortex, a code in which relatively few neurons are required to encode and represent an object. A well-known example used to illustrate this concept is the 'grandmother' cell. Does IT cortex have neurons that are selective for just one shape (such as a grandmother's face), and is the firing of this small subset of neurons sufficient to signal the presence of that shape? The idea does not seem far-fetched, considering the studies discussed. However, given the flexibility of the visual system to perceive and identify novel shapes, a sparse representational code has to be complemented by a more distributed and population-based code. A population code uses many neurons to encode and represent an object, each neuron contributing slightly different information about the same object. This sort of code is not only better equipped to handle the myriad of new objects experienced throughout adult life but is also able to identify well-known objects in unfamiliar contexts.

Short-Term Dynamics

It is interesting that the neural response reflecting the nonlinear integration of parts into wholes appears to take more time to develop than does the response to the individual parts alone. This suggests that the informational content of a single neuron's response varies as a function of time. Specifically, the early and late responses have the ability to indicate different facets of the same visual stimulus. Studies that have examined the temporal structure of the informational

Figure 4 Parts- and whole-based shape coding. (a) Monkeys were trained to classify 'baton' stimuli as belonging to one of two classes. The stimuli from different categories shared the same parts, so the monkeys had to encode the upper and lower parts of the stimuli simultaneously to perform the classification correctly. (b) Compared to stimuli that were not learned, inferotemporal (IT) neurons showed enhanced selectivity for individual parts. (c) More interesting, some cells responded to learned stimuli as wholes. The preferred object here shared its parts with two other images; however, neither of the images had both parts together and, as such, did not elicit a response from the neuron. The response is thus 'nonlinear' because the activation to a whole object cannot be predicted on the basis of its response to the individual parts composing that object. Neuronal responses of this sort imply the presence of a sparse representational code within IT. From Baker CI, Behrmann M, and Olson CR (2002) Impact of learning on representation of parts and wholes in monkey inferotemporal cortex. *Nature Neuroscience* 5: 1210–1216.

content have shown that a neuron's early response transmits coarser information about the stimulus, such as its category, whereas the late response carries information about the finer aspects of the stimulus, such as its identity. This is congruent with the intuitive notion that not all information about a visual stimulus is immediately available for conscious access. For instance, when presented with a face, we are much more likely to first identify it as a face, as opposed to a car or a house, than we are to make judgments about its identity or emotional state.

Noninvasive Imaging: Three-Dimensional Shape Representation, Human IT Homologs, and Future Directions

Recently, functional magnetic resonance imaging (fMRI) has been extensively used in studies exploring shape representation in the visual system, allowing for a more broadscale investigation of all the brain regions involved in a specific function. As such, it has been particularly useful in investigating the areas of cortex mediating the representation of complex, three-dimensional shapes. The importance of real-world three-dimensional shape representation extends beyond perception into cognitive domains. As expected, studies employing fMRI have shown that a distributed network of brain regions, including the occipital, temporal, parietal, and frontal lobes, mediates three-dimensional shape representation. These observations are consistent, not only with three-dimensional shapes playing an important role in perception, action, and cognitive functions, but also with three-dimensional shapes being defined through a variety of cues – similar to two-dimensional shapes. It is intriguing to note that within IT cortex itself, there seems to be a specialized area that responds only to three-dimensional shapes.

The use of fMRI in both monkeys and humans has also provided an opportunity to compare and contrast the brain regions important for shape representation in the two species. It has emerged from such comparisons that a likely human homolog of the monkey IT cortex is most likely the lateral occipital complex (LOC). This is a region in the human ventral occipitotemporal cortex that responds preferentially to images of intact objects. It shares with IT cortex the property of cue invariance: LOC will respond to shapes regardless of whether the shapes are luminance-, texture-, or motion-defined. Furthermore, LOC exhibits relative invariance to image transformations involving size and position.

This article has focused on what most would agree to be the critical role of the IT cortex: the representation of visual shape. Although it has examined several pieces of converging evidence that all point toward individual IT neurons being sensitive to some aspect of a shape, the representation of shapes is unlikely to be confined to a small, localized region of cortex. Rather, given the large role that the perception and recognition of shapes plays in daily life, the neural code underlying shape representation is likely to be distributed across several different interconnected areas of cortex, with IT cortex being an integral part of this circuit. To gain a more thorough understanding of this complex circuit, recent research has focused on delineating the interactions between the bottom-up hierarchical processes required for the initial representation of shapes and the top-down attentional and cognitive modulations that influence exactly how the sensory information is perceived and utilized. With the advent of fMRI, it has become possible to observe the functional connectivity between disparate areas of cortex during various perceptual and cognitive tasks. Furthermore, fMRI has enabled electrophysiologists to localize their recording sites and will also guide single-cell recordings made from different areas of cortex. Only recently have studies begun to record the simultaneous activity of multiple neurons from the same cortical area. This will potentially allow for a better understanding of the computations that populations of neurons withinan area carry out. While there is little doubt that IT cortex plays a critical role in shape representation, many details about how this area contributes to shape recognition in the real world remain to be worked out.

Shift Work and Circadian Rhythms

T H Monk, University of Pittsburgh Medical Center, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Biological Underpinnings

Homo sapiens is without doubt a diurnal creature, designed to sleep at night and to be up and about during daylight (except, perhaps, for a short nap after lunch). The endogenous circadian system facilitates this process by the generation and synchronization of various circadian rhythms which are appropriate to a diurnal (i.e., day-oriented) lifestyle. Thus, for example, higher values of endogenous melatonin in its circadian rhythm (which peaks at night) are associated with sleepiness in the diurnal human but activity in the nocturnal hamster. Therefore, having to work at night (as many shift workers do) is definitely an unnatural act for a human being. Humans, of course, do many things which are unnatural; some of them are not harmful at all. A key question (which this article seeks to address) is whether shift work is not only unnatural but also harmful. This article is divided into sections devoted to alertness and safety at work, sleep at home, social and domestic factors, and physical and mental health.

The Significance of Shift Work

In most industrialized countries, approximately one-fifth of all employees are engaged in some form of paid occupation that requires their presence at work outside of the 'daylight' 7 a.m. to 6 p.m. working day on a regular basis and who can thus be regarded as 'shift workers' using a broad definition of the term. This figure is expected to rise as second jobbing and mandatory overtime increase. The fastest growing sector of most Western economies is the service sector, and people are increasingly demanding and receiving around-the-clock availability of such services. Even in the production sector, plant machinery has become so expensive and so quickly obsolete that it has to be run 24 h per day, 7 days per week in order for it to be profitable. Also, the United States has adopted health care provision and business evaluation strategies (e.g., in assessing profitability) that encourage employers to squeeze as many work hours per year as possible from their existing employees, rather than hiring new ones, as the volume of business increases. This leads to extended work weeks and fewer different work teams covering each 24-h day.

Some people cope well with shift work, others poorly. At the extreme, one can define a 'shift work maladaptation syndrome' in those failing to cope, and thus having problems sleeping at home and being alert and productive at work. Several international classifications also refer to a sleep disorder associated with abnormal work hours. The International Classification of Sleep Disorders formally lists shift work sleep disorder as one of the circadian rhythm sleep disorders. The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, lists shift work as a subtype of the circadian rhythm sleep disorder (No. 307.45). Thus, there is increasing acceptance that the difficulties some people experience with shift work should properly be regarded as a disorder worthy of medical diagnosis and treatment.

In many countries, shift work is not simply restricted to a small group of people who can be carefully selected or self-selected to experience minimal problems. Neither is it restricted to the youngest and fittest of workers who can bid their way out of abnormal hours when they advance into their middle age. Employment trends, particularly in the manufacturing sector, now dictate that the 'bidding out of shift work by seniority' option often no longer applies. For many middle-aged and late middle-aged workers, the only option is between shift work and no work. Thus, people are 'doing shift work' typically for many years at a time, perhaps even almost until retirement. This is particularly important as the 'baby boom' generation reaches their late fifties because several studies have indicated that late middle age is a time of particular vulnerability to shift work coping problems.

What Does Night Work Involve?

As has been documented by several sleep diary and time budget studies, most night workers like to have their evenings free to be with family and friends and thus take their sleep immediately after work rather than after an interval of recreation. Night workers therefore have to phase shift (delay) their sleep by approximately 9 or 10 h from day-working society and from their own routine when on a diurnal ('day-oriented') schedule. The latter point is important because even permanent night workers seldom keep to a nocturnal schedule on their days off and are thus, *de facto*, rotating between nocturnal and diurnal schedules. This enables them to meet family and social commitments such as taking their children to soccer games on a Saturday morning or going to church on a Sunday. Monk and Wagner suggested that social and religious commitments on a Sunday could

be invoked to explain an observed Sunday night increase in industrial accidents (relative to other nights) in 10-year data from open cast mining operations. There is also empirical evidence for a reversion to a diurnal orientation after an off-duty break. In a study of permanent night nurses, it was shown that after an off-duty (weekend-type) break of at least 2 days, nurses' circadian temperature rhythms were identical in phase to those of day workers. Thus, those who work at night (even on fixed shifts) are continually challenging their circadian system with phase adjustments, perhaps for many years at a time.

What Do Evening Shifts Involve?

From the standpoint of sleep and circadian rhythms, evening shift work is relatively benign. Such workers typically finish work between 10 p.m. and 2 a.m. and can thus take most of their sleep during the night hours. Should social and domestic constraints allow it (which they often do not), the evening shift worker can sleep in late, and typically such workers on average obtain much more sleep than night workers and slightly more sleep than day workers. As discussed later, however, evening shifts are often devastating from a social and domestic standpoint, particularly for those with school-age children.

What Do Rotating Shifts Involve?

The term 'rotating shifts' describes a shift roster in which a given individual, over time, works all three shifts (day, evening, and night). The time that the individual spends on each of the given shifts is termed the 'speed of shift rotation.' Many shift workers rotate on a weekly or 2-weekly basis. A very common shift system in the United States is the 'southern swing' in which the individual works 1 week of nights, followed by 1 week of evening shifts, followed by 1 week of days. Parenthetically, most experts would agree that such a system is a disaster from a chronobiological standpoint. In Europe, a 'rapid rotation' of shifts is often seen, with all three shift timings done within a given week. In the 2-2-2 system, for example, individuals work 2 day shifts, 2 evening shifts, and 2 night shifts and then have 2 days off – all within one 8-day period.

As one might expect, no rotating shift system is easy to cope with. Many rotating shift workers report being in a state of permanent circadian desynchrony, in which they find themselves moving to a new timing just as they are starting to get used to the old one. Typically, most rotating shift workers sleep at night whenever they possibly can, thus further complicating the phase adjustment picture.

Consequences of Shift Work

Alertness and Safety at Work

One major function of the human circadian system is to 'shut down' various processes so that a restful 7 or 8 h of uninterrupted sleep can be obtained. *H. sapiens* is a social and inquisitive creature, and thus in addition to shutting down hunger, thirst, and the need to void during the night hours, the circadian system also renders the individual sleepy and inattentive during these night hours. The trough in these measures typically occurs at or around 4 a.m., leading to night shift workers often describing a '4 a.m. slump.' This slump is beneficial for the day worker who is asleep at night, but it is potentially harmful for the night worker who must perform his or her job during the night hours, often with complex critical processes and/or dangerous machinery.

Many studies have shown that there is are circadian rhythms in alertness and performance which are endogenously generated by the circadian pacemaker, and are of nontrivial magnitude. These performance effects are equivalent in magnitude to that seen when the 'legal limit' of alcohol is ingested. The human circadian system typically requires 1 day for each 90 min of phase delay adjustment, and thus for at least the first several nights of a run of night duty, individuals will be performing at work during the down phase of the circadian performance rhythms with resultant impairments in alertness, productivity, and safety.

In addition to night shift alertness and performance suffering from being in the down phase of the circadian performance cycle, there are also the effects of partial sleep loss. If the circadian system is at a diurnal (day-oriented) circadian phase, then it will not be doing its job of preparing the individual for a restful sleep during the daylight hours at home. Thus, the day sleep of the night worker is likely to be, from biological processes alone, shorter and less refreshing than the night sleep of the day worker. However, as noted later, to this must be added environmental and psychosocial factors such as daytime noise and domestic responsibilities which will further worsen the night worker's day sleep .

There are several things that a tired night shift worker might do, all of which could potentially compromise safety. First is the obvious one of falling asleep. This is most prevalent in the long-haul trucking industry, where every year several thousand lives are lost by truckers falling asleep and running off roads. However, this has also happened in the airline industry, where the entire cockpit crew was asleep as one airplane full of passengers failed to make its

approach to a west coast US city and headed out over the Pacific Ocean, and in the nuclear power industry, where regulators made a surprise visit to Peach Bottom Nuclear Power Plant in Pennsylvania and found everyone in the control room asleep. Safety can also be compromised by night workers making a simple error in response, even though they are not asleep. The classic example of this is the 4 a.m. accident at Three Mile Island, where the operators were very much awake but were not processing information appropriately. A nocturnal increase in the errors of reading industrial gas meters was also reported in a classic study in the field. A third way in which safety can be compromised is by the night shift worker being angry. This is comparatively neglected as an area of scientific enquiry but undoubtedly contributes to poor safety on the night shift given that affect dysregulation is a major consequence of sleep loss and circadian desynchrony, and that the social and domestic lives of shift workers are often in a state of turmoil.

As one review of shift work and safety notes, acquiring good quality data to support the hypothesis that safety on the night shift is impaired is not easy. Often, there are very different numbers of people present at the facility at different times of the day and night, and the work is often of a different nature (e.g., saving long production runs for the night shift and saving new additions to the process for the day shift). Thus, a simple comparison of accident rates on the night and day shifts will often fail to reveal a night shift increase. One study obtained accident data from a UK automobile manufacturing plant where conditions were exactly the same over day, evening, and night shifts. An analysis of 4645 injuries revealed that the relative risk of an accident was approximately 20% higher (relative risk, 1.2) on the night shift compared to the day shift. Importantly, when only serious injuries occurring away from the production line were considered, the relative risk for the night shift increased to 1.8.

Sleep at Home

Sleep is the major preoccupation of most night shift workers. In both Europe and the United States, surveys have indicated that night workers get approximately 5–8 h less sleep per week than their day-working counterparts. There are both biological and psychosocial reasons for this decrement. To the shift worker, the most salient disruptions are the psychosocial ones of traffic noise, household noise, and family commitments. The day sleep of the night worker is not protected by society's taboos as is the night sleep of the day worker. Few people would make a nonurgent telephone call to a day worker at 1 a.m., whereas few would think twice about making a 1 p.m. call to a day-sleeping night worker. Also, as discussed later, the family will often make demands on the shift worker (particularly if she is a mother of young children) which are unreasonable and which will severely limit her sleep.

To these psychosocial disruptions must be added the biological ones. As noted previously, the biological reasons for day sleep disruption stem from the fact that *H. sapiens* is a diurnal species, hard-wired to sleep at night rather than during the day. The circadian system is slow to make the approximately 9-h phase delay adjustment required by night work, typically taking at least 6 days to make the full 9-h change, and often failing to achieve a full nocturnal orientation. Unlike the transmeridianal traveler, the night shift worker experiences photic cues stemming from daylight and darkness which are resolutely opposed to any circadian adjustment. Studies have shown that the commute home in daylight following a night shift can be particularly problematic since it involves bright light exposure at the point in the phase response curve which inhibits the circadian phase delay that the night shift worker is trying to obtain.

Because the circadian system is not anticipating a day sleep, it thus fails to do its job of shutting down processes so that a restful 7 or 8 h of sleep during the day can be obtained. Thus, even when traffic noise, domestic noise, and family commitments are removed from the picture, the day sleep of night workers will be disrupted. This was demonstrated clearly in a study in which shift workers were removed from their family and domestic constraints and placed in a sound-attenuated, electrically shielded bedroom for their sleep periods, with the subjects commuting to their work from the laboratory rather than from home. Even in this closely protected environment, there was a highly significant difference between the duration of the day sleep of night workers and the night sleep of day workers (5.1 vs. 6.7 h). In addition, there were reliable differences between the polysomnographic characteristics of the sleep, with a smaller amount of rapid eye movement (REM) sleep and a greater proportion of slow wave sleep for the night workers.

In Akerstedt's general surveys of field and laboratory shift work sleep studies, it was concluded that the shortening in a night worker's day sleep comes primarily from a reduction in stage 2 and REM sleep, with slow wave sleep relatively unaffected. Not surprisingly, given the prolonged levels of partial sleep deprivation involved, sleep latency can be somewhat reduced in night workers, and some studies have found shorter REM latencies to occur. Essentially,

the problem is usually one of sleep maintenance insomnia rather than sleep onset insomnia. A shift worker's sleep loss is sometimes partially recouped on days off but does represent a chronic state of partial sleep deprivation which undoubtedly affects the mood and performance abilities of the individual. Laboratory studies have shown that 1 week of sleeping only 5 h per 24 h (as is typical of some individuals performing night work) shows significant cumulative effects on subjective alertness and objective performance abilities. There are several well-controlled studies which document the pathological sleepiness levels exhibited by many shift workers, both at work and on the drive home after work.

Social and Domestic Interactions

Human beings are essentially social creatures, and one could argue that the social and domestic factors are at least as important in shift work as the biological ones. Certainly, if a shift worker's domestic and social life is unsatisfactory, then the individual will not be coping well, however well adjusted the sleep and circadian rhythm factors may be. Usually, however, poor domestic adjustment adversely affects the ability of the shift worker to do the 'right thing' with regard to sleep and circadian rhythms. A common example concerns the child care and household management tasks that can be expected of a female shift worker. Unlike her male colleagues, she is often expected by her spouse to continue to run the household and can thus find herself completely unable to comply with the routine that good sleep hygiene and circadian adjustment might require.

Another aspect of domestic disruption concerns the role of the male shift worker as husband and parent. With regard to the former, there are three major spouse roles that are affected: sexual partner, social companion, and protector–caregiver. All three roles are compromised. Perhaps as a consequence, shift work has been shown in a longitudinal follow-up study to increase the risk of divorce by 57%. Although some of the problems are sexual in origin, many arise from the spouse's inability to be there when needed. Feelings of loneliness and insecurity in a wife left alone at home every night, for example, can represent a much more chronic and insoluble problem than that associated with the timing of lovemaking. Similarly, the evening shift, which has minimal impact on the sleep and circadian factors, can have a crushing impact on the role of the shift worker as social companion. With regard to the family role of parent, the evening shift is again the most disruptive. Often during the school week, the shift worker may only get to see his or her children when they are asleep in bed. In addition, both spouse and parent roles are heavily disrupted when the shift worker is required to work on weekends.

In addition to disrupted family roles, the shift worker often suffers from social isolation from day-working friends and from religious and community organizations that work under the expectation that evenings or weekends will be free for meetings and activities. One might advance the view that perhaps a shift worker who is denied access to community meetings and social and political associations is as much disadvantaged as a handicapped person who is denied wheelchair access to a museum.

Health

A number of reviews have documented the health consequences of shift work. Apart from the obvious problems related to sleep and alertness, there appear to be both physical health and mental health consequences of shift work exposure. In terms of physical health, the main problems implicated are gastrointestinal disorders, cardiovascular disorders, and cancer. All are nontrivial and cannot be attributed simply to lifestyle factors attributed to shift work, such as diet and smoking. For example, in one study, having more than 10 years of shift work exposure doubled the risk of cardiovascular disease. Other studies have confirmed this relation between shift work and cardiovascular disease, even when other risk factors are controlled for. In a prospective study of almost 80 000 nurses, extensive (>30 years) rotating night work exposure increased the risk of breast cancer by 36%. Again, this increase has been confirmed in other studies. In terms of mental health, neuroticism, substance abuse, and alcohol abuse increases have all been implicated in rotating shift workers. Also, a telephone survey of 98 current and former shift workers suggested a more than fivefold increase in the lifetime prevalence of formally diagnosed major depression in those with 6–20 years of shift work exposure compared to those with less than 5 years of exposure.

Clearly, any consideration of the effects of chronic shift work must also be concerned with the weight (or, rather, the body mass index (BMI)) of the worker. From work at the University of Chicago and elsewhere, it is now well established that partial sleep deprivation affects glucose tolerance, and it would thus not be surprising were such effects, compounded with the poor dietary choices that shift workers often make (or have to make), to result in increased BMI and an increased likelihood of sleep apnea and type II diabetes as years of shift work exposure increase. Supportive evidence for this comes from a study

from The Netherlands which concludes that BMI increases with shift work experience, a study from Sweden which concludes that there is an association between shift work and the metabolic syndrome, and a study from Japan that found that shift work is associated with insulin resistance in shift workers younger than 50 years of age.

Conclusions

Shift work is a multifaceted challenge resulting not only from our biology as a diurnally oriented species but also from the social structures which we have built around us. These structures make assumptions regarding sleep and recreation times that can be unhelpful for the shift worker. Thus, shift workers are likely to have problems concerning alertness and safety at work, sleep at home, social and domestic interactions, and the maintenance of good health. It is unrealistic to assume that the prevalence of shift work will do anything other than increase, and it thus behooves the scientific community to provide information to employees, employers, and governments so that the negative effects of shift work can be ameliorated to the greatest extent possible.

Short Term and Working Memory

Introduction

Definition

Short-term memory (STM) refers to the active retention (for humans, the 'keeping in mind') of information when it is not accessible from the environment. Working memory can be thought of as 'STM+,' the '+' referring to the ability to manipulate or otherwise transform this information, to protect it in the face of interference, and to use it in the service of such high-level behaviors as planning, reasoning, and problem solving. STM and working memory are of central importance to the study of high-level cognition because they are believed to be critical contributors to such essential cognitive functions and properties as language comprehension, learning, planning, reasoning, and general fluid intelligence.

Historical Backdrop

The modern study of working memory began with the work of Jacobsen, who, in the 1930s, demonstrated that large bilateral lesions of the prefrontal cortex (PFC) in the monkey produced profound deficits in spatial working memory, and thus Jacobsen ascribed to the PFC a function he termed "immediate memory." A subsequent study, however, revealed that this deficit could be erased by darkening the testing cage and thus reducing interference during the memory delay. These results highlighted a critical question, still the subject of an active debate, which is whether PFC plays a critical role in storage in addition to its role in behavioral control.

The early 1970s witnessed two developments that were seminal in shaping contemporary conceptions of working memory. The first was the observation made by Joaquin Fuster that individual neurons in PFC of monkeys, trained to compare visual stimuli separated by a memory delay, exhibit sustained activity throughout that delay. This observation suggested a neural correlate of two potent ideas from physiological psychology – that of a PFC-dependent immediate memory and that of a reverberatory mechanism for "a transient 'memory'" proposed by psychologist Donald Hebb. The second development, which occurred in the field of human cognitive psychology, was the multiple component model of working memory proposed by Alan Baddeley and Graham Hitch. In its initial instantiation this model comprised two independent buffers for the storage of verbal and of visuospatial information, and a central executive to control attention and to manage information in the buffers. Prompted by these two developments, the neuroscientific and the psychological study of working memory each proceeded along parallel, but largely independent, paths until the late 1980s, when a third important advance occurred.

The third advance was the conceptual integration of the neuroscientific and psychological traditions of working memory research, proposed by Patricia Goldman-Rakic, that the sustained delay-period neural activity in PFC and the storage buffers of the multiple-component model of Baddeley and Hitch were cross-species manifestations of the same fundamental mental phenomenon. This association between prefrontal cortex and working memory has been very influential in systems and cognitive neuroscience.

Current State of Working Memory Research

A growing body of evidence provided by behavioral, physiological, and neuroimaging studies indicates that information about sensory stimuli may be stored in a segregated, feature-selective manner, and that the relevant cortical regions include relatively early stages of sensory cortical processing. The principle emerging from this work is that the same brain regions that are responsible for the precise sensory encoding of information also contribute to its short-term retention. In the remaining portions of this article we briefly describe these recent advances, with the emphasis on working memory for fundamental dimensions of sensory stimuli.

Visual Working Memory

In the laboratory, the ability to briefly retain visual information can be measured with delayed discrimination tasks. In the simplest version of such tasks, individuals discriminate between two stimuli, the sample and the test, separated by a temporal delay of various durations, and report whether and how the test differs from the previously seen sample. The results of such experiments have revealed that fundamental stimulus features, such as orientation, contrast, size, or speed, can be faithfully preserved for many seconds, although the duration of this preservation often differs for different features. For example, stimulus size or orientation can be retained accurately longer than can luminance contrast. This

difference suggests that different stimulus attributes may be retained by separate, feature-selective mechanisms. More direct support for feature-selective storage mechanisms comes from studies that have used interference consisting of an irrelevant stimulus (a 'memory mask') introduced during the delay separating S1 and S2. With this procedure, determination of the parameters that maximize the interfering effects of the mask can provide insights into the nature of the remembered stimulus and thus into the mechanisms involved in its short-term retention. For example, the memory for spatial frequency of gratings (size) can be disrupted only if the masking stimulus is of a different spatial frequency, irrespective of its orientation. This selective interference suggests that information about spatial frequencies may be preserved by mechanisms that are narrowly tuned for that stimulus attribute, and closely associated with its processing, but distinct from mechanisms concerned with stimulus orientation. Similar specialization is seen within the domain of visual motion, in that stimulus speed can be preserved by the mechanisms that are relatively narrowly tuned for speed, independently of stimulus direction.

Representation of visual motion in memory appears to be localized in space in a manner consistent with properties of neurons in cortical area MT, a region specialized in processing of visual motion, thereby supporting the idea that neurons processing visual motion may also be involved in its short-term storage. Overall, behavioral studies of mechanisms that preserve basic attributes of visual stimuli can be characterized as narrowly tuned, spatially localized filters, supporting a model of working memory that involves the contribution of sensory cortical areas.

A close link between visual processing and storage is also suggested by the consequences of cortical damage. For example, damage to motion processing area MT in monkeys results in deficits in remembering motion direction, but only when the remembered stimuli require area MT for their encoding (**Figure 1**). Similarly, damage to inferotemporal cortex, associated with processing of complex shapes, results in deficits in remembering such shapes. Humans with focal lesions in the occipitotemporal cortical area, implicated in processing of specific visual features, also have difficulties remembering these features.

The activity of visual cortical neurons during working memory tasks also attests to their role in sensory maintenance. Such tasks similar to the delayed discrimination tasks described earlier, require the comparison of two stimuli separated by a memory delay. When such stimuli consist of moving random-dot stimuli and the monkeys are required to identify and remember the dot direction, the activity of MT neurons during the memory delay shows selectivity reflecting the remembered direction. This activity is pronounced early in memory delay but weakens toward its end and does not correlate with the animals' decision, suggesting that additional neural mechanisms are needed to account for the maintenance of motion signals. However, at the time of the comparison and decision, these neurons are strongly affected by the remembered direction, suggesting that throughout the task they have access to the remembered direction, and thus are likely to participate in the circuitry subserving storage. Similar behavior has been observed in inferotemporal (IT) cortex, associated with the processing of complex shapes, in that stimulus-selective activity occurs not only in response to specific shapes but also during the memory delay. During the comparison phase of the task, these neurons, like neurons in area MT, reflect the remembered shape. This type of activity is consistent with the possibility that visual cortical neurons actively participate the circuitry subserving storage of signals they process, although the nature of this participation awaits further study.

Functional imaging studies of visual working memory indicate that regions of the visual system are differentially recruited by working memory tasks, depending on the stimulus dimension that must be remembered. For example, working memory for the location versus the identity of visual stimuli, such as color patches and geometric shapes, recruits domain-specific memory-related activity in posterior cortical regions associated with the 'where' and 'what' visual streams, respectively. For location memory this includes dorsal occipital cortex, the intraparietal sulcus, and superior parietal lobule, whereas for object identity it includes ventral temporal and occipital cortex. Location memory tasks also typically recruit frontal regions associated with oculumotor control – the frontal eye fields and the supplementary eye fields.

Within the ventral streams, delay-period activity is segregated in a category-specific manner. For example, multiple images of faces and of naturalistic scenes can be presented as samples, with a postsample cue indicating which is the to-be-remembered category. When individuals are cued to remember the faces, delay-period activity is selectively elevated in the fusiform face area (FFA). When they are cued to remember scenes, delay-period activity is selectively elevated in the parahippocampal place area (PPA). Another study of working memory for faces featured three delay periods interposed between the presentation of the first and second, second and third, and third and fourth stimuli. The logic was that the multiple distracting events in this task might serve to 'weed out' from the first delay period activity that was not involved directly in storage, because only regions

Figure 1 The role of cortical areas processing visual motion in remembering motion direction. (a) Monkeys with unilateral lesions of motion processing areas MT/MST performed a task requiring integration of complex motion and remembering its direction. In this task, sample and test stimuli were separated by a delay and positioned in opposite hemifields, so that one was placed in the lesioned and the other in the corresponding location in the intact hemifield. The monkeys reported whether sample and test moved in the same or in different directions by pressing one of two response buttons. During each trial the monkeys fixated a small target at the center of the display (blue dot) while attending to moving random dots (indicated by arrows) presented in the periphery. (b, d) Normalized direction range thresholds (1/(360-range threshold)/360) measured when the delay between sample and test was minimal (0.2 s). The sample or the test stimulus was composed of dots moving in a range of directions, while the other stimulus contained only coherent motion (stimulus configurations shown to the right of each set of plots). Performance was decreased whenever the stimulus containing noncoherent motion, and thus requiring integration, was placed in the lesioned field, demonstrating the importance of areas MT/MST for motion integration. (c, e) Effect of memory delay on performance for two direction range tasks. Performance was measured with both stimuli placed in the intact (gray circles) or in the lesioned hemifields (blue circles), either by varying the range of directions in the sample, while the test moved coherently (left plots), or by varying the range of directions in the test, while the sample moved coherently (right plots). Thresholds were normalized to the data measured at a 0.2 s delay. Error bars are SEM. A delay-specific deficit was present only when the remembered stimulus (sample) contained a broad range of directions and required integration. This result demonstrates that stimulus conditions requiring motion integration depend on intact areas MT/MST. However, coherently moving random dots can be discriminated and remembered at a normal level even in the absence of areas MT/MST. This shows that a cortical area involved in processing of sensory signals is also involved in their storage. Adapted from Bisley JW and Pasternak T (2000) The multiple roles of visual cortical areas MT/MST in remembering the direction of visual motion. *Cerebral Cortex* 10: 1053–1065.

with activity necessary for retaining the information to the end of the trial would maintain their activity across distracting stimuli. The results revealed that the posterior fusiform gyrus was the only region that retained the relevant signal during the last delay, immediately preceding the decision. Still other studies of working memory for faces have varied memory load (i.e., the number of items to be remembered),

on the logic that storage-related activity is sensitive to variations in load. These studies confirmed the importance of posterior fusiform gyrus in short-term storage.

Studies of working memory for spatial location have also addressed the mechanisms that support storage. One of these is attention-based rehearsal, a mechanism hypothesized to contribute to the short-term retention of locations via covert shifts of attention to the to-be-remembered location. These studies presented sample stimuli in one or the other visual hemifield while individuals fixated a central spot. Delay-period activity was greater in the hemisphere contralateral to the target location, an effect comparable to what one sees in studies of attention. This lateralized delay-period bias was strongest in extrastriate regions, decreased in magnitude across the parietal cortex, and was no longer reliable in frontal cortex. A second mechanism for the short-term retention of location information is prospective motor coding – the formulation, and then retention, of a motor plan for the acquisition of a target with, say, a saccade or a grasp. Electrophysiology studies in monkeys and neuroimaging studies in humans that encourage a prospective strategy localize this activity to frontal oculomotor regions, to prefrontal cortex, and to the caudate nucleus.

Tactile Working Memory

As with visual stimuli, tactile stimuli can be faithfully represented in working memory. Delayed discrimination of vibration stimuli can be performed with delays of many seconds, although the accuracy of this discrimination is maximal at short delays and decreases rapidly during the first 5 s of the delay. At longer delays, however, performance does not continue to deteriorate, suggesting that a two-stage memory process might be involved. Delayed discrimination of vibration stimuli can be disrupted by the application of transcranial magnetic stimulation (TMS) to human primary somatosensory cortex (area S1) during the initial portion of the delay period. This effect not only implicates area S1 in storage of vibration information, but also demonstrates the vulnerability of the storage mechanism early in the delay, an effect also observed in studies of working memory for visual motion.

In the awake behaving monkey, electrophysiological evidence for delay-period activity in S1 is mixed, with some laboratories reporting evidence in favor of it and others failing to find it. In area S2, however, there is no such equivocality, with strong evidence for stimulus frequency-specific activity persisting far into the delay period. Furthermore, responses of S2 neurons to the test stimulus contain information about the remembered stimulus, thereby reflecting the relationship between the two stimuli.

The ability to recognize and remember objects based on tactile input has also been studied with human neuroimaging. For example, positron emission tomography (PET) studies have revealed activation in the parietal operculum (area S2), an associative somatosensory area, during working memory tasks involving vibratory stimuli or palpated wire forms.

Auditory Working Memory

Although humans discriminate both pitch and loudness of sounds with high accuracy and remember these dimensions for many seconds, memory for pitch and loudness decline at different rates, suggesting that the two dimensions may be processed separately in auditory memory. The observed differences in the precision of memory for intensity and pitch parallel the findings in vision for contrast and spatial frequency (see earlier). As with vision, the use of interfering stimuli during the memory delay has revealed the nature of representation of auditory stimuli in memory. For example, memory for pitch can be disturbed by distractor tones, but only if these tones are within a narrow range of frequencies, relative to the frequency of the remembered stimulus, supporting the existence of separate pitch memory modules. Furthermore, sound frequency is likely to be stored separately from its location, suggesting that auditory memory obeys the same patterns as does auditory perception for physical parameters of the remembered stimuli.

In the auditory cortex, neuronal activity during the delay period of a delayed two-tone discrimination carries information about the frequency of the sample tone. In addition, the response to the second tone depends on whether its frequency matches that of the first, implicating neurons in auditory cortex in the circuitry subserving working memory for tone frequency. Participation of auditory cortex in auditory working memory is also supported by studies of the human using magnetoencephalography (MEG).

Memory-related activity has also been seen in associative auditory cortex of humans during tasks requiring memory for differences in pitch and tonal sequences; the right superior temporal lobe was associated with tonal sequences, and pitch judgments were associated with increased right frontal lobe activation. Interestingly, the auditory cortex appears to be maximally active early in the delay, whereas regions in the supramarginal gyrus and parts of the cerebellum are activated later, suggesting that for audition, too, working memory may be accomplished in multiple stages.

The involvement of regions processing auditory information in working memory is also supported by selective deficits in patients with damage to auditory associative cortex in the right temporal lobe. These patients are impaired primarily on tone discrimination with long, distracted delays.

Multiple Encoding in Working Memory

It seems unlikely that the representational bases of working memory are limited to the domain in which stimuli are perceived. In addition to the multiple serially ordered stages in working memory for visual, tactile, and auditory domains, sensory information can also be represented in parallel in multiple formats. Thus, as reviewed earlier, working memory for location can be accomplished via retrospective sensory memory-based mechanism, as well as a prospective motor planning mechanism. Analogously, there is growing evidence that working memory for visual identity recruits verbal (and, perhaps, semantic) representations in addition to the ventral stream visual mechanisms already discussed.

Working Memory and Prefrontal Cortex

For many years PFC has been strongly associated with the storage of sensory information in working memory. Consistent with this idea are the facts that PFC is directly interconnected with cortical areas processing fundamental sensory dimensions, and that PFC neurons often display stimulus-related activity during the memory delay. However, a growing body of evidence suggests that PFC is more likely to play a key role in directing attention to behaviorally relevant sensory signals and in making decisions concerning these signals, than in directly supporting their retention in short-term and working memory. Consistent with this view is the fact that extensive damage to prefrontal cortex does not eliminate the ability to perform simple short-term memory tasks, such as the digit span and spatial span variants of immediate serial recall. The limited effect of such lesions is apparent on delay tasks if during the memory period there is no interference and no requirement to keep track of multiple items. Also consistent with this view is the finding that although the delay activity of PFC neurons recorded in monkeys performing a delayed direction discrimination task (see earlier) was direction-specific, it did not predict decisions about stimulus direction that they made at the end of the trial. The contribution of these neurons to the task became apparent only after the end of the memory delay, when the monkeys compared test direction with that of the remembered sample. Furthermore, direction selectivity in PFC neurons, prevalent during the task, was greatly reduced when the monkeys were not required to use the information about stimulus direction. This work showed that PFC neurons are capable of gating sensory signals according to their behavioral relevance, it but does not support the key role for PFC neurons in the maintenance of these signals. Other studies, designed to isolate the contributions of attention and response selection from those of sensory storage, indicate a stronger role for the former in PFC.

In the human neuroimaging literature there is some debate about stimulus domain- or category-specific segregation of delay-period activity in PFC – for example, comparable patterns of delay-period activity during tasks involving memory for location versus memory for objects or memory for faces versus memory for scenes. The same is true for tasks that involve haptic object encoding versus those that involve visual object encoding. Similarly, in tasks requiring cross-modal integration, individual PFC neurons can be active during the memory delay following the presentation of different stimulus modalities. These examples suggest that PFC assists early-level sensory processing regions to form supramodal mental representations of objects and/or of task contingencies when the relevant stimuli belong to more than one sensory domain.

Another strategy for evaluating the neural basis of sensory storage is to require the retention of information across multiple delay periods interrupted with intervening distracting stimuli. This approach has revealed that neurons in the monkey PFC, but not IT cortex, could sustain a representation of the sample stimulus across multiple delays. Robust sample-specific activity across multiple delay periods is not limited to PFC, however, and has also been observed in other regions, including the temporal pole and the entorhinal cortex of the medial temporal lobe. Functional magnetic resonance imaging (fMRI) studies in humans remembering faces showed that only posterior fusiform gyrus retains sustained activity across all three delay periods, although many regions displayed activity during the first delay period. An analogous result was seen in the individuals remembering spatial locations, with distraction-spanning delay-period activity distributed across multiple areas, including intraparietal sulcus, superior parietal lobule, frontal eye fields, and supplementary eye fields in frontal cortex (Figure 2). Finally, repetitive TMS (rTMS) applied to PFC has failed to disrupt working memory performance, but has altered performance when applied to parietal cortex.

Although the weight of evidence is inconsistent with a storage role for PFC, virtually every electro-

Figure 2 A functional magnetic resonance imaging experiment demonstrating sustained memory-related activity for location across multiple delay periods. (a) Behavioral task. Individuals view and encode the target location, then, after a 7 s delay, indicate with a button press whether the probe does or does not appear in the same location. One-third of the trials end after probe 1. On two- and three-delay trials, the offset of probe 1 is followed by another delay period, after which individuals evaluate the location of probe 2 with respect to the target. On one- and two-delay trials, the 'END' message appears at times 12 and 20 s, respectively. (b) Results from a single representative individual. Voxels in red showed sustained delay-period activity for delay 1 only. Voxels in blue are the subset of voxels

physiological and neuroimaging study of primate working memory finds delay-period activity in this region of the brain. Thus, it is important to address the role of this activity. If this activity does not represent the storage of information, what are alternative explanations of its function? One possibility is that PFC plays an important role in the control of potentially disrupting effects of distraction and interference during working memory tasks. Lesion, electrophysiology, and fMRI studies have all provided evidence that dorsolateral PFC can accomplish this by controlling the gain of activity in sensory processing regions, such that the delay-period processing of potentially distracting stimuli is suppressed. Analogously, a region of ventrolateral PFC has been implicated in the control of proactive interference, the deleterious effect of previous mental activity on current task performance. In addition, an important function of delay activity in PFC may be the attentional selection of task-relevant information, as well as in planning for the response. This is consistent with the well-characterized role for PFC in the biasing of stimulus–response circuits so that novel or less salient behaviors can be favored over well-learned associations and behavioral routines. Finally, the potential role of PFC in the integration of cognitive and motivational factors is supported by the modulation of delay-period activity of its neurons during spatial memory tasks by the type of the anticipated reward.

Conclusion

The emerging picture of the neural basis of working memory is of a class of behaviors that does not depend on one or more functionally specialized regions. Rather, working memory is supported by the coordinated activity of circuits responsible for the sensory processing of the critical information, and, to varying degrees, those that control the flexible allocation of attention and the selection of task-relevant behavior.

Signal Design Rules in Animal Communication

H C Gerhardt, University of Missouri, Columbia, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Communication occurs when signals produced by one animal affect the behavior of another animal; here the focus is on exchanges between members of the same species. A widely held assumption is that communication leads to behaviors that ultimately increase the fitness of both senders and receivers. Signal design is the result of natural and sexual selection on signal structure that contributes to this increase in fitness. The rationale is that if receivers use signal information to make behavioral decisions, those decisions are likely to affect both their own fitness and that of the signaler and henc e, directly or indirectly, exert selection on the form of the signal. Such reciprocal selection by senders and receivers is a hallmark of communication and generates the expectation that signal form and receiver selectivity will coevolve to some degree. One obvious outcome is elaboration or exaggeration of one or more components of a signal, and such changes may also result in more efficient communication by increasing signal detectability against background noise. Receivers can also promote innovations in signal design if, for example, rare mutations result in signals that tap sensory biases that conventional signals do not.

Understanding signal design depends on analyzing the physical properties of signals and assessing variation in these properties that correlates with the behavior of both the sender and the receiver under a given set of circumstances. We also need to know about the capabilities of the species in question to produce and perceive signals and the characteristics of the environment that can affect the signal during transmission. The signal's modality immediately delimits the set of relevant physical properties needed to describe signals as well as the likely constraints on signal production, reception, and the environmental variables that are likely to affect its transmission. The need to objectively describe signals is reinforced by the fact that many animals use signals (many chemicals, ultraviolet and infrared wavelengths of light, infrasonic and ultrasonic sounds, and weak electric currents) that humans cannot even perceive.

The three signal modalities that are most widely used for animal communication will be the main organizing feature of this article. Within each modality, signals that operate over relatively long distances often have two functions in a reproductive context: attraction of mates and repulsion of potential competitors. Other long-range signals serve to recruit members of a social group to exploit a food resource or for defense. Short-range signals are most frequently used for further assessments of potential mates or rivals. Whereas the opportunistic nature of evolution assures that signals with the same function will show a diversity of forms, it is possible to describe some generalizations about the properties of signals within each modality that make them suitable for long- or short-range communication.

Olfactory Signals

The first signals to evolve were almost certainly chemical in nature. Chemical messengers are used extensively within and between cells, so modifications for their use in intraspecific communication would include mechanisms for senders to expel them into the environment and for receivers to acquire, detect, and recognize them. Chemical signals that are transmitted from individual to individual are called pheromones.

One of the first formal approaches to signal design considered relationships between the chemical composition of pheromones, the capabilities of senders and receivers to produce and detect these signals, problems of transmission, and the kinds of information to be communicated. Pheromones should generally have a minimum size of about five carbon atoms plus functional groups (alcohol, ketones, etc.) because smaller and less complex molecules can be too volatile in air and may not be sufficiently specific for coding information. The latter limitation can be offset by mixtures of simple pheromones, which are commonly found in invertebrates and mammals. The upper limit of about 20 carbons may be set by production and storage costs and by low diffusion rates in air. Even though production costs have seldom been determined, pheromones are still probably less energetically expensive than signals of other modalities because conversion from chemical to some other form of energy is unnecessary.

The active space of a pheromone is the area in which its concentration is above the threshold of detection by receivers; the active space corresponds to the maximum range or distance over which communication is possible. The fade-out time refers to the time after emission when the concentration falls below threshold everywhere. In still air or water, animals can increase the active space either by increasing

Table 1 The predicted spread and fade-out (active space) of a signal comprising a substance of low molecular weight

Q/K[a]	*Diffusion coefficient*		*Maximum radius of active space (cm)*		*Time required to reach maximum radius (s)*		*Fade-out time (s)*	
	Air	*Water*	*Air*	*Water*	*Air*	*Water*	*Air*	*Water*
1	10^{-1}	10^{-5}	0.6	0.6	0.4	4×10^3	1	10^4
10^2	10^{-1}	10^{-5}	2	2	8	8×10^4	20	2×10^5
10^4	10^{-1}	10^{-5}	10	10	1.5×10^2	1.5×10^5	5×10^2	5×10^6
10^6	10^{-1}	10^{-5}	60	60	4×10^4	4×10^7	10^4	10^8

Diffusion coefficient arbitrarily set at 0.1 cm S^{-1}.
[a]Q, number of pheromone molecules released at one time; K, detection threshold.

the number of pheromone molecules released at one time (Q) or by increasing their sensitivity (K = detection threshold). As shown in Table 1, the active space is limited and the time to reach its maximum range is long for a pheromone with a relatively high diffusion rate, even when its concentration is high initially and receivers are sensitive. Although the maximum transmission distance can be achieved by releasing pheromones into a wind or current, transmission is uncertain because the location of the receiver is unknown and the direction of flow is unidirectional and may change unpredictably. Moreover, if the wind or current is too strong, many molecules are dispersed laterally, thus reducing the concentration downrange. These attributes make olfactory communication the least reliable modality for long-range communication and source localization.

The fade-out time in still air or water is also dependent on the ratio of Q to K and the diffusion rate. For example, the use of small molecules with a relatively high diffusion rate will result in the rapid dispersal of the message to its maximum range and decrease the fade-out time. Rapid dispersal is a desirable characteristic of alarm, threat, and recruitment signals used for guiding members of a social group to a new food source or to defend against a predator. Short fade-out times mean that alarm and recruitment signals do not persist after the food source is depleted or the predator is no longer present. Pheromones with short fade-out times are also useful for short-range courtship because they do not alert rivals in the neighborhood of the presence of a receptive female, and they also allow senders to change messages more rapidly. In contrast, large molecules with slow diffusion rates can have long-duration effects that are useful for marking of territories or a trail to a long-lasting food source or shelter.

The disadvantages of pheromones with respect to reliable transmission and localization are offset by the fact that they can be used day and night in a variety of habitats. Another advantage is that the extreme specificity of some olfactory systems facilitates the identification not only of species and populations but also of colonies and individuals. Human olfaction is sufficiently poor that we cannot appreciate the subtle information in pheromones, and special instrumentation is necessary to show the effects of selection on the evolution of pheromones. For example, gas chromatography has been used to assess individual and population variation in cuticular hydrocarbon pheromones in *Drosophila*. These data made it possible to study geographic variation and to conduct genetic experiments that demonstrated the shift in signals that sometimes occurs when two formerly isolated species come into contact (reproductive character displacement).

Visual Signals

In contrast to olfactory communication, visual communication is extremely rapid and has the potential to operate over long distances. Moreover, because nearly all communication by light is line-of-sight, detection and localization of visual signals are usually simultaneous. The line-of-sight requirement does, however, limit communication range whenever there are opaque objects between senders and receivers, and the fact that most visual signals depend on reflected light means that communication at night, in caves, and in murky or deep water is difficult if not impossible. Animals that produce their own light source (bioluminescence) to produce signals may be limited by energetic costs.

The design of visual signals used for long-distance intraspecific communication hinges on making signals conspicuous against the visual background. Such signals make use of color, contrast, and movement, to which visual systems of receivers are especially sensitive. At the same time, predators may take advantage of these same features, imposing a fitness cost to senders that may exceed the production cost.

Thus, many species have evolved mechanisms by which conspicuous body parts can be concealed until potential mates or rivals are present. Indeed, the visual design of whole animals often serves as camouflage unless they are protected by toxins or venom (or mimic such creatures), in which case, conspicuous patterns and colors are common. One fascinating innovation for increasing detection by prospective mates without incurring significant risks of predation is the use of decorations as signals in Australian bowerbirds (Figure 1). The items used to adorn their bowers show greater visual contrast in their respective habitats than do their plumage characteristics, even in males that are more brightly colored and patterned than females.

Because long-range mate attraction often involves large repetitive movements that are energetically costly and risky, prospective mates (usually females) often use the rate and duration of such displays to assess the physical condition and perhaps the genetic quality of the signaler. The same is probably true for some rivals. These qualities can be assessed by the color and intensity of nuptial pigmentation in animals such as fish, lizards, and birds. At closer distances, the ability to rapidly change display elements makes visual signals especially suitable for courtship, in which interactions between individuals of both genders depend on rapid exchanges of signals. Here subtle differences and quick reactions to the behavior of the prospective mate are more important than conspicuousness, which would also have the disadvantage of attracting rivals or predators. Visual signals used in short-range threats often involve postures that make the animal seem larger and that display body parts that can serve as weapons.

Figure 1 Photograph of a male satin bowerbird (*Ptilonorhynchus violaceous*) in its bower, which is decorated (foreground) with natural objects (feathers) and artificial objects (e.g., straws) that are light blue. In terms of the bird visual system, the dark blue, iridescent plumage of the male bird shows far less contrast (= less conspicuousness) against the visual background than do the bower ornaments. See Endler JA, Westcott DA, Madden JR, and Robson T (2005) Animal visual signals and the evolution of color patterns: Sensory processing Illuminates signal evolution. *Evolution* 59: 1795–1818 for details. Photo by H.C.G.

Specificity in visual signals resides in traits at two ends of a continuum. Some visual patterns are permanent (badges) that are specific to the species, population, or even individuals. Other such patterns may be temporary: appearing at the onset of the breeding season and gradually disappearing afterwards. Displays, which involve postures and movements, may also contain some highly stereotyped components (static properties) that vary little from one repetition to the next. Such elements are sufficiently stereotyped to identify the sender's species and sometimes even its individual identity. Other elements of displays show great variability (dynamic properties) and are often correlated with the sender's motivation, the social context (proximity of a prospective mate or rival), or the sender's physical or genetic fitness. The degree of stereotypy in individual signals can be quantified statistically and also applies to auditory signals.

Auditory Signals

Auditory signals are rapidly transmitted and can have a large active space. Depending on their physical properties, sounds can be relatively easy or hard to localize. Auditory signals can be used at any time of day, and sound waves readily bend around objects, such as trees, and hence can propagate well in densely vegetated habitats. The energetic costs of producing auditory signals can be high, and some species of insects and frogs exhaust nearly all their stored reserves during a breeding season. The risk of predation may be somewhat lower than in visual communication because sounds are harder to localize. Moreover, in vertebrates and other animals that power signals with their respiratory system, the sender can signal during ongoing behavior or from a concealed, stationary position without making large movements that could attract predators. Animals can also use private channels for auditory communication by using sounds that have frequencies below the hearing range of other animals (infrasonic signals of elephants), above the hearing range of predators (small birds), or even in the ultrasonic range (bats, whales, and dolphins). Most ultrasonic production occurs in the context of echo-location, however, and the social signals of most bats and marine mammals are much lower in frequencies that lie within the hearing range of ordinary mammals. Short-range signals, commonly produced during courtship or as predator alarms, are inconspicuous by virtue of low intensity. In addition, alarm signals of small birds

typically consist of high single-frequency notes with gradual onsets and offsets. These features make them difficult to detect and localize by predators. By contrast, sounds that serve to rally individuals of the same and other species for mobbing predators have properties (intense, broadband, with sharp onsets and offsets) that increase their conspicuousness and ease of localization.

The design of long-distance auditory signals used in intraspecific communication is constrained by mechanisms of production and environmental transmission. On the one hand, low-frequency sounds travel farther with less attenuation by the environment than do high-frequency sounds. On the other hand, the most efficient production of auditory signals requires that the dimensions of the sound producing structure be not very much smaller than the wavelength of the frequency with the most energy. In other words, small animals, such as insects, frogs, and small birds, will usually be limited to producing signals with relatively high frequencies. Some species ameliorate this problem to some extent by using leaves as acoustic baffles (to direct the sound energy) or take advantage of the resonant properties of burrows or hollows. Another tactic is to produce sounds from elevated positions because ground attenuation of high-frequency sounds is especially severe. Some studies of birds confirm that small species with relatively high-frequency songs tend to sing at higher elevations than do large species with low-frequency signals. Still another, counterintuitive tactic is for small animals such as frogs or insects to call on the ground at night when temperature inversions create a channel for lower-than-expected attenuation. Some birds and mammals may not be as constrained as insects and frogs, and correlations between the context ('motivation' or function) and signal structure are widespread. Aggressive vocalizations tend to be low in frequency and broad in bandwidth, whereas vocalizations of submissive or fearful animals are high in frequency and more tonal in nature.

The effective range of communication is also limited by the fact that features of the signal that convey information will be affected by the environment in various ways. Two common forms of signal degradation mainly affect the temporal structure of signals: reverberations and amplitude fluctuations. Reverberations arise because at a distance, sound waves reach the receiver both directly and indirectly after being reflected from the ground or vegetation. The indirect waves arrive with a slight delay and can interfere and partially cancel the direct waves or, more important, obscure the silent intervals between repeated short notes. Reverberations are especially problematic in forests when animals use signals that are rapidly modulated or trilled. Because degradation by reverberation is somewhat predictable in a given habitat, some birds have been found to take advantage of this phenomenon to estimate the distance of the singer. An additional cue for species with broadband signals is that the excess attenuation mentioned above will result in a greater loss of high-frequency components relative to low-frequency ones as distance increases. Amplitude fluctuations occur when pockets of warm air rise from the ground, especially during the day in open habitats. In contrast to reverberation, the periodicity of amplitude fluctuations is unrelated to any features of the signal but typically occur irregularly at rates of about 50 Hz or less. Some evidence for signal design (including signaling behavior) is that birds in forests tend to produce relatively long tonal signals that lack rapid modulations (**Figure 2(a)**). Birds in open habitats often have relatively long, rapidly trilled signals; low-frequency, short amplitude fluctuations will only partially degrade these trills, with enough consecutive pulses getting through to preserve information used by receivers. Numerous studies, however, have discovered only weak correlations between environmental variation and signal structure, and there are many counterexamples in which the auditory signals of a species propagate farther and with less degradation in nonpreferred habitats than in preferred ones.

Perhaps the most serious problem with auditory communication is masking interference from the sounds produced by rushing water, wind, and other animals, both conspecific and heterospecific. Masking by rushing water may result in the use of relatively high frequencies (higher than the dominant frequencies of this noise), the augmentation or substitution of auditory with visual signals, or both. For example, some neotropical frogs in such habitats have elaborate hand-waving signals. Because animals such as orthopteran insects, cicadas, frogs, and some birds often signal from aggregations, the most severe masking problems are biological. Some amelioration occurs because some simple animals such as insects and frogs have auditory systems that are roughly tuned to the frequencies emphasized in their advertisement calls. Hence the masking effect of signals of other species with different frequencies will be somewhat reduced. However, members of the same species, whose signals will be especially effective maskers because of their similarity in both frequency and temporal structure, will always be an individual's most serious competitor for clear 'airtime.' Indeed, the production of very loud advertisement calls, typical of temperate-zone anurans, probably represents an evolutionary response to masking interference in

choruses rather than a tactic for attracting mates from a distance. Masking interference has resulted in the evolution of diverse tactics involving signal timing among nearby individuals. At one end of the continuum, individuals vie to time their calls to lead and overlap those of rivals; at the other end, individuals seemingly attempt to maintain a completely nonoverlapping, alternating form of etiquette. In

Figure 2 Habitat effects on signal structure. Sonograms (frequency vs. time) of bird songs of (a) and (b) the chingolo sparrow (*Zonotricia capensis*) and (c) and (d) great tit (*Parus major*) in different habitats are shown. Notice that the songs of both species in forests lack long rapid trills that would be subject to degradation by reverberations. Long rapid trills are typical in chingolo sparrows living in grasslands, and extensive frequency modulation is prevalent in great tits in open woodland where amplitude fluctuations rather than reverberations are the major source of signal degradation. From Bradbury JW and Vehrencamp SL (1998) *Principles of Animal Communication.* Sunderland, MA: Sinauer.

still other species, calls may be produced in a highly synchronous fashion to make the localization of individuals difficult for acoustically orienting predators.

As in the visual modality, auditory signals have the potential to encode many messages and to change them rapidly. Some properties, however, show limited variation within the signals of an individual (static properties), whereas other properties may change dramatically from one signal to the next (dynamic properties). The degree of variability may be quantified for comparison across signal properties and species (**Figure 3(a)**). Although variability within the signals of individuals is continuous, comparative studies usually find a distinctly bimodal distribution in which static and dynamic properties occupy opposite ends of the continuum. Static properties such as frequency are potentially useful in insects, anurans, and birds for identifying individuals or assessing their body size because they are consistent within the signals of individuals but typically vary significantly among individuals in the same population. Other static properties, such as fine-scale temporal patterning, are species specific and show little variation within and among individuals in any population and limited geographical variation as well. These properties are analogous to the static features used in visual communication, such as breeding plumage. By contrast, dynamic properties such as the rate and duration of signaling correlate with energetic costs and may be useful indicators of male fitness.

Both physical constraints on signal production, such as body size and energetic reserves, and the preferences of prospective mates contribute to patterns of variation in signal properties. For example, preference functions show a strong trend for stabilizing selection for static properties and directional selection (preference for one end of the range of values) for dynamic properties (**Figure 3(b)**). Directional selection on dynamic properties is probably an especially effective process for assessing the physical and genetic status of prospective mates because high values of these properties are costly both in terms of energy and predation risks. Of course, receivers respond to the entire signal, which has both static and dynamic properties, and the relative influence of such criteria on signal selection may vary according to the fitness consequences of mate choice. For example, females in areas of overlap with other species having static properties with values similar to those of conspecific males weigh static properties more heavily than dynamic properties that may indicate differences in quality among conspecific males. This can result in reproductive character displacement of the mean values of static properties because mating with a male of the wrong species will result in a much greater fitness loss than will mating with a low-quality conspecific male. This and other examples serve to emphasize that traits providing information that enhances receiver fitness may become subject to selection in the context of communication even if those traits did not originally evolve as signals.

Multimodal Communication

Animals are not restricted to using signals of a single modality, and many displays that are especially fascinating to humans combine elaborate visual and auditory elements. Sequential use of different kinds of signals is also common. Loud long-range auditory signals produced in a dense forest, for example, are likely to be replaced by short-range auditory, visual, and olfactory signals at close range. Chemical and tactile signals are more common at even closer distances. Signals of different modalities can also be used to transmit different kinds of messages and can be directed to different kinds of receivers. The diversity of animal communication systems and sensory capabilities makes it difficult to find general correlates between signal modality and function.

Summary

Visual and auditory signals have the greatest potential for rapid long-range communication. The properties of these signals or the kind of signal can also be changed quickly, thus allowing for a multitude of messages to be delivered in a short time. Visual and auditory signals can also be designed or modified to make the localization of their source easy or difficult. Visual signals have three disadvantages in comparison with auditory signals: (1) They usually depend on reflected light, and hence are they not as useful at night or in other dark environments; (2) they are not useful in densely vegetated or other habitats where line-of-sight vision is restricted; and (3) in many animals, visual displays require the commitment of body parts (wings, legs) that are also needed for flight or locomotion. Chemical signals are almost certainly less expensive to produce than are other kinds of signals, and they can be used at night and in all sorts of habitats. But the range of action is limited, and the localization of long-range pheromones is uncertain; the persistence of chemical signals can also limit the ability to change messages rapidly. Signals of all three modalities have physical properties whose values vary more or less at the individual and among-individual levels, thus providing the potential for most signals to convey multiple messages. One of the great challenges

	Dominant frequency	Pulse rate	Call duration	Pulse number	Call rate
H. versicolor	0.8	1.5	**16.4**	**15.0**	**25.4**
H. cinerea	0.5		3.7		**12.3**
P. crucifer	0.8		4.0		**16.0**

Figure 3 Static and dynamic acoustic properties in treefrogs. (a) Gray treefrogs (*Hyla versicolor*), green treefrogs (*Hyla cinerea*), and spring peepers (*Pseudacris crucifer*) produce long-range advertisement calls that vary from call to call in dominant frequency, call duration, and call rate; the repetition rate of the pulses making up the calls (pulse rate) of gray treefrogs also varies, and the number of such pulses largely determines call duration; (b) Variability in these properties is quantified by the coefficient of variation (CV), which is the standard deviation expressed as a percentage of the mean, thus allowing comparisons of variability across properties and across species. Static properties (unshaded) generally have a CV of 5% or less whereas dynamic properties (shaded) have a CV of 10% or more. (c) Female gray treefrogs prefer values near the mean (= stabilizing preferences) for static properties such as pulse rate, and values with high values (= highly directional preferences) for dynamic properties such as call duration. The percentages of females choosing each of two alternatives with different values are shown by circles connected by lines (e.g., in the left panel, 100% of the females chose a call with a pulse rate of 20 pulses s^{-1}, the mean for the population, and none chose the call with a pulse rate of 30 pulses s^{-1}). Histograms show the distribution of values of pulse rate (left panel) and duration (right panel) in a population of gray treefrogs. From Bradbury JW and Vehrencamp SL (1998) *Principles of Animal Communication.* Sunderland, MA: Sinauer.

of the study of animal communication is to learn how receivers assess multiple messages, especially conflicting ones, in order to make fitness-enhancing decisions.

Signal Identification: Peripheral and Central Mechanisms

G Pollack and Krahe R, McGill University, Montreal, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

Communication signals may contain various sorts of information about the sender, including its identity (whether of species, gender, or individual), sexual receptivity, aggressiveness, and fitness. This information is encoded into physical features of the signal, such as its chemical composition, sound frequency, or rhythmical structure. The receiver must detect the signal, discriminate it from other sensory stimuli, and decode the signal's contents (its 'message'). Signal processing begins with accessory sensory structures (e.g., pinnae and olfactory mucosa), which may constitute a first filtering stage. Further, more detailed processing is accomplished by sensory receptor neurons and within the central nervous system. This article focuses on the neural mechanisms underlying the processing of communication signals. The emphasis is on sensory systems that are highly specialized for communication, namely olfaction, electroreception, and audition.

Peripheral Processing

Matched Peripheral Filters

Communication signals are often narrow in bandwidth, consisting of a restricted range of sound frequencies, chemical compounds, or light wavelengths. A common peripheral mechanism for enhancing signal reception is selective responsiveness, by the receiver, to the same bandwidth used by the signaler. Selective 'tuning in' to the signal bandwidth attenuates sensory stimuli falling outside of this bandwidth, thus increasing the signal-to-noise ratio of signal reception. It should be noted, however, that selective tuning of the receiver may also be a mechanism by which the receiver evaluates how well the sender is able to produce the signal, which may be an indicator of fitness.

Matched filters for sound frequency In several insects that communicate acoustically, the frequency sensitivity of the receiver is matched to the sound frequencies used in acoustic signals. For example, the acoustic signals (songs) of crickets have most of their power in restricted frequency ranges, and the majority of their auditory receptor neurons are most sensitive to frequencies in this same range (Figure 1). The ears of mosquitoes are their antennae, which vibrate in response to near-field sound, thereby exciting a sensory organ in the antenna's basal segment. Vibrational amplitude of the antenna of male *Toxorhynchites brevipalpis* is greatest for sound frequencies near 420 Hz, which matches precisely the wingbeat frequency of females. The acoustical properties of the antennae are set in part by 'standard' physical parameters such as length, mass, and stiffness. However, active mechanical input to the system, analogous to that provided by outer hair cells of the organ of Corti of vertebrates, also contributes to the frequency selectivity and remarkable (nanometer-level displacement) sensitivity of the system.

Matched filtering also occurs in acoustically signaling vertebrates; indeed, the concept of the matched filter was developed in the context of acoustic communication among frogs. Communication sounds of the bullfrog, *Rana catesbeiana*, have a bimodal spectrum. Power is divided into low- and high-frequency bands, centered on approximately 200 and 1500 Hz, respectively, with a pronounced absence of power at an intermediate range centered on 500 Hz. Upon hearing the calls of conspecifics, males respond with their own calls. Studies using evoked calling as a behavioral assay showed that for maximal effectiveness, a signal must contain energy in both the low- and the high-frequency bands and, in addition, must lack energy in the intermediate band. These spectral requirements have clear parallels in the frog's peripheral auditory system. There are two distinct sensory structures in the inner ear: the amphibian papilla, which responds best to low-frequency sounds, and the basilar papilla, which is tuned to higher frequencies. Neurons of the amphibian papilla have the interesting property that their responses to a low sound frequency are suppressed by simultaneous stimulation with a slightly higher frequency. Thus, neurons from the basilar papilla are stimulated by high frequencies, and those from the amphibian papilla are driven by low frequencies, with the additional requirement of an absence of midfrequencies. The combined input from both papillae thus represents the structure of the natural signal and matches the spectral requirements for behavioral effectiveness.

The degree of matching between sender and receiver may vary through time. Male midshipman fish court females using acoustic signals. The tuning at the level of the inner ear of females is modified seasonally by steroid hormones and more closely matches the spectral properties of male calls during the breeding season than when the females are in nonreproductive state.

Electroreception Weakly electric fish produce electrical discharges and monitor the resulting electrical

Figure 1 A matched frequency filter. The red curve shows sensitivity of the auditory nerve of a cricket (*Gryllus campestris*) as a function of sound frequency. The blue area represents the frequency content of the species' calling song, a signal that is produced by males and serves to attract females and adjust intermale spacing. Auditory sensitivity is greatest (threshold sound level required to produce a neural response is lowest) at frequencies near 4 and 16 kHz, the same frequencies that are most prominent in the song. Adapted from Nocke H (1972) Physiological aspects of sound communication in crickets (*Gryllus campestris* L.). *Journal of Comparative Physiology* 80: 141–162.

fields with electroreceptors in the skin. In wave-type fish, the discharges are periodic and quasi-sinusoidal. The frequency of the electric organ discharge can range from 50 to 2200 Hz (depending on species, gender, and individual identity), but it is quite constant within an individual. The fields of conspecifics cause modulations in the fish's self-generated field; thus, detection of communication signals relies on the tuning of the electroreceptor organs in the skin to the fish's own electric organ discharge frequency. Accordingly, the best frequency of the primary afferent fibers is matched to the discharge rate of the electric organ of the individual fish, and their spiking activity shows enormously steep filter curves with slopes of up to 60 dB per octave. The mechanism underlying this sharp tuning seems to be based on electrical resonance of the receptor cells, as determined by the kinetic properties of ion channels. In a manner similar to that described previously for midshipman auditory receptors, the tuning of the electroreceptors follows changes in the fish's discharge frequency that occur in connection with changes in reproductive status. Interestingly, discharge rate and electroreceptor tuning are both under the control of steroid hormones, although apparently via independent pathways.

Another group of electric fish produces discrete, pulse-like electrical discharges rather than waves. Their electroreceptors are more broadly tuned than those of wave-type fish. Broad tuning presumably supports the exquisite sensitivity of the receptors to the timing of the onset and offset of electric organ discharges of conspecifics. This would allow the fish to measure pulse duration, an indicator of species and sex. In this case, broad, rather than narrow, receptor tuning may contribute to the processing of communication signals.

Vision A rare example of matched filters in a system using visual signals is found in fireflies, in which the absorption spectra of visual and screening pigments result in color sensitivity that is tuned to the wavelengths of conspecific bioluminescent emissions.

Matched temporal filters A typical feature of acoustic communication signals is that much of the information that is transmitted is contained in modulations of signal amplitude. Auditory receptor cells of grasshoppers as well as primary auditory afferents of bull frogs show enhanced transmission of information about sound stimuli if the distribution of amplitudes and the frequency characteristics of amplitude modulations match the characteristics of the natural species-specific songs. The optimal stimuli driving grasshopper auditory receptor cells, however, do not match the full song structure but, rather, resemble a subset of features of the songs, such as the sharp increases in sound level following the gaps between pulses. For particularly salient features of the songs, the variability of spike timing of receptor cells can be as low as 0.15 ms, an order of magnitude smaller than the fastest stimulus timescale.

Chemoreception Precise matching between signaler and receiver is perhaps most spectacular in pheromonal communication systems, in which the signal consists of a mixture of chemical compounds, the precise makeup of which may code for the species, gender, and/or individual identity of the signaler, as well as the signal's meaning. The complex social systems of ants and other hymenopteran insects are regulated in large part by chemical signals, which are used in reproduction, to lead nest mates to food sources, to alert them to possible threats, and for a host of other purposes. Male moths locate sexually receptive females by tracking the pheromone plumes that they release into the air. Mammalian pheromones mediate mother–infant communication as well as recognition of the gender, strain, reproductive state, and unique identity of conspecific individuals.

The neuronal basis of pheromonal communication has been studied most thoroughly in insects and mammals. In both groups, pheromones are detected by peripheral chemoreceptor neurons that combine high sensitivity with exquisite selectivity. It has been estimated that capture of as few as five pheromone molecules by the moth *Spodoptera littoralis* is

sufficient to elicit a physiological response (change in heart rate). Pheromone-sensitive olfactory receptor neurons of mice may respond to concentrations of their specific ligand as low as 10^{-11}M yet remain unresponsive to other pheromone components at much higher (100 000-fold) concentrations. This remarkable specificity of the receptor neurons reflects the properties of the receptor molecules that they express, and it differs from the broader response profiles of olfactory receptors that respond to nonpheromonal stimuli. Thus, pheromone detection appears to be accomplished by a series of 'labeled lines': distinct receptor neurons, expressing distinct receptor molecules, report the presence and concentration of specific, semiotically important, chemicals to central processing areas where inputs from the separate lines are integrated.

Central Processing

Signals, once detected peripherally, are processed further in the central nervous system. The tasks of central processing include further sharpening of neural responses to specific stimulus features; generating new forms of selectivity, for example, for the combined presence of stimulus components that are detected by separate groups of receptor neurons, and performing more 'abstract' functions, such as decoding the information that is encoded into receptor–neuron spike trains, discrimination among signals, and evaluation of the signal's (and thus the signaler's) quality.

Inhibition Enhances Selectivity

In some systems, the selectivity for communication signals that is established by peripheral tuning is sharpened in the central nervous system through inhibition. Some of the most selective neurons yet described occur in brain nuclei of songbirds. These neurons may respond exclusively to the song of the same individual bird in which the neuron resides. This exquisite selectivity is believed to be important for song learning and is due in part to inhibition. When an ionic current that mediates inhibition is blocked pharmacologically, the neurons respond to a broader range of stimuli. In the midbrain of frogs, selectivity for frog song-like sound frequencies is sharpened by 'lateral' inhibition – that is, inhibition elicited by sound frequencies above and/or below that to which the neuron is most sensitive (Figure 2). A remarkable example of the role of inhibition in sharpening spectral selectivity occurs in an identified interneuron of tettigoniids (long-horned grasshoppers) that is tuned, in a species-specific manner, to the major spectral component of conspecific song. The species specificity of tuning is 'sculpted' from a broadly tuned response curve, which is identical across species, by synaptic inhibition originating in neurons (the identities of which are unknown) that are tuned to higher and lower frequencies. The species-specific differences in the tuning of this neuron are eliminated when inhibition is blocked pharmacologically.

An inhibitory mechanism is responsible for the dedication of an entire class of electroreceptors to communication signals in mormyrid weakly electric fish. Primary afferents conveying information from Knollenorgan electroreceptors in the skin of these fish to a hindbrain nucleus respond to both the fish's own electric organ discharge and the discharge of conspecifics. At the level of the hindbrain, a corollary discharge mechanism effectively gates information about conspecific signals by inhibiting all responses

Figure 2 Sharpening of frequency tuning by lateral inhibition. The graph on the left (control) indicates the frequency/intensity combinations that excite (green) or inhibit (red) an auditory neuron in the brain of a frog. The range of sound frequencies that excites the neuron is restricted by inhibition produced by lower and higher sound frequencies. When this inhibition is blocked using the drug bicuculline (right), the formerly inhibitory regions become excitatory, broadening the range of frequencies that can excite the neuron. Adapted from Hall JC (1999) GABAergic inhibition shapes frequency tuning and modifies response properties in the auditory midbrain of the leopard frog. *Journal of Comparative Physiology A* 185: 479–491.

related to the fish's own electric activity such that only the electric signals generated by conspecifics are processed.

Combination Sensitivity

Another common theme of central processing is combination sensitivity – that is, selective responsiveness to the simultaneous occurrence of separate components of a communication signal. In the auditory midbrain of frogs, most neurons at early stages of processing have frequency-tuning properties similar to those of auditory receptors, with best sensitivity to frequencies corresponding to receptors of either the amphibian or the basilar papilla. At higher processing levels (midbrain and thalamus), however, neurons are found that can be driven only by simultaneous presentation of both the low- and high-frequency components of conspecific acoustic signals, paralleling the requirement for both spectral components for maximum behavioral effectiveness. Pheromonal signals of moths typically consist of blends of several components. Closely related species may use the same chemical components but with species-specific differences in their relative concentrations. Thus, an important task of central processing is to gauge the level of activity across component-specific peripheral channels. Inputs from these channels converge in the central nervous system. In the antennal lobes of moths, different neuropil areas (glomeruli) receive input from receptor neurons that are selective for different pheromone components. Some interneurons within the lobe have dendrites projecting to only a single glomerulus and accordingly are excited by only one of the pheromone components (and in fact may be inhibited by the other component via local circuitry), whereas other interneurons, with dendritic branches in multiple glomeruli, are excited by multiple components. Further convergence of excitation induced by multiple pheromone components occurs at still higher processing stations in the brain.

Central Processing of Temporal Pattern

Communication signals are often strongly rhythmic, with distinct components occurring at specific times, and a signal's 'message' may be carried by its temporal pattern. For example, the temporal structure of insect and frog songs may inform listeners of the species identity of the signaler and may also carry information about its sex, size, robustness, and other fitness-related attributes. Neural specializations for behaviorally relevant features of signals may be expressed in two ways: (1) increased responsiveness to meaningful temporal features (i.e., higher firing rate) and (2) more accurate representation of the rhythmical structure by the timing of action potentials (Figure 3).

Figure 3 Firing-rate and time codes for temporal pattern. Each graph depicts the responses of two neurons that are 'tuned' to the intermediate pulse rate. The traces on the right represent the spike trains of the two neurons to three stimulus pulse rates: one slower than optimal (1), the optimal rate (2), and a rate that is faster than optimal (3). The red neuron uses a firing rate code; firing rate is highest for the optimal pulse rate, but the precise time of each action potential is unrelated to the times of the individual stimulus pulses. The blue neuron uses a time code; firing rate does not vary with stimulus pulse rate, but action potentials are precisely time-locked to the stimulus pulses only for the optimum pulse rate. These are idealized examples. In real neurons, both firing rate and precision of spike timing typically vary with stimulus pattern, although one or the other type of coding strategy may predominate.

Sensitivity to pulse rate In crickets, tettigoniids, and frogs, communication signals consist of brief sound pulses that are repeated at species-specific rates, and neurons in the central nervous systems of these animals respond most strongly and/or with greatest temporal accuracy to stimuli with species-typical pulse rates. Several central mechanisms have been implicated in pulse rate sensitivity. 'Filter' neurons are found in the brains of both crickets and frogs, which may be low-pass (i.e., respond most strongly to low pulse rates), high-pass, or bandpass. An intriguing, although unconfirmed, idea is that bandpass selectivity might be an example of a neural implementation of a logical 'AND' operation, whereby bandpass neurons would acquire their selectivity for a restricted range of pulse rates by requiring simultaneous input from low-pass and high-pass neurons, the pass bands of which would overlap for species-typical signals (Figure 4). If true, this would be yet another example of combination sensitivity as a mechanism for signal recognition.

Figure 4 Pulse rate-selective filters. The top graph represents the responses of two neurons, one of which has 'low-pass' filtering properties (i.e., responds best to low pulse rates) (blue) and the other of which has high-pass properties (red). The bottom graph represents a bandpass neuron, which responds best to the species-typical range of pulse rates. The diagram on the right illustrates a neural circuit that could produce bandpass selectivity. The blue and red neurons correspond to the low-pass and high-pass curves shown in the top graph. They provide input to the magenta neuron, which responds best when receiving input simultaneously from both presynaptic cells. This occurs when the pulse pattern falls within the high-response ranges of both the low- and the high-pass neurons. Thus, the magenta neuron has bandpass selectivity.

Figure 5 Pulse rate selectivity through neuronal resonance. The top traces illustrate the membrane potential of a neuron in response to a single stimulus pulse. The neuron experiences repeated waves of excitation, occurring with a specific period. The bottom traces show that if the stimulus pulses arrive at the neuron's resonant frequency, succeeding pulses will coincide with the intrinsic excitatory wave resulting from earlier stimuli. The responses to stimuli with this pulse rate will thus be enhanced, resulting, in this illustration, in production of action potentials.

The cellular mechanisms underlying pulse rate filtering are unknown in these examples, although studies on the sensitivity of electric fish to amplitude-modulation rates show that basic features of neuronal physiology can be exploited to build rate filters. For example, rate-dependent synaptic depression and/or electrotonic filtering of synaptic inputs can result in low-pass selectivity. Summation and/or facilitation of synaptic inputs, as well as intrinsic subthreshold ion conductances, might contribute to high-pass filtering.

Another mechanism for pulse rate selectivity, which does not require low-pass or high-pass filters, is based on the concept of neuronal resonance – that is, the endogenous generation of regular, periodic activity by single neurons or neural circuits. Oscillatory activity has been well studied in neural circuits underlying rhythmic motor behaviors such as walking, swimming, and flying. The initial sensory input (i.e., from the first stimulus pulse of a series) would serve to initiate resonance, and inputs from succeeding pulses would, if their period matches that of the resonator, reinforce the endogenous activity, resulting in response enhancement (Figure 5). A prediction of this model is that inputs arriving at integer fractions of the resonant frequency would also result in partial response enhancement because they would coincide with every second, third, *n*th cycle of the endogenous oscillation. Behavioral experiments on an insect, *Tettigonia cantans*, have provided tantalizing evidence for a resonant mechanism. Phonotaxis responses of females are strongest for stimuli with the species-typical pulse rate, 25 pulses s^{-1}, but secondary response peaks occur at 12.5 and at 8 s^{-1} (i.e., at one-half and one-third the optimum rate).

Central processing of bird song Bird song is characterized by complex modulations of amplitude and frequency of sound. Neurons at the level of the auditory midbrain show enhanced temporal precision when stimulated with species-specific sounds compared to noise stimuli that were modulated in amplitude and frequency over the same ranges as the natural signals. The enhanced precision of single neuron firing may support the high fidelity of encoding of natural song patterns by the neuronal population.

Although matched filters are of obvious benefit for the detection of signals from background, apparent 'mismatch' may play a role in enhancing discrimination between different natural signals. This relates to one hypothesis of optimal coding – that the responsiveness of a sensory neuron to particular stimulus components should be inversely related to the probability with which those components occur. Increased sensitivity to stimulus features other than the most common

ones maximizes a neuron's ability to discriminate among different naturally occurring stimuli. Such a relationship between stimulus statistics and neural responses has been observed in a number of systems, although without specific reference to its role in communication. With respect to bird song, neurons in the auditory midbrain and forebrain of zebra finches show a similar relationship between the temporal coding properties of neuronal ensembles and the power distributions of temporal modulations of natural songs. As a consequence, differences in the responses to similar, but nevertheless distinct, song segments are enhanced.

Signal rejection The emphasis thus far has been on mechanisms for recognition of a 'correct' signal. A related concept is the active rejection of 'incorrect' signals. Songs of male grasshoppers, *Chorthippus biguttulus*, consist of a sequence of syllables, each produced by a series of up-and-down stridulatory movements of the hindlegs. The legs are slightly out of phase so that the brief silent periods that occur at the transitions between upward and downward movements of one leg are obscured by sound produced by the other leg. Syllables produced by males that have lost one leg (presumably in an encounter with a predator), however, contain distinct gaps. These songs are rejected by females, suggesting that male sound production is under intense sexual selection. Peripherally, gap detection is accounted for by the synchronous, precisely timed action potentials of groups of receptor neurons in response to a sharp sound onset following silence. Centrally, an interneuron has been identified that is a good candidate for detecting, and reporting to the brain, the 'gappiness' of syllables. The neuron responds well throughout the duration of gap-free syllables, but its response falls off with increasingly wide gaps, paralleling precisely the preference functions of females. The mechanism responsible for the neuron's selectivity is synaptic inhibition, which is evoked by the onset of sound following silence. For gap-free syllables, only a single inhibitory synaptic potential occurs at the onset of each syllable, but for syllables that contain gaps, inhibition is renewed with each gap. The summation of these successive inhibitory potentials suppresses the neuron's response to syllables that contain gaps.

Summary

Both peripheral and central mechanisms participate in the identification of communication signals. For sensory systems that are dedicated to communication, peripheral processing serves mainly to restrict activity to behaviorally relevant signals through matched filtering. Peripheral tuning is further enhanced by central processing. Other central functions include analysis of temporal patterns, integration of separate signal components, discrimination among different signals or components, and evaluation of signal quality.

Avian Vocal Signals

Calls and Songs

Birds are a highly mobile group of vertebrates that depend on vocal signals for communication over long distances, through dense vegetation, and in dim light. Their vocalizations include calls and songs. Calls are typically short, acoustically simple sounds that have a social or survival function, such as maintaining contact between individuals, establishing dominance, or warning of the approach of a predator. They are generally used over short distances and are produced by both sexes throughout the year. Nearly all calls are thought to be innate. Songs, on the other hand, usually have a more complex, often musical, acoustic structure than calls. They are usually, but not always, sung only by the male and primarily during the breeding season, when they are broadcast over a large area to attract a mate or defend a territory.

Vocal Learners and Nonlearners

Oscine songbirds (i.e., members of the oscine suborder of the Passeriformes), parrots, and some hummingbirds learn their species song with the aid of sensory feedback. Only a few vertebrate groups besides humans are known to be capable of vocal learning. Birds which possess this ability thus provide a valuable animal model in which to study this phenomenon. Just as human children must be exposed to speech in order to acquire normal language skills as adults, avian vocal learners must hear conspecific song as juveniles and require auditory feedback of their own 'practice' vocalizations in order to develop normal adult song. In some birds, vocal learning is restricted to critical periods during the first year of life; other species undergo seasonal periods of vocal motor plasticity throughout their lives when they add or replace song syllables. The brain of the oscine songbirds contains a well-developed network of song control nuclei devoted to vocal learning and song production. Analogous areas are present in the brains of parrots and hummingbirds, but no similar system has been found in other avian taxa. The songs of these nonvocal learners appear to be innate and do not depend on auditory experience.

Structure of the Avian Vocal Organ

Songbirds

Birds have evolved a unique vocal organ, the syrinx, which is located in the interclavicular air sac at or near the point where the two primary bronchi converge to form the trachea. The syrinx consists of a framework of modified tracheal and/or bronchial cartilages that support the syringeal membranes or fleshy labia, depending on the species, which vibrate in respiratory airflow to generate sound.

Vocal organ anatomy varies considerably between different avian taxa. In the oscine songbirds, the syrinx is formed from the caudal end of the trachea and the cranial end of each bronchus (Figure 1). Each bronchial portion contains a thin medial tympaniform membrane adjacent to a pair of fleshy labia. It was long assumed that the tympaniform membranes were the vibratory sound source, but ablation of the membranes and endoscopic observations of syringeal biomechanics by Goller and Larsen in anesthetized birds during sounds elicited by forced airflow or brain stimulation indicate that sound is generated by oscillation of the labia at the end of each bronchus. Songbirds thus have a separate sound source on each side of their syrinx (Figure 2). This bipartite vocal organ is controlled by several bilaterally arranged pairs of syringeal muscles innervated by the ipsilateral tracheosyringeal branch of the hypoglossal nerve and is under primary control of the song control nuclei on the same side of the brain.

Non-Songbirds

Many non-songbirds also have a similarly constructed bipartite syrinx at the confluence of the bronchi and trachea, but they have fewer syringeal muscles and the tympaniform membranes may replace the labia as the vibratory sound source. In some species, the syrinx is controlled only by extrinsic muscles in which only one end is attached to the syrinx.

In other non-songbirds, the syrinx is located either in the trachea or in the bronchi. The syrinx of doves and parrots, for example, is in the caudal portion of the trachea (Figure 3(a)). Sound is generated by the vibration of a pair of lateral tympaniform membranes situated on the wall of the trachea. A still different anatomical arrangement is present in many nocturnal birds, including owls, nightjars, the echolocating oilbird (*Steatornis caripensis*), and some cuckoos. In these birds, half of the syrinx is located in each

primary bronchus and sound is produced by oscillation of a tympaniform membrane on the medial side of each bronchus (Figure 3(b)).

Respiratory and Syringeal Dynamics of Song Production

Birdsong, like human speech, requires the precisely coordinated activity of many muscles in both the respiratory and vocal systems. Together, these muscle groups determine the temporal and spectral properties of the sound that enters the suprasyringeal vocal tract, on its way to the beak and radiation into the external environment as a vocal signal.

Vocalization begins with the contraction of respiratory muscles that causes air to flow through the syrinx. As air flows across the labia (or syringeal membranes in some species) it causes them to oscillate, generating sound. Birds do not have a muscular diaphragm like mammals do, so respiratory airflow is determined by the activity of thoracic and abdominal muscles that expand or compress several pairs of thin-walled air sacs in the thorax and abdomen. These air sacs function as bellows connected to the lungs and bronchi, through which they pump air.

A singing bird must adapt both the amplitude and the timing of its respiratory pattern to meet its requirements for vocal communication, as well as those for pulmonary gas exchange. During song, respiratory pressures are increased approximately ten-fold compared to those of quiet, silent respiration. Phonation is accompanied by high-amplitude bursts of electrical activity in expiratory muscles that alternate with similar bursts in inspiratory muscles (Figure 4(a)). The temporal pattern of respiration is also modified and determines the tempo of the song.

Song Tempo and Duration

Nearly all song is produced during expiratory airflow. The overall temporal pattern of song is thus determined by the timing and duration of each expiration. Within the expiratory phase, the timing of phonation can be further fine-tuned by the muscles that adduct the sound oscillators into the syringeal lumen. In addition to generating sound, these structures function as a pneumatic valve that gates phonation and can prevent or interrupt sound production during expiration by closing the syringeal lumen, thus blocking airflow despite a positive subsyringeal pressure.

Birds face a trade-off between achieving a high syllable repetition rate and the length of time they can sustain the phrase or song. At relatively low repetition rates (<30 or <16 syllables per second for canaries and cardinals, respectively), the volume of air required to produce each syllable is replaced by a brief 'minibreath' immediately after the syllable. As repetition rate increases, it reaches a point where there is not enough time between syllables for a minibreath. Syllable repetition rates higher than this are produced by pulsatile expiration (Figure 4(b)). This motor pattern maintains a positive subsyringeal pressure while keeping one side of the syrinx closed to conserve respiratory air for phonation. The trill is generated by rapid repetitive opening of the other side. Each escaping puff of air generates a syllable, but the duration of the trill is limited since air is not being replaced.

In songbirds this syringeal valve is formed by the medial and lateral labia at the cranial end of each bronchus (Figure 2(a)). Its aperture is controlled by the dorsal syringeal muscles on the same side of the syrinx (Figure 2(b)). When the dorsal muscles relax and other antagonistic abductor muscles contract, the

labia are fully abducted out of the air stream to provide a low-resistance pathway during inspiration and silent respiration. During phonation, the dorsal muscles are active, causing the labia to move toward each other into the syringeal lumen, where they form a slit and vibrate in airflow, generating sound. Fine gradations of dorsal muscle action during phonation can modulate the amplitude and spectral properties of the sound. Further contraction of the dorsal syringeal muscles fully adducts the labia, which meet in the middle of the lumen and prevent phonation on that side of the syrinx by blocking airflow.

In many non-songbirds, including doves, the syringeal valve is controlled by tracheal muscles. If the song contains trills with high-note repetition rates, the muscles controlling the syringeal valve must be able to operate very rapidly. The coo of the ring dove includes a trilled portion with note repetition rates up to $30\,s^{-1}$. Dove tracheal muscles controlling the syringeal valve are specialized for high-speed contractions and have half-twitch times of approximately 9 or 10 ms. It is likely that syringeal muscles serving a similar function in songbirds are also superfast.

The production of stereotyped vocal signals requires precise coordination between respiratory and syringeal motor patterns. By opening and closing the syrinx, motor commands to the dorsal syringeal muscles can determine which side(s) is producing sound at any instant and whether one or several notes are produced within a single expiration. A neural pathway believed to be important in coordinating respiratory and syringeal motor patterns during learned song involves the robust nucleus of the arcopallium, a song control nucleus in the songbird's telencephalon, which projects to respiratory premotor nuclei as well as to syringeal motor neurons.

Control of Fundamental Frequency

The ventral syringeal muscles of songbirds have an important role in determining the fundamental frequency

Figure 4 Respiratory patterns during song. (a) Segment of zebra finch song showing air sac pressure, together with alternating EMG patterns of the envelope of rectified abdominal expiratory muscle (green) and thoracic inspiratory scalenus muscle (red). Schematic drawing of bird indicates approximate location of air sacs (blue). (b) Portion of a song by the northern cardinal. Envelope of rectified EMG is shown. The first four syllables are produced by airflow through the left side of syrinx. Despite positive air sac pressure during the syllables, there is no airflow through the right side, indicating it is closed by full adduction of labia. Shaded airflow between syllables indicates minibreaths. The fourth syllable is followed by a pulsatile trill in which a high syllable repetition rate is achieved by maintaining a continuous positive air sac pressure and releasing repetitive puffs of air through the left side of the syrinx while keeping the right side closed. Top shows the sound spectrogram of song. F_L and F_R, rate of airflow through the left and right side of syrinx, respectively. Shaded flow is inspiratory. Horizontal line equals zero airflow. *P*, air sac pressure driving airflow. Horizontal line is ambient external pressure. Negative pressure accompanies inspiratory flow; *V*, time waveform of vocalizations. (a) Reproduced from Wild J, Goller F, Suthers R (1998) Inspiratory muscle activity during bird song. *Journal of Neurobiology* 336: 441–453, with permission from Blackwell. (b) and bird adapted from Suthers RA (2004) How birds sing and why it matters. In: Marler P and Slabbekoorn H (eds.) *Nature*'s *Music. The Science of Birdsong*, pp. 272–295. New York: Elsevier, with permission.

of vocalizations (Figure 2(c)). Unlike the human vocal fold, the avian labia do not contain intrinsic muscles. The fundamental frequency at which they oscillate can be varied by the ventral syringeal muscles which increase the tension on the labia when they contract. The electrical activity of these muscles is positively correlated with changes in the song's fundamental frequency.

The complexity of song in many oscine songbirds is at least in part related to the fact that they have multiple pairs of syringeal muscles. This increases the potential for particular muscles to be functionally specialized and facilitates the ability to independently control various acoustic and aerodynamic parameters. Non-songbirds with few syringeal muscles may face a challenge in controlling fundamental frequency independent of subsyringeal pressure, for example.

Ring doves (*Streptopelia risoria*) provide an interesting case in which perisyringeal pressure controls sound frequency independent of subsyringeal pressure. The tracheal syrinx of doves has only two muscles. Tension in these muscles may influence the range of frequencies over which the syringeal membranes can oscillate, but the fine control of fundamental frequency during the course of the coo is precisely correlated with pressure fluctuations in the interclavicular air sac that surrounds the syrinx. This interclavicular pressure impinges directly on the outer surface of the syringeal membranes, presumably controlling their frequency of oscillation by varying their tension as they bulge into the tracheal lumen. Interestingly, the subsyringeal pressure measured in the thoracic air sac varies independent of that in the interclavicular sac and is not correlated with sound frequency.

Sensory Feedback in Adult Song

Auditory Feedback

These complicated vocal motor patterns of songbirds are dependent on sensory feedback, even in adult,

crystallized song. Auditory feedback, in addition to its essential role in song learning, continues to be important in the maintenance of adult song. The song of deafened adults gradually deteriorates over a time course that varies from days to months, depending on the species. One of the more dramatic demonstrations of the importance of auditory feedback after song crystallization comes from the work of Leonardo and Konishi, who placed a microphone and speaker in the cages of adult zebra finches (*Taeniopygia guttata*). Whenever the bird sang, it heard its song reproduced through the speaker after a delay of 100 ms, disrupting the normal sensorimotor integration. The normal crystallized songs of these zebra finches began to deteriorate after a few weeks. Abnormal features of this 'decrystallized' song included stuttering, distortion or deletion of syllables, or the addition of new syllables. If the delayed auditory feedback was discontinued, the song gradually returned to its original form over a few months, indicating that memory of the original song persists.

Somatosensory Feedback

Respiratory and syringeal motor patterns of adult cardinals are also modulated by somatosensory feedback. If the subsyringeal pressure is briefly increased by injecting a small amount of air into an air sac during a syllable, there is a real-time (latency of approximately 50 ms) compensatory decrease in the contraction of expiratory muscles (Figure 5). There are also compensatory responses by syringeal muscles. These adjustments in muscle activity minimize the increase in syringeal airflow that would otherwise accompany the increased air sac pressure and distort the vocalization.

Figure 5 Real-time modulation of song respiratory motor pattern by somatosensory feedback. (a) Northern cardinal song. A fraction of a milliliter of air was injected into the thoracic air sac early in the third syllable (vertical line). (b) Relative mean amplitudes of abdominal expiratory muscle EMG during syllables with air injection compared to the same syllable without air injection in deafened bird. Blue shading indicates one SE for control (dark blue) and experimental (light blue). Reduction in amplitude of expiratory muscle EMG following air injection stabilizes syringeal airflow and minimizes the acoustic effect of unpredictable pressure change. F_{inject}, thermistor output showing rate of airflow through cannula into air sac. ABD, EMG of abdominal expiratory muscle (rectified below and integrated envelope above); F_L and F_R, rate of airflow through the left and right side of syrinx, respectively; *P*, air sac pressure driving airflow. Adapted from Suthers RA, Goller F, and Wild JM (2002) Somatosensory feedback modulates the respiratory motor program of crystallized birdsong. *Proceeding of the National Academy of Sciences of the United States of America* 99: 5680–5685, with permission.

Song Lateralization

Lateralized neural control of behavior was first described by Broca in 1861 with regard to human speech. Birdsong was one of the first nonhuman examples of functional lateralization in the brain. Early studies on songbirds by Nottebohm and others assessed lateralization by comparing song deficits following unilateral denervation of the syrinx. With rare exceptions, species tested in these experiments all showed a larger song deficit when the left side of the syrinx was denervated, limiting song production to the right side, than when the right side was denervated. This left dominance is most pronounced in a Wasserslager strain of Belgium canaries (*Serinus canaria*). Paralysis of the left side of the Wasserslager's syrinx eliminates approximately 90% of the syllables in the bird's song repertoire, whereas only approximately 10% is lost after paralysis of the right side. The extreme left side dominance of song production by the Wasserslager canary is unique among the birds that have been studied, including even a conspecific domestic strain of canary.

Insight into the neural basis of song lateralization was obtained from recordings of syringeal muscle electromyograms in brown thrashers. These experiments showed that lateralization is based on the motor commands to the dorsal syringeal muscles responsible for gating airflow through each side of the syrinx. The action of these muscles determines which side of the syrinx produces sound. The ventral syringeal muscles that primarily control the phonetic structure of

syllables are active on both sides of the syrinx regardless of which side is phonating. The song control nuclei above the hypoglossal motor nucleus do not exhibit anatomical or functional laterality. These findings argue against the hypothesis that song lateralization evolved in order to free brain space for other tasks such as memory storage of songs or in order to provide a single command center for both sides of the song control system. Respiratory motor patterns are not lateralized during song.

Patterns of Song Lateralization

The most important contribution that the bipartite syrinx makes to avian vocal communication is not the possibility of unilateral dominance in song production but, rather, the additional degrees of freedom for signal diversity and complexity provided by two independently controlled sound sources. Songbirds have exploited this opportunity by evolving different acoustic specializations for each side of the syrinx and using the two sides in particular ways that appear optimized for producing the species-specific features of their song.

Independent Voices from the Bipartite Syrinx

By singing with both sides of the syrinx simultaneously, syllables containing two harmonically unrelated fundamental frequencies can be generated. Such two-voice syllables are common, for example, in the repertoires of brown thrashers (*Toxostoma rufum*) and catbirds (*Dumetella carolinensis*) (family Mimidae) (Figure 6(a)). The separate 'voices' in such syllables may be frequency modulated in different directions and often have a distinctive dissonance to our ears. Since the sounds from the two sides of the syrinx are combined in the trachea they can, in certain circumstances, generate a vocalization containing rapid amplitude modulation at a modulation frequency higher than can be produced by cyclical contractions of the syringeal or respiratory muscles.

Surprisingly little is known about the behavioral significance in vocal communication of this two-voice phenomenon. Ironically, the exception to this statement comes from studies on a non-songbird, the penguin, by Aubin and colleagues. Emperor and king penguins (*Aptenodytes forsteri* and *A. patagonicus*) are faced with the daunting task of finding and identifying mates or chicks in a noisy, tightly packed colony of thousands of birds. Since these two species carry the egg on their feet, there is no nest site to which to return. Emperor and king penguins produce display calls in which each side of the syrinx simultaneously generates a different fundamental frequency (Figure 7). The fundamentals of these two-voice calls interact to produce individually identifiable amplitude-modulated beat notes that propagate well through the crowded colony.

The bipartite syrinx of songbirds also facilitates increased temporal complexity in song. This is illustrated in the songs of the brown-headed cowbird (*Molothrus ater*). Each song begins with two or three clusters of notes produced in rapid succession at different frequencies and with little or no silent interval between them (Figure 6(b)). Recordings of respiratory airflow, pressure, and bronchial sounds show that within each note cluster the first note, which also has the lowest fundamental frequency, is produced on the left side of the syrinx and the following notes originate alternately from opposite sides of the syrinx. This motor pattern allows abrupt frequency steps between successive notes despite the absence of a silent interval between them. This is possible because while one note is being produced, a motor program to the contralateral side of the syrinx is presetting muscle tensions needed for the next note. Each cowbird song ends with a high-frequency, loud 'final whistle' that is produced on the right side of the syrinx.

Lateralized Functional Specialization of the Syrinx

In all songbirds studied, each side of the syrinx has a partially different frequency range. Frequencies below approximately 3.5–4 kHz are generally produced on the left side and higher frequencies are produced on the right, although there is typically an extensive band of midrange frequencies that can be generated on either side. This lateralized specialization for different frequencies is particularly pronounced in the northern cardinal. Much northern cardinal (*Cardinalis cardinalis*) song is characterized by FM sweeps that often extend over two or more octaves. To the human listener, these whistled sweeps sound continuous, but recordings from the syrinx during song show that fundamental frequencies below approximately 3 or 4 kHz are sung by the left syrinx, whereas higher frequencies are sung by the right syrinx (Figure 6(c)). When the frequency of a syllable extends across this frequency divide, the bird switches phonation in midnote from one side to the other, depending on the direction of the FM. Usually, this lateral switch is so expertly executed that there is no perceptible interruption in the sound or perturbation of the frequency.

Acoustic Role of the Vocal Tract

A Variable Resonance Filter

The sound that is produced by the syrinx is modified by resonances of the suprasyringeal vocal tract which

Figure 6 Species differences in the pattern of syringeal lateralization. (a) Independently modulated two-voice syllable of brown thrasher. (b) Two note clusters from song of brown-headed cowbird. Abrupt frequency steps without a silent interval between notes are achieved by alternating note production between opposite sides of the syrinx. Final whistle is not shown. (c) Frequency modulated sweeps from northern cardinal song with smooth transition of phonation from one side of syrinx to the other in the middle of the sweep. (d) Part of a 'sexy' phrase from a domestic canary, showing the high repetition rate, wide bandwidth, and two-note structure of the syllables. In all species studied, the right side of syrinx tends to produce higher frequencies than the left. allow some frequencies to pass through the vocal tract and attenuate other frequencies. The resonance frequencies are expressed in the emitted vocalization as bands of relatively high acoustic energy called formants.

Evidence that the vocal tract acts as a resonance filter of syringeal sound was obtained through experiments with songbirds singing in a light gas mixture consisting of 80% helium and 20% oxygen. These experiments indicated that the vocal tract resonance in air is tuned to the fundamental frequency of the song. Because the speed of sound is faster in heliox than in air, the resonant frequency in heliox shifts upward nearly an octave, increasing energy in the normally suppressed second harmonic and reducing the energy in the fundamental of the emitted vocalization. Light gas experiments also suggested that songbirds adjust the tuning of their vocal tract resonance to match changes in the fundamental frequency, thus increasing the tonality, or whistlelike, quality of the vocalization by reducing the relative amplitude of the higher harmonics generated by the syrinx.

In order to vary the vocal tract's resonance frequency, the bird must be able to alter its shape. Which part of the vocal tract is responsible for this, and the mechanism by which shape is regulated, is a topic of controversy and current research. Primary candidates include the trachea, the oropharyngeal cavity including the tongue, and the beak.

The Trachea

The tracheal resonance can be approximated by modeling it acoustically as a tube closed at the syrinx and open at the glottis. Songbirds can only make very small changes in the length of their trachea, however, making it an unlikely candidate for the tracking filter. Nevertheless, the trachea appears to have evolved a special role in vocal communication by some non-songbirds, such as cranes. The trachea of these species is coiled inside the body, greatly increasing its length (Figure 8). Tecumseh Fitch showed that the amount of tracheal elongation is inversely correlated with the distance between formants in the call. He hypothesized that birds use formant spacing to assess the sender's body size and that tracheal elongation may have evolved as a means of exaggerating the sender's size.

The Oropharynx and Esophagus

The acoustic role of the oropharyngeal cavity, which lies between the glottis and the beak, has been studied using x-ray cinematography. Data from northern cardinals show that the oropharyngeal cavity undergoes large cyclical, song-related changes in its shape and volume due to movement of the hyoid apparatus and larynx. The volume of this cavity varies inversely with the fundamental frequency of the syringeal sound. At low fundamental frequencies the oropharyngeal cavity is further enlarged by expansion of the cranial end of the esophagus (Figure 9). A computational acoustic model of this cavity predicts that the primary resonance frequency of the oropharyngeal–esophageal cavity closely tracks the song's fundamental frequency, reinforcing the fundamental while attenuating the higher harmonics. It appears to be an important part of the songbird's tracking filter.

The Tongue

The tongue lies within the oropharyngeal cavity but little is known about its acoustic role in avian vocalizations. The base of the tongue is attached to the hyoid apparatus and moves with it and the larynx. Parrots have a thick muscular tongue, in contrast to the relatively much thinner, smaller tongue of songbirds. In the monk parakeet (*Myiopsitta monachus*), small changes in the position of the tongue can alter the formant frequencies, and tongue movements appear to contribute to the articulation of vowel sounds when gray parrots mimic speech. Although

Figure 8 (a) Example of four types of tracheal elongation that may have evolved as a way of exaggerating body size by altering the formant frequency dispersion. Species shown are (a) intraclavicular coiling, crested guinea fowl *Guttera edouardii*; (b) intrathoracic coiling, European spoonbill *Platalea leucorodia*; (c) intrasternal coiling, trumpeter swan *Cygnus buccinators*; and (d) subdermal coiling, trumpet manucode *Manucodia keraudrenii*. (b) Segment of a song sparrow song sung in air (top) and in heliox (bottom). Second harmonic is attenuated compared to fundamental in air but is relatively prominent in heliox due to an upward shift in the resonant frequency in light gas. The arrows indicate a syllable in which the second harmonic, which is suppressed in air but prominent in helium, is at the same frequency as the fundamental of the following syllable, suggesting a change in the tuning of the vocal tract filter. some songbirds, such as the hill mynah (*Gracula religiosa*) and starling (*Sturnus vulgaris*), can also mimic speech sounds, the role of the passerine tongue in vocal communication is unknown.

The Beak

The beak is the only part of the vocal tract that can be readily observed during song. A number of experiments have shown that the beak opening, or gape, also exhibits song-related changes, being large when the fundamental frequency is high and relatively small when the frequency is low. It has been widely assumed that these song-related beak movements provide the mechanism by which birds adjust their vocal tract resonance to support the fundamental frequency. According to this hypothesis, changes in beak gape alter the resonance frequency of the vocal tract by varying its end correction or effective length. The emission of high frequencies is facilitated by a large beak gape. Conversely, by nearly closing its beak, a bird can suppress the higher harmonics of a low-frequency fundamental. The relative contribution of the oropharyngeal–esophageal cavity versus beak gape to the vocal tract's resonance filter is controversial. Although there is general agreement that beak gape is correlated with changes in the filter properties of the vocal tract, the physical basis of this relationship is unclear. Some data suggest that the beak *per se* has a limited acoustic effect, raising the possibility that related changes in the upper vocal tract that are linked to beak gape may be acoustically important.

Production Constraints

Two of the important functions of birdsong are territorial defense and mate attraction. Exactly how song contributes toward accomplishing these essential behaviors is a subject of current research and beyond the scope of this article. Advances in understanding the mechanisms of singing underline the need for precise and often very rapid coordination between the two sides of the syrinx, the respiratory rhythm and movements of the suprasyringeal vocal tract. To what extent do the vocal gymnastics that are required to produce the distinctive acoustic features of much species-specific song impose performance limits? The fact that females of some species prefer males that sing in certain ways raises the possibility that by attending to how well a prospective mate sings difficult song elements, a female may be able to assess the relative quality of competing males.

Female Preference and Song

A growing body of evidence suggests that at least in some species, males that excel in rapid, precise coordination of vocal motor patterns have an advantage in attracting a mate. Behavioral experiments on brown-headed cowbirds by West and King suggest that the temporal precision of high- and low-frequency notes, which alternate between the two sides of the syrinx in the introductory note clusters (Figure 6 (b)), is an important factor in eliciting copulation solicitation displays from females. Researchers at the University of Paris showed that female domestic canaries are most likely to solicit copulation from

Figure 9 The northern cardinal tunes the major resonance of its vocal tract to the changing fundamental frequency of its syllables. (a) The volume of the oropharyngeal cavity (red curve) increases at low fundamental frequency of upward sweeping song syllable (black lines). At high fundamental frequency, cavity volume decreases and the beak opens. Each dot is a measurement from successive frames of an X-ray movie. Red dots indicate movement of larynx relative to anatomical reference. Upward movement of the red line corresponds to increased volume of the oropharyngeal cavity. (b) Four song syllables in which the fundamental sweeps upward from approximately 1 to approximately 5 kHz. (c, d) X-ray images at the beginning (1 kHz) and end (5 kHz) of syllable 1. (c) The pink polygon shows the expanded oropharyngeal cavity and cranial end of the esophagus at the beginning of syllable. (d) At the end of syllable, the esophagus has collapsed and the volume of the oropharynx is much reduced. A computational acoustic model based on the volume of the upper vocal tract estimated from a three-dimensional model indicates the primary resonance is approximately 1 kHz in (c) and 5 kHz in (d). The trachea forms the tube slanting upward from the syrinx (not in image) to the larynx which opens into the mid-ventral region of the oropharynx. Adapted from Riede T, Suthers RA, Fletcher NH, and Blevins W (2006) Songbirds turn their vocal tract to fundamental frequency of their song. *Proceedings of the National Academy of Sciences of the United States America* 103: 5543–5548, with permission.

males that include special 'sexy syllables' in their songs. Important features of these FM syllables include their high repetition rate, a relatively large frequency bandwidth, and the fact that each syllable is composed of two notes sung in rapid succession. In subsequent studies on song production in these canaries, it was found that the two successive notes of these sexy syllables are generated on opposite sides of the syrinx, requiring extremely rapid switching of phonation from side to side (Figure 6(d)). The ability to maintain a wide frequency bandwidth at high syllable repetition rates is also behaviorally important in swamp sparrows (*Zonotrichia georgiana*). Scientists at Duke University found that males who are able to maintain exceptionally wide frequency bandwidth at high trill repetition rates are more successful than other males in eliciting sexual displays from females.

Performance Constraints in Vocal Mimicry

Further insight into the likely influence of performance constraints on the evolution of birdsong comes from experiments on how the northern mockingbird, a vocal mimic, produces heterospecific songs. If there are multiple ways a songbird can achieve specific acoustic effects, one might expect that, by trial-and-error motor learning, the mockingbird would sometimes produce heterospecific song using different motor strategies than those used by the tutor species. Alternatively, if the mockingbird uses the same production mechanism as the tutor, it suggests there may be only one way to achieve the particular acoustic properties of the tutor song.

Juvenile northern mockingbirds (*Mimus polyglottus*) were tutored with the natural or computer synthesized songs of other species. When the mockingbirds sang these heterospecific songs during their first breeding season as adults, the motor pattern they used to produce the song was similar to that of the tutor (Figure 10). When a mockingbird's motor pattern deviated from that of the tutor, the acoustic accuracy of the copy also decreased. The fact that the vocal mimic uses the same pattern of lateralization as the tutor suggests that production constraints have played an important role in the evolution of song diversity.

Signal Transmission in Natural Environments

R H Wiley, University of North Carolina, Chapel Hill, NC, USA

Introduction

All communicatory signals consist of energy or matter transferred from a signaler to a receiver, but not all transmitted energy is a signal. The fundamental property of a signal is its ability to elicit a response from a receiver without providing all the power for the response. Coercion is not communication. Instead, a signal produces a response that is mediated by the receptors, decision mechanisms, and effectors of the receiver. Even tactile signals are separated from coercion by this property of insufficient power and thus rely on the receiver for their effectiveness.

Insufficient power to produce a response assures that transmission is a fundamental property of all signals. Transmission of a signal to the receiver in turn introduces the possibility of alterations in the structure of the signal and of masking by irrelevant energy in the environment. These possibilities result in errors in the receiver's responses, and the possibility of errors has in turn some fundamental consequences for the evolution of optimal behavior by both receivers and signalers. Understanding signal transmission is thus fundamental to understanding communication in general.

The alterations and masking of signals during transmission are most easily studied and most thoroughly understood in the case of sounds in the atmosphere.

Acoustic Signals in Air

Spherical Spreading

Sound radiating from a point in a homogeneous medium spreads spherically, so that the density of energy in a unit of area (the intensity) decreases in inverse proportion to the square of the distance from the source. The energy emitted by a source at any instant spreads over an imaginary spherical surface that depends on how far the sound has traveled from the source. Once beyond about one wavelength and one diameter from the source (in the far field), sound propagates as a wave of pressure as a result of minute movements of the molecules in the medium. Closer than this distance (the near field), sound has somewhat different properties as a result of the larger movements of molecules in the medium. Although no real source emits sound exactly from a point and no natural environment is exactly homogeneous, nevertheless measurements have shown that, at least in the far field, sounds produced by animals in relatively homogeneous conditions spread approximately spherically. As a result, the intensity of sound in general attenuates at least in proportion to the inverse square of distance from the source. This attenuation equals approximately 6 dB for every doubling of distance from the source, by the definition of decibels as -10 times the log of a ratio, in this case $-10\log((1/2)^2)$.

In the presence of gradients of wind speed or temperature, sound no longer spreads spherically. These conditions result in sound that attenuates from spreading either more or less than the 6 dB for a doubling of distance expected from spherical spreading. Sound travels faster in warmer than in cooler air, so a temperature inversion (warmer air near the ground, because of sunlight heating the surface, and cooler air above) results in sound that refracts upward as it propagates over the ground. This bending reduces sound spreading horizontally. As a result, attenuation in a horizontal direction is greater than 6 dB for a doubling of distance. Probably for this reason, few birds in open environments sing near the ground on sunny days. Instead, many sing in flight well above ground, behavior that increases the horizontal distance at which their songs can be heard.

In forests during early morning, the air above the canopy warms faster than the air below the canopy. In this circumstance sounds produced in the canopy are refracted downward from the air above, so the intensity of the sound in the canopy attenuates less than expected by spherical spreading. Primates of tropical forests often vocalize in the canopy at this time and thus get the advantage of this focusing effect to boost the propagation of their vocalizations.

Gradients of wind speed have somewhat similar effects on the propagation of sound. Wind speed is slowest next to the ground (or other surfaces) and increases with height, sometimes for 20 m or so. In these conditions, sound propagating upwind refracts upward, and sound propagating downwind refracts downward. As a consequence, a shadow zone develops upwind beyond which little sound penetrates, whereas downwind, sound is channeled horizontally. Thus under windy conditions, sound attenuates more in the horizontal direction upwind but less downwind than expected by spherical spreading. Although this effect is prominent, there are no documented cases of animals that selectively communicate downwind. For instance, we might expect in windy conditions

that birds would sing closer to the upwind sides of their territories so as to equalize the reception in all neighboring territories.

Frequency-Dependent Attenuation

Absorption of sound by molecular vibrations in the medium results in additional attenuation. Because absorption occurs in addition to the universal attenuation from spreading, it is a form of excess attenuation. Absorption of sound by molecules in the atmosphere is complex, but the practical consequences for communication with frequencies in the range of many animals' hearing (100–10 000 Hz) are relatively simple. In this range, absorption is not significantly affected by temperature or humidity of the air. However, absorption increases monotonically with frequency in all natural environments. As a result, the lowest frequencies produced by animals propagate farthest in any natural environment.

There are two other important sources of excess attenuation. First, near a boundary layer, such as the ground, sound propagating in the atmosphere interacts with energy propagating near the boundary or reflected from the boundary. This effect is also strongly frequency-dependent in accordance with the properties of the boundary. Highly porous soil can result in a nearly 180° phase shift of the low frequencies in reflected sound, so there is nearly complete destructive interference between direct and reflected sound at these frequencies during transmission near the ground. As a result of this ground effect, many birds that forage on the ground move to higher perches when they sing.

Second, sound is absorbed and reflected by objects in the path of transmission. Large objects simply reflect sound and create a sound shadow beyond. Smaller objects absorb sound in their vibrations or refract sound away from the path of transmission in complex ways. Very small objects, those well below a wavelength in diameter, have little effect on the transmission of sound. The leaves in forests have particularly interesting effects on reverberation. Many broad leaves should refract or reflect sounds with wavelengths smaller than roughly 10 cm, corresponding to frequencies greater than 3400 Hz in air. In contrast, coniferous needles should only affect sounds with much higher frequencies (1 cm diameter would correspond to a frequency of 34 000 Hz). As expected, birds in coniferous forests use higher frequencies on average in their songs that do birds of similar size in broad-leaved forests.

Provided the air and vegetation are homogeneous in composition along the path of propagation, excess attenuation is a constant fraction of the intensity of sound for each unit of distance. Because atmospheric absorption results in constant decreases in intensity of sound with distance but spherical spreading results in exponential decreases, spherical spreading dominates attenuation at short ranges, and atmospheric absorption dominates at long ranges. As a result, we should expect to find adaptations to minimize excess attenuation in communication only at relatively long ranges. Human speech, for instance, has notably poor transmission at a distance. Presumably it has evolved for communicating lots of information rapidly at short range rather than for efficacy of communicating a few crucial messages at long range.

Reverberation and Amplitude Fluctuations

Frequency-dependent attenuation alters the spectrum of sound as it propagates by disproportionately reducing the higher frequencies in a sound. Reverberation and amplitude fluctuations also have pronounced effects on the temporal properties of sound, sometimes called degradation rather than attenuation.

Reverberation results from multiple refractions and reflections of sound from objects in the path of transmission. As a result, sound no longer arrives at the receiver along a single, direct path. Instead, it arrives from a wide angle along many paths of different lengths. Some of the sound is thus delayed, in relation to the rest, in reaching the receiver. The result is a smearing of any temporal patterns in the sound. Distinct notes at the source arrive as blurred sounds. Staccato becomes sostenuto. To the extent that shapes or timing of notes is important for a receiver's response, reverberation degrades signals. Reverberation is more severe in environments with greater density of objects in the path of transmission. Forests, for instance, produce more reverberation than open air above grasslands. As expected, birds in forests, especially broad-leaved forests, are less likely to incorporate rapid repetitions of notes at any one frequency in their songs than are birds of grasslands. Because broad leaves reflect mostly sounds with higher frequencies in the range used by many songbirds, reverberation is greater for these frequencies. Greater reverberation of higher frequencies, as well as greater attenuation, can explain why birds in forests use lower frequencies on average than do birds of open habitats.

Amplitude fluctuations also degrade the temporal structure of propagating sounds. These fluctuations arise from turbulence in the flow of air. Even a gentle breeze, particularly near a rough surface such as the ground or the canopy of a forest, includes irregular eddies. The dimensions of these eddies (or their periodicities as they pass any one point) have an exponential spectrum with progressively decreasing representation of smaller dimensions (or smaller

periodicities). These eddies refract sound away from a direct path of transmission and thus impose fluctuations in the intensity of the sound for a receiver. Because the periods of these fluctuations are mostly long in relation to the time constants for animals' ears, they produce dropouts in sounds (periods of irregular length with lower intensity). Amplitude fluctuations affect sounds primarily in open environments, where wind is rarely absent, as opposed to, for instance, the interior of a forest. As a result, birds in open country (such as sandpipers, larks, pipits, and longspurs) often have prolonged tinkling songs (several seconds of extremely rapid notes in complex patterns). These birds appear to produce songs with high specificity in any brief part so that unpredictable dropouts in the song would not affect the possibility for recognition. Conspecific listeners might identify these songs by hearing any brief part them.

Background Sound

All natural environments include background sound, sound not relevant to communication by any one species or particular individuals. This background sound arises from physical features of the environment – wind, vegetation, and water. It also includes sounds made by other organisms – often not only different species but also other individuals of the same species. In recent centuries, especially in recent decades, human-generated noise, especially from airplanes and automobile traffic, pervades natural environments even at surprising distances from the source. These sources of irrelevant sound mask to varying degrees the sounds produced by animals for communication.

In tropical forests, insects (mostly Tettigoniidae, Gryllidae, and Cicadidae) create a nearly constant and ubiquitous band of noise with frequencies of 4–10 kHz. The tendency of birds in the interior of tropical forests to use lower frequencies in their songs than do those in open habitats might result primarily from the ceiling imposed by noise from insects and the floor imposed by the dimensions of the birds themselves. In addition, as described above, reverberation and excess attenuation of sound increase more rapidly with frequency in forests (particularly broad-leaved forests) than in the open. The combination of these features often creates a sound window for communication in these forests.

For any level of background sound, attenuation sets a distance beyond which the signal can no longer be detected in the noise. To determine the active space of a signal, we need measurements of attenuation and background energy and also experiments to find the signal–noise ratio necessary for recognition by conspecific listeners. Such investigations have shown that the signal space for birds' songs, primates' loud calls, or insects' stridulations equals approximately twice the average spacing of individuals, as expected if individuals moving around in their territories or home ranges stay in touch with all their neighbors at all times.

Minimizing or Compensating for Attenuation and Degradation

Investigation of the transmission of animals' sounds in natural environments has led to the environmental adaptation hypothesis: animals' sounds should evolve features that transmit well in the relevant habitat. Although sometimes not explicitly acknowledged, this hypothesis should apply primarily to signals used for relatively long-range communication. At short range, transmission should be dominated by spherical spreading. Only at long range should transmission be dominated by excess attenuation, reverberation, amplitude fluctuations, or background energy. Recent analyses of independent phylogenetic contrasts have often confirmed that birds in forests (especially broad-leaved forests) use lower frequencies on average and avoid rapid repetitions of notes in comparison with species in open habitats, as predicted by this hypothesis. Comparisons of different populations of the same or closely related species have often had similar results. Nevertheless, not all studies have confirmed the hypothesis.

Insects and anurans (frogs and toads) in particular have provided little support for the environmental adaptation hypothesis, perhaps because communication in these animals often occurs over relatively short distances. One study of cricket frogs *Acris crepitans* in Texas, however, did reveal two populations that differed as predicted in the frequencies of sound in their calls. The population that inhabited denser vegetation had lower-frequency calls, which propagated with less distortion in this habitat. These calls also propagated better in the more open habitat, although the difference was much less there. The tuning of the females' auditory neurons nearly matched the differences in calls between the populations. As a consequence, the auditory neurons of the population with high-frequency calls did a better job of rejecting the predominantly low-frequency noise in both habitats.

Adjustments to pervasive human influences on environments have also come under investigation recently. Birds in areas subject to intense and continual noise from traffic produce louder songs than conspecifics in quieter environments (the Lombard effect). They also produce songs with higher frequencies, which avoid overlap with most of the predominantly low-frequency noise from traffic.

Almost no research has focused on adjustments of signal perception (as opposed to signal production) to attenuation, degradation, and masking of acoustic

signals. A suggestion of the possibilities comes from one study that determined thresholds for hearing in the great tit *Parus major*, both in quiet conditions, as such measurements are usually conducted, and in the presence of noise matching natural background sound. In quiet conditions, the best frequencies for hearing were considerably lower than those in the species' songs, but in the presence of noise, there was a close match between the best frequencies for hearing and the frequencies in songs. Because the masking bandwidth for hearing decreased steadily with frequency, the optimal frequency for hearing shifted upward in the presence of noise.

Using Attenuation and Degradation to Localize Signals

Attenuation and degradation of signals could be put to good use by listeners to determine the distance to a signaler, an ability called ranging. Any change during transmission of a sound might be used for ranging. This capability is studied experimentally by playing back signals (such as birds' songs) in order to compare responses to relatively clean signals and to artificially or naturally attenuated and degraded signals. If the subjects decide the signals come from a distance, they might respond as if they came from a neighboring territory rather than from their own. A responding bird can also reveal a judgment of distance simply by overshooting or undershooting its approach to the speaker.

Overall intensity of sound (as affected, for instance, by spherical spreading) might not be a good cue for distance, at least in competitive interactions, because intensity can be manipulated by the sender. Nevertheless, experiments have shown that overall intensity is used by birds for ranging conspecific songs. However, they also use frequency-dependent attenuation and degradation by reverberations to judge distance, even when overall intensity is held constant. Furthermore, ranging can occur, at least approximately, even when the birds lack prior experience with a particular song pattern. Experience does play a role, however, because birds adjust their responses to reverberated songs depending on the season. During spring and summer in temperate forests, when more leaves are present and reverberation accumulates more rapidly with distance, Carolina wrens *Thryothorus ludovicianus* give territorial responses only to songs with more reverberation than during winter.

Acoustic Signals in Water

Sound propagates in water about 5 times faster than in air, in most natural conditions, and thus wavelengths for any frequency of sound are 5 times longer. As a consequence, reverberation in water results only from objects that are 5 times the size of objects that produce reverberation at similar frequencies in air. No studies have documented effects of reverberation on animals' signals in water. Excess attenuation as a result of molecular absorption also occurs much less rapidly with distance than in air. As a result, signal space is much greater in water. In addition, background sounds from farther away can effectively mask signals. One consequence is that human-generated sound, principally from ships' engines and propellers, pervades underwater habitats much more than it does terrestrial habitats.

A further complexity of sound in water, as a consequence of the longer wavelengths of sounds at audible frequencies, is the likely importance of wave guides. Any body of water less than a few tens of meters in depth might constitute a wave guide for sound. The practical consequences are reduced attenuation because of nonspherical spreading and dispersive transmission as a result of frequency-dependent speed of sound in wave guides. Dispersion alters the basic frequency–time structure of sound because a listener hears different frequencies in the source as they arrive at different times.

Although it is clear that sound is a major modality for communication by marine mammals, fish, and invertebrates, we know little about how transmission affects the structure of signals or responses to them. Because of the lower attenuation and longer wavelengths of sound in water, more communication occurs at ranges where spherical spreading dominates or even in the near field, where particle movement rather than pressure dominates. Nevertheless, there is evidence that some whales maintain communication over great distances in the oceans, distances at which frequency-dependent attenuation, reverberation, and dispersion during transmission could affect the structure of signals.

Visual and Olfactory Signals

Visual communication differs from acoustic communication because the source of the transmitted energy is not the signaler (except in the special cases of bioluminescence). Instead the signaler provides a surface that reflects light from the sun. Because sunlight can arrive either directly from the sun or indirectly from the atmosphere (the blue sky) and because it is also reflected and transmitted by any nearby objects, including vegetation, the light incident on a visual signal varies with the exact location of the signaler. Furthermore, the ability of a conspecific to detect a visual signal depends on its contrast with light reflected from the background as well as with diffuse

light scattered from particles in the atmosphere. In some cases at least, the colors of animals' signals, the places they choose to display these signals, and even their modifications of their immediate surroundings all serve to increase the contrast of signals with the background light as viewed by conspecific observers.

Because the wavelengths of visible light are so small in comparison with those of audible sound, reverberation and attenuation of visual signals over relatively short distances in the atmosphere are minor. Instead, the problem in environments with dense vegetation is assuring direct line-of-sight paths to the potential receiver. Indeed, animals communicating over large distances in the interiors of forests make little use of visual signals and correspondingly prominent use of acoustic signals.

In water, light attenuates much more rapidly than in air, and the frequency dependence within the visual spectrum is much more prominent. Long wavelengths of light attenuate more rapidly than short wavelengths, so that even at modest depths in water, red light is largely absent. Red objects near the surface appear black at depths of a few meters. Although many fish and other animals that live in relatively shallow water have conspicuous visual signals for communication, we know little about how these signals are perceived by conspecifics.

Olfactory communication often takes one of two extreme forms. Either a chemical, often one with low diffusion in the atmosphere, is deposited on the substrate to await an occasion when a receiver might pass nearby, or a chemical is released into the atmosphere for propagation by wind and diffusion to a distant receiver. Communication can thus occur over long distances in relatively short times, as in acoustic or visual communication, but also over long times but short distances. In both cases, environmental conditions affect the duration or distance of potential communication.

The dispersal of an odor in the atmosphere depends on both diffusion in the air and movement of the air. Because movement of air is turbulent, the process is complex. As a result of eddies in the atmosphere, the concentrations of an odorant at even a few meters from a source can vary substantially over distances of centimeters, a situation that complicates any calculation of the distance at which an odor can be detected by a receiver.

Errors and the Evolution of Communication

The attenuation and degradation of signals during transmission and the possibilities for masking by background energy make it clear that a signal rarely if ever arrives at its intended receiver in the form that it left the signaler. As much of the attenuation and degradation of signals and the generation of background energy depends on random turbulence and heterogeneities in the environment, every signal arrives at a receiver with some unpredictable properties. This situation raises the issue of errors in communication.

Signal detection and decision theory provide a way to understand the consequences of errors in communication. In these conceptualizations of communication, every time a receiver checks its receptors for a signal, there are four possible outcomes: a correct detection (if the receiver performs an appropriate response to the signal, one that in evolutionary terms tends to increase the spread of its genes in the population by increasing its survival or reproduction), a correct rejection (if the receiver fails to respond when there is in fact no signal present), a missed detection (if the receiver fails to respond when a signal is in fact present), and a false alarm (if the receiver responds when there is in fact no signal present). These four possibilities are the logically exhaustive set of two possibilities for response (present or absent) for each of two possibilities for the occurrence of a signal (present or absent).

Signal detection theory has had only minor application to animal communication so far, but its implications suggest that it should receive more attention. A fundamental insight is that, in realistic conditions, a receiver cannot simultaneously minimize its probability of false alarms and its probability of missed detections. Raising its threshold for response, for instance, reduces false alarms but also increases missed detections. Lowering its threshold for response has the opposite effects. Complex criteria for response likewise cannot avoid an inevitable trade-off between false alarms and missed detections. In the real world, a receiver cannot usually avoid errors. It can only adjust its criterion for response (either by evolution or by learning) to optimize its expected utility. The expected utility is a function of the probability that a signal will occur and the probabilities and the consequences of each of the four possible outcomes listed above.

An optimal threshold for response thus depends critically on the probabilities and consequences for errors. For instance, if false alarms are more costly than missed detections, then with all else equal, a high threshold would be optimal. Choosing a suitable mate might fit these conditions. In this case, an optimal receiver would behave as if it were choosy, often passing up suitable mates in order to avoid choosing an unsuitable one. This case can be called adaptive fastidiousness. As a consequence, signalers should evolve more exaggerated signals in order to surpass the high thresholds of optimal receivers. From the

perspective of signal detection theory, exaggeration and redundancy of signals evolve to increase the detectability of signals by fastidious receivers.

Alternatively, if missed detections are more costly than false alarms, then with all else equal, a low threshold would be optimal. Responding to alarm calls for predators might fit these conditions. In this case an optimal receiver would behave as if it were error-prone, often responding to false alarms in order to avoid missing an actual signal. This case can be called adaptive gullibility. As a consequence, some signalers might evolve deceptive signals to take advantage of the low thresholds of optimal receivers. There are several cases among primates and birds of such deceptive alarm calls that, for instance, occasionally allow a subordinate to scare a dominant away from food or a potential mate.

Conclusion

An understanding of the alteration and masking of signals as they pass from the signaler to the receiver is necessary for an understanding of evolutionary adaptations in communication. It is the possibility of error arising from the attenuation, degradation, and masking of signals that leads to predictions for the optimal behavior of receivers and thus for the optimal behavior of signalers.

Single Cell Electroporation

D Dunfield and K Haas, University of British Columbia, Vancouver, BC, Canada

© 2009 Elsevier Ltd. All rights reserved.

Single-cell electroporation (SCE) is a method for delivering DNA or other charged compounds to individual cells in dissociated culture or within intact tissues, including *in vivo* preparations. SCE can be used to simultaneously control expression of multiple genes within the same cell while leaving surrounding tissue unaltered, allowing the testing of the cell-autonomous effects of gene expression. SCE is particularly useful as a method to label neurons by introducing fluorescent dyes or DNA encoding fluorescent proteins, enabling morphological imaging.

SCE is a specialization of the general electroporation technique commonly used to transfect dissociated cells. Electroporation refers to the ability to permeabilize cell membranes by the application of an external electric field, and it is typically used in conjunction with the electrophoretic transfer of charged molecules, primarily DNA, into cells. Traditional electroporation employs an electric field generated between two flat plate electrodes on opposing sides of a solution containing both dissociated cells and the exogenous molecules to be delivered. An applied voltage between the electrodes induces movement of ions within the cells to membrane regions adjacent to the electrodes, creating localized increases in transmembrane potential. When the transmembrane potential reaches a critical point of approximately 0.5 V, the electrostatic forces maintaining the lipid bilayer integrity break down to form water-permeable pores. Charged molecules in the external medium are moved by the applied field and enter cells through these open pores. On termination of the field, pores remain open for tens to hundreds of milliseconds before collapsing to reestablish a contiguous lipid bilayer, trapping exogenous molecules within the cells. Electroporation is a versatile technique applicable to the delivery of a wide range of charged molecules relevant to research and medicine, including DNA, RNA, oligonucleotides for antisense knockdown, peptides, proteins, antibodies, dyes, and drugs. Furthermore, electroporation lacks cell type or maturational stage restrictions, has no residual transfer agents, and can be used to simultaneously co-deliver multiple compounds or genes.

More recently, electroporation has been applied to the delivery of DNA and other compounds to cells within intact tissues, including the skin, muscle, testis, spinal cord, retina, and brain. Efforts have been made to control the extent of electroporation by focally applying the delivery molecules or using smaller electrodes. The ability to restrict electroporation to an individual cell within an intact tissue represents the culmination of this effort. The SCE technique uses a pulled-glass pipette electrode with tip area approximately two to three orders of magnitude smaller than the surface area of a cell body to target electroporation to an individual cell by restricting the electric field and concentrating molecular delivery. The pipette is filled with a solution containing the delivery compound, and electrical stimulation is generated between a wire inserted into the pipette in contact with the delivery solution and a second external electrode placed in electrotonic contact with the preparation. The pipette and preparation electrodes are connected to a standard voltage source capable of generating stimulation parameters appropriate for SCE tranfection or molecular loading. Once the pipette tip is positioned in contact with a target cell, electrical stimulation induces membrane permeation near the tip and causes the delivery of charged compounds from the pipette solution through these pores and into the cell. Following the termination of the electric stimulation, the pores reseal, the pipette is retracted, and the delivery compounds are sequestered within the target cell.

Single-Cell Electroporation Pipettes – Electrodynamics

The physical geometry of the SCE pipette directly affects the amplitude and spatial distribution of the generated electric field, dramatically influencing the success of SCE. The field strength at the tip increases steeply with decreased tip diameter and increased taper angle (**Figures 1(c)** and **2(a)**). Pipette tips that have been found to be most effective for SCE have tip diameters in the range of 0.5–1 μm and taper angles greater than 10°. **Figures 1(a)** and **1(b)** show electron micrograph pictures of an SCE pipette tip of the type used for transfecting neurons within the intact *Xenopus laevis* tadpole brain, as shown in **Figures 3** and **4**. We have modeled the electric field a few micrometers within and outside of these pipettes using finite element analysis (**Figures 1(d)** and **1(e)**). These models predict that the field produced is nonuniform, with the field strength gradually increasing within the pipette toward the tip. External to the tip, the field

In (c), R_0 is the radius of the tip opening and θ is the cone angle of the inner wall of the pipette. In (d), the diagram represents a cross section through one-half of the pipette tip, which is represented in gray on the lower right-hand side of the figure. In (e), the color code represents the amplitude of field strength and the arrows indicate the direction of the field. FEA, finite element analysis; SCE, single-cell electroporation.

Figure 2 Electric fields and voltage potentials for various pipettes: (a) electric field along the pipette axis out of the pipette away from the tip; (b) voltage potential along the pipette axis out of the pipette away from the tip. As shown in (a), the electric fields drop off as second-order exponential decay curves. Pipette B is a typical SCE micropipette. SCE, single-cell electroporation.

strength peaks directly outside but then rapidly decays as a second-order exponential, which explains the ability of SCE to restrict transfection to individual cells within intact tissues.

The strong effect of tip aperture on SCE success is due to the varying strengths and spatial distributions of the electric fields and voltages generated by pipettes of different sizes. For a given applied voltage, as tip aperture diameter increases, the electric field strength at the tip gets weaker and broader. Although the function is not perfectly linear, doubling the aperture diameter requires approximately tripling the applied voltage to achieve the same field strength just outside the tip opening (Figure 2(a)). The decay constant for the exponential fall-off of the electric field outside the pipette tip increases as the aperture diameter increases. Because the voltage potential of an exponentially decaying electric field is the product of the electric field and the reciprocal of its decay constant (Gauss's law), the potential drop in response to the same applied voltage becomes smaller as tip aperture increases (Figure 2(b)). Therefore, as the pipette diameter increases, higher voltages are required to induce the threshold transmembrane potentials required for poration. Nonetheless, matching the electric field strength at the tip openings of two pipettes with differing aperture sizes by increasing the voltage applied to the larger pipette will not result in the same electroporation effects (Figure 2(b)). The

distance over which the potential drop occurs is greater for larger tips and higher voltages, producing a broader spatial distribution for cells to be affected. The spatial distribution of cells affected by a pipette tip with twice the diameter of a standard SCE pipette will be 2–3 times larger. Therefore, small tips are better able to generate the tip voltage amplitudes required to induce pore formation while restricting poration to a target cell. Larger tips either generate a low-amplitude voltage insufficient for poration or electroporate a cluster of cells.

The choice of pipette tip shapes must also take into account preparation-specific considerations involving interactions with tissue, clogging, and tip strength. Although tips with wide-tapered angles and small tip apertures are optimal for SCE, wider-tapered angles produce more displacement when inserted into intact tissues. Clogging is more common as the tip diameter and taper angle decrease and can arise from particles within the pipette solution or the accumulation of debris from the preparation. To reduce internal clogging, pipette solutions should be centrifuged at high speeds to remove contaminants. In especially sticky preparations, such as organotypic slice cultures, the application of positive pressure to the pipette can help counter clogging from external tissue. If significant layers of tissue, such as skin, must be penetrated, then increasing the tip strength by increasing the taper angle will help prevent breaking.

Single-Cell Electroporation Currents

Another critical component of SCE is the behavior of the specific charged molecules to be delivered when they are exposed to the electric fields in SCE pipette tips. Three major forces influence the movements of ions within the SCE pipette: electroosmotic flow, electrophoresis, and dielectrophoresis. Electroosmotic flow refers to the movement of liquids when a voltage is applied to an ionic fluid within a narrow glass tube. In the case of SCE, which uses common borosilicate glass, negative charges are adsorbed onto the glass surface, leaving behind a layer of positive ions (the Debeye layer), which is pulled toward the negative electrode with the application of the electric field. The motion of the Debye layer is transmitted to the rest of the fluid by friction. Electrophoretic flow is caused by the attraction or repulsion of charged ions within solutions by the oppositely charged electrodes. Dielectrophoresis occurs when particles within a solution are subjected to a nonuniform electric field and is dependent on the product of the scalar electric field and its gradient. The dielectrophoretic force affects all particles, independent of their charge, but has a strong dependence on the particles' size, shape, and chemical makeup. In the case of an SCE pipette, dielectrophoresis results in a nonlinear force from the pipette regardless of the polarity of the applied voltage. In most SCE experiments, it is expected that electrophoretic flow will be larger than the electroosmotic flow because the delivery compound will consist of a high salt concentration at a neutral of physiological pH at which the electroosmotic flow is known to be low.

Single-Cell Electroporation Pore Formation

Our current understanding of the process of SCE-mediated poration is incomplete. The creation and evolution of pores in plasma membranes induced by electric fields have been extensively modeled. However, these models, largely based on the Smoluchowski equation, may have only partial relevance to SCE because they typically describe entire cells within a relatively large and uniform electric field. During SCE, only a discrete area of the cell membrane is exposed to the applied field because the micropipette tip is relatively small (0.5–1 μm in diameter) compared to the size of neuronal somata (approximately 10–50 μm in diameter) and the applied potential is negligible, less than 1 μm outside the tip opening (**Figure 2(b)**).

Therefore, recent attempts to mathematically describe the effects of a locally applied field to a patch of membrane may be more applicable to SCE. These models describe electroporation as a multistep process initiated when exposure to an external electric field induces a sufficient transmembrane potential to overcome the electrostatic forces maintaining the lipid bilayer, inducing membrane breakdown and the formation of water wires that penetrate the lipid bilayer. The number of pores initially formed is controlled by the membrane voltage achieved, with the number of pores increasing exponentially with increasing voltage amplitude. The majority of the minute hydrophobic breaks in the lipid bilayer are rapidly destroyed by lipid fluctuations, but a small proportion continues to expand. Once growing pores exceed a radius of approximately 0.5 nm, the fatty acids of the lipid bilayer reconfigure, forming a more stable configuration with acyl groups lining the pore to create a hydrophilic channel. Membrane potential and membrane tension initially promote pore creation and expansion, but as relative pore area increases, membrane potential and tension decrease,

eventually leading to the cessation of pore growth. Therefore, initial pore density contributes to the size to which pores expand. Thus, high voltages produce numerous pores that remain small, and low voltages produce few pores with greater expansion. Because of the addition of effective tension into these membrane patch models, these findings are in contrast with previous theoretic results, which predict that high voltages create larger pores which expand rapidly, sometimes beyond the point where electroporation becomes irreversible. On termination of the voltage pulses, the pores shrink and collapse to reform the lipid bilayer by lipid fluctuations. However, if pore growth is unchecked, the pores reach a diameter at which they are unable to reverse expansion, leading to cell lysis and death. Further modeling studies predict that a second pulse delivered at short intervals changes the pores' parameters generated by the first pulse and that, by modulating the amplitude of the second pulse and interpulse interval, pore size and stability can be controlled.

Single-Cell Electroporation for DNA and Dyes

Here, we review the design of SCE stimulation parameters for the delivery of two commonly used, but disparate, compounds: plasmid DNA and dextran conjugates of fluorescent dyes. As expected from the theoretical models, different electrical stimuli are required for SCE of compounds of different charges and sizes. SCE-mediated DNA transfection is particularly challenging due to the large size of typical supercoiled plasmid expression vectors, which are often greater than 4 kb and estimated to have effective radii of 5–9 nm. Furthermore, successful transfection probably requires that DNA be delivered to the nucleus for transcription. Much debate has centered on the precise mechanisms by which DNA translocates across the plasma and nuclear membranes given the relatively large size of DNA and the small pores produced by electroporation. Using models designed for focal membrane poration, Smith et al. suggest that the formation of pores sufficiently large for DNA yet small enough to reseal can occur within a limited voltage range and that repeated pulses improve the stabilization of pores appropriate for DNA transfer. Given that DNA is strongly negatively charged, the pipette wire is typically connected to the negative pole of the voltage source and the external preparation electrode is connected to the positive pole. The application of voltage pulses induces DNA to be repelled by the pipette electrode and attracted to the external electrode. In this case, electroosmosis is negligible, and electrophoresis and dielectrophoresis drive DNA out of the pipette. However, DNA expulsion from micropipettes and DNA transfection have also been demonstrated by reversing the polarity of the voltage field to induce a phenomenon termed trapping. In this case, voltage pulses induce the electroosmostic and electrophorestic flow of DNA away from the pipette tip and back into the shaft, whereas dielectric flow remains directed out of the pipette. Near the tip, the dielectrophoretic force is slightly greater than the opposing forces, causing DNA to concentrate and become trapped. When the voltage pulse ends and the pipette field collapses, the dielectrophoretic force overwhelms electroosmosis and electrophoresis, resulting in brief ejection of a high concentration of DNA from the tip. Trapping from micropipettes has been employed for controlled DNA deposition, as well as for loading cells. The use of SCE for DNA transfection has been applied to cells in dissociated cultures, neurons in organotypic brain slice cultures, and neurons within the intact brain (**Figures 3 and 4(a)**). One of the advantages of SCE for DNA is the ability to co-deliver multiple plasmids expressing different genes to the same cell. Optimal tip diameters for SCE-mediated DNA transfection range from 0.5 to 1 μm. Reports vary, however, on the concentration of DNA required and whether additional salts in the pipette solution contribute to SCE success of cell viability. Some groups use low DNA concentrations (0.2–33 ng μl^{-1}) dissolved in saline solutions; we use DNA concentrations of 1–2 μg μl^{-1} diluted in dH_2O because no effect of additional salts was observed. Groups agree on the general stimulation parameters that yield the highest SCE transfection efficiencies: brief high-frequency trains of short pulses. For *in vivo* SCE of neurons in the *Xenopus laevis* tadpole brain (see **Figures 3 and 4(a)**), using pipettes with tip diameters of 0.5–1 μm and resistances of 20–40 MΩ, typical stimulation parameters include a DNA concentration of 1–2 μg μl^{-1} dissolved in dH_2O; 500-ms-long trains of 1-ms square pulses delivered at 200 Hz and 25–50 V; and a current of 1–2 μA.

A second type of commonly electroporated compounds are dyes (**Figure 4**), such as dextran-conjugated fluorescent dyes (Molecular Probes, Eugene, OR). The same SCE pipettes effective for DNA loading are effective for the SCE of dyes. In contrast to DNA, these dyes are small, readily pass through minute pores, and need to cross only the plasma membrane. The ease of passing through minute pores and the rapid movement of charged dyes in electric fields make it challenging to load an individual cell with

sufficient dye for complete filling of neuronal processes without also labeling neighboring cells. A solution to this problem is to use a high concentration of dye and brief high-voltage stimuli. High voltages induce many small pores and brief high voltage delivers a discrete concentrated bolus of dye only to the cell at the SCE pipette tip. The great advantage of loading neurons with dyes over SCE-mediated DNA transfection, which has a 4- to 12-h lag in the detection of the exogenous fluorescent protein, is that dye loading allows direct and immediate feedback on SCE success. Direct visualization of SCE using fluorescent microscopy allows the researcher to rapidly test a range of stimulation parameters for optimal SCE. We recommend the use of either single square pulses or brief trains of short (1-ms) pulses lasting 10–50 ms. By adjusting both the voltage amplitude and pulse or train duration while examining cell loading, the researcher can rapidly determine the parameters that brightly label but restrict labeling to single neurons. Both positive and negative polarity should be tested for any new dye because the effective charge and contribution of dielectrophoresis and electroosmosis forces may counter expected movement. It is best to fine-tune the stimulation parameters for each pipette by direct fluorescence observation of loading. However, given the phototoxic effects of fluorescent excitation, once the optimal parameters are determined, subsequent loading should be performed without fluorescent illumination. Neurons can be checked for complete loading of neuronal processes 10–30 min following SCE. SCE-mediated dye loading is a rapid and effective method for dye loading neurons for morphological imaging and for testing the quality of SCE pipettes to be used for DNA transfection. Although different stimulation parameters are required, pipette tips that function well for SCE-mediated dye loading work well for DNA transfection.

There are two approaches to carrying out SCE: blind and direct visualization of the target cells. The blind approach is useful in preparations such as the hippocampal brain slice and the *in vivo* tadpole brain (Figure 3) in which regions containing target neurons can be readily determined using low-magnification long-working-distance microscopy. In these conditions, the SCE pipette can be inserted into these regions and the stimuli applied without directly observing tip–cell contact. Although incorrect tip–cell interactions probably contribute significantly to SCE failure and lower efficiency, the long working distance and ability to reuse the same tip allow the rapid repositioning of the pipette tip to multiple sites within the same preparation. An alternative approach is to use high-magnification microscopy to directly visualize SCE tip–cell contact. Although the shorter working distances inherent in such systems restrict the rapid targeting of many sites, visualization has been shown to greatly improve SCE efficiency.

Long-Term Effects of Single-Cell Electroporation on Neurons

An important consideration for applying electroporation to neural tissue is the long-term effects induced by transient membrane breakdown. A number of studies using morphological and electrophysiological methods have detected no lasting effects on neuronal growth or neuronal function. Whole-cell patch clamp recordings of neurons 24 h following SCE transfection found no alterations in resting membrane potential, characteristics of action potential discharge, or evoked Ca^{2+} transients. Neurons in culture transfected using a similar electroporation method (microporation) also found no effects on electrophysiological measures, including synaptic transmission. *In vivo* time-lapse imaging of the growth of developing neurons within the *Xenopus laevis* tadpole brain, considered a sensitive measure of altered neuronal function, found no differences in dynamic growth between neurons transfected by SCE and those labeled with DiI. Furthermore, the expression of fluorescent proteins can be seen for up to 2 weeks in slice cultures and 3 weeks *in vivo* following SCE, the longest we have examined, suggesting continued neuronal health.

Summary

SCE is a timely advance in the technology for controlled compound delivery and gene expression for determining the roles of specific proteins in neuronal growth and function. Recent advances in genomic sequencing and gene discovery have created a bottleneck of orphan genes whose functions are poorly understood or unknown. At the same time, there have been tremendous advances in the development of dyes and molecular biology tools, such as RNAi, peptide inhibitors, and genetically encoded constructs, including fluorescent-tagged proteins and fluorescence resonance energy transfer (FRET) compounds. The effective application of these tools is limited by our ability to control their delivery to appropriate cells. SCE offers the unprecedented ability to direct these tools to individual neurons within intact tissues. Significantly, such targeted manipulation leaves the remaining tissue unaltered, so any effects observed are not caused by the secondary alteration of the target cell's environment.

Single Cell Genomic DNA Analysis

P B Crino, University of Pennsylvania Medical Center, Philadelphia, PA, USA

The use of human brain tissue for basic and disease-based research has rapidly expanded over the past decade. Tissue resected during tumor or epilepsy surgery or obtained postmortem from patients with a variety of neurological or psychiatric diseases can provide a new window for viewing the cellular processes that are involved in disease pathogenesis, and our understanding of many human brain disorders has been greatly facilitated by human tissue studies. In addition, many fundamental neurobiological processes that are well defined in rodent systems can also be studied in frozen or fixed human brain tissue. Perhaps most exciting, however, is that new experimental methodologies to extract genomic DNA from archival tissue samples now permit an in-depth analysis of the molecular mechanisms and genetic causes of virtually any inherited or sporadic neuropsychiatric syndrome. With the advent of tissue microdissection, an even finer experimental resolution can be gained, so gene sequence alterations can be defined in select cell populations. There are new protocols and optimization procedures to assay DNA sequences in human brain tissue that are now widely available.

Why Evaluate DNA Sequences in Human Brain Tissue?

For many neurological and psychiatric disorders, there is little, if any, evidence for genetic or Mendelian inheritance patterns. For example, epilepsy, schizophrenia, autism, sporadic brain tumors, developmental malformations, and vascular abnormalities often occur as sporadic disorders without a clear family history. Thus, the only plausible genetic or molecular mechanism to account for these disorders is a *de novo,* rather than inherited, gene mutation. From an experimental perspective, these disorders provide a significant challenge because large family pedigrees or even monozygotic twins are unlikely to yield insights. Perhaps even more challenging is that brain structure in many sporadic neuropsychiatric disorders is intact and thus morphological analysis may not be helpful.

One interesting hypothesis is that sporadic neurological disorders may in some cases result from somatic mutations occurring in brain progenitor cells but that are not present in the germline DNA. In this scenario, a deleterious gene mutation might occur during the many rounds of cellular mitosis occurring throughout the course of brain development or perhaps within a progenitor cell in the mature brain. There is extensive evidence in the brain tumor literature that somatic mutational events are commonly detected in genes such as EGFR, KIT, and PDGFR in brain tumor tissues. Furthermore, large heterozygous gene deletions in chromosomes 1 and 19 have been detected in tumors and often correlate with clinical variables such as survival. Thus, studies sequencing genomic DNA from resected or postmortem brain tissue specimens may aid in identifying somatic mutations that are confined to small regions of the brain but cannot be identified in peripheral blood (Figure 1). Furthermore, because the gene mutation may affect only a subset of cells within a given brain region, the ability to sequence DNA from phenotypically defined cell populations is a powerful approach.

Cataloging Tissue

Most human brain tissue used in research is obtained either directly from a neurosurgeon in the operating room, through a pathologist, or from an existing tissue bank. In view of the Health Insurance Portability and Accountability Act (HIPAA) regulations on the security of electronic healthcare information, it is of the utmost importance to maintain patient confidentiality in human research. Unless specific phenotypic parameters are under investigation, investigators must avoid including patient-identifying information in their research publications. It should be noted that birth dates, social security numbers, medical record numbers, and pathology/autopsy numbers are considered patient identifiers and thus cannot be used to label tissue in the laboratory. Nonetheless, it remains imperative for researchers to have some ability to track samples for a variety of reasons such as collaboration, phenotypic analysis, and requests for more tissue, and thus a system should be designed for tissue identification and storage of necessary patient information. One strategy is to assign each tissue sample a lab-specific number or label so that no member of the lab can identify the source of the sample. A separate strictly confidential database (for example, in Excel) of information for each specimen is maintained (in duplicate) in a password-protected limited-access file. Thus, an investigator can maintain tissue identity for research purposes but protect patient confidentiality. Prior to investigators' embarking on human tissue research, we strongly suggest that investigators meet with

Figure 1 Schematic representation of how a somatic mutation could affect a focal brain region. In this scenario, a small brain area (depicted in green) contains cells that have sustained a mutation during brain development (e.g., a malformation) or after maturity (e.g., a brain tumor). The altered morphology (brain lesion) can harbor a causative gene mutation (DNA sequence) that can be detected only by an analysis of DNA extracted from that brain area. Note that the mutation is not detectable in cells outside the brain lesion.

appropriate protocol personnel at their home institutions to assure complete compliance with the standards for human tissue research.

Tissue Fixation and Storage

A common myth is that resected tissue used for molecular analysis must be kept frozen or used immediately after removal. Although it is true that frozen tissue yields high-quality mRNA or DNA, paraformaldehyde- or formalin-fixed paraffin-embedded (FFPE) tissue can be used for both DNA and mRNA analysis. As a general rule, frozen tissue is exquisitely sensitive to transient rises in temperature. Even 10–20° changes can lead to mRNA and protein degradation over time. Frozen tissue should be maintained at –70 °C in a frost-controlled freezer. The freezer should have a backup power source with an alarm system should the internal temperature rise above –50 °C. Contact people and appropriate information should be displayed prominently near the freezer in case of emergencies. A backup freezer should be identified in a nearby lab to prevent loss of tissue in case the power should fail. Perhaps the most optimal situation for tissue analysis is to obtain both fresh-frozen and fixed material, although this may pose logistical procurement problems because specimens must typically be analyzed by a neuropathologist prior to experimental analysis. The use of fixed tissue has particular appeal because molecular analysis can be combined with tissue immunohistochemistry to define, for example, protein expression or to use protein expression as a phenotypic marker for cell-specific DNA analysis. In addition, it is often much easier to obtain archival FFPE pathological material stored than fresh-frozen tissue.

Investigators may have little control over the selection of tissue fixatives by pathologists. In most cases, fixation for pathological preparation uses paraformaldehyde or 10% neutral buffered formalin. These protein cross-linking fixatives afford excellent protein fixation, but paraformaldehyde can compromise the successful extraction of nucleic acids. Boiun's fixative is occasionally used; it combines picric acid with formalin and is very stringent. In general, most labs avoid using Bouin's fixed tissue for nucleic acid work. Ethanols are denaturing fixatives and thus do not pose significant problems for nucleic acid extraction. Carnoy's fixative and 10% neutral buffered formalin do not appear to compromise DNA extraction. Some recent studies have shown that the fixative methacarn yields highly successful amplification of long DNA stretches extracted from FFPE.

In general, for small blocks of tissue (less than 2 cm^3), a fixation period of 2–3 weeks may be effective, whereas for larger blocks or for whole brains or hemispheres several more weeks are necessary. One question that arises is whether there is a fixation time after which DNA or mRNA cannot be extracted from fixed tissue. There is no definite answer to this question; in general, an initial failure to recover DNA can often be overcome by the manipulation of various protocols. There is reasonable evidence that DNA extracted from tissue stored for long periods may fragment, leading to small or short sequences that can prove problematic for sequencing studies. DNA fragmentation becomes an issue when longer sequences are needed to define gene mutations or polymorphisms or when DNA is used to probe array platforms such as single nucleotide polymorphism (SNP) arrays. Paraffin blocks should be kept in cool, dark, dust-free boxes. However, DNA is a stable biomolecule, and thus its breakdown is unlikely even in fixed, paraffin-embedded tissue blocks. Our lab has sequenced through several genes including *PTEN*, *TSC1*, and *TSC2* in genomic DNA extracted from paraffin-embedded tissue blocks stored for up to 5 years, and reports in the literature cite successful polymerase chain reaction (PCR) amplification of DNA extracted from brain tissue stored for up to 30 years.

Work Environment

In contrast to mRNA analysis, DNA degradation is uncommon due to lab practices. However, all glassware should be autoclave sterilized and fresh

Figure 2 Microdissection of cells and DNA extraction and sequencing: (a) microdissection of multiple single cells (arrows); (b) pooling of microdissected cells; (c) DNA extraction (agarose gel; arrow depicts PCR amplicon); (d) sequencing of the band for mutation or polymorphism detection using specific DNA primers. PCR, polymerase chain reaction.

plasticware should be used to avoid contamination. Fresh tissue and frozen unfixed tissues should be treated as potentially infectious, and thus universal precautions (gloves, eye protection, and lab coat) should be implemented. Although fixation of human tissue largely inactivates most pathogens (e.g., HIV and hepatitis B and C), universal precautions for everyday work with fixed human tissue should be implemented. It is useful to know or ascertain the HIV and hepatitis serology status in the patient samples, and these data are usually available if the tissue is procured from existing tissue banks. For those working on surgical specimens associated with known human pathogens, communication with institutional safety offices is requisite to ensure safe practices for all lab staff. Transmissible spongiform encephalopathies are a particularly serious risk when working with human brain tissue. Even though it is believed that formalin fixation at least diminishes the risk of lab-related transmission of spongiform encephalopathy, utmost care must be taken to protect lab personnel. As a general practice, gloves must be worn for every instance of contact with human brain tissue, whether it is during microtome sectioning, transfer of slides, or immunohistochemistry. Investigators should review their own institutional policies on working with human tissues and pathogens prior to embarking on human tissue research.

Microdissection of Single Cells

Single cells (e.g., neurons, astrocytes, and endothelial cells) can be microdissected from either frozen or FFPE brain tissue with good success. It is up to the investigator's discretion to determine how cells will be grouped (e.g., morphology, age, laminar location, or protein expression). Although individual cells can be recognized by phase-contrast microscopy or by simple cresyl violet labeling, perhaps a more elegant method for visualizing cells is with immunohistochemistry. In this way, individual cells can be phenotyped on the basis of protein expression. For both frozen and fixed tissue, immunohistochemistry provides a reliable strategy for identifying classes of cells, either by fluorescence or by diaminobenzidine visualization.

The technical feat of microdissection can be accomplished by a single joystick-driven micromanipulator system or by a laser-capture microdissection system. In the former approach, a stainless steel microscalpel can be used to remove single cells under light microscopy; microdissected cells can then be pooled for DNA extraction. In the latter approach, multiple cells can be removed by laser capture and thereby provide a more rapid means of attaining adequate concentrations of DNA for analysis (Figure 2).

Extraction of Genomic DNA

There are several commercially available kits for DNA extraction that use proprietary reagents and buffer systems. These can be applied to whole tissue blocks and to single sections. For example, the Trizol reagent provides a means of simultaneously extracting DNA, mRNA, and protein from a single fixed or

frozen tissue block, but does not work well for single microdissected cells from FFPE tissue.

One protocol that provides high-quality DNA from FFPE tissue sections or blocks is the following. The sections are first rehydated through xylenes and graded ethanols. The cells are digested in a digestion buffer (NaCl 0.1 M, Tris–Hcl 0.01 M, EDTA 0.025 M, SDS 0.5%) overnight at 55 °C. Then, cells are treated with Proteinase K ($20\,mg\,ml^{-1}$) to reverse cross-linking fixation and permit more effective DNA extraction. Following Proteinase K, the sample is extracted in phenol-chloroform-isopropyl alcohol. The DNA is then extracted with ammonium acetate (7.5 M)/glycogen. The extracted DNA is then assessed by an optical density (OD) measurement to determine its concentration and purity and assessed by agarose gel analysis to determine the size of extracted products.

Single-cell DNA extraction requires a bit more technical expertise and specific protocols. In particular, companies (e.g., Arcturus) that make laser-capture microdissection systems also provide proprietary kits for extracting genomic DNA from single pooled cells. These generally work well for most applications. It is implied that for most single-cell DNA work, an amplification procedure such as PCR will be necessary to screen for mutations. Alternatively, several new whole-genome amplification kits exist that can adequately enhance the copy number of large numbers of genes. DNA extracted from paraffin-embedded tissue can be used for DNA sequencing and as a probe for SNP arrays. As already discussed, immunolabeling aids in identifying cells for dissection. In our lab, we use immunohistochemistry and visualize antibody labeling with the avidin-biotin-diaminobenzidine approach. It is recommended that multiple cells be dissected and pooled for analysis. For most applications, the isolation of DNA from 50 to 200 cells provides adequate template DNA for PCR analysis, although in high-quality tissue samples 20–50 cells may be adequate.

Applications of Genomic DNA Analysis in the Brain

Analysis of genomic DNA provides a unique opportunity to study gene sequences in human tissue. For example, in monogenic disorders, if the genotype of a particular patient is unknown, it can be determined by direct sequencing of the candidate gene in genomic DNA from a brain tissue specimen. Gene sequencing in brain DNA can define mutations or polymorphisms as easily as in peripheral blood DNA. Indeed, reliable and reproducible results can be determined with published DNA sequence primers for most genes. Sequencing of DNA extracted from brain tissue also has a unique application – the detection of somatic gene mutations that cannot be otherwise detected in the blood. For example, there is good evidence that a variety of brain malformations (e.g., vascular malformations) and tumors result from somatic, not germline, gene mutations. In these disorders, the putative molecular mechanism is that mutations occurred not as inherited or meiotic events but rather in progenitor cells during brain development. For some glial-derived tumors, there is evidence that an accumulation of mutations in multiple sites occurs as the lesions progress. Thus, screening DNA extracted from brain tissue provides a new and high-yield strategy for studying the molecular pathogenesis of these disorders. Note that labs must meet Clinical Laboratory Improvement Amendments (CLIA)-directed regulatory requirements; if not, the genetic screening results cannot be communicated to the patient or family member, nor can it be used for clinical practice, decision making, or counseling.

Although there have been a growing number of studies that assay DNA sequence alterations in human brain tissue, especially in brain tumor specimens, there have been only a few recent studies that have used single-cell DNA analysis in human brain tissue. In an initial analysis, sequencing of the TSC1 and TSC2 genes was accomplished in human tuberous sclerosis complex. A compelling study demonstrated the feasibility of performing loss of heterozygosity (LOH) and microsatellite instability assays in human brain malformations. *In silico* high-throughput sequencing was accomplished in microdissected cells in ganglioglioma, a congenital brain tumor. An analysis of genomic DNA from microdissected single cells demonstrated an intact gene sequence and several potentially significant polymorphisms in the PTEN gene in focal brain malformations associated with epilepsy. Similarly, the β-catenin gene was sequenced in human hemimegalencephaly, a brain malformation characterized by unilateral hemispheric enlargement and associated with severe seizures.

If adequate template DNA is extracted, there is no limit to the potential technical applications. For example, in addition to gene sequencing, analysis of SNP arrays to search for heterozygous or homozygous deletions can be accomplished. Alternative techniques include LOH and muliplex ligation product amplification (MLPA) assays. Recent studies have shown that single-strand conformation polymorphism analysis (SSPA) can be used in microdissected tissue specimens to identify gene mutations. Array-based comparative genome

hybridization (aCGH) is a high-throughput strategy for detecting deletions in candidate gene regions. This approach has been successfully implemented in FFPE brain tumor specimens.

Single Cell mRNA Analysis Using *In Situ* Hybridization

In situ hybridization was the first technique developed to detect target mRNAs in individual cells. It simply involves the hybridization of a labeled RNA or single-stranded DNA probe with a specific target nucleic acid (RNA or genomic DNA) within a cell. The initial *in situ* hybridization experiments were performed to detect DNA and ribosomal RNA in individual cells. This technique was later used to map the locations of particular genes on chromosomes. This procedure has been successfully used to analyze mRNA expression at cellular and subcellular levels in several different sample preparations – tissue sections, cultured cells, or intact whole mounted tissues. Studies in the nervous system frequently enhanced this procedure by performing *in situ* hybridization in combination with immunocytochemistry. This approach can be used to detect mRNAs in immunocytochemically defined cell types and also determine subcellular localization of the mRNAs and their corresponding protein products. The main limitations of the *in situ* hybridization technique are that only a small number of mRNAs within the same cell can be analyzed, it lacks the sensitivity to detect low-abundance mRNA transcripts and correlating functional properties, and the mRNA expression profiles within the same neuron are experimentally challenging. Therefore, this approach is not always the best option for studies using neuronal tissues. The main advantages of using *in situ* hybridization are that technically it is the simplest single cell mRNA analysis procedure to perform and this technique can be used to quantitatively analyze mRNA levels in single cells.

General Considerations for mRNA Analysis by *In Situ* Hybridization

The primary precautions that need to be taken when analyzing mRNA expression by *in situ* hybridization are essentially high-quality general lab practices. Gloves need to be worn when handling the samples and reagents to avoid contamination by RNA-degrading enzymes. All solutions, reagents, glassware, and dissecting instruments need to be prepared RNAase-free and preferably designated for RNA or *in situ* hybridization work only. As an extra precaution, all the final working solutions can be filtered through 0.2-μm filters before use and a high-grade fixative, such as electron microscopy grade paraformaldehyde, should be used for cell fixation. Fundamentally, successful *in situ* hybridization experiments depend on designing high-quality gene-specific probes and stringent hybridization conditions. The probe sequence should be checked in BLAST search to confirm specificity to target mRNA. Depending on the target mRNA, the probe length will most likely range between 100 and 1000 bp. This probe size range has three important advantages: (1) It allows efficient access to the cellular mRNAs; (2) it is sufficient in length for highly specific probe target mRNA hybridization; and (3) it is an adequate length for visualization detection. A stringent hybridization temperature ranges between ~37 and 50 °C. Finally, depending on the abundance of target mRNA, the probe concentration is usually between 0.1 and 10 ng μl^{-1}. One potential pitfall to consider when using the *in situ* hybridization procedure is the obscuring of the mRNA target sequence by a secondary RNA structure or association with RNA-binding proteins. Generating multiple probes to the same target mRNA is a simple approach to solving this problem.

Subcellular mRNA Analysis Using *In Situ* Hybridization

In the nervous system, cell-specific gene expression provides a potent mechanism for altering the properties of individual neurons. Neurons can be regulated to modify the expression profile and ultimately their functional properties by limiting specific mRNAs to different cellular compartments of a neuron. Cell-specific mRNA expression coupled with mRNA localization provides a neuron with a highly sophisticated focal mechanism to regulate the functional properties of neurons and regulate synaptic transmission. *In situ* hybridization is the best procedure to analyze subcellular mRNA expression patterns. For example, the Arg 3.1 gene encodes activity-regulated cytoskeleton-associated protein and the mRNA for Arg 3.1 is rapidly transported to the dendrites of cortical neurons in an activity-dependent manner. The *in situ* hybridization procedure was used to demonstrate the selective transport and localization of Arg 3.1 to active synapses in dendrites required for the activation of the glutamatergic NMDA receptors. *In situ* hybridization has also been used in combination with transgenic mice to correlate the disruption of subcellular mRNA expression patterns in the absence of the

RNA-binding protein, FMRP (fragile X mental retardation-1). *In situ* hybridization analysis of neurons from *Fmr1* knockout mice showed changes in the subcellular distribution of several known FMRP cargo mRNAs.

Single Cell Reverse-Transcriptase Polymerase Chain Reaction

Several studies have successfully used the polymerase chain reaction to analyze mRNA from single cells. This technique greatly increases sensitivity and the number of RNAs that can be analyzed in a single cell. The first studies to use single cell reverse-transcriptase polymerase chain reaction (scRT-PCR) demonstrated mRNAs encoding different glutamate receptor subunits, and these were present at various abundances in single neurons. Because of the sensitivity and versatility of the procedure, scRT-PCR was the first method to correlate molecular analysis at the single cell level with electrophysiological responsiveness in neurons. For splice variant analysis at the single cell level, scRT-PCR is usually the best approach compared to amplified antisense RNA amplification (aRNA) and *in situ* hybridization. The population of RNA products generated by aRNA amplification limits its use for splice variant analysis to the 3′ region of mRNAs. *In situ* hybridization lacks the sensitivity to detect low-abundance splice variants and probe design could be problematic when creating splice variant-specific probes. All of these limitations are overcome by using the scRT-PCR approach. Primers can be designed to amplify any region of the mRNA, and splice variants that differ in only a single based can be separated on high-resolution gels. However, unlike aRNA amplification and *in situ* hybridization, scRT-PCR is an exponential amplification so quantification of mRNA levels is challenging. Another potential limitation is designing high-efficiency PCR primers for mRNA or a specific region of the mRNA of interest. The sequence of the target mRNA must be known and the region of interest must not be overly G–C rich to permit the placement of high-quality PCR primers in the appropriate region of the target mRNA.

General Considerations for mRNA Analysis by Single Cell RT-PCR

Different precautions need to be taken when analyzing genes at the cellular level compared to whole tissue RT-PCR analysis. When making cDNA from single cells, one of the main concerns is preventing the small amount of mRNAs from degrading. Therefore, some type of RNase inhibitor must be used during the cDNA synthesis reaction. To optimize the single cell cDNA synthesis reaction and to make the protocol more cost-efficient, the reverse transcription reaction should be downscaled to levels more appropriate to single cells. To ensure primer specificity, the primer sequences should be checked by BLAST search in GenBank to confirm specificity for the target gene. The PCR primers should be placed on different exons to avoid amplification of genomic DNA. The reliability and efficiency of the PCR primers can be determined by testing the primers on cDNA derived from whole tissue. The whole tissue cDNA samples can be diluted to levels of total RNA corresponding to approximately 10 cells (1 ng) and a single cell (100 pg). If the primers perform well under these conditions, they should be suitable for scRT-PCR. Lastly, the PCR products should be cloned and sequenced to confirm the identity of the sequence of the PCR product from both whole tissues and single cells. To reduce variability from the reagents, RT-PCR reagents and enzymes should always be divided into aliquots to screen single cells in large groups (~50 neurons) with identical stocks of RT-PCR reagents and enzymes. Negative controls lacking cDNA have to be performed and processed in parallel with single cell RT-PCR reactions.

Splice Variant Analysis by Single Cell RT-PCR

The nervous system contains thousands of functionally distinct subsets of neurons. These neuronal populations express specific subsets of genes that underlie their unique properties. Cell-specific alternative splicing offers a finer level of control within specific regions of the nervous system. Several studies have used scRT-PCR to analyze splice variant expression patterns at the cellular level. For example, the KCNMA1 gene encodes the pore-forming α subunit of BK channels and is subjected to cell-specific alternative splicing. scRT-PCR was used to show select KCNMA1 splice variants and show differential expression along the tonotopic map in individual hair cells. Functionally, the splicing of KCNMA1 plays a role in altering the repolarization rate of the hair cell, thus setting the electrical tuning frequency in individual auditory hair cells. scRT-PCR has also been used in combination with whole cell patch recordings to correlate to functionally analysis with cell-specific splicing in nociceptive neurons of dorsal root ganglia. The Cav2.2 gene encodes the pore-forming α subunit of N-type calcium channels, and a splice variant of this gene was identified by scRT-PCR to be preferentially expressed in subsets of nociceptive neurons. Functionally, scRT-PCR has been used to link this splice variant to changes in the N-type calcium current densities in these neurons.

Antisense RNA Amplification

Some of the limitations of *in situ* hybridization and scRT-PCR have been overcome by a technique called amplified antisense RNA amplification. This procedure is useful to amplify RNA from a small amount of material and is employed particularly for amplifying RNA from single cells in which the level of the RNA is approximately 0.1 pg. As shown in Figure 1, a cell is isolated by using a patch pipette or by laser capture microdissection, and then it is aspirated and transferred to a microcentrifuge tube. The RNA of a cell is reverse transcribed into cDNA by using an oligo-dT primer that contains a T7 RNA polymerase promoter site. Then, the obtained cDNA contains the T7 promoter sequence at the 5′ end. After cDNA is double stranded, T7 RNA polymerase is used to transcribe RNA copies. The aRNA product can be used as a template for cDNA synthesis and conversion into double-stranded cDNA containing a T7 RNA polymerase promoter site so that subsequent rounds of RNA amplification can be made. Only two rounds of RNA amplification are required to obtain a sufficient amount (approximately 106-fold) of RNA from the original pool. This procedure can be used in fixed cells following a similar protocol. Figure 2 provides a brief summary of the protocol. The aRNA protocol is a linear amplification so the mRNA levels can be quantified. This technique is predominantly used to screen microarrays and macroarrays. Approximately, 70% of published microarray studies have used aRNA amplification to generate their probes.

Figure 1 Schematic of single cell mRNA procedures. Individual cells can be collected from a culture or tissue by aspirating a single isolated cell into a recording micropipette. Once the single cell is collected, the mRNAs expressed by the cell can be analyzed by either single cell RT-PCR or aRNA amplification. Another single cell methodology, *in situ* hybridization (not shown), is used predominately to analyze mRNA localization in cells.

Application of aRNA Amplification

Single cell aRNA amplification, along with other techniques, can be used for expression profile studies and other approaches. Thus, the RNA amplification technique has been employed for demonstrating the presence of neuronal mRNA species in individual senile plaques in Alzheimer's disease and the presence of mRNA in dendrites and dendrite growth cones. In combination with array platforms, expression profiling demonstrated a decrease in G-protein transcripts, GluR3, GluR5, synaptic-related markers, and signaling molecules from the affected brain area in schizophrenia. In addition, there was senescence-associated cell type-specific downregulation in dopamine receptor mRNA in brain regions related to learning and memory. The combination of patch clamp recording and aRNA amplification methods in single dentate granule cells from an animal model of temporal lobe epilepsy allows the demonstration of a different expression profile in $GABA_A$ receptor subunits correlating with alterations in GABAergic function that precede the epileptic episode. Gene expression profile or any other approach using the single aRNA amplification technique can be performed in other neurological disorders in order to gain insight into the molecular basis of the diseases and then help develop new strategies to prevent or cure them. On the other hand, these techniques have been used in tissues different from the brain with positive results.

Future Directions

The regulation of gene expression eukaryotes can occur at several different levels: transcriptional, posttranscriptional (alternative splicing, mRNA localization, and mRNA stability), translational, and posttranslational. All of these processes can be regulated in a cell-specific manner. In neuronal tissues, studying gene expression profiles at single cell levels is of particular importance because the nervous system contains thousands of functionally distinct subsets of neurons. These neuronal populations express specific subsets of genes that underlie their unique functional properties. Studying gene expression at the cellular level with single cell molecular analysis procedures will lead to a better understanding of the molecular mechanisms

Figure 2 RNA amplification procedure in single cells. A single cell is isolated from primary culture using a patch pipette or by laser capture microdissection and then transferred into a tube. An oligo-dT primer containing a T7 RNA polymerase promoter site is hybridized into poly A tail of mRNAs present in the cell and RNA is reverse transcribed into cDNA. As a result, a double-stranded mRNA–DNA hybrid is obtained. Then, a second strand of DNA is synthesized by using DNA polymerase. Subsequently, T7 RNA polymerase mediates transcription from DNA that contains a T7 RNA polymerase promoter site, creating amplified antisense RNA copies. At this point, further rounds of amplification can be performed.

that underlie functional diversity in neuronal cell types. In addition to a better understanding of the molecular basis of neuronal function, the identification of cell-specific mRNAs and splice variants may be clinically relevant to human disease states, such as ion channelopathies. Cell-specific mRNAs and splice variants in functionally distinct sets of neurons may be useful as potential therapeutic targets for neurological disorders.

Single Cell Neuronal Circadian Clocks

S Honma and K-i Honma, Hokkaido University Graduate School of Medicine, Sapporo, Japan

Neuronal Activity Rhythms of the Suprachiasmatic Nucleus

The suprachiasmatic nucleus (SCN) of the hypothalamus is the site of the mammalian master clock, where individual neurons exhibit robust circadian firing rhythms. Electrical activity of SCN neurons has been measured *in vitro* using acutely prepared SCN slices from adult animals as well as *in vivo* by monitoring multiunit activity (MUA) using chronically implanted electrodes. Irrespective of nocturnality or diurnality of behavioral rhythms, the firing rate of SCN neurons is higher in the subjective day than in the subjective night; however, in most of the brain areas outside the SCN, neuronal activity rhythms of nocturnal and diurnal animals are 180° out of phase with each other.

Measuring circadian periodicity of SCN neurons requires analysis of the order of days or even weeks. Nevertheless, in traditional slice physiology, duration of a single-unit activity recording was limited to the order of minutes, which is hardly sufficient for circadian rhythm analysis. Therefore, until recently, it had been difficult to demonstrate whether the circadian rhythm was driven by single pacemaker neurons or emerged from neural networks within the SCN. This problem was solved by the use of the multielectrode array dish (MED) system. In addition, bioluminescent and fluorescent reporters enabled us to monitor gene expression rhythms in single SCN cells for days and weeks.

Circadian Periods of Single-SCN Neuronal Rhythm

Most SCN neurons in nocturnal rodents exhibit robust circadian rhythms in their spontaneous discharges (Figure 1), and their periods were specific to each neuron. The percentage of SCN neurons that exhibit significant circadian periodicity depends on the culture methods. In wild-type rats, about 75% of SCN neurons exhibit significant circadian periodicity in their spontaneous discharges in the dispersed cell culture, while nearly 85% exhibit in the organotypic slice culture. The percentage of rhythmic neurons is significantly higher in the slice culture than in the dispersed cell culture. In the dispersed cell culture, many SCN neurons exhibit circadian firing rhythms with individually different periods, indicating that the SCN is comprised of multiple autonomous single-neuronal oscillators. However, some of them seem to exhibit circadian firing rhythms driven by other neurons. The range of circadian period distribution of single-SCN neurons also depends on culture methods. In rats, the periods of dispersed neurons vary between 20.0 and 30.9 h with an average period of 24.1 ± 1.4 h (mean $\pm$ SD), while those from slice culture vary between 22.4 and 26.7 h, with an average of 24.2 ± 0.7 h. In both cultures, circadian periods follow a Gaussian distribution, and their mean circadian periods are not significantly different from each other. However, the distribution range of circadian period is significantly different between the two culture systems (Figure 2). Circadian periods of single-SCN neuronal rhythms are widely varied in dispersed neurons even within a single culture dish, whereas they are basically synchronized in a single-SCN slice culture. Therefore, the SCN cell assemblage for cell-to-cell interactions is critical for coherent circadian rhythm expression from the SCN. Not only the intact SCN cell assemblage but also the intrinsic circadian period is suggested to play an important role in synchronizing the constitutional cellular oscillators in the SCN. Compared to the cultured neurons, the free-running periods of behavioral rhythms in rats are distributed in a strikingly narrow range of 24.0–24.8 h with an average of 24.4 ± 0.2 h (Figure 2). The entire SCN structure with intact afferents and efferents seems to be necessary for the SCN neurons to exhibit rhythms with physiological periodicity.

Regional Specificity and Neuronal Properties

The SCN is functionally and anatomically organized into two subdivisions: ventrolateral (core) and dorsomedial subdivisions (shell). The former lies adjacent to the optic chiasm and comprises predominantly neurons producing vasoactive intestinal peptide (VIP) and gastrin-releasing peptide (GRP). The core receives major afferents to the SCN from the retina and midbrain, whereas the shell surrounds the core where arginine vasopressin (AVP)-containing neurons are predominated. In addition, basically all SCN neurons produce γ-aminobutyric acid (GABA), a major inhibitory neurotransmitter in the central nervous system. The percentage of neurons exhibiting significant circadian firing rhythm is higher in the dorsomedial subdivision than in the ventrolateral. Dissociation of

Circadian periods of spontaneous locomotor activity in individual rats (c) are expressed in histograms. Numbers are mean ± SD. Reprinted from *Neuroscience Letters,* 358, Honma S, Nakamura W, Shirakawa T, et al., Diversity in the circadian periods of single neurons of the rat suprachiasmatic nucleus depends on nuclear structure and intrinsic period, 173–176, Copyright 2004, with permission from Elsevier.

the circadian rhythms in the SCN evidentially supports the existence of two subdivisional pacemakers in the SCN. Such dissociations have been observed in the rhythms in AVP and VIP releases from cultured SCN slices and clock gene expression rhythms *in vivo* after the abrupt shift of light–dark (LD) cycles. Interestingly, dissociation of clock gene rhythms following LD shift does not accompany similar dissociation in the MUA rhythms. The neural networks within the SCN seem to connect the two subdivisional rhythms, because surgical dissection dissociates them. Therefore, with intact neuronal connections, single neuronal rhythms we can measure are the integrated outputs of their own intracellular clocks and extracellular rhythmic signals.

The two oscillatory components within the SCN are also observed in relation to the photoperiodic responses in circadian rhythms. In the coronal SCN slices, the MUA always exhibits unimodal circadian rhythm with a peak in the subjective day. However, two distinct peaks are detected at the subjective dawn and dusk in the MUA from horizontal SCN slices of hamsters, the phases of which depend on day length. A long-standing hypothesis for photoperiodic responses of the behavioral rhythms in nocturnal rodents is mutually coupled two oscillators, evening (E) and morning (M) ones, which separately track dawn and dusk. The horizontal SCN slices have entire rostrocaudal interactions yet lack the dorsal SCN. One of the E and M oscillators may be lacking in coronal slices, while both of them still exhibit

each peak in horizontal slices. Even under steady entrainment to an LD cycle, cellular clocks seem to be differentially phased in different subdivisions of the SCN.

Mechanisms Generating Circadian Rhythms in Spontaneous Action Potentials

In addition to the spontaneous firing, SCN neurons exhibit circadian rhythms in various functions such as neuropeptide release, metabolic rate, and intracellular Ca^{2+} levels. Current understanding of the intracellular molecular machinery for circadian rhythm generation consists of interlocked transcriptional and translational feedback loops involving several clock genes, as positive elements, *Clock* and *Bmal1*, and as negative ones, *Per1*, *Per2*, *Cry1*, and *Cry2*. Various kinds of clock gene-deficient as well as mutant mice have been developed for the study of molecular clock mechanisms, and the results support these molecular feedback loops. However, the intracellular signal transduction mechanisms from the molecular core to cellular functions are basically unknown. Although SCN neurons possess various kinds of ion channels, the target channels of the cellular clock and the mechanisms of circadian regulation remain to be studied. Substantial data support the hypothesis that voltage-dependent calcium channels contribute to the clock function. Diurnal modulation in the calcium currents may suggest that the channels are the targets of intracellular circadian signal output. Circadian modulation is also observed in Na^+ channels, and Ca^{2+} gated and voltage-gated K^+ channels. Almost all SCN neurons contain GABA, and $GABA_A$ receptors are also found in SCN neurons. However, controversial data have been reported on the effects of GABA in the SCN, whether it is an inhibitory transmitter throughout the day or as an excitatory and inhibitory transmitter depending on the circadian phase. These conflicts may be partly due to the dose of the drug application. In addition, different types of SCN neurons may respond to GABAergic transmission differently. Neuronal activities are often measured in a limited number of neurons without identifying their localization within the SCN and types of neurotransmitters, channels, or receptors. SCN neurons are functionally as well as anatomically heterogenous. NMDA and 5-HT receptors are localized in the ventrolateral subdivision. The dorsal neurons lack K^+–Cl^- cotransporter 2, which results in elevated intracellular Cl^- concentration. Although it is apparent that the SCN is composed of multiple autonomous single-neuronal oscillators, they are not homogenous, especially in their response to the external signals.

Figure 3 Effects of TTX on the firing rhythms of single SCN neurons. Double plotted firing rhythms of single SCN neurons treated with 200 nM TTX for 1 (#D56-8, full scale 3 Hz) and 7 days (#D87-1, full scale 1.5 Hz). Arrows and shaded areas indicate days in TTX treatment.

Administration of tetrodotoxin (TTX), a sodium channel blocker, into the SCN suppresses the spontaneous firing of SCN neurons *in vitro*, and behavioral rhythms *in vivo*. However, TTX does not terminate the intracellular circadian oscillation (Figure 3). Circadian firing rhythms reappear after the TTX washout from the phase predicted by the pretreatment rhythm. Furthermore, neither clock gene expression rhythm nor intracellular Ca^{2+} rhythm in each SCN neuron is affected by TTX. TTX does block synaptic interaction among SCN neurons, which eventually results in the dissociation of the SCN neuronal rhythms. On the other hand, membrane hyperpolarization reversibly abolishes the clock gene expression rhythms. Therefore, membrane phenomena such as electrical impulses and ionic currents of the SCN cell membrane are not only output or input for the intracellular clock machinery but may also participate in the rhythm generation mechanisms.

Circadian Signal Communication between SCN Neurons

The SCN is composed of a number of neurons with slightly but significantly different circadian periods. Therefore, it is critical for them to communicate with each other in order to synchronize individual rhythms for the circadian output from the SCN. The SCN *in vivo* receives daily photic inputs via the retinohypothalamic tract, which reset the period of individual cellular oscillators to 24 h. Even without daily entraining cues, individual neuronal rhythms synchronize with each other in the SCN. At least three modes of communication patterns have been reported for SCN neurons to convey circadian information – chemical synapses, gap junctions, and diffusible

factors. Cross-correlation analyses of spike timings is useful to determine the existence of synaptic coupling and, if so, the mode of transmission (Figure 4). Both excitatory and inhibitory connections have been observed between neurons exhibiting synchronized firing rhythms in dispersed cell culture. On the other hand, no functional connections are detected in neuron pairs with different circadian periods. Sodium-dependent action potential exerts its influence as one of the synchronization signals. Recently, VIP, a predominant neurotransmitter in the core, has been shown to exert as a synchronization signal among cellular oscillations in the SCN. Type 2 VIP receptor (VPAC2) of the SCN neurons receives these synchronizing signals, since VPAC2 knockout mice have no circadian output due to the desynchronization among multiple cellular oscillators. In addition to chemical synapses, gap junctions are found in SCN neurons as well as in astrocytes. Presence of connexin 32 and dye coupling, especially during daytime in the SCN, also suggests gap-junctional communication among SCN neurons.

Imaging of Single-SCN Cellular Rhythms and Clock Gene Dysfunction

Transcriptional and translational feedback loops involving clock genes and their protein products are the molecular machinery for intracellular circadian rhythm generation. Bioluminescent reporters are successfully introduced to long-term monitoring of clock gene expression or their protein products in the cultured SCN. Especially, clock functions in individual cells are assessed using real-time imaging of circadian gene expression in cultured SCN of transgenic mice carrying a *Per1* promoter-driven luciferase reporter gene. Most SCN cells exhibit robust and synchronized circadian rhythms in their clock gene expression. TTX treatment desynchronizes cellular circadian gene expression rhythms. Cycloheximide, a protein synthesis inhibitor, stops the intracellular circadian oscillation. Clock gene dysfunctions can also be examined in single SCN cells. Individual cellular rhythms of *Cry1*- and *Cry2*-deficient mice exhibit no circadian fluctuation in *Per1* expression, whereas desynchronized is observed among SCN cells of VPAC2-deficient mice, although both of them are behaviorally arrhythmic in constant darkness.

Mouse mutant in the gene *Clock* are known to exhibit altered circadian rhythms. Under constant darkness (DD), heterozygotes exhibit circadian behavioral rhythms with periods longer than those in wild-type mice, and homozygotes eventually become arrhythmic (Figure 5). However, in the organotypic SCN slice culture, robust circadian firing rhythms are observed in 77% neurons of the homozygotes examined. The percentage is still smaller than that in the wild-type SCN neurons of 95%. Notable is a dramatic decrease of neurons exhibiting circadian firing rhythm in dispersed cell culture (only 15% and 46% in homozygote and wild-type mice, respectively). In addition, the circadian firing rhythms in the dispersed cell culture were much unstable in *Clock* mutants than wild-type mice, indicating that

Figure 4 Cross-correlation analyses of single SCN neuronal rhythms. (a) Spike discharges from three electrodes. Synchronized circadian firing rhythms among three neurons (A53, A53, and A54) and one desynchronized (A22) exhibiting a different phase and a period from the other three. Figure 5 Spontaneous firing rhythms of the SCN neurons in *Clock* mutant mice. Double-plotted firing rhythms of the SCN neurons from *Clock* mutant mice (*Clock*/*Clock*) and wild-type mice in slice culture and dispersed cell culture. Circadian period of each neuron is indicated on the top right of each rhythm. Adapted from Nakamura W, Honma S, Shirakawa T, et al. (2002) *Clock* mutation lengthens the circadian period without damping rhythms in individual SCN neurons. *Nature Neuroscience* 5: 399–400.

circadian firing rhythms in single-SCN neurons are affected by genotypes as well as culture system. Similar results are obtained in luciferase reporter activity rhythms in the slice and dispersed cultures of the SCN from *Cry*- or *Per*-deficient mice. These results suggest that intense cell-to-cell communication in the SCN increases the stability of single-neuronal oscillators to exhibit robust circadian rhythms to orchestrate peripheral clocks throughout the body. The intercellular interaction is especially important for mice having genetic dysfunctions in clock system.

Neurons Are Not All the Same

The enormous computational capacity of the brain is in large measure a reflection of its cellular heterogeneity. Most brain nuclei or regions are composed of complex mixtures of neurons that differ in many ways. A powerful array of tools has been developed during the past century to explore this diversity in an attempt to understand how it shapes brain function in health and disease. Most of these approaches, however, are limited to one aspect of the cellular phenotype. For example, traditional anatomical techniques that utilize light or electron microscopy are limited to revelations about neuronal structure. *In situ* hybridization and immunocytochemical techniques provide information about gene and protein expression but little about structure or function.

A major leap forward occurred approximately 30 years ago when electrophysiological techniques were combined with intracellular labeling that allowed the function of a neuron to be correlated with its morphology. Although this approach has provided important clues about how structure influences function, its principal value is in cellular identification; that is, it allowed a dynamic, physiological signature or phenotype to be connected to a more static morphological phenotype.

With the genomics 'revolution' has come the opportunity to determine how differences in gene expression are translated into functional differences. Conventional *in situ* hybridization and immunocytochemical approaches only allow the co-localization of one or two genes in any one particular cell. Moreover, both approaches are difficult to make quantitative. An alternative approach combines patch clamp recording with reverse transcription (RT) and amplification of the complementary DNA (cDNA), allowing gene expression and physiology to be linked. There are two ways in which cDNA from single cells is typically amplified. One uses a T7 RNA polymerase strategy. The other uses the polymerase chain reaction (PCR). The strengths and weaknesses of this so-called single cell RT-PCR (scRT-PCR) approach are discussed here. This technique has been used extensively during the past decade to generate expression profiles from electrophysiologically characterized individual neurons.

Harvesting Cellular mRNA

Cellular mRNA can be harvested from patch clamped neurons that have either been acutely isolated or been accessed *in situ*, usually in tissue slices (although *in vivo* patch clamping is becoming more common). The patch electrode, with its relatively large diameter tip (~0.5 μm), provides an excellent means of accessing cytoplasmic mRNA.

Neurons can be acutely dissociated from tissue slices by a variety of methods. Dissociation generates a suspension of individual neurons that is plated into a sterile recording chamber and allowed to settle (Figure 1). These isolated neurons have short dendritic and axonal processes, making them excellent subjects of voltage clamp studies aimed at characterizing ion channel gating and modulation. Following electrophysiological study, cells can be harvested for scRT-PCR profiling. When harvesting acutely isolated neurons, the entire cell (cytoplasm and nucleus) is sucked up into the patch pipette by applying negative pressure to the back of the pipette/electrode. It is critical in these experiments to approach cells for patching with positive pressure on the electrode to prevent harvesting cellular debris that might contain mRNA. It is also important during the harvesting phase that the cell be lifted off the bottom of the chamber where debris has settled; the best strategy is to lift the cell with the patch electrode into a stream of sterile saline solution, aspirate the cell into the pipette, and then quickly remove the electrode from the chamber solution. All of these steps must be visually monitored.

Neurons in tissue slices also have been subjected to scRT-PCR analysis following patch clamp recording. This preparation is better suited to questions about the synaptic and integrative properties of neurons (for example, how synaptic currents are translated into spike trains). However, there are several obstacles to reliable harvesting of mRNA from neurons in tissue slices. The first is that the recording/harvesting electrode can easily be contaminated with mRNA from surrounding cells as it is driven through the tissue to the desired cell. Positive pressure must be maintained on the electrode during the descent into the tissue. The second obstacle is related to the first. During the harvesting procedure, it is critical that the high-resistance seal that forms between the electrode and the cell be maintained to prevent tissue surrounding the cell from being harvested. This is accomplished by monitoring seal resistance while applying modest negative pressure to the back of the electrode for 5–10 min at the conclusion of the recording phase,

Figure 1 Somatodendritic A-type conductance in striatal cholinergic (expressing choline acetyltransferase (ChAT) mRNA) neurons is directly correlated with estimates of Kv4.2 mRNA abundance assessed using scRT-PCR. (a) Low-threshold, TEA-resistant A-type current was recorded before aspirating cell cytoplasm. (b) After serial dilution of RT product, PCR targeting Kv4.2 was performed. (c) The threshold distribution from a sample of neurons was fit with a Gaussian function. (d) Average maximal conductance of A-type channels was plotted against the mean estimated number of copies of Kv4.2 cDNA for five cell groups: striatal cholinergic interneurons (ChAT/str), basal forebrain cholinergic neurons (ChAT/bf), high and low expressing GABAergic striatal medium spiny neurons (MS/h and MS/l, respectively), and GABAergic globus pallidus neurons (GP).

bringing cytoplasm (and mRNA) into the pipette. Next, the electrode must be slowly withdrawn to form an outside-out patch, capping the harvesting electrode. Unlike the situation with acutely isolated cells in which the entire cytoplasm and nucleus are harvested, only a limited amount of cytoplasm is obtainable from neurons in slices without compromising cellular specificity. Another issue with this approach is that larger bore pipettes that do a better job of harvesting often compromise the electrophysiological recording because the cytoplasm is too well dialyzed; this is particularly problematic for small neurons. In this case, harvesting can be performed with a second pipette at the conclusion of the recording phase.

The amount of mRNA within a single vertebrate neuron is estimated to be between 0.1 and 1 pg, making the detection of mRNA transcripts a technical challenge, even with the most efficient harvesting. This makes it critical that as near an RNase-free environment be maintained during harvesting as possible. Several steps are helpful. RNase-free gloves should be worn during preparation and handling of electrodes, recording solutions, and harvested material. Electrodes should be baked to denature RNases. Silanes can be used to minimize binding of mRNAs to the interior wall of the harvesting pipette. The solutions, particularly the harvesting solution placed in the pipette, should be free of RNase contamination; RNase inhibitors can be included in the harvesting solution. Electrode holders and wires need to be decontaminated between harvesting neurons to avoid cross-contamination. Although degradation of mRNAs can be reduced during harvesting, it cannot be completely stopped, leading to diminished profiling fidelity with prolonged electrophysiological recording.

The efficiency of the RT step, leading to the conversion of mRNA to more stable cDNA, is critical to the fidelity of profiling. There are several steps that need to be taken to maximize the quality of profiling. First, the volume of the solution in the harvesting pipette needs to be carefully controlled (~10 μl). The ionic composition of this solution, particularly the Mg^{2+} concentration, needs to be taken into account (and compensated for) in the RT step because the enzymes involved are very sensitive to divalent ion concentration. Efficient priming of RT is important. Three types of primers can be used. Most commonly, oligo-dT primers are used that bind to the poly A tail of mature mRNA. This prevents reverse transcription of immature heteronuclear mRNA and ribosomal RNA, which can be a major fraction of the harvested RNA. The disadvantage of this priming strategy is

that the reverse transcriptase must work through the 3′ untranslated region (UTR) of the mRNA before it gets to the coding sequences. The 3′ UTR can be very long for some mRNAs and possess secondary structure that can lead to premature termination of the RT reaction. An alternative strategy is to use random hexamers to prime the RT reaction. This does not limit reverse transcription to mature mRNA (or to mRNA). A third RT priming strategy is to use gene-specific antisense primers that target specific mRNAs. This strategy is less common because it limits subsequent amplifications to these mRNAs.

Positive controls should be run for diagnostic purposes in every experiment. The simplest control is to spike an RT sample with a highly diluted RNA from whole brain or a tissue known to express a gene of interest. Because of potential contaminants in mRNA harvesting, solutions, and instruments (e.g., pipettors), it is crucial to also run negative controls with each experiment. Two types of negative controls should be performed. First, a sample of the reaction solutions that ostensibly lacks cellular mRNA should be processed to ensure that reaction solutions are not contaminated with PCR products from previous reactions or some other undesirable RNA. Second, cells should be harvested without the RT enzyme to verify that genomic DNA is not amplified in subsequent PCR steps. To reduce the chances of contamination, several precautions should be taken. Separate areas of the lab should be devoted to procedures in which high concentrations of potential contaminants are handled (e.g., tissue RNA preparations and electrophoresis of PCR products). Aerosol-resistant pipette tips are an absolute prerequisite. Pipettors should be dedicated to one task and frequently cleaned.

Characterization of Cellular mRNAs

Following reverse transcription of cellular mRNAs to cDNA, PCR can be used to amplify specific transcripts. There are two ways to approach such a task. The simplest one is to divide total cellular cDNA and then use each aliquot of cDNA for separate PCR reaction. Although simple, this approach significantly limits the number of cDNAs that can be tested for because each reaction requires a substantial fraction of the total cDNA. An alternative approach is to perform 'multiplex PCR,' in which a combination of primers (one pair for each transcript under investigation) is used in the same PCR reaction. After several cycles of amplification, aliquots of resulting PCR product are used as a template for a second round of PCR amplification with a single pair of transcript-specific primers. Often, the primers used in this second stage of amplification are nested; that is, they target sequences inside the stretch of cDNA targeted by the primary primer set. If targeted transcripts belong to the same gene family, 'degenerate' primers can be used in the first round of PCR. Although appealing because it broadens the single cell profile that can be generated, designing multiplex primers that do not dimerize and yield spurious amplicons is often very difficult.

A variety of factors influence the efficiency of transcript amplification with PCR. One of the most important determinants of success with scRT-PCR is primer design. There are a variety of excellent computer programs available to make this task easier. The length of primers, their homology with target nucleic acids sequences, and guanosine–cytosine content all influence amplification efficiency. In addition, primers should not have any significant amount of homology with other sequences in the targeted transcript or other genes. The primers should not have complementary 5′ and 3′ ends to prevent the formation of hairpin structures or primer dimers, since these can lower amplification efficiency. When possible, primers should span splicing sites to reduce the chances of amplifying genomic DNA.

Correlating mRNA Expression and Cellular Function

In many situations, the goal of scRT-PCR following patch clamp recording is simply cellular identification, much like intracellular labeling. For this type of analysis, the goal is to determine whether a particular mRNA is detectable or not. Because inefficiencies in harvesting, reverse transcription, or amplification can lead to a failure to detect an mRNA that is in fact present, it is important to draw a distinction between detection and actual expression of mRNAs. It is also possible to miss low-abundance transcripts when the cellular cDNA is divided into separate aliquots for amplification. As a consequence, with low-abundance mRNAs, it is important to replicate profiling results to yield estimates of detection probability; without this kind of replication, it is impossible to interpret negative results. Positive controls that target ubiquitously expressed high-abundance mRNAs (e.g., actin) are always a good idea but they do not exclude the possibility that undetected mRNAs are expressed.

Quantitative analysis of mRNA expression in individual neurons can be combined with electrophysiological studies to establish a more compelling association between mRNA expression and physiological function. This approach also helps address the uncertainty about the relationship between mRNA and protein abundance. Posttranscriptional control of mRNA (e.g., stability) and posttranslational processing of protein can influence the RNA/protein

Figure 2 (a) Kv4.2 cDNA was quantified in striatal and basal forebrain ChAT expressing striatal and basal forebrain neurons using real-time PCR detection. Plot of fluorescence as a function of PCR cycle number is shown. (b) Calibration plot generated with known concentrations of plasmid Kv4.2 was used to estimate Kv4.2 cDNA copy numbers.

ratio. Combining quantitative electrophysiological assays of protein abundance and quantitative analysis of mRNA expression provides a direct assessment of this relationship.

A number of strategies have been developed for quantifying cDNA generated from reverse transcription of cellular mRNAs. In competitive or end point analysis PCR, mRNA abundance can be estimated by using carefully designed internal standards. The base sequence of these standards needs to be very close to that of the targeted, comparison transcript to ensure similar amplification efficiency. A single base can be changed to introduce a restriction site that will allow the internal standard to be distinguished after amplification. Alternatively, the standard might contain a small deletion in the region between the two primers, allowing it to be distinguished on the basis of size. A key assumption of this approach is that amplification remains in a linear range. In practice, this is often difficult to ensure. Moreover, this requires that the number of amplification cycles be kept reasonably small (<35 cycles), making detection of amplicons difficult when starting from single cells.

Another rather simple quantitative approach is the serial dilution technique. With this semiquantitative method, a sample is serially diluted until the detection threshold is reached. The more abundant a transcript, the greater the number of dilutions possible before the detection threshold is crossed. Thresholds determined in this way typically have a near normal distribution when sampling is done from a homogeneous population of neurons. Different cell types can then be compared for their relative expression of a particular mRNA. These levels of expression can be compared with a functional measure. For example, the relative abundance of the K^+ channel subunit Kv4.2 was strongly correlated with the amplitude of A-type K^+ currents in a wide variety of brain neurons (Figure 1).

Real-time fluorescence-based PCR has gained in popularity. In this approach, the accumulation of PCR product is monitored by its fluorescence (Figure 2). The abundance of a particular mRNA is estimated from the number of amplification cycles required to distinguish sample fluorescence from background fluorescence. Cloned cDNA can be used to establish calibration curves for absolute quantification. Probes that hybridize to the amplicon (TaqMan) give the most reliable quantitation and also allow for multiplexing. SYBR green (intercalating DNA dye) can also be used if the PCR reaction is optimized to yield only the product to be quantified.

Note that all methods described previously only allow quantification of cDNA molecules, not mRNA. It is often assumed that the efficiency of the RT reaction is perfect, but this is unlikely. RT efficiency depends on the secondary structure of mRNA, priming strategy, and length of the 3′ UTR when using oligo-dT priming. In the absence of appropriate RNA standards, absolute quantitation of mRNA is not possible. Standards used in competitive PCR usually do not have full 3′ UTRs and the efficiency of their transcription is likely to be different from that of native mRNA.

Single Photon Emission Computed Tomography (SPECT)

J K Staley and F Bois, Yale University School of Medicine and VA Connecticut Healthcare System, New Haven, CT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Single photon emission computed tomography (SPECT) imaging offers the unprecedented opportunity to visualize specific brain chemicals, including sites of drug action as well as distinct functional states of the living human brain, using radioactive drugs (also known as radiotracers or radiopharmaceuticals). Over the past three decades, significant advances have been made both in the technology and in the development of novel radiopharmaceuticals for imaging of specific neural receptors and transporters in the living human brain using SPECT. These advances have allowed researchers for the first time to visualize the chemical state of the brain; this is important in persons suffering from neuropsychiatric disorders that result from an imbalance of chemicals in the brain, such as alcoholism, Alzheimer's disease, bipolar disorder, cocaine dependence, major depression, Parkinson's disease, schizophrenia, and tobacco dependence. Furthermore, SPECT imaging has permitted the visualization of sites of drug action as well as the quantitation of drug levels in the brain and the relationship with treatment response, thus facilitating the design of drug therapies for the treatment of these devastating brain disorders.

SPECT Radiochemistry

SPECT cameras (Figure 1) measure gamma rays emitted from radioactive atoms, called radionuclides. The SPECT radionuclides, iodine and technetium, ^{123}I and ^{99m}Tc, respectively, emit a single photon at 159 and 140 keV, and have half-lives of 13.2 and 6 h. The longer half-life of ^{123}I allows it to be generated by a central cyclotron facility and then shipped to imaging centers within a 3000-mile radius. ^{99m}Tc is easily produced on site in the local nuclear pharmacy using a molybdenum generator. For SPECT imaging of specific neural receptors, ^{123}I or ^{99m}Tc is attached to a drug (specific for a receptor in the body or brain), resulting in a radioactive drug, commonly called a radiopharmaceutical.

Iodine-123 forms strong covalent bonds with carbon and conveniently can take different chemical forms (metal, anion, cation). Molecular I_2 is treated with an oxidant such as hydrogen peroxide or chloramine T (Bolton–Hunter method) to generate the cation (I^+). I^+ is the reactive form of iodide that is incorporated into the chemical compound by 'exchange' or by 'electrophilic substitution' (Figure 2). The sensitivity of the molecule to oxidation and the labeling kinetics are the parameters that usually define the labeling method used. Since iodine is a fairly large atom, when it is introduced into a compound, the affinity and/or specificity of binding may change dramatically compared to the parent drug. For this reason, preexisting drugs that already have iodine in their structure are obvious prime candidates for development of novel radiotracers.

There is considerable ongoing effort to develop SPECT radioligands that incorporate ^{99m}Tc because of its significantly lower cost and more convenient availability (generated on site by inexpensive molybdenum generators). Several SPECT brain radiotracers have been produced incorporating ^{99m}Tc in their structure. However, its metallic properties (chelation required) and its incorporation generally result in a drastic loss of affinity, and the large size of the ^{99m}Tc moiety significantly reduces penetration of the blood–brain barrier, thus far limiting its use to image neural receptors in brain imaging studies.

Since large interindividual differences in metabolism occur due to genetics, environment, nutrition, and age, the metabolic fate of the radiopharmaceutical must be evaluated after administration to a human. Catabolism (breakdown) of the radiopharmaceutical into metabolites or by-products decreases the concentration in the blood and thus the amount available to enter the brain. To evaluate radiopharmaceutical metabolism, blood samples are obtained at various time points before and after radiotracer administration, and are analyzed to determine the amount of remaining total parent radiotracer, free parent radiotracer, plasma protein binding of the radiotracer, and the lipophilic and polar metabolites. These measurements are used to normalize brain radioactivity levels, to correct for individual differences in metabolism and plasma protein binding.

SPECT Physics

The radiopharmaceutical is most commonly introduced to the individual's body by intravenous injection. The radiopharmaceutical is administered in trace (at least 500-fold lower than the EC_{50}) quantities that do not disturb the biochemical process of interest.

The SPECT image is created by measuring the gamma photons that are released when the radionuclide

Figure 1 Picture of Picker Prism 3000XP SPECT camera.

Figure 2 SPECT radiosyntheses.

decays. The high-energy gamma photons pass through the body tissue and bone, and are measured by the SPECT camera. In the SPECT camera, the gamma photon passes through a channel in a lead block called a collimator. Collimators are made from pieces of lead approximately 4–5 cm thick and measuring 20 × 40 cm on the side that contain thousands of channels through which the gamma rays pass. Behind the collimator is a crystal (commonly made of sodium iodide) that releases light in the visible range when a photon interacts with it. Photomultiplier (light-sensitive) tubes adjacent to the crystal collect the emitted light. The holes in the collimator limit the possible origins of the emitted photon, because the lead walls (septae) block all photons that do not enter at a straight angle. SPECT images are produced by computers linked to the SPECT camera (Figure 1); the software processes the light signals and reconstructs the original site in which the activity was emitted, in a slice (or a tomograph), using the principle of back-projection.

Physical Constraints of SPECT

Attenuation

Between the site of origin and the detector in the camera, the gamma photon may travel through many different mediums, including bone, air, tissue, and fluid. Passage through these mediums may reduce the energy intensity of the photon such that it is not detected by the camera. Thus the activity is 'attenuated' by the tissue.

Measurements of absolute tissue activity levels are not accurate without a correction for the attenuated signal. Typically SPECT images have been corrected for attenuation using a first-order approximation in which an ellipse is drawn around the edge of the skull and attenuation is assumed to be uniform and equal to that of water. In general, SPECT activity is attenuated by about 15% per centimeter of path length of the photon. Thus the greater the distance the photon travels to the detector in the camera, the greater the attenuation. This type of attenuation correction, commonly referred to as uniform attenuation correction, does not take into account differences in attenuation that occur between different mediums (bone, air, tissue, fluid), or between individuals with heads that vary in size and shape, for example. Individual differences in attenuation may be corrected by obtaining a transmission scan. The transmission scan, which is similar to a computed tomography (CT) scan, provides a measurement of attenuation specific for each individual head. Although not yet common practice in the clinical setting, this type of attenuation correction, called nonuniform attenuation correction, is commonly used for research studies.

Scatter

Scattered activity is when the high-energy gamma photons deviate from the straight path; scattered activity is measured in a location different from that of its site of origin. Compton scattering occurs when the interaction of gamma photons with tissue results in the transfer of electrons from the photon to the tissue. Because of the lower energy, scattered photons are typically measured at a photopeak value less than the primary photopeak (e.g., 159 keV for ^{123}I). Scatter alters the accuracy of quantification of SPECT images throughout the brain, although the effects will vary by tracer and by brain region. For cerebral blood flow studies, scatter alters quantitation in brain areas including the precentral, temporal, posterior hippocampus, and cerebellum, with minimal effects in the parietal and central areas. Importantly, the cerebellum, which is often used as a reference region for both cerebral blood flow and neuroreceptor imaging studies, appears to be the most vulnerable to scatter.

Several methods for scatter correction have been developed over the past few years, including (1) the triple energy window (TEW) method, which estimates scatter based on photons detected in adjacent energy windows, (2) image-based scatter correction (IBSC), in which scatter is estimated based on the reconstructed image and Chang's attenuation correction factor determined from the transmission scan, and (3) a Monte Carlo (MC)-based scatter correction, which applies a simulation code of all image-degrading effects, including attenuation, fanbeam collimator response, and scattering for nonhomogeneous voxelized objects, into the reconstruction algorithm. While not yet routinely used, incorporation of a scatter correction will increase the accuracy of quantitative measurements of SPECT images.

Spatial Resolution

Scattered activity causes the SPECT image to appear blurred. The blurred image limits the ability to distinguish two distinct points or the spatial resolution. The spatial resolution is commonly measured by the determination of the full width at half-maximum (FWHM) of the line-spread function. If the activity emitted from a point source is measured, the result is a Gaussian curve in which the amount of activity in the peak is significantly less than the actual activity in the point source, and the residual activity is measured in adjacent areas of no activity. The resolution of the image may be defined as the width of the Gaussian curve at 50% of the maximum value. To visualize two point sources of equal activity, they must be separated by a distance equal to the FWHM.

SPECT is often criticized for having poorer spatial resolution as compared to positron emission tomography (PET) imaging. However, while this is currently true, in that the spatial resolution of the most commonly used SPECT cameras is around 8–10 mm, compared to the most commonly used PET cameras, 3–6 mm. It is important to note that, theoretically, SPECT is capable of having greater spatial resolution than PET has because the gamma photons that are measured with the SPECT camera are back-projected to the site of original emission, in contrast to PET, wherein dual gamma photons are measured using coincidence detection, a site a short distance away from the site of original emission. As SPECT technology advances, spatial resolution will continue to improve and will soon be comparable to PET.

Partial Volume Effects

The limited spatial resolution of SPECT alters the accuracy of the quantitation of the regional activities. Activity from a point is spread out or blurred in three

dimensions. Thus, the measured activity in any one area reflects the actual activity and also scattered activity from the surrounding areas. This 'partial volume' effect causes errors in quantitative measurements that increase as resolution decreases. While currently a limitation , as SPECT technology advances and resolution improves, partial volume effects will be minimized.

Quality Control

Quality control is crucial to optimize image quality and quantification of neural receptor numbers using SPECT. Artifacts may be visualized in the image by errors in the ability of the detector to measure counts uniformly or by the center of rotation being off. Quality control procedures should be performed as recommended by the manufacturer and typically include (1) photomultiplier (PM) tube gain calibration, (2) linearity calibration, (3) sliding energy calibration, (4) center of rotation calibration, and (5) crystal uniformity calibration. PM gain is performed to measure the energy gain near the centers of the photomultiplier tubes; this calculates a correction factor to ensure that the photons emitted are within the correct energy window (159 keV for ^{123}I). The linearity calibration measures and corrects for the residual spatial distortion. The sliding energy calibration measures the response of the detector at each location on the crystal and calculates a correction factor for the peak energy response at each location. The center of rotation calibration measures the angle of the center of each collimator segment relative to a sensor on the camera, and the crystal uniformity calibration measures the inhomogeneity of detector response to a uniform distribution of radioactivity.

Perfusion Imaging

SPECT imaging has been used to measure blood flow patterns in brain, a procedure also known as regional cerebral blood flow (rCBF). Brain tissue regions with a lot of blood flow are imaged using brain perfusion agents that are lipophilic (or 'fat-liking'), so that they cross the blood–brain barrier in sufficient quantities to create a good visual image. These agents, which enter the brain quickly (90–120 s), are rapidly metabolized into a lipophobic (or 'fat-disliking') compound that is trapped in the brain neuron. The slow washout restricts the localization to brain areas that are active and have a lot of blood flow. Brain tissue known as gray matter, which contains neuron cell bodies and terminals, has higher rates of blood flow compared to white matter, which contains neuronal axons. Regional cerebral blood flow has been measured using ^{99m}Tc-labeled hexamethylpropyleneamine oxime (HMPAO), and bicisate ethyl cysteinate dimer (ECD). In a perfusion or blood flow SPECT images, the radiotracer is typically symmetrically distributed throughout the cerebral cortex, cerebellum, thalamus, and basal ganglia.

Brain perfusion SPECT is used clinically for the diagnosis and clinical maintenance of a variety of neurological conditions, including cerebrovascular disease, Huntington's disease, and dementia disorders such as Alzheimer's disease. Brain perfusion SPECT is superior to anatomic imaging (CT or magnetic resonance imaging (MRI)) for the detection of acute stroke in the first few hours following the event. The sensitivity and specificity of brain SPECT for stroke localization are 85.5% and 97.6%, respectively. The sensitivity of perfusion SPECT for detection of transient ischemic attacks is 60% in the first 24 h and 40% in the first week.

Brain perfusion SPECT can be used in identifying the location of brain tumors. Thalium-201 (^{201}Tl) and ^{99m}Tc are used to evaluate recurrences of brain tumors after therapy; the differential diagnosis between tumor and radiation changes is of importance for the consequent therapy. SPECT permits to distinguish metabolically active and nonactive regions – a process difficult to obtain with technologies that provide only images of structures in the body, such as MRI. [^{123}I]Iodomethyltyrosine (IMT) has been used to diagnose primary or recurrent cerebral gliomas and has been found to be superior to 2-[^{18}F]fluoro-2-deoxy-D-glucose (FDG) PET in delineating the extension of gliomas. In epilepsy, SPECT is used to localize the seizure focus for surgical therapy. Presently SPECT is the only imaging modality that can capture the rCBF changes that occur with seizures. Brain perfusion SPECT is also useful in the diagnosis of different dementia disorders. Each disorder has its own distinct rCBF pattern. Alzheimer's disease is diagnosed with SPECT with a diagnostic confidence of 98%.

SPECT Neuroreceptor Imaging

SPECT neuroreceptor imaging studies have provided insight into the neurochemical status of numerous neural receptors and transporters throughout the spectrum of neuropsychiatric brain disorders (Table 1; Figure 3). While there are millions of chemical sites in brain tissue, only a handful of neural receptors and transporters have been imaged using SPECT to date; these include the dopamine transporter, dopamine D2 receptors, serotonin transporters, serotonin (5-hydroxytryptamine 2A, or 5-HT_{2A}) receptors, cannabinoid (CB_1) receptors, nicotinic acetylcholine receptors (containing the β_2 subunit), γ-aminobutyric

Table 1 SPECT neuroreceptor radiopharmaceuticals

acid (GABA)$_A$–benzodiazepine receptors, *N*-methyl-D-aspartate (NMDA receptors), and the norepinephrine transporter.

[^{123}I]2β-Carbomethoxy-3β(4-iodophenyl)tropane ([^{123}I]β-CIT) SPECT imaging has demonstrated decreased expression of the serotonin (5-HT) transporter in the diencephalon in major depressive disorder, which appears to be limited to women under the age of 50 years, suggesting a sex-specific decrease in 5-HT transporter availability. Several studies have suggested that 5-HT transporter availability does not predict or differentiate responder and nonresponders to antidepressant treatment; however, since these studies failed to evaluate sex-specific differences, it remains to be determined if this would be useful for young women suffering from major depressive disorder. In contrast, occupancy of 5-HT transporter by citalopram is correlated with a better clinical response in patients suffering from obsessive–compulsive disorder.

[^{123}I]Iomazenil SPECT imaging of the benzodiazepine site on the GABA$_A$ receptor is decreased in patients with probable Alzheimer's disease. The

same site has been shown to upregulate over the first week of abstinence in alcohol-dependent nonsmokers but not in alcohol-dependent smokers and to correlate with the severity of alcohol withdrawal, suggesting that smoking suppresses the upregulation of the receptor and also decreases the severity of alcohol withdrawal symptoms. [^{123}I]Iomazenil SPECT imaging of the benzodiazepine site on the $GABA_A$ receptor in alcohol-dependent patients abstinent for 1–6 months suggests that the receptor normalizes and/or decreases to below control levels.

[^{123}I]β-CIT SPECT imaging in cocaine-dependent patients has demonstrated higher striatal dopamine transporters that normalize after 6 months of abstinence. SPECT [^{123}I]β-CIT imaging of the loss of striatal dopamine transporter expression is a highly sensitive marker for the presence and severity of Parkinson's disease. SPECT imaging of the dopamine D2 receptor before and after amphetamine administration has demonstrated greater amphetamine-induced dopamine release in schizophrenic patients compared to healthy individuals. SPECT *N*-(1-naphthyl)-*N*′-(3-[^{125}I]iodophenyl)-*N*′-methylguanidine ([^{123}I]CNS-1261) imaging of the NMDA receptor demonstrated a significant decline in receptors throughout the brain of clozapine-treated schizophrenic patients but did not demonstrate this decline in the brain of drug-free schizophrenic patients.

While these are just a few illustrations of the knowledge that neuroreceptor imaging has provided on the chemical abnormalities in neuropsychiatric disorders, the utility of SPECT for understanding the neuropathological bases of these highly complex brain disorders is clear. Additional information about SPECT imaging research studies may be sought in the literature listed in the section 'Further reading.'

Clinical Utility of and Future of SPECT

Over the past two decades, SPECT has gained merit as a tool to image brain function and neurochemistry in living humans. Perfusion SPECT is routinely used for the clinical diagnosis and assessment of several neurological disorders. Neuroreceptor SPECT imaging has been useful in research to begin to identify the chemical state of different neuropsychiatric disorders that result from abnormal expression of neuroreceptors and transporters. While in its youth, neuroreceptor SPECT imaging holds tremendous potential in the clinical setting for the diagnosis of a myriad of psychiatric disorders for which currently there are no biological or chemical diagnostic tools. SPECT is highly amenable to being used as a tool in a majority of clinical settings. Compared to positron emission tomography, SPECT is less costly, does not require an on-site cyclotron, and, because of major technological advances, is rapidly improving in sensitivity and resolution. With continued progress in the development of radiopharmaceuticals and in the technology for the acquisition and image processing of SPECT data, SPECT imaging has the potential to radically change the way that neuropsychiatric disorders are diagnosed and treated.

Single Photon Emission Computed Tomography (SPECT): Technique

A B Newberg and A Alavi, University of Pennsylvania, Philadelphia, PA, USA

Introduction

Single photon emission computed tomography (SPECT) was developed in the 1960s and was used to obtain the first transaxial reconstructions of radionuclide distribution in the brain. This technique was used to study a number of neurological and psychiatric disorders and the impact of these disorders on radionuclide distribution in the central nervous system (CNS). SPECT was the first functional imaging modality that was used in the study of the CNS, andthese early studies met with much success. The SPECT studies employed single-photon emitters such as iodine-123 (^{123}I) or technetium-99m (^{99m}Tc) as the radionuclide that was attached to the substrate. The most commonly used clinical radioligands for SPECT are ^{99m}Tc hexamethyl propylene amine oxime (HMPAO) and technetium-99m bicisate to measure blood flow. However, a number of radiopharmaceuticals (see Table 1) for SPECT imaging have been developed to study various aspects of cerebral function, including a wide array of neurotransmitters. The radiopharmaceuticals used with SPECT imaging has been widely used in the evaluation of patients with various neurological and psychiatric disorders as well as various activation states of the brain.

SPECT imaging is highly advantageous for a number of reasons, comparing favorably with other imaging modalities such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET). Several noteworthy points about SPECT imaging include:

- *In vivo* imaging techniques allow the study of humans over extended periods of time. These longitudinal studies provide valuable information and may be particularly important in studies of the progression of disease and the response to treatment.
- The SPECT system, using the fan beam collimator, has good sensitivity and excellent spatial resolution (although not typically as good as PET or fMRI).
- The single-photon tracers, especially ^{99m}Tc- and ^{123}I-labeled agents, are readily available at a relatively low cost.
- The tracers can be readily prepared from premade kits without the need for an on-site cyclotron.
- There is little or no possibility of saturating cerebral binding sites with the SPECT tracers because the specific activity of these tracers is very high, $>100\,000$ Ci mmol^{-1}. The chemical amount to be injected in humans is too small to affect the number of available binding sites in the brain. Such tracers do not result in any measurable pharmacological effects.
- The localization and density of specific binding sites or biological processes in their native states can be investigated. The kinetic information determined by SPECT imaging can only be obtained by such techniques.

Normal Variants in SPECT Imaging

The ability to detect abnormalities on clinical brain SPECT scans or in research studies initially requires a determination of the normal variations that might be observed on such scans. One of the primary issues related to the definition of normal that arises with brain imaging is the determination of the baseline brain state (Figure 1). There has been considerable attention in the literature regarding the best conditions for obtaining a baseline functional imaging study. What the patient is doing and experiencing may have a profound influence on brain function. This has provided a foundation for activation studies that are typically performed on healthy individuals involved in various sensorimotor, cognitive, or affective tasks. For example, the brain function with eyes open is markedly different than the brain with the eyes closed. Once the eyes are open, there is a dramatic increase in the primary visual areas. This activity increases with the complexity of the scene being presented to the brain and may also include other association areas. Movement in the external environment also alters function in the visual centers of the brain as well as in the medial prefrontal cortex, temporoparietal junction, basal temporal regions, and extrastriate cortex. Sounds also elicit changes in cerebral function and, therefore, whether the ears are occluded may influence brain function.

Technical factors must also be considered when evaluating brain function because they may introduce artifacts and findings that are, in reality, variants of normal brain perfusion. These include the time between injection and scanning, the dose administered, filtering and processing steps, test–retest variability, and the type of scanner. As the duration of time from the injection increases, it is possible that

Table 1 Partial list of existing SPECT tracers[a]

Compound	*Application*
HMPAO, bicisate	Cerebral blood flow
IQNB	Muscarinic cholinergic receptor
Iodopride, IBZM, iodospiperone	Dopamine receptor
AMIK, DOI	Serotonin receptor
TRODAT	Dopamine transporter
ADAM	Serotonin transporter
β-CIT	Dopamine or serotonin transporter
Iomazenil	Benzodiazepine
2-Iodomorphine	Opioid receptor
^{123}I-d(CH_2)5[Tyr(Me)$_2$, Tyr(NH_2)$_9$]AV	Vasopressin receptor

Figure 1 SPECT scan using ^{99m}Tc bicisate showing uniform distribution of blood flow throughout the cortical and subcortical structures in a healthy subject. The images are axial slices from the top of the head to the cerebellum.

certain tracers may have an altered cerebral distribution. Obviously, the ideal tracer would remain completely fixed within the brain at the time of extraction from the blood. However, most tracers do experience some degree of washout and some even undergo redistribution. ^{99m}Tc bicisate, for example, begins to wash out of the cortical regions faster than the subcortical areas. The result is that a scan obtained several hours after injection might appear to have pathologically low activity in the cortex compared to a scan of the same person obtained within the first hour of the injection. Other tracers, especially neurotransmitters, may have altered biodistribution over time, and this is a factor that must be considered for any clinical or research study.

Filtering and processing of the images is also crucial to determining cerebral activity. SPECT imaging with fan beam collimators and the appropriate application of filters is necessary to adequately visualize subcortical structures and central cortical areas (Figure 2). Attenuation correction is also necessary for adequately visualizing and comparing activity in various structures (Figure 3). Patient motion can always complicate interpretation of SPECT scans. Methods for

Figure 2 Transaxial SPECT images of ^{99m}Tc bicisate showing the differences in scans when processed via different Weiner filter multipliers of: (a) 0.3; (b) 0.6. In (a), the scan appears very grainy, making some structures difficult to observe. In (b), the scan appears to be much smoother, but there is less delineation between structures.

Figure 3 Transaxial SPECT images of ^{99m}Tc bicisate: (a) before correction for photon attenuation; (b) after correction for photon attenuation. The ability to restore counts to central structures results in much better observation of the subcortical structures, such as the thalamus, after attenuation correction is applied.

preventing patient motion from interfering with scanning include firm head holders and the use of tape or some other method to hold the head in place. Also, shortening image acquisition makes the session easier on the patient. Alternatively, breaking up the acquisition time into multiple shorter scans can be useful because scans with motion can be excluded without losing the entire study. Another processing factor that can affect the visual inspection of brain scans is head tilt. Because a patient's head is rarely in complete alignment with the camera, slight and especially significant head tilt might result in certain areas appearing asymmetric in comparison to the contralateral structure. For example, the thalami can frequently

appear to have asymmetric activity if there is head tilt. However, this can usually be identified by examining all the slices containing the structure. As the slices proceed through the structure, asymmetries associated with head tilt should flip from one side to the other. This can usually be corrected by computer programs that realign brain images.

In spite of many of these issues, most studies of cerebral blood flow, metabolism, or even neurotransmitter systems have demonstrated good test–retest results with small variability within structures. Most studies have shown that in healthy controls repeat scans typically demonstrate regional activity and absolute activity to be within 5–10%.

SPECT Imaging from Infancy to Adulthood

The normal aging process is associated with a number of biochemical changes in the brain. Although postmortem studies may help to elucidate the nature of these changes, the advent of functional neuroimaging techniques allowed these biochemical changes in the brain to be measured *in vivo* across the life span of the person.

During the first year of normal development, studies have shown that the pattern of activity observed on functional brain scans generally corresponds to the phylogenetic order of development. Thus, the functional maturation (as measured by increased metabolism) of developmentally older structures precedes that of structures that develop later. For example, as the visuospatial and visuosensorimotor function and primitive reflexes develop, increased cerebral function is observed in the parietal, temporal, cerebellar, and primary visual cortices. Increases have also been observed in the basal ganglia as movement and sensorimotor function becomes more integrated. Function in the frontal lobe remains low during the first 4 months of life and increases as the infant begins to develop higher cortical and cognitive capabilities. Thus, as the infant develops more complex social interactions as well as improves his or her abilities in various neuropsychological tests that specifically involve frontal lobe function, these changes are reflected by increases in frontal lobe activity. By 1 year of age, the overall pattern of activity is qualitatively similar to that of a young adult.

The results of studies in adults that have measured cerebral blood flow in normal aging have generally noted a global decrease in cerebral blood flow with age. This typically affects the gray matter more than the white matter. Furthermore, the decrease appears to be nonlinear, with a sharper decrease prior to the age of approximately 36 years followed by a slower decline. Several areas appear to be affected, but the most commonly observed decrease is in the frontal lobes bilaterally (Figure 4). However, age-related decline in tracer uptake also occurs in the anterior cingulate gyrus, bilateral basal ganglia, left prefrontal, left lateral frontal, and left superior temporal and insular cortex.

Figure 4 Transaxial SPECT images of ^{99m}Tc bicisate in normal aging with decreased bilateral frontal lobe perfusion (arrow).

Neurotransmitter Function in Aging

In addition to measuring changes in cerebral blood flow with age, SPECT can measure neurotransmitter activity, which may also change with age. A large number of neurotransmitter systems can be studied using SPECT (see Table 1). Many of these have been used to study the effects of aging.

The nigrostriatal dopaminergic pathways have been studied with SPECT imaging. This pathway is important with regard to extrapyramidal symptoms that occur in the elderly. This system also has particular significance in the study of Parkinson's disease (PD). *In vitro* studies have generally shown decreases in both pre- and postsynaptic receptor levels with age. Several SPECT studies have been performed with ligands that bind to postsynaptic receptors such as D1 and D2. Radioligands that can measure the dopamine transporter system, which removes dopamine from the neuronal synapse into the terminal for storage, have also been developed. One study, using the cocaine analogs such as ^{99m}Tc TRODAT-1 and 2β-carbomethoxy-3β-(4-iodophenyl)tropane (β-CIT), indicated an age-related decrease in dopamine transporters. ^{99m}Tc TRODAT-1, has demonstrated a nonlinear decrease

Figure 5 Multiple projections of ^{123}I ADAM SPECT and corresponding MRIs showing areas of substantial serotonin transporter binding in the midbrain with relatively little uptake in the cortex and cerebellum: (a) coronal; (b) transaxial; and (c) sagittal. CER, cerebellum; MB, midbrain.

in uptake with age. With this tracer, most of the decline appears to occur before the age of 40 years, with a slower decline from 40 to 75 years of age.

The serotonergic system is critical for a number of functions in the brain and is most notably involved in the regulation of mood. Several studies have examined the changes with age of the serotonin (5-HT) system using ^{123}I β-CIT or ^{123}I ADAM (Figure 5). Generally, there is a decline in binding to the 5-HT transporter of approximately 10% per decade in the thalamus and midbrain. An age-related decreased activity for the 5-HT1A receptor has also been reported, with a decline of approximately 10% per decade in a number of cortical areas except for the medial temporal cortex. Similar decreases have been reported for the 5-HT2A receptor.

Other neurotransmitter systems have not been widely studied with regard to the effects of aging. However, given the list of radioligands available for SPECT imaging, it seems that these techniques may have vast applications in the study of the neurotransmitter effects that result from normal aging as well as neurological and psychiatric disorders. Several studies have been mentioned, but there remains a significant amount of neurotransmitter systems which have yet to be thoroughly explored with regard to the effects of aging.

SPECT Imaging in Neuropsychiatric Disorders

Alzheimer's Disease

Since 1980, a large number of studies have used SPECT in the assessment of patients with Alzheimer's disease (AD). Most studies show that the bilateral parietal and temporal lobes are particularly affected in AD. This parietal hypoperfusion (Figure 6) is often referred to as representing the typical pattern of AD

Figure 6 Transaxial SPECT images of ^{99m}Tc bicisate in a patient with late Alzheimer's disease (AD). There is moderately decreased perfusion in both temporoparietal regions (thin arrow) in comparison to the control studies shown in previous figures. In this later stage of AD, there is also decreased perfusion in the frontal lobes with preservation of perfusion only in the sensorimotor areas (thick arrow), visual cortex, and subcortical structures.

and may be particularly pronounced in patients younger than 65 years. However, it should be noted that, although the bilateral parietal pattern is highly predictive of AD, the pattern is not pathonomic for AD and may be seen in patients with PD, bilateral parietal subdural hematomas, bilateral parietal stroke, and bilateral parietal radiation therapy ports. In spite of this limitation, until recently, SPECT has been widely used for assisting in the diagnosis of AD. More recently, fluoro-2-deoxyglucose (FDG) PET has been used for the diagnosis of AD and frontal lobe dementia. Given the superior image quality of FDG PET, this may ultimately replace the use of SPECT in the workup of patients with memory problems.

In patients with AD of varying severity, the magnitude and extent of hypoperfusion correlate with the severity of the dementia symptoms. Other areas (the sensorimotor and visual cortices, subcortical nuclei,

Figure 7 Transaxial SPECT images of ^{123}I IMPY: (a) in a elderly control subject; (b) in a patient with Alzheimer's disease (AD). There is substantially greater binding in the cortex in the AD patient than in the control (arrows).

brain stem, and cerebellum) have relatively preserved perfusion except in patients with specific neuropsychological deficits.

Newer SPECT radiopharmaceuticals are being developed to specifically target the pathophysiological process of AD. For example, ^{123}I IMPY, which binds to the amyloid protein, has recently been developed and tested in human subjects (Figure 7). It is hoped that such compounds will be useful for early diagnosis as well as monitoring responses to interventions designed to attenuate the pathophysiological process.

Cerebrovascular Disease

Cerebrovascular disease is the third leading cause of death in the United States and affects approximately half a million people. However, stroke is often associated with a poor outcome, in part due to the lack of understanding of the mechanisms that underlie stroke and the process by which recovery may take place. SPECT, in addition to PET, imaging has been of great benefit in advancing the understanding of the pathophysiology of cerebrovascular disorders. SPECT imaging allows for the detection of stroke earlier and with higher sensitivity than anatomic imaging with either MRI or computed tomography (CT). Further, SPECT imaging has been useful in evaluating the extent of the functional damage because areas not immediately affected by the infarct may show hypoperfusion (Figure 8). However, SPECT studies have not become prominent in the management of stroke patients for several reasons. One of the most important initial issues is whether a stroke is hemorrhagic, and SPECT cannot make this determination. Further, SPECT has not been shown to substantially alter management in the acute setting. In the chronic setting, SPECT may help with prognosis and to predict functional recovery, but this is not often useful in the clinical setting.

Figure 8 Transaxial SPECT images of ^{99m}Tc bicisate in a patient with recent left frontal lobe stroke. The scan shows near-absent activity in the left frontal region. There is also decreased perfusion in the ipsilateral thalamus (arrow), which may be associated with deafferentation from the affected regions in the left frontal lobe.

Where SPECT has been helpful is in the evaluation of cerebrovascular reserve, patients are given an initial SPECT scan followed by a second scan in which they have been pretreated with acetazolamide. Acetazolamide causes cerebral vasodilation, which unmasks areas that are at risk for future ischemic events. This helps to guide possible surgical interventions such as carotid endarterectomy.

Head Trauma

There have been a limited number of studies using SPECT in the evaluation of patients with head trauma. One of the problems with the use of SPECT in these cases is that SPECT cannot distinguish between structural damage and cerebral dysfunction because these may all result in areas of decreased perfusion. Thus, it is helpful to compare SPECT to anatomic images such as those obtained by MRI or CT, especially because cerebral dysfunction can extend beyond the boundary of anatomic lesions and may appear even in locations remote from the trauma.

Lesions such as cortical contusions, intracranial hematoma, and resultant encephalomalacia have perfusion defects that are confined primarily to the site of injury . However, subdural and epidural hematomas often cause widespread hypoperfusion and may affect even the contralateral hemisphere. Another entity, diffuse axonal injury, has been found to cause diffuse cortical hypoperfusion, but there is a particularly marked decrease in metabolism in the thalamus which appears to correlate with the severity of cognitive dysfunction. Further, crossed cerebellar diaschisis, as well as ipsilateral cerebellar hypoperfusion, has been found in head-injury patients with supratentorial lesions.

Seizures

Epilepsy affects 0.5–1.0% of the population, can cause focal or generalized seizures, and usually begins in childhood. In general, during an epileptic seizure, cerebral metabolism and blood flow are markedly increased. The focus of partial seizures can be identified using SPECT imaging because these areas have increased blood flow during the seizure and decreased blood flow in the interictal period (Figure 9). It has been shown that single hypoperfused regions can be identified in up to 80% of patients with focal electroencephalogram (EEG) abnormalities. The degree of asymmetry in the region of the seizure focus appears greater with increasing duration of the seizure disorder. The type of seizure preceding the SPECT study may also affect the cerebral blood flow landscape such that hypoperfusion is limited to the epileptogenic zone if the preceding seizure is focal limbic,

Figure 9 Transaxial SPECT images of ^{99m}Tc bicisate in a patient with seizures: (a) interictal scan; (b) ictal scan. The interictal scan in (a) shows decreased activity in the region of prior surgery with mildly decreased activity in the adjacent cortex (thin arrow). The ictal scan in (b) shows the surgical area as decreased perfusion, but there is an intense focus of activity in the adjacent cortex (thin arrow), clearly delineating the seizure focus.

whereas patients with widespread limbic seizures have hypoperfusion that includes one or several additional areas of the limbic cortex.

The temporal lobe is the most common focus of partial epilepsy (Figure 9). Studies show that the sensitivity of interictal SPECT in detecting temporal lobe epilepsy (TLE) foci is over 70%. Ictal SPECT studies provide a more sensitive evaluation of seizure foci and can detect areas of hyperperfusion in up to 80% of patients. When statistical parametric mapping or coregistration with MRI is used to enhance detection, the sensitivity can be improved up to 90%. When additional cerebral areas of abnormality are detected, the implication is that the seizures have a more complex origin. This also makes surgical excision of the seizure focus, an important intervention in patients refractory to medications, less likely to be successful.

Depression

Depression is generally characterized by decreased cortical perfusion, particularly affecting the frontal lobes (Figure 10). However, the exact pattern has been somewhat controversial, with different studies reporting slightly discrepant findings. Furthermore, generalized decreases in cortical perfusion have also been reported with a number of psychotropic medications such as benzodiazepines, sedatives, antipsychotic medications, and anticonvulsant medications. Thus, SPECT cerebral blood flow imaging of depression has generally not been very useful in a clinical or research setting.

A number of functional neuroimaging studies have focused on the role of the 5-HT system in depression, including both pre- and postsynaptic receptors. 5-HT2A postsynaptic receptors are generally reduced in the frontal cortex. SPECT studies of the 5-HT transporter using ^{123}I β-CIT and ^{123}I 2-((2-((dimethylamino) methy) phenyl)thio)-5-iodophenylamine (ADAM) revealed reductions in binding in the brain stem in drug-free depressed patients compared to controls. Several initial SPECT studies of treatment effects suggested that antidepressant medication and also psychotherapy improve 5-HT function in patients who demonstrate a good response.

Movement Disorders

Parkinsonian symptoms are associated with a number of neurodegenerative disorders, such as PD, multiple system atrophy (MSA), and progressive supranuclear palsy (PSP). These disorders are frequently associated with abnormalities in a number neurophysiological processes. In particular, pathological evidence has shown that these disorders are associated with a loss of neurons, particularly in the nigrostriatal dopaminergic pathway.

SPECT and PET have become important tools in the differential diagnosis of these diseases and may have sufficient sensitivity to detect neuronal changes before the onset of clinical symptoms. Imaging is now being used to elucidate the genetic contribution to PD and, in longitudinal studies, to assess the efficacy and mode of action of therapeutic interventions such as neuroprotective drugs and surgery.

SPECT studies of radiotracer binding to postsynaptic dopamine receptors and presynaptic dopamine

Figure 10 Transaxial SPECT images of ^{99m}Tc bicisate in a patient with depression show overall decreased perfusion in the cortex, with the frontal lobes most prominently affected. There is preserved perfusion in the visual cortex and thalamus.

Figure 11 Transverse SPECT images of [^{99m}Tc]TRODAT-1 binding to dopamine transporters in human subjects: (a) histology slice through the brain at the level of the striatum showing the head of the caudate nucleus (CAUD) and the putamen (PUT); (b) image at the same level from a healthy subject showing high concentrations of [^{99m}Tc]TRODAT-1 binding to dopamine transporters in the caudate and putamen; (c) image at the same level in a patient with bilateral Parkinson's disease showing significant reductions of [^{99m}Tc]TRODAT-1 binding in the putamen but with the caudate relatively spared.

transporters and neurons have proved to be powerful techniques for quantifying the loss of dopaminergic neurons in normal aging and in PD and other neurodegenerative disorders. SPECT studies have indicated a consistent pattern of dopaminergic neuronal loss in PD, usually with a more pronounced decrease in the putamen rather than in the caudate (Figure 11). In addition, there is often a marked asymmetry of uptake in the striatum, particularly in the early stages of the disease. This asymmetry usually has a good correlation with symptom severity and illness duration. Most important, SPECT imaging studies may be sensitive enough to detect very early PD, perhaps even before clinical symptoms become apparent.

Although most of the SPECT studies have shown highly significant differences between groups of PD patients and age-matched normal controls, the statistically significant differential diagnosis of an individual subject is more problematic. Patients with severe PD are easily separated from healthy controls just from a simple visual inspection of striatal images, which can be quantified using some form of discriminant analysis which has a sensitivity and specificity from 90% to 100% in the proper clinical setting. However, patients presenting much earlier in the course of the disease are more difficult to detect because there can be a substantial overlap with an age-matched control group and, consequently, a loss of diagnostic accuracy. The situation may be further complicated if the early differential diagnosis among several different neurodegenerative disorders is required. Many of the symptoms associated with parkinsonian disorders are nonspecific, which is why the accurate clinical diagnosis of these diseases is difficult. Indeed, some histopathalogical studies have shown that as many as 25% of all patients who were diagnosed with PD before death had been misdiagnosed. Studies measuring dopamine transporter activity have had more difficulty in separating PD from MSA or PSP. Essential tremor (ET) is another possible diagnosis to consider when evaluating a patient for PD. ET may be easier to distinguish from PD because the former does not typically involve the dopaminergic pathways to the same degree.

Conclusion

Functional imaging using SPECT has provided detailed *in vivo* measurements of cerebral biochemical activity that occur in the normal brain and various neuropsychiatric conditions. The ability to interpret findings depends both on technical issues that may affect the normal pattern of activity and on normal age-related changes. Changes with aging and various neuropsychiatric conditions can be reflected in cerebral blood flow and neurotransmitter concentrations. Overall, SPECT imaging will probably continue to play an important role in the evaluation of brain function in both the clinical and research setting.

Single-Nucleotide Polymorphism (SNP) Analysis

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

Single-nucleotide polymorphisms (SNPs) are individual nucleotide positions in the genome that vary at polymorphic levels in human populations. Most SNPs are diallelic (i.e., the SNP site may be occupied by either of two different bases), and the less common base must have a frequency of at least 1%, else it is classed as a rare mutation rather than a polymorphism. SNPs represent the most abundant form of genetic variation in humans, accounting for more than 90% of all differences between unrelated people. SNPs influence many central nervous system phenotypes, including susceptibility to neurological disorders. For example, an important genetic determinant in Alzheimer's disease is the *APOE* gene, which encodes apolipoprotein E (ApoE). The presence of two SNPs in this gene yields three common variants – *APOE* ε2, ε3, and ε4, which produce the proteins ApoE2, E3, and E4. Each of these variants is associated with a different level of disease susceptibility, *APOE* ε4 conferring the greatest risk and *APOE* ε2 the lowest. *APOE* ε4 homozygotes are the highest-risk group for Alzheimer's disease.

As well as affecting disease susceptibility, SNPs also affect our responses to drugs and other xenobiotics. Extending the example presented above, SNPs in the *APOE* gene contribute not only to the risk of Alzheimer's disease but also to drug responses, with the high-risk *APOE* ε4 homozygotes showing the poorest response to tacrine, an acetylcholinesterase inhibitor. SNPs therefore play a major role in all stages of the drug development process, from target identification through to clinical trials. The analysis of SNPs may help scientists tailor drugs and drug regimes to particular genotypes, which is the underlying principle of pharmacogenomics. In this context, it has been necessary to develop techniques for the rapid, high-throughput genotyping of SNPs in large samples.

Principles of SNP Genotyping

All SNP genotyping methods combine two distinct steps – one to discriminate between alternative alleles at the SNP locus and one to report the nature of the allele by generating a signal that can be detected, in an automated fashion if possible.

There are three general allele discrimination methods: hybridization/annealing (sometimes with a downstream enzymatic discrimination step), primer extension, and enzyme cleavage. In each case, the discrimination assay may take place in solution (so-called homogeneous assays) or in a solid phase immersed or coated in liquid, such as a microarray (so-called heterogeneous assays). In many of these assays, it is necessary to amplify the genomic DNA prior to detection of the allele, and amplification may indeed be integrated into the detection step. In other cases, the detection assay is sensitive enough to work directly on nonamplified genomic DNA or complementary DNA.

While allele discrimination methods come in three broad varieties, there are many different ways to generate and detect the signal, some based on fluorescence, others based on enzymatic reactions, and a few based on direct quantification. Most follow the fate of a label, either in real time or at the assay end point. Some methods based on mass spectrometry (MS) measure the masses of allele-specific oligonucleotides, so a label is not required.

Allele Discrimination

Allele-Specific Hybridization

The simplest method for discriminating between alleles at a SNP locus is hybridization using allele-specific oligonucleotide (ASO) probes. Two probes are required, one specific for each allele, and stringency conditions are employed such that a single-base mismatch is sufficient to prevent hybridization of the nonmatching probe (Figure 1). The two probes can be combined in labeled/unlabeled pairs, in which case two separate assays are required for each SNP (one in which probe 1 is labeled and probe 2 is unlabeled, and one in which these roles are reversed). Alternatively, and preferably in the case of high-throughput assays, distinct labels can be used for each probe (e.g., different fluorophores or mass tags) so that each SNP can be genotyped in a single reaction.

Allele-specific polymerase chain reaction (PCR) is an extension of the allele-specific hybridization principle, in which discrimination is achieved by allele-specific primer annealing followed by PCR amplification rather than the direct detection of a hybridized probe (Figure 2). Three primers are required, two to match alternative alleles at the SNP site and one to anneal to the opposite strand. Two reactions are set up, each containing one of the SNP primers together with the reverse primer. Although the variable base position can be sited somewhere in the middle of the SNP primers, in a manner directly analogous to the ASO strategy, this method tends to allow the extension of a mismatched primer–template because the

stringency of annealing cannot be optimized (annealing has to favor both primers in the reaction and is therefore difficult to optimize for the allele-specific primer alone). The preferred approach is to place the 3′ end of one of the primers at the variable base position since extension is dependent on perfect complementarity at the 3′ end of the primer.

A further extension of the allele-specific hybridization approach is allele-specific ligation, in which two oligonucleotides are annealed at adjacent sites and DNA ligase is used to join them together. One of the oligonucleotides has two allele-specific variants, and the discriminatory base is at the most 3′ position. If there is perfect complementarity between the allele-specific oligonucleotide and the template, it will be successfully ligated to the common oligonucleotide. If there is a mismatch, then ligation will fail, and the two oligonucleotides will remain separate. The assay benefits from the inclusion of additional steps such as the ligase chain reaction (in which the ligation reaction is reiterated with further oligonucleotides complementary to the first ligation product) or rolling circle amplification technology, in which two allele-specific oligonucleotides about 80 nt in length are designed to form a circle on the template, generating a closed loop (or padlock probe) when ligated. Primers annealing to this circle can be extended with a strand-displacing DNA polymerase so that when the nascent strand completes the circle and encounters itself, it is continually displaced, generating a long concatemer that is easy to detect using fluorescence methods.

Figure1 Principles of allele-specific hybridization as an allele discrimination method.

Minisequencing

Minisequencing is also known as allele-specific primer extension. Like allele-specific PCR, it involves the extension of a primer annealing to the template DNA, but the primer in minisequencing is nondiscriminatory. The primer anneals one base upstream of the polymorphic site, and discrimination is achieved by detecting which base is incorporated in the first polymerization step (Figure 3). Allele-specific primer extension methods are more adaptable than hybridization/annealing assays because a much greater diversity of labeling strategies can be used. The free nucleotides in solution can be labeled with four different fluorescent tags, mass tags, or haptens, allowing the same mix to be used in the detection of many SNPs in a highly multiplexed fashion, such as on a microarray. Primer extension methods for genotyping have been developed commercially, for example as Genetic Bit Analysis technology by Orchid Biosciences, and they form the basis of many popular commercial genotyping systems, such as SNaPshot (Applied Biosystems).

Allele-Specific Enzymatic Cleavage

The use of enzymes to distinguish between alternative alleles is the basis of one of the earliest genotyping

Figure 2 Principles of allele-specific polymerase chain reaction (PCR) as an allele discrimination method.

Figure 3 Principles of allele-specific primer extension (minisequencing) as an allele discrimination method.

methods – the analysis of restriction fragment length polymorphisms (RFLPs). An RFLP is generated when a single nucleotide polymorphism occurs at a restriction endonuclease recognition sequence, and one allele preserves the sequence while the other destroys it. In a sequence of genomic DNA with three adjacent restriction sites, the middle one containing a SNP, then digestion of amplified genomic DNA with the appropriate restriction endonuclease will produce either a single large fragment (if the central restriction site is absent) or two smaller fragments (if the central restriction site is present and cleavage occurs).

Traditional RFLP analysis cannot be applied on a large scale because it relies on gel electrophoresis and Southern blot hybridization, which are cumbersome to use in high-throughput experiments. Modern takes on RFLF analysis which combine restriction enzymes and PCR amplification can accelerate this process and facilitate moderate multiplexing (e.g., amplified fragment length polymorphisms and cleaved amplified polymorphic sites). However, these have been used more for linkage analysis than for genotyping. One enzymatic assay developed for genotyping is the Invader assay, which employs a unique method of allelic discrimination involving overlapping probes and an enzyme that specifically recognizes the resulting 'flap' (Figure 4). An advantage of the Invader assay is that it requires no PCR amplification. Two signal probes are used, one recognizing each allele, plus an invader probe. The signal and invader probes hybridize in tandem, and the signal probe overlaps the invader probe, generating a flap that is recognized by an enzyme called cleavase, a modified form of the thermostable FEN-1 (for flap endonuclease) enzyme. A flap with the appropriate structure is generated only if the signal probe completely matches the template and there is a one-base invasion. The cleaved flap can then be used in a second-round invader assay to generate a fluorescent signal, or the cleaved flap can be detected by MS.

Figure 4 Principles of allele-specific invasive cleavage as an allele discrimination method.

Allele Detection

Fluorescence Methods

Direct detection of incorporated fluorescent labels The most straightforward way to detect an allele-specific product is to incorporate one or more nucleotides conjugated to a fluorescent dye. Direct fluorescence detection is generally used with heterogeneous assay formats (microarrays, bead arrays) and is particularly suitable for minisequencing methods since single-base extension can be carried out with four nucleotides bearing different fluorophores, which allows the immediate detection of alleles on the basis of the emission wavelength of the extension product. Direct fluorescence is also often used when gel or capillary electrophoresis is used to separate allele-specific products.

Direct detection of intercalated fluorescent labels Intercalating fluorescent dyes such as ethidium bromide fluoresce much more brightly in the presence of double-stranded DNA than single-stranded DNA. This is the basis of a unique detection method known as dynamic allele-specific hybridization, which involves a single (unlabeled) allele-specific oligonucleotide probe that is added to a PCR product containing an SNP site and allowed to anneal when ethidium bromide is present. The mixture is then heated, and fluorescence is measured in real time as the temperature rises. The fluorescence decreases as denaturation (melting) occurs, and the thermal melting profile for each allele will be different because only one is perfectly complementary to the probe and the other contains a mismatch.

Fluorescence resonance energy transfer Fluorescence resonance energy transfer (FRET) occurs when two fluorophores are in proximity and one of them (the donor) has an emission spectrum that overlaps the excitation spectrum of the other (the acceptor). When a lone donor fluorophore is excited, light is produced with a characteristic emission spectrum. However, when the donor fluorophore is excited in proximity to the acceptor, energy is transferred to the acceptor fluorophore with the result that the intensity of emission from the donor is reduced (quenched) while that of the acceptor is enhanced.

Although FRET enhancement can be used for SNP genotyping, two of the most popular homogeneous assays in current use employ FRET quenching. The *Taq*Man assay exploits the intrinsic 5′ nuclease activity of *Taq* DNA polymerase to generate a fluorescent

Figure 5 Principles of the *Taq*Man assay; A, acceptor fluorophore; D, donor fluorophore.

Figure 6 Principles of the molecular beacon assay; A, acceptor fluorophore; D, donor fluorophore.

signal from a short allele-specific oligonucleotide probe. Two probes are required, one specific for each allele. Each probe contains a unique donor fluorophore and a common acceptor fluorophore and is short enough for the donor to be quenched when the probe is intact (either hybridized or in solution). When the probe hybridizes to the PCR template, however, the 5′ exonuclease activity of *Taq* DNA polymerase digests it, thus releasing the two fluorophores into solution and eliminating the quenching effect (Figure 5). The molecular beacon assay involves the use of longer probes that have self-complementary ends labeled with the donor and acceptor fluorophores. Nonhybridized probes will self-anneal, bringing the donor and acceptor fluorophores together, resulting in quenching. Where hybridization occurs, the donor and acceptor fluorophores are separated such that the quenching effect is eliminated and a fluorescent signal is produced. As with the *Taq*Man assay, two probes labeled with different donor fluorophores are required, one specific for each allele (Figure 6).

Fluorescence polarization When a fluorophore is excited by plane polarized light, the fluorescence emitted by the dye is also polarized, a phenomenon termed fluorescence polarization (FP). Complete FP occurs only when a dye molecule is stationary. The degree of FP thus depends on the movement of molecules in solution, which in turn depends on various factors, including the molecular mass. SNP genotyping assays can change the molecular mass of a target oligonucleotide, for example by primer extension, probe hydrolysis, or invasive cleavage, and this is the basis of commercial genotyping systems such as SNaPshot. Such changes can be recorded as changes in FP as long as the temperature and viscosity of the solution remain the same.

Pyrosequencing

Pyrosequencing is a novel method for sequencing short stretches of DNA on the basis of the detection of pyrophosphate, a normal by-product of DNA synthesis. Although similar in principle to primer extension allele discrimination methods, pyrosequencing is suitable not only for typing SNPs but also for scoring entire haplotypes (groups of linked SNPs). Pyrosequencing works on the basis that pyrophosphate can be used to generate adenosine triphosphate (ATP), which then stimulates luciferase activity, causing the emission of a chemiluminescent signal. To achieve this, the primer extension reaction must include APS and the enzyme ATP sulfurylase, which converts adenosine 5′ phosphosulfate into ATP in the presence of pyrophosphate. Also present are luciferin (the substrate of luciferase) and the enzyme apyrase, which continuously degrades unincorporated deoxynucleotide triphosphates (dNTPs) and excess ATP. The dNTPs are added to the reaction one by one. Only if the incoming dNTP is complementary to the template will it extend the primer and release pyrophosphate, resulting in the production of an equimolar amount of ATP. Visible light is generated in proportion to the amount of ATP and is detected as a peak on a pyrogram. When the degradation of the present dNTP is completed by apyrase, the next is added. A thioderivative of dATP must be used to avoid constant stimulation of luciferase activity.

Mass Spectrometry

Genotyping assays involving MS are distinct from those discussed above in that signal detection is direct, based on differing molecular weights of small DNA fragments rather than the behavior of a label. The analysis of DNA by MS requires soft ionization (i.e., without fragmentation) and is usually achieved by matrix-assisted laser desorption/ionization (MALDI) followed by time of flight (TOF) analysis. The MALDI procedure involves mixing the allele-specific products of the discrimination assay with a matrix compound on a metal plate. The mixture is then heated with a short laser pulse, causing it to expand into the gas phase, where ionization is achieved by application of a strong potential difference. Ions are accelerated toward the detector, and the TOF (the time taken to reach the detector) is measured, allowing the mass–charge ratio to be calculated.

High-resolution mass spectrophotometers can accurately discriminate between alternative alleles in DNA fragments of three to 20 nt in length. The smallest difference in mass between alternative allelic products is about 9 Da, representing an adenosine–thymidine polymorphism. Advantages of MS-based methods include accuracy, as long as the sample is very pure, and the fact that each genotyping reaction takes a fraction of a second, which allows thousands of reactions to be carried out serially in a single day.

The majority of current MS genotyping platforms involve the use of DNA chips because the chip can be used directly as a MALDI plate. Thus far, the technique has been used to determine the masses of allele-specific hybridization probes, allele-specific primer extension products, and the products of invasive cleavage reactions. Commercial systems utilizing MS include MassArray (Sequenom) and PinPoint (PerSeptive Biosystems).

Another promising MS genotyping technology involves the use of cleavable mass tags (chemical moieties of known molecular mass) as labels to replace fluorophores. The advantage of mass tags is that, because of the accuracy of MS-based mass determination, the range of labels that can be used is virtually limitless, so ultrahigh-throughput genotyping is possible. The MassCode system (Qiagen Genomics) uses this technology.

Summary

High-throughout SNP genotyping has helped facilitate association studies aiming to find patterns among the 0.1% of variation in the human genome (mostly represented by SNPs) corresponding to differences in complex neurological phenotypes such as susceptibility to neuropathophysiological disorders, psychiatric disorders, and responses to drugs. Many of the technologies described above facilitate highly multiplexed analysis, although MS stands out as a platform in which increased throughput is realized by ultrarapid serial processing.

The sensitivity of most genotyping techniques reflects some form of amplification step either before, during, or after the actual allele discrimination assay. In the majority of cases, this amplification step relies on the PRC, but novel formats such as the invader assay and rolling circle amplification technology are also becoming popular. While homogeneous assay formats are versatile, array-based technology platforms have the advantage of higher throughput. Recent developments include the use of electrostringent hybridization arrays, in which electric currents are used to increase the speed and sensitivity of hybridization, and the detection of allele-specific products on the basis of their electrochemical properties when hybridized to oligonucleotide probes attached to minute electrodes. Another emerging technology, bead arrays, combines the flexibility of the homogeneous assay format with the convenience and throughput of chip-based detection systems. Bead array systems that employ fluorescence-based detection and sorting are commercially available from Lynx Therapeutics and Illumina.

siRNA: Utility

RNA interference (RNAi) is a highly conserved, naturally occurring cellular process that mediates the sequence-specific silencing of gene expression. The discovery of this process has challenged the long-held idea that the flow of genetic information occurs in a unidirectional manner from DNA to RNA to protein. In fact, it is now clear that RNA can act bidirectionally, with certain types of RNA being translated into proteins, whereas other forms can direct the regulation of gene expression. Regulatory RNAs have been shown to regulate a variety of processes, including transcription, splicing, and translation. In addition, the discovery of these regulatory RNAs has helped to begin to explain why the genomes of complex organisms retain large amounts of DNA that lack protein coding genes, referred to as intergenic regions. Analysis of the total RNA content, the so-called transcriptome, of a variety of organisms has shown that the transcriptional output of many organisms' genomes is much greater than the number of protein coding genes and that the intergenic regions of the genome are rich sources for noncoding RNAs, the majority of which are probably involved in various regulatory processes.

Small Regulatory RNAs

The small regulatory RNAs involved in RNAi have garnered a great deal of attention, both for their biological role as endogenous regulators of gene expression and as research tools for the selective suppression of gene expression. These small RNA molecules, ranging in size from approximately 19 to 26 nucleotides (nt), are highly conserved across diverse organisms from plants to worms and mammals and have been found to be involved in the regulation of a variety of cellular processes, including development and differentiation, metabolism, and the suppression of mobile genetic elements (e.g., transposons and retrotransposons) and viruses. Although micro (mi)RNAs were the first class of small regulatory RNA molecules identified, with the discovery that let-7 and lin-4 were noncoding RNAs involved in the regulation of genes responsible for proper developmental timing in the nematode *Caenorhabditis elegans*, the impact of this discovery was not immediately appreciated. It was the demonstration that the introduction of long double-stranded RNA (dsRNA) molecules into *C. elegans* led to the sequence-specific suppression of gene expression that signaled the beginning of a new era in molecular biology. It was for this discovery, termed 'RNA interference,' that Drs. Andrew Fire and Craig Mello were awarded the 2006 Nobel Prize in Physiology or Medicine. In rapid succession, it was shown that these long dsRNAs were rapidly cleaved into small duplexed RNA molecules of 19–21 nt, referred to as small interfering (si)RNAs, and that these siRNAs were the effector molecules that guided the degradation of the homologous mRNA. It soon became clear that RNAi was related to a variety of silencing phenomena, including quelling in fungus and posttranscriptional gene silencing in plants. Since these initial discoveries, an increasing number of small regulatory RNAs have been identified using biochemical, genetic, and computational approaches. These small RNA species include miRNAs, siRNAs, repeat-associated siRNAs (rasiRNAs), and piwi-interacting RNAs.

Both miRNAs and siRNAs are processed from dsRNA precursor molecules – long hairpin RNAs for miRNAs and long dsRNAs for siRNAs – by RNase III-type endonucleases (**Figure 1**). miRNAs are expressed as long transcripts, termed primary miRNAs (pri-miRNAs), from RNA polymerase II or III promoters. These highly structured pri-miRNAs are recognized by the nuclear localized RNase III-type enzyme Drosha that cleaves the pri-miRNA into an approximately 60–70 nt precursor miRNA (pre-miRNA) stemloop containing both the mature miRNA and the accompanying passenger strand separated by a noncomplementary loop region. This truncated stemloop is recognized by exportin-5 and translocated from the nucleus to the cytoplasm. In the cytoplasm, it is cleaved by the RNase III-type endonuclease Dicer into a short-lived small (~21 nt) duplexed RNA containing 2 or 3 nt 3′ overhangs characteristic of an RNase III-type cleavage reaction. In addition to producing miRNAs, Dicer is also able to cleave long dsRNAs into siRNAs. In fact, Dicer was originally identified based on its ability to process long dsRNAs. Additional dsRNA-binding proteins help Dicer to distinguish between these two precursor molecules. Interestingly, in plants, the pre-miRNA processing and long dsRNA cleavage activities of Dicer have been segregated into two RNase III family members, Dicer-like 1 (DCL-1) and DCL-2, respectively. In each case, the small duplexed RNAs, either the siRNAs or the miRNA, are loaded into an effector complex whereupon the passenger strand is dissociated from the active silencing strand (guide strand). Both siRNAs and miRNAs have an asymmetric nature that helps to distinguish the guide strand from the passenger strand. This asymmetric nature is determined by the relative thermodynamic

Figure 1 RNA interference pathways. (a) Biochemical structure of siRNAs. siRNAs have the characteristic structure of an RNase III cleavage product with 5′ phosphorylated ends, a 19 nt duplexed region, and 2–3 nt overhangs at the 3′ termini. (b) The 'classic' RNAi pathway. Long dsRNAs were the first 'trigger' molecules associated with RNAi. These long dsRNAs were processed by the RNase III family member Dicer into siRNAs that serve as the effector molecules that guide the sequence-specific silencing of gene expression. Although Dicer can cleave the long dsRNAs in the absence of additional factors, the dsRNA-binding protein R2D2 helps to identify the end of the siRNA that has the lowest thermodynamic stability, a mechanism used to differentiate the active guide strand from the passenger strand. The duplexed siRNA enters a multiprotein complex, termed the RNA-induced silencing complex, where the passenger strand is cleaved and released, leaving the guide strand to identify the target mRNA sequences. Although the structure of RISC is not well understood, the key component of this complex is the Argonaute protein, Ago2, which is responsible for holding the siRNA (the 5′ phosphorylated termini of the siRNA binding to a cleft in the Piwi domain and the 3′ termini interacting with the PAZ domain) in the proper conformation to facilitate its interaction with target mRNA. In addition, Ago2 contains the endonuclease activity, located within the Piwi domain, responsible for cleaving the target mRNA. This pathway can be harnessed for the experimental silencing of gene expression by providing either the long dsRNA trigger molecules, a technique commonly used in *C. elegans* and *Drosophila*, or by directly transducing cells with the siRNA effector molecules. Although the RNAi machinery is highly conserved from plants to mammals, endogenous siRNAs, which are present in lower eukaryotes, have not been identified in mammalian cells. (c) The microRNA pathway. miRNAs, the most sequence-diverse class of small RNA regulatory molecules, are encoded on long, highly structured primary transcripts (pri-miRNA). These transcripts can be produced by RNA polymerase II or III and can encode a single miRNA or a cluster of miRNAs. These pri-miRNAs are processed by the nuclear localized RNase III family member Drosha, which recognizes the structure of the miRNA-encoding RNA hairpin and not the specific miRNA sequence. The Drosha-mediated cleavage reaction releases a short hairpin RNA, termed the precursor (pre)miRNA. This approximately 60–70 nt pre-miRNA is translocated to the cytoplasm by Exportin 5, where it is cleaved by Dicer into a dsRNA duplex containing the mature miRNA and the usually short-lived passenger strand (miRNA*). Similar to the long dsRNA-directed RNAi pathway, Dicer is associated with a dsRNA-binding protein called loquacious in *Drosophila* or TRBP (HIV-1 TAR RNA-binding protein) in mammals. The duplexed miRNA molecule is taken up by the effector complex, variously termed the

properties of each of the 5′ termini, with the end having the lower stability being preferentially maintained in the effector complex and used to guide the silencing reaction. Although this effector complex, variously termed the RNA-induced silencing complex for siRNAs or the miRNA-containing RNA-induced silencing complex (miRISC) for miRNAs, is poorly defined, it contains at its core a member of the Argonaute (Ago) family of proteins. The guide strand of the siRNA or the mature miRNA provides the specificity determinant for the effector complex by binding to complementary sites on the target mRNA. Gene silencing can take place by one of two mechanisms, either the inhibition of translation or the endonucleolytic cleavage of the mRNA. The method of silencing used for any target depends largely, but not entirely, on the degree of sequence complementarity between the siRNA or miRNA and the cognate mRNA. Those interactions with complete or nearly complete homology lead to mRNA cleavage, whereas interactions with a lower level of homology induce translation inhibition.

The analysis of these silencing mechanisms has not only allowed for a better understanding of the role that small RNA molecules play in the regulation of many important cellular processes but also facilitated the development of technologies for the targeted silencing of gene expression. Although long dsRNAs had been used for silencing gene expression in *C. elegans*, this technology was not amenable for use in higher eukaryotes due to innate immune responses that have evolved in mammalian cells to recognize long dsRNA species and induce the activation of cell death pathways. In normal circumstances, the interferon response serves to protect cells from viral pathogens, many of which produce long dsRNAs as intermediates in their life cycle. Since the interferon response is efficiently triggered by dsRNAs more than 30 nt in length, it was believed that siRNAs, which fall below this size threshold, would be unable to activate this response. This was borne out by experiments that showed that the treatment of mammalian cells with chemically synthesized siRNAs could effectively silence gene expression without any untoward toxicity. This discovery led to the development of RNAi-based technologies allowing reverse genetic experiments to be performed in organisms that were intractable to more traditional gene-silencing approaches and laid the groundwork for the application of RNAi-based silencing approaches as novel therapeutic modalities. In fact, the use of siRNAs for the localized silencing of gene expression has already entered clinical trials for the treatment of age-related macular degeneration and Rous sarcoma virus infections.

siRNAs as a Gene-Silencing Tool

There are several features that make the use of siRNAs an attractive approach for the targeted silencing of gene expression. Foremost among these features is the fact that these silencing technologies take advantage of an endogenous gene-silencing mechanism that is conserved in organisms as diverse as plants, *C. elegans*, *Drosophila*, mice, and humans. In addition, unlike antisense approaches, potential target sequences can be readily identified. Initial studies showed that siRNA-mediated gene silencing was highly specific, being able to distinguish between genes that differed by as little as a single nucleotide, with no apparent toxicity.

siRNA Sequence

A better understanding of the characteristics that distinguish highly potent siRNAs from nonfunctional siRNAs will facilitate the optimization of siRNA design to maximize silencing potential and minimize off-target effects. There are a number of traits associated with highly active siRNAs, including low internal stability, moderate to low GC content (optimally between 30% and 52%), lack of secondary structures within the siRNA sequence, and low thermodynamic stability at the 5′ end of the guide strand. In addition, siRNA sequences that have homology with unintended targets or that contain immunostimulatory sequence motifs should be avoided to reduce the potential off-target effects. Many of these criteria have been incorporated into computer algorithms designed to aid in the identification of effective siRNA sequences targeting a particular gene of interest. Although these algorithms can improve the selection of potential siRNA sequences, experimental testing is necessary to determine the optimal siRNA sequence for any given gene.

siRNA Specificity

Early studies using siRNAs to mediate gene silencing suggested that siRNAs, by virtue of their action,

miRNA-containing RISC (miRISC) or the miRNA nucleoprotein (miRNP) complex; the passenger strand (miRNA*) is dissociated; and the mature miRNA guides the complex to the target mRNA. The binding of the miRNA to target sites that have partial complementarity leads to the induction of translational repression. Although these pathways represent the classic views of the RNA interference pathways that induce posttranscriptional gene silencing, in actuality, siRNAs and miRNAs have interchangeable effector functions and either molecule can induce translational repression or mRNA cleavage depending on the degree of target site complementarity.

required full complementarity and that a single nucleotide difference between the siRNA and the target binding site would be sufficient to abrogate silencing. In fact, it appears that mismatches between the siRNA and the target site can be accommodated without the complete loss of silencing. The degree to which mismatches can be tolerated depends on a number of factors, including the position and nucleotide composition of the mismatch. For example, the central nucleotides of the siRNA, around the site where cleavage of the mRNA occurs, are more sensitive to mismatches than either the 5′ or 3′ ends of the molecule. This is presumably due to steric constraints imposed by the active site of the Ago2 endonuclease, the core enzymatic component of RISC. It is not simply the presence of mismatched nucleotides that lends specificity but, more important, it is the nature of the mismatched nucleotides. That is, the juxtaposition of two purines within the central region of the siRNA:mRNA binding site will interfere with silencing more readily than the juxtaposition of two pyrmidines or a non-base-pairing purine:pyrmidine pair. However, by judiciously choosing the site and type of mismatch, it is possible to selectively silence genes that differ by as little as a single nucleotide. This has permitted the development of silencing tools that can distinguish between disease-causing alleles of a gene that differ by a single nucleotide from the 'normal' allele. This has been applied to disease causing single nucleotide polymorphisms (SNPs) involved in the development of cancer (e.g., RasV12), sickle cell anemia, and several dominantly inherited neurodegenerative disorders including superoxide dismutase 1 in amyotrophic lateral sclerosis and tau in frontotemporal dementia. Even for diseases whose phenotype is not directly attributable to an SNP, selective targeting of the disease can be accomplished by targeting SNPs that are linked to the disease allele. This has been used for the preclinical development of tools for the silencing of MJD1 (ataxin-3) in Machado–Joseph disease by targeting an SNP that tightly segregates with the pathogenic allele.

Off-Target Effects

Although the initial studies using siRNAs for the targeted silencing of gene expression showed a high level of specificity and a lack of toxicity, as the technology has become more widely applied, the potential for off-target effects has become more apparent. The off-target effects of siRNAs are classified into two categories: (1) the silencing of unintended targets that have partial complementarity to the siRNA and (2) the induction of cellular responses that nonspecifically silence gene expression. The analysis of mRNA levels in cells treated with specific siRNAs has shown changes to a large number of genes. Although the majority of these changes are small, a few genes can be severely affected. These nonspecific effects have been found for targets that share as few as 15 complementary nucleotides with as few as 11 contiguous nucleotides. These nonspecific effects can be generated from either strand of the duplexed siRNA. Microarray analysis can effectively measure changes in the amount of mRNA but fails to represent the changes that may occur due to translational inhibition, the common form of RNAi-mediated gene silencing induced by miRNAs in animal cells. Since miRNAs require a much lower level of complementarity, the potential off-targets could be significantly higher. It is difficult to evaluate these changes in protein levels since high-throughput proteomic approaches are much more difficult. Since effective translational repression mediated by miRNAs requires the concerted action of several miRNAs, the overall impact of these miRNA-style off-target effects may be minimal.

As part of the innate antiviral response, mammalian cells have mechanisms for the recognition of dsRNA species, a common intermediate found in the life cycle of many viruses. This response induces the global inhibition of gene expression by impairing the cellular translation machinery. Although initial studies using siRNA for gene silencing found no induction of the interferon response with dsRNA smaller than 30 nt, subsequent studies using highly sensitive microarray analysis found that in certain circumstances expression of a subset of interferon-responsive genes was upregulated. This induction of the interferon response was found for only certain siRNA sequences and only when cells were treated with high concentrations of siRNAs. The treatment of cells with different siRNA sequences led to an increase in the expression of different subsets of interferon genes. Since no cytotoxicty was associated with any of these siRNA treatments, it appears that only a partial interferon response was induced. Experiments have suggested that the induction of the interferon genes may not be through the dsRNA-activated protein kinase; instead, interferon gene expression may be indirectly induced by the activation of Toll-like receptors (TLRs), TLR7 and TLR8. These TLRs can recognize specific immunostimulatory sequence motifs, particularly GU-rich sequences. The mode of administration of the siRNA affected the ability of the siRNA to stimulate an interferon response, suggesting that the method of cellular uptake plays a role in determining the immunostimulatory potential of an siRNA. For example, transduction of the cell by lipid-based transfection reagents resulted in a pronounced enhancement of off-target gene expression compared to delivery by electroporation.

Since these off-target effects are concentration dependent, many of them can be avoided by minimizing the siRNA dosage. This can be accomplished by identifying highly potent siRNAs that can efficiently silence target gene expression at doses below the threshold necessary to induce off-target effect. Potential off-target effects can be minimized by careful siRNA sequence selection. Important criteria to reduce the potential for off-target effects include the avoidance of immunostimulatory sequences and designing the siRNA to minimize uptake of the passenger strand into RISC. In addition, all the potential siRNA sequences should be compared to the mRNA in the human genome to minimize the potential off-target binding sites. Although it may be impossible to avoid short stretches of homology, siRNAs that have extensive homology with unintended targets should not be used. In addition, the incorporation of chemical modifications within the siRNA can mitigate the immunostimulatory effects of the siRNA while retaining its silencing efficiency.

RNAi-Based Silencing Technologies

Two basic approaches have been used for the targeted silencing of gene expression by siRNAs: (1) the introduction of chemically synthesized siRNAs into cells and (2) the introduction of DNA vectors expressing siRNA precursors that are processed intracellularly into active siRNAs (Figure 2). Each of these methods has distinct advantages and disadvantages.

Chemically Synthesized siRNAs

The demonstration that chemically synthesized siRNAs could induce the silencing of a target gene of interest without activating an innate immune response has revolutionized biological research, providing a powerful tool for gene function analysis and opening up the possibility for the therapeutic application of these potent technologies. The transfection of synthetic siRNAs into tissue culture cells remains the most widely used method for gene silencing because of its specificity, ease of use, and adaptability to a variety of experimental conditions and cell types. An increasing number of lipid-based transfection reagents have been developed to effectively deliver the siRNAs into the cytoplasm of target cells. There are a number of factors that have limited the use of this technology, principal among these are the transient nature of the siRNA-based silencing response in actively dividing cells and the inability of traditional transfection reagents to transduce many important cell types. In most dividing cell lines, the silencing phenotype peaks at approximately day 3 posttransfection and subsides approximately 5–7 days posttransfection. This loss of silencing over time appears to be due to the diluting out of the siRNAs during cell division until the intracellular concentration of the siRNA falls below a critical threshold needed to maintain the silencing phenotype. Long-lasting silencing (up to 3 weeks) has been achieved in cells that are nondividing, as demonstrated by *in vitro* experiments in postmitotic, terminal differentiated primary macrophage cells and *in vivo* delivery to hepatocytes. The degree to which a specific protein can be silenced depends on the half-life of the protein, the effectiveness of the siRNA, and the rate of cell doubling. Since the silencing phenotype is mediated by the targeted degradation of mRNA and not by degrading the protein, it is possible to effectively deplete the cell of a specific mRNA without altering the levels of the protein. This is particularly the case for proteins that are long-lived. Although the transfection of a wide variety of tissue culture cells is possible with the judicious choice of transfection reagents, there are a large number of cells that are refractory to lipid-based transfection protocols, including many clinically important primary cell types. In addition, the inherent toxicity of many of these lipid-based transfection reagents limits their usefulness for *in vivo* applications. Therefore, a variety of alternative transduction mechanisms have been developed (Figure 2(a)). One approach for the *in vitro* delivery of siRNAs to cell types that are difficult to transfect has been the combination of electroporation technologies with lipid-based transfection reagents, termed nucleofection. Although this approach can have some untoward toxicity, it has been effectively used for the silencing of gene expression in a wide range of cell types, including many primary cells. Another approach that has been proved to be effective for the delivery of siRNAs both *in vitro* (in tissue culture cell experiments) and *in vivo* has been the conjugation of the siRNA with cholesterol. Not only did this lead to the efficient uptake of the siRNA while retaining the siRNA's silencing activity but also it improved the pharmacological properties of the siRNA by increasing the retention of the siRNA within the circulatory system. Since cholesterol receptors are relatively ubiquitously expressed, the cholesterol-conjugated siRNAs can enter a wide variety of cells. The broad spectrum of cells that can be effectively transduced by cholesterol-conjugated siRNAs makes this technology widely applicable. However, when cholesterol-conjugated siRNAs are given *in vivo*, they will be delivered to a wide variety of cells and tissues, only some of which are the intended target. This increases the risk of silencing gene expression in unintended cell types and could increase off-target effects. In addition, this nonspecific uptake increases the amount of the

Figure 2 Methods for siRNA delivery. (a) Methods for the delivery of chemically synthesized siRNAs into cells. Although the use of lipid-based transfection reagents remains the most common method for the transduction of siRNAs into tissue culture cells, several methods have been developed that allow for the efficient delivery of siRNAs into cells for both *in vitro* and *in vivo* gene-silencing experiments. The covalent coupling of the siRNA, through the passenger strand, with either a cholesterol moiety (i) or an RNA aptamer (ii) has been shown to increase the pharmacological properties of the siRNAs (e.g., increasing the retention time of the siRNA within the circulatory system) while facilitating the uptake of the siRNA and maintaining its silencing capacity. Cholesterol permits the binding of the siRNA to cellular low-density lipoprotein receptors, which are expressed in a wide variety of cell types, and the uptake of the siRNA. Alternatively, the passenger strand of the siRNA can be incorporated into the termini of an aptamer, a structured RNA molecule that has been selected *in vitro* for specific properties, such as high-affinity binding to a distinct molecule. Using this approach, one can achieve cell type-specific delivery by choosing an aptamer that has a high affinity for a particular cell surface molecule. Similarly, cell type-specific delivery has been achieved using a recombinant protein containing the recognition domain of a single chain antibody or a fragment antibody fused to a nucleic acid binding motif (e.g., protamine) (iii). In this case, the siRNA interacts with the nucleic acid binding motif and is directed to the cell type of interest by the affinity of the antibody for a specific cell surface molecule. Although the majority of lipid-based transfection reagents have associated toxicities that prevent their use for *in vivo* applications, there are some lipid formulations that can be used for efficient delivery *in vivo* with negligible toxicity (iv). This usually involves the encapsulation of the siRNA into a lipid nanoparticle composed of several different types of lipids to provide it with the appropriate stability while allowing for the uptake and release of the siRNA into the cytoplasm of target cells. These lipid particles can be made to target specific cell types by the incorporation of specific moieties (e.g., antibody fragments) on their surface. (b) Stable silencing using DNA-based siRNA expression systems. Long-term silencing of gene expression can be achieved by expressing siRNA precursors, either (i) short hairpin (sh)RNAs or (ii) long hairpin RNAs based on the structure of endogenous miRNAs. These hairpin RNAs are processed by the endogenous RNAi machinery producing active siRNAs. These siRNA expression cassettes have been incorporated into a variety of DNA-based expression systems, including viral systems such as retroviral (oncoretroviral or lentiviral) and adeno-associated viral vectors. Typically, shRNAs have been expressed from RNA polymerase III (pol III) promoters that are uniquely suited for the production of short RNA species, whereas longer hairpin RNAs can be expressed from either Pol III or RNA polymerase II (pol II) promoters. Unlike pol III promoters that are ubiquitously expressed, pol II promoter-driven siRNA expression systems can be developed that permit the tissue-specific or inducible expression of the siRNA.

siRNA needed to effectively silence expression of the target gene in the intended tissue or cell type. Therefore, delivery vehicles that could deliver siRNAs to specific cell types would be beneficial, particularly for therapeutic siRNA-based gene-silencing technologies. A number of technologies have been developed for the cell type-specific delivery of siRNAs. One such approach uses a recombinant bifunctional protein that contains a peptide that can recognize a specific cell-surface antigen (e.g., a single chain antibody or a fragment antibody against a cellular receptor or a ligand for a specific receptor) fused to a nucleic acid binding domain. Unlike the cholesterol-conjugated siRNAs, the siRNAs bind noncovalently to the recombinant protein and can be delivered to the cytoplasm of only those cells that express the specific protein on the cell surface. Therefore, the same deliver vehicle can be used to deliver any siRNA of interest for delivery. Cell type-specific delivery has also been achieved by conjugating the siRNA to an aptamer. Aptamers are structured nucleic acids that have been selected *in vitro* for specific characteristics, such as the ability to bind to specific proteins or to have a specific catalytic activity. The conjugation of an RNA aptamer that recognizes a specific cell surface protein to an siRNA can effectively deliver the siRNA to the cell type or tissue of interest. In order to retain the activity of the siRNA, the protein or RNA moiety is conjugated to the passenger strand of the siRNA, leaving the guide strand to perform its silencing function unimpaired. The mechanism by which the siRNAs are taken up and delivered to the cytoplasm to silence gene expression remains an area of active research. It remains to be determined how broadly applicable these technologies will be for the delivery of siRNAs. Despite these unknowns, these approaches have taken the therapeutic application of siRNAs one step closer to becoming a reality.

Vector-Mediated RNA Interference

To overcome some of the intrinsic limitations of siRNA transfections, the transient nature of the silencing phenotype in actively dividing cells, and the difficulty of efficiently transducing certain cell types that are refractory to traditional lipid-based transfection protocols, siRNA-expressing DNA vectors have been developed (Figure 2(b)). Although Dicer was originally identified as an endonuclease that is capable of cleaving long dsRNA into siRNAs, it was soon realized that Dicer was also capable of processing the hairpin precursor molecule of miRNAs. By mimicking the structure of endogenously produced miRNA precursors, short hairpin RNAs were designed that could be efficiently expressed from DNA vectors and processed into active siRNAs. The majority of these expression systems were based on expression from RNA polymerase III (pol III) promoters, either the U6 or the H1 promoter, which are uniquely suited for the expression of small RNA species since all of the necessary sites for activation of transcription are present upstream of the transcription start site and a run of uridine residues is sufficient to terminate transcription. The initial attempts to develop RNA pol II-based siRNA expression systems were unsuccessful. Although the transcripts were expressed, they were not processed by Dicer into functional siRNAs. It was only after the mapping of several miRNA transcripts that it was demonstrated that miRNA was encoded on primary transcripts that were highly structured hairpin RNAs containing frequent bulges and mismatched base-paired interactions. Based on these longer hairpin RNA structures, successful expression and processing of siRNAs was achieved. Unlike the ubiquitously expressing pol III promoters, pol II promoters that allow inducible, tissue- and cell type-specific transcription can be used for the regulated expression of siRNAs. In all these cases, the promoter drives transcription of a hairpin RNA containing the siRNA sequence and the accompanying passenger strand separated by a short noncomplementary loop sequence. These hairpin RNAs are processed by the endogenous RNAi machinery producing active siRNAs that enters RISC and direct the silencing of gene expression. The siRNA expression cassettes have been incorporated into an assortment of plasmid and viral vectors for the transduction of cells. Unlike synthetic siRNAs, plasmid vectors can be used for the transient delivery of siRNAs and, if the vector contains a suitable selectable marker, the stable delivery of siRNAs into many cell lines. However, their use is limited, in the same way as synthetic siRNAs, to cells that can be readily transfected. In addition, the low efficiency of generating stable silencing clones further limits their use in primary cells to transient siRNA expression. On the other hand, recombinant viral vectors have been developed which incorporate the siRNA expression cassette into the viral genome that is packaged into viral particles allowing for the infection of susceptible cell types. A variety of viral vectors have been adapted for use as siRNA delivery vehicles, including retroviral- and adeno-associated viral-based vectors. Since these viruses possess the necessary factors to facilitate uptake into cells, they are not limited to cells that can be readily transfected. Each of these systems has unique cell tropisms and life cycles, allowing them to productively deliver the siRNA expression cassette to specific subsets of cells. However, by changing the characteristic of the viral surface proteins involved in cellular recognition and uptake, it is possible to broaden the variety of cell types that can be infected. For example, HIV-1-based lentiviral constructs that utilize the HIV-1 viral

envelope glycoprotein will infect only human cells that express the CD4 molecule on their surface. However, if the viral envelope glycoprotein is replaced by the glycoprotein from the vesicular stomatitis virus, which has a broad cell tropism, the lentiviral construct can be used to infect a variety of cell types from many different organisms, including human, mouse, rat, and even avian cells. Retroviral-based systems, derived from either lentiviruses or oncoretroviruses, have been used extensively for siRNA delivery. In these recombinant retroviral vectors, the genes necessary for productive infection have been deleted to ensure that the virus is unable to replicate in the target cells. Retroviruses are particularly well suited for the stable, long-term expression of siRNAs since they become integrated into the host genome and are replicated along with the host DNA. In addition, vectors based on lentiviral genomes, a class of retroviruses that include HIV-1, feline immunodeficiency virus, and equine infectious anemia virus, can infect postmitotic, nondividing cell types (e.g., terminal differentiated macrophage cells and neuron). Despite these advantages, retroviral vectors have the potential to cause insertional mutagenesis, leading to oncogenic transformation and clonal expansion of affected cells. Since these effects were seen in cells that were already actively replicating, it may be that this insertional mutagenesis will not be a significant barrier to the use of retroviral vectors in quiescent cells, such as those found in most tissues including the brain. Adeno-associated viral vectors have also been used successfully for *in vivo* siRNA delivery. Unlike retroviral vectors, adeno-associated vectors do not integrate into the host genome but can readily mediate long-term siRNA expression, particularly in nondividing tissues. In addition, adeno-associated viral vectors lack expression of viral proteins and as a result induce a limited immune response. Although these viral-based siRNA delivery systems have been shown to be effective both *in vitro* and *in vivo*, the packaging and purification of the recombinant viral particles can be a laborious process. For *in vivo* applications, siRNA expression from DNA-based vector systems is usually limited to the injection site and delivery requires a local regional administration (injection) or surgical procedure.

Applications of RNAi-Based Technologies

RNAi-mediated gene silencing has been widely applied as a research tool for reverse genetic experiments, which determine the function of a gene based on its disruption. The majority of these experiments have been done in a focused manner, examining the function of a single gene of interest at a time as well as other genomes, coupled with the ubiquitous nature of the RNAi machinery, this has made it possible to silence any gene in the genomes of humans and other organisms. These approaches have been extensively applied in *C. elegans* and *Drosophila* cells to identify unknown genes involved in a wide array of cellular functions. Although large-scale screens in mammalian cells have presented a greater technical challenge, the refinement of RNAi-based technologies (siRNA transfection protocols and shRNA-based expression systems) has made these screens increasingly popular.

It took very little time after RNAi was discovered in mammalian cells for researchers to recognize the potential of harnessing these pathways for therapeutic gene silencing. RNAi-based approaches have been extensively used for the silencing of pathogenic states ranging from viral infections to tumor development and metabolic and neurological disorders. The ease of design and synthesis, the low cost of production relative to other therapeutic agents such as antibodies and recombinant growth factors, the specificity of silencing, and the potency of silencing make siRNAs an attractive candidate for therapeutic applications. Delivery remains the major challenge for the successful therapeutic application of RNAi-based gene-silencing approaches. This is particularly the case for the systemic administration of siRNAs since unmodified siRNAs are sensitive to serum RNases and their small size results in their rapid clearance from the circulatory system. Despite these challenges, localized delivery of siRNAs has entered clinical trials for the treatment of age-related macular degeneration and respiratory syncytial virus infection. In a very short period of time, RNAi has gone from a novel silencing phenomenon in *C. elegans* to a highly conserved and ubiquitous gene regulatory network involved in many important cellular processes and, along the way, has been harnessed, providing an indispensable research tool and potential novel therapeutic modality.

Sleep and Circadian Rhythm Disorders in Human Aging and Dementia

M V Vitiello, University of Washington, Seattle, WA, USA

© 2009 Elsevier Ltd. All rights reserved.

General Introduction

In 2007, approximately 12% of the United States population consisted of people 65 years of age or older. By 2030, this proportion will rise to 20%. Because the older portion of the population is increasing twice as fast as other age groups, the number of people 65 year of age or older in the United States will effectively double, to 72 million, by 2030.

Alzheimer's disease (AD) is a progressive neurodegenerative disorder, common in older adults, that accounts for approximately two-thirds of all dementias worldwide. In the United States, it has recently been estimated that between 2 and 4 million older adults have AD. Further estimates suggest that this number is likely to quadruple over the next 50 years.

Among older adults, one of the major changes that commonly accompany the aging process is an often profound disruption of an individual's daily sleep–wake cycle. This disruption is often further exacerbated in older individuals suffering from neurodegenerative disorders, such as AD. Here we review what is known about sleep and circadian rhythms in normal aging and in AD.

Normal Aging

As many as 50% of older individuals complain about sleep problems, including disturbed or light sleep, frequent awakenings, early morning awakenings, and undesired daytime sleepiness. Such disturbances are often associated with impaired daytime function and compromised quality of life. The most striking change in the sleep in older adults is the frequent interruption of nighttime sleep by periods of wakefulness, possibly the result of an age-dependent intrinsic lightening of sleep homeostatic processes. Further, older adults are more easily aroused from nighttime sleep by auditory stimuli, suggesting that their sleep may be more easily disrupted by exogenous stimuli. Both of these changes are indicative of impaired sleep maintenance and depth and contribute to the characterization of the sleep of older adults as lighter, or more fragile, than that of younger adults.

These age-associated increases of nighttime wakefulness are mirrored by increases in daytime fatigue, excessive daytime sleepiness, and increased likelihood of napping or falling asleep during the day. Aging is also associated with a tendency to both fall asleep and awaken earlier. That is, a tendency for older individuals to be larks rather than owls. Older individuals also tend to be less tolerant of phase shifts in time of the sleep–wake schedule such as those produced by jet lag and shift work. These changes suggest an age-related breakdown of the normal adult circadian sleep/wake rhythm.

Polysomnographic (PSG) studies of sleep architecture have consistently demonstrated four age-related changes in nighttime sleep quality: reductions in total sleep time, reductions in sleep efficiency, reductions in slow wave sleep, and increases in waking after sleep onset. Nevertheless, age-related changes in numerous other PSG sleep measures remain unclear. Sleep onset latency, stages 1 and 2, and rapid-eye movement (REM) have all been reported to change with age, whereas other studies have observed no such age-related changes.

It is important to note that even carefully screened older adults who do not complain of sleep disturbance and who have minimal medical burdens show the changes described when compared to younger adults. This suggests that at least some of the sleep disturbance seen in older adults is part of the aging process *per se*, apparently independent of any medical or psychiatric illnesses or primary sleep disorders and often referred to as age-related sleep change. As to whether this age-related decline in the ability to generate sleep equates with a decreased need for sleep in the later years of the human life span remains unclear. Nevertheless, the available scientific evidence suggests that it is important to remember that as individuals age, they make need to modify their expectations about the duration and quality of their nighttime sleep.

Sleep in Normal Aging

Clearly sleep changes with advancing age, but an important question remains: exactly when during the adult life span do these changes occur? It has typically been assumed that the age-related sleep changes that characterize the sleep of older adults begin to appear in early adulthood and progress steadily across the full continuum of adult human life span, including the older adult years, so that, for example, the sleep of the typical 75-year-old was assumed to be worse than that of the typical 65-year-old.

However, the results of a recent and comprehensive meta-analysis of objective sleep measures across the

human life span demonstrated that the bulk of the age-related changes seen in adult sleep patterns do not occur continuously across the human adult life span but, rather, occur between early adulthood, beginning at age 19, and that after age 60 changes in sleep macroarchitecture becomes effectively asymptote, declining only minimally from age 60 to age 102. These sleep changes across adult life-span are summarized in Table 1. When the full adult life span is examined (2391 adults, ages 19–102 years), such analyses confirmed the four most consistently reported age-related changes in PSG studies of sleep macroarchitecture: decreases in total sleep time (TST), decreases in sleep efficiency (SE), decreases in slow wave sleep (SWS), and increases in waking after sleep onset (WASO). Also confirmed were less consistently reported age-related sleep changes; increases in stage 1 (S1) and stage 2 (S2) sleep and decreases in REM sleep were all observed in their meta-analyses. Conversely, age-related changes in both sleep latency (SLAT) and REM latency (REMLAT) were minimal.

It is crucial to note that all these significant age changes in objectively assessed sleep architecture were found only when the full adult life span of 19–102 years was examined. When the sleep of only older adults (1142 adults, ages 60–102 years) was examined, the meta-analyses demonstrated that no sleep measures showed any significant age-related change within the older adult portion of the study sample, with the single exception of SE, which declined significantly but at a modest rate of ~3% per decade.

Table 1 Summary of significant findings from meta-analyses examining the association between various sleep measures and age

	Adults 19–102 years[a]	*Older adults 60–102 years*[b]
Total sleep time	⇓	⇔
Sleep latency	⇔	⇔
WASO	⇑	⇔
Sleep efficiency	⇓	⇓
Stage 1 (%)	⇑	⇔
Stage 2 (%)	⇑	⇔
SWS (%)	⇓	⇔
REM (%)	⇓	⇔
REM latency	⇔	⇔

[a] $n = 2391$ adults.
[b] $n = 1142$ adults.
From Ohayon MM, Carskadon M, Guilleminault C, and Vitiello MV (2004) Meta-analysis of quantitative sleep parameters from childhood to old age in healthy individuals: Developing normative sleep values across the human lifespan. *Sleep* 27(7): 1255–1273.
⇓, decreased; ⇑, increased; ⇔, unchanged; REM, rapid-eye movement sleep; SWS, slow wave sleep; WASO, waking after sleep onset.

These findings were comparable for both older men and older women.

These findings seem counterintuitive and fly against our commonly held concepts of sleep changes with aging. However, it is important to remember that Ohayon and colleagues used very rigorous selection criteria, such that the subjects involved in the studies analyzed were not representative of the older population *per se* but, rather, were in excellent health and more likely represented individuals who were optimally or successfully aging. That is, these findings represent normative age-related changes in sleep architecture and not average sleep changes of the entire aging population. When various medical and psychiatric comorbidities that typically accompany the aging process were controlled for and optimal aging was examined, the bulk of age-related sleep changes occurred in early and middle adulthood (ages 19–60 years); after age 60, assuming the individual remained in good health, further age-related sleep changes were likely to be, at most, modest. Conversely, if such comorbidities were present, these minimal age-related sleep changes might well be exacerbated, consistent with the level of sleep-related complaints seen in the general aging population.

Circadian Rhythms in Normal Aging

Not only does the quality of sleep change across the human life span, but the timing of when that sleep occurs also apparently changes with aging. Circadian rhythms are those that occur within a period of 24 h (from the Greek about (*circa*) a day (*dies*)), such as the adult human sleep–wake cycle. Interestingly, as with sleep, there is a considerable disparity in the conventional wisdom concerning circadian rhythms and aging and which evidence is supports or does not support these conventionally held beliefs. The conventional wisdom regarding what happens to human circadian processes with aging holds that (1) the circadian amplitude is reduced; (2) the circadian phase is advanced (i.e., the circadian rhythm moves earlier relative to the environment); (3) the circadian free-running period (tau) is shortened; and (4) the ability to tolerate rapid phase shifts, such as those experienced in shift work or rapid transmeridian travel (jet lag), declines.

However, the available evidence convincingly supports only two of these beliefs: that older people tend to have earlier circadian phases, with a corresponding tendency to go to bed and arise from bed earlier than younger adults; and that they have more trouble than younger adults adjusting to the rapid phase shifts due to shift work and jet lag, at least in terms of sleep quality, subjective complaint, and performance measures. Interestingly, the data in support of

diminished circadian amplitudes and shortened circadian taus in healthy older adults are, at best, equivocal. Again, it is important to note that these circadian changes are those seen in normal, or more accurately normative, aging, in which age-related health comorbidities have been carefully screened out.

Excessive Daytime Sleepiness and Napping in Normal Aging

Two other commonly held assumptions about sleep and aging are that older adults typically report more excessive daytime sleepiness (EDS) and nap more than younger adults. Few community-based epidemiological studies have reported the prevalence of regular napping and its association with sleep complaints and other mental and physical health problems, especially in relation EDS. Somewhat counterintuitively, although epidemiological studies typically show a significant increase in the prevalence of regular napping with advancing age, EDS does not demonstrate a similar increase in prevalence among older adults. Consistent with the findings already described for nighttime sleep measures, very recent findings indicate that the presence of comorbidities (medical illness, depression, etc.) is highly associated with the likelihood of an older adult reporting regular napping or EDS. That is, healthy older adults, even those complaining of significant nighttime sleep disturbance, are much less likely to report regular napping or EDS than their more health-burdened cohorts.

There is considerable debate as to whether regular napping among older adults, particularly those in good health, may be beneficial to daytime wakefulness or perhaps detrimental to their nighttime sleep propensity. Studies of naps in healthy noncomplaining older adults demonstrated that napping had only a mild to moderate impact on nighttime sleep quality and may even result in improved postnap cognitive performance. However, these results should be interpreted with caution because, again, it is important to emphasize that the subjects involved were carefully screened healthy older adults. It is unclear if similar results would be obtained, for example, with a sample of older insomniacs.

Causes of Sleep and Circadian Disturbances in Older Adults

It is often repeated that epidemiological studies report that as much as 50% of older adults complain of significant, chronic sleep disturbance. However, it is important to keep in mind that the other 50% of older adults do not so complain. As previously reviewed, the sleep of very healthy older adults changes only very slowly across the later human life span. Conversely it has also been shown that older adults who do not complain of any sleep problems nevertheless have objective sleep quality that is markedly compromised (e.g., less TST, less SE, less SWS, and more WASO) compared to that of healthy, non-sleep-complaining, younger adults. Nevertheless, there are many factors in addition to the age-related sleep and circadian changes already discussed that contribute to the significant sleep disturbance reported by half of all older adults. These include (1) medical and psychiatric comorbidities and their treatments, such as cardiovascular disease, arthritis, depression, or AD and many of the drugs used to treat them; (2) primary sleep disorders, many of which, such as sleep apnea, restless legs syndrome, and REM behavior disorder, tend to occur with increasing frequency in older adults; (3) the many behavioral, environmental, and social factors, often collectively referred to as sleep hygiene, that have the potential to maximize or compromise an individual's sleep quality; and (4) some combination of these factors. A more comprehensive list of such contributing factors with specific examples appears in Table 2.

Table 2 Causes of poor sleep in older adults

Cause/problem	*Examples*
Physiological	Age-related sleep change
	Age-related circadian rhythm change (phase advance)
Medical illnesses	Arthritis or other conditions causing chronic or intermittent pain
	Chronic cardiac or pulmonary disease
	Gastro-esophageal reflux disorder
Psychiatric illnesses	Depression
	Alzheimer's disease
Medications	Diuretics (leading to nocturnal awakenings)
	Inappropriate use of OTC medications
Primary sleep disorders	Sleep disordered breathing (sleep apnea)
	Restless legs syndrome
	REM behavior disorder
Behavioral/social	Retirement/lifestyle change reducing need for regular bed and rise times
	Death of a family member or friend
	Inappropriate use of social drugs
	Transmeridian air travel
	Napping
Environmental	Bedroom environment (e.g., ambient noise, temperature, light, bedding)
	Moving to a new home or downsizing to a smaller space or a retirement community or related facility
	Institutionalization

OTC, over-the-counter; REM, rapid-eye movement.

Alzheimer's Dementia

Both normal aging and AD are associated with disturbances in the daily sleep–wake cycle, although the disturbances in AD are typically much more severe. Within the AD population itself, significant sleep disturbances are quite common, affecting as much as half of community- and clinic-based samples.

For AD patients, sleep disturbance adds an additional burden to the compromised function and quality of life directly attributable to dementia. For AD caregivers, disturbances in patients' sleep and nighttime behavior, particularly the reduced nighttime sleep time, increased nighttime wakefulness, and wandering that commonly require considerable caregiver attention, with a subsequent chronic sleep loss for the caregivers themselves, are a significant source of physical and psychological burden and are often cited as one of the principal reasons for a family's decision to institutionalize a demented person.

The Biological Bases of Sleep Disturbances in AD

The sleep disturbances that accompany early-stage or mild dementia are remarkable in that they appear as exacerbations of the sleep changes found in normal aging rather than as unique disease-related phenomena. The sleep of AD patients is marked by an increased duration and frequency of awakenings, decreased SWS and REM sleep, and more daytime napping. Damage to neuronal pathways that initiate and maintain sleep is the most likely cause of the acceleration of these age-related sleep changes in AD patients. These compromised neural structures, including the suprachiasmatic nucleus (SCN) of the hypothalamus and neuronal pathways originating in subcortical regions, also regulate arousal and the sleep–wake cycle. Recent work suggested that at least some of the sleep disruption seen in AD many be an inherent trait, probably linked to apolipoprotein E (APO E) status, such that AD patients positive for the APO E $\varepsilon 4$ allele show greater sleep disruption over time.

There is considerable evidence that sleep disturbance grows more severe with increasing severity of AD. However, the moderate, or intermediate, stages of the disease are typically when most other behavioral disturbances occur with peak frequency. The breakdown of the basic circadian sleep–wake rhythm of dementia patients can be severe and in extreme cases may lead to an extremely fragmented sleep–wake pattern or nearly complete day–night sleep pattern reversals. In end-stage AD, patients may appear to sleep throughout most of the day and night, awakening only for brief periods. However, as of this time there have been no prospective longitudinal studies of sleep in AD that would inform an accurate understanding of both the course and the individual differences of these sleep disturbances. This remains an important gap in both the biology and therapeutics of sleep disturbances in demented patients.

The current standard of care for treating cognitive disorders in AD is the use of oral acetylcholinesterase inhibitors. These drugs may improve sleep patterns in some AD patients, particularly by increasing REM sleep. Because they act by enhancing cholinergic transmission in the brain, the involvement of both forebrain and brain stem cholinergic nuclei in regulating sleep–wake cycles and arousal forms the rationale for expecting both positive and negative sleep effects with use of these agents.

Circadian Rhythm Disorder in AD

AD patients commonly manifest a breakdown of their circadian sleep–wake rhythm. Termed irregular sleep–wake rhythm disorder (ISWRD), this perturbation of circadian rhythmicity is commonly associated with neurological impairment in older adults, such as the deficits experienced by AD patients. ISWRD is characterized by the relative absence of a circadian pattern in the sleep–wake cycle. Total sleep time can well be comparatively normal, but, instead of being consolidated into a single long relatively continuous major sleep period, sleep times are shortened and, in extreme cases, relatively brief sleep periods are distributed almost randomly throughout the day and night. The cause, or more likely the causes, of this association are unknown, but AD-related damage to the SCN, locus of the circadian pacemaker, is clearly implicated as an important, if not a major, etiological factor. Experimental ablation of the SCN in animals produces a loss of circadian rhythmicity that strongly resembles the sleep–wake pattern typically seen in older adults with dementing disorders, particularly in the later stages of the dementia. However, it is important to note that clinical studies, the bulk of which have been carried out in older adults with dementia (particularly AD), have rarely used formal sleep diagnostic criteria for ISWRD.

Although complaints of nighttime sleep fragmentation and daytime napping have been consistently reported to increase with age, the weight of the available evidence strongly indicates that, although the prevalence of ISWRD increases with age, this increase is secondary to the increased prevalence of associated medical disorders with advancing age. Age is apparently not an independent risk factor for ISWRD; rather, it is probably the age-related medical comorbidities which constitute the main risk factors

for sleep pathology, including both increasing disturbances in sleep architecture and the increase in prevalence of ISWR with advancing age. ISWRD is particularly associated with neurological impairment in older adults, most significantly AD.

Although there is no direct evidence for a genetic basis for ISWRD, there are several lines of evidence that suggest that the sleep disturbance seen in AD is at least partially based on genetic factors. Actigraphic studies of AD patients have demonstrated longitudinal deterioration of sleep quality, and most of this longitudinal variance in sleep appears to be related to an inherent trait of the individual patient. This suggests that genetic factors may help determine the ultimate course and level of sleep deterioration seen in a given AD patient, a hypothesis consistent with research indicating that much circadian variation in physiological systems is controlled by a limited number of similar genes across species. Regardless, the tentative relationship of genetic factors as a risk for ISWRD remains to be fully explored.

Older adults are exposed to reduced light levels in their daily lives relative to younger individuals. This reduction may be exacerbated by disorders of vision, which are common in older adults and which many further attenuate the impact of ambient light on the SCN. Finally, the SCN itself is adversely impacted by age. The impact of each of these factors is magnified in patients with AD, including those who are community dwelling, who have been shown to be exposed to less light than age-matched healthy normal controls. Furthermore, the retina and the optic nerve can both be compromised in AD. Older adults, especially those who are institutionalized, are exposed to less intense light than younger people, but questions remains as to the importance of reduced light exposure as an etiological factor in ISWRD.

Other Causes of Sleep and Circadian Disturbances in AD

Population-based studies examining the causes, incidence, and persistence of sleep disturbances in AD patients are lacking; consequently, little is known about the risk factors for their development. Therefore, we must look to the literature concerning sleep disturbance in the nondemented elderly and factor this with clinical assessments of individual patients to make informed inferences about the AD population. Certainly the same neurodegenerative mechanisms that result in the evolving cognitive deficits seen in AD are a potential primary cause of the sleep disruption seen in this population. However, it is important to recognize that sleep can be disrupted for many other reasons as well. The likely major causes of sleep disruption in AD, as with normal aging, include (1) physiological changes that arise as part of normal nonpathological aging; (2) sleep problems due to comorbid physical or mental health conditions, including AD, and possibly their treatments; (3) primary sleep disorders; (4) poor sleep hygiene or sleep-related habits; or (5) commonly, some combination of these factors.

Studies of patients living in institutional settings provide much of the available information about sleep and circadian disturbance in cognitively impaired patients. Environmental factors that promote circadian dysregulation in dementia patients living in such settings include light, noise, activity schedules, and the needs of staff. Ambient light levels are typically too low in many congregate care facilities to support natural light-dependent internal rhythms, and noisy conditions, especially during the night, are both common and inimical to sleep. The staffing schedules and timing of specific activities in many facilities that care for demented people may be driven less by the needs of the patients than by compliance with federal and state requirements governing nursing-home operations. Regulatory requirements in general fail to incorporate many of the positive evidence-based practices found to be beneficial for demented residents, focusing more attention on feeding and bathing schedules, injury prevention, and detection of medical problems than on sleep and other issues related to quality of life.

Conclusion

Previously it was assumed that sleep and circadian rhythms decline inexorably with advancing age. However, recent research shows that, at least for health older adults, most of the age changes in sleep that have typically been thought to progress steadily across the adult human life span actually occur before age 60 and that adults over age 60 who remain healthy can expect their sleep quality to remain relatively stable as they age. Similarly age-related changes in circadian changes, again in older adults free of comorbid illnesses, are not as marked as was previously assumed. However, even healthy older adults tend to have earlier circadian phases, with a corresponding tendency to go to bed and arise from bed earlier than younger adults and to experience more trouble than younger adults adjusting to the rapid phase shifts such as those experienced in shift work and jet lag, at least in terms of sleep quality, subjective complaint, and performance measures.

Although sleep quality and circadian rhythms are apparently relatively well preserved in healthy older

adults, the negative impact of age-related comorbid illnesses on sleep and circadian rhythms is also clear. AD is a classic example of this negative impact, with AD patients typically demonstrating progressively fragmented sleep and irregular circadian rhythms with increasing severity of the disease.

Nevertheless, there is a growing body of evidence that the sleep quality and circadian rhythmicity of AD patients can, like those of other less-than-healthy older adults, be improved through nonpharmacological treatment approaches, whether the AD patients are community dwelling or institutionalized. Such groundbreaking work offers a firm foundation for future efforts to improve the sleep and related circadian rhythms of older adults, regardless of their health status.

Introduction

Sleep is of central importance to neurobiology, yet our understanding of the biochemical and neurophysiological mechanisms of sleep is rudimentary and sleep function has not been experimentally demonstrated. Our quality of life, performance, and mental well-being are all adversely affected by even a single night's loss of sleep. Chronic sleep loss is associated with pathologies such as the metabolic syndrome. Primary sleep disorders increase morbidity and mortality. Sleep plays a central role in many mental and physiological functions – for example, memory improves during sleep. It is thus important that we understand sleep regulatory mechanisms. This article focuses on the biochemical regulation of sleep and discusses how recent knowledge has led to new insights into how the brain is organized to produce sleep.

There are two somewhat independent literatures concerning the fundamental mechanisms of sleep regulation. One is based on neurophysiological methods, and this literature has led to the identification of circuits involved in non-rapid eye movement sleep (NREMS) regulation, such as corticothalamic projections and the hypothalamic ventrolateral preoptic and median preoptic circuits, and those involved in rapid eye movement sleep (REMS) regulation, such as the laterodorsal tegmental nucleus. Satisfactory explanations of how these circuits impose sleep on the brain and how they keep track of past sleep–wake activity likely will involve the biochemical mechanisms that interact with these circuits. Such interactions are particularly important for sleep homeostasis, the phenomenon exemplified by sleep rebound after prolonged wakefulness. The second sleep regulatory literature is based on biochemical methods. This work has its basis in the homeostatic nature of sleep and the nearly 100-year-old finding that has been replicated many times showing that the transfer of cerebrospinal fluid from sleep-deprived, but not control, animals enhances sleep in the recipients.

During the past 25 years, several sleep regulatory substances have been identified and extensively tested. However, only a handful are strongly implicated in sleep regulation. The list includes tumor necrosis factor-α (TNF-α), interleukin-1β, growth hormone releasing hormone (GHRH), prostaglandin D_2, and adenosine for NREMS regulation and vasoactive intestinal peptide, prolactin (PRL), and nitric oxide for REMS. When injected into animals, each of these substances promotes sleep; if they are inhibited, spontaneous sleep is reduced, their levels in brain vary with sleep propensity, and they act on sleep regulatory circuits to promote sleep. Here, we focus on TNF-α in NREMS regulation because it is the only substance identified whose circulating levels in humans correlate with sleepiness and sleep. We also discuss PRL because it has been implicated in REMS regulation by several laboratories and is a cytokine. In addition to these humoral agents, all neurotransmitters have been implicated in sleep–wake regulation; this literature is not discussed here. There is yet another literature demonstrating changes in gene expression, usually determined by changes in mRNA levels using gene chips, with sleep or sleep loss. That literature is distinguished from the sleep regulatory literature because every physiological function changes during sleep; thus, it is not possible from gene expression data alone to know if sleep *per se* is causative of the change. It is important to recognize that those humoral agents implicated in NREMS and REMS regulation affect each other's production and seem to act in concert with each other to affect sleep (Figure 1).

TNF-α in Sleep Regulation

The ability of TNF-α to promote NREMS was first described in 1987. TNF-α given directly into the brain or systemically enhances the duration of NREMS. For instance, mice receiving 3 μg TNF-α intraperitoneally spend approximately 90 min extra in NREMS during the first 9 h postinjection. In addition, NREMS after TNF-α treatment is associated with supranormal electroencephalogram (EEG) delta (0.5–4 Hz) waves, which are indicative of a greater intensity of NREMS. TNF-α is somnogenic in all species thus far tested: rabbits, mice, rats, and sheep. TNF-α has little effect on REMS if low NREMS-promoting doses are used; however, higher doses inhibit REMS. Sleep following TNF-α treatment appears to be normal in that sleep architecture remains normal, sleep remains easily reversible, postures remain normal, and animals remain responsive to handling. Changes in sleep-coupled autonomic functions, such as the decreases in brain temperature upon entry into NREMS, also persist after TNF-α treatment.

Figure 1 Molecular networks are involved in sleep regulation. Substances in boxes inhibit sleep and inhibit the production or actions of sleep-promoting substances illustrated via feedback mechanisms. Inhibition of one step does not completely block sleep since parallel sleep-promoting pathways exist. These redundant pathways provide stability to sleep regulation. Our knowledge of the biochemical events involved in sleep regulation is more extensive than that illustrated. The molecular network shown here possesses many of the characteristics of biological networks and engineered systems. Thus, the network is modular in that several proteins (cytokines) are working in 'overlapping coregulated groups' in this pathway. Second, the molecular network is robust in that removal of one of the components does not result in complete sleep loss. Third, the network operates as a recurring circuit element with multiple feedback loops affecting other pathways to the extent that similar networks involving many of the same substances and component network parts are used to regulate body temperature, inflammatory responses, microcirculation, memory, food intake, etc., and these systems, to a limited degree, coregulate. Specificity for any one physiological process, such as sleep, results from multiple interacting molecular and cellular circuits, each possessing different, but similar, reactivity. A1R, adenosine A1 receptor; αMSH, α-melanocyte-stimulating hormone; anti-IL1, anti-IL-1 antibodies; anti-TNF, anti-TNF antibodies; BDNF, brain-derived neurotropic factor; COX2, cyclooxygenase 2; CRH, corticotrophin-releasing hormone; GHRH, growth hormone releasing hormone; IGF1, insulin-like growth factor 1; IL-1RA, IL-1 receptor antagonist; LPS, lipopolysaccharide; MPs, muramylpeptides; NF-κB, nuclear factor-kappa B; NGF, nerve growth factor; NOS, nitric oxide synthase; PGD_2, prostaglandin D_2; sIL-1R, soluble IL-1 receptor; sTNFR, soluble TNF receptor; TGFβ, transforming growth factor-β.

Inhibition of TNF-α inhibits spontaneous NREMS. Thus, treatment with anti-TNF-α antibodies, the full-length soluble TNF receptor, or TNF soluble receptor fragments containing the TNF recognition site all inhibit spontaneous NREMS in rabbits and rats. Furthermore, pretreatment of animals with TNF inhibitors prior to sleep deprivation reduces the expected sleep rebound that normally occurs after sleep loss. Substances that inhibit TNF-α action or production also inhibit spontaneous sleep (e.g., interleukin-4, -10, and -13) (Figure 1). In addition, these substances also inhibit the production of certain other cytokines, such as interleukin-1β; therefore, their action on sleep may not be specific to TNF. However, they do form part of the negative feedback loops that help to regulate these nuclear factor-kappa B (NF-κB)-sensitive cytokines. Furthermore, inhibition of TNF also blocks the increases in NREMS observed in response to an acute mild increase in ambient temperature. Mice lacking the TNF 55-kDa receptor fail to exhibit NREMS responses if given TNF-α, thereby implicating this receptor in TNF-α-enhanced sleep. These mice also sleep less than corresponding control strains; the reduced NREMS occurs mostly during daylight hours.

Brain levels of TNF-α and the TNF-α mRNA vary diurnally and are influenced by sleep deprivation. The highest levels in rats occur at daybreak. The amplitude of the day–night changes in TNF protein is approximately tenfold and that in mRNA approximately twofold; this reflects the predominate posttranscriptional regulation of TNF. After sleep loss, hypothalamic TNF-α mRNA also increases. Sleep deprivation also increases the expression in brain of the 55 kDa TNF receptor mRNA. TNF-α serum levels increase in mice after sleep deprivation but not after stress. In normal humans, blood levels of TNF-α correlate with EEG delta wave activity. After sleep loss, circulating levels of TNF-α and the 55 kDa soluble TNF receptor, but not the 75 kDa TNF soluble receptor, increase.

Clinical conditions associated with sleepiness correlate with higher blood levels of TNF. Thus, patients with sleep apnea, chronic fatigue, chronic insomnia,

myocardial infarct, excessive daytime sleepiness, and preeclampsia all have elevated TNF plasma levels. AIDS patients have disrupted TNF and sleep rhythms. Postdialysis fatigue is associated with higher TNF levels, and cancer patients receiving TNF report fatigue. Furthermore, the 308A TNF-α polymorphic variant is associated with the metabolic syndrome and sleep apnea. Rheumatoid arthritis patients receiving the soluble TNF 75 kDa receptor report reduced fatigue. Sleep apnea patients treated with the soluble TNF receptor have reduced sleepiness. If obstructive sleep apnea patients are surgically treated, their elevated TNF-α plasma levels return to normal.

Systemic TNF, like several other cytokines, signals the brain via multiple mechanisms; one involves vagal afferents since vagotomy attenuates intraperitoneal TNF-α-induced NREMS responses. The effects of systemic bacterial products such as endotoxin, a component of gram-negative bacterial cell walls, may also involve TNF. For instance, in humans, endotoxin doses that induce transient increases in sleep also induce concomitant increases in circulating TNF-α. In addition, the soluble TNF receptor fragment attenuates bacterial cell wall peptidoglycan-enhanced NREMS in rabbits.

The site(s) of action of TNF-α-induced NREMS includes the preoptic area of the anterior hypothalamus, the locus coeruleus, and the somatosensory cortex. Thus, microinjection of TNF-α into the preoptic area enhances NREMS in rats. In contrast, injection of a soluble TNF receptor fragment into this site inhibits spontaneous NREMS. Microinjection of TNF-α into the locus coeruleus, after a brief period of excitation, induces prolonged increases in sleep and EEG synchronization. These effects are antagonized by anti-TNF-α antibodies. Microinfusion of TNF-α into the subarachnoid space just beneath the basal forebrain in rats enhances NREMS and reduces REMS. Finally, unilateral application of TNF-α onto the surface of the somatosensory cortex induces unilateral state-dependent increases in EEG delta wave power. Conversely, the soluble TNF receptor unilaterally reduces EEG power during the NREMS occurring after sleep deprivation. These latter two findings are germane to the brain organization of sleep and are discussed further later.

TNF Cell Biology

TNF signaling is an intense area of research due to its clinical importance and its inherent interest. TNF-α is synthesized as a 26 kDa membrane-associated protein. Soluble TNF-α, a 17 kDa protein, is cleaved from the 26 kDa membrane-associated protein by TNF-α converting enzyme. TNF-α production is tightly regulated in a tissue-specific manner, with transcription, translation, and secretion all controlled at multiple points. For instance, the 3′ UTR of TNF contains 24 miRNA complementary sites, suggesting translational regulatory sites. TNF-α induces its own expression, in part, via an NF-κB regulatory site (Figure 1). TNF-α can exist as a transmembrane protein that has biological activity. This membrane integrated form of TNF-α also receives signals and thus acts as a receptor, as well as a ligand.

There are two TNF cell surface receptors, the 55 kDa TNF receptor and the 75 kDa TNF receptor. The intracellular domains of these receptors lack intrinsic enzymatic activity. Rather, both receptors signal by recruitment of cytosolic proteins via protein–protein interaction domains. The diversity of these adaptor proteins and their ability to interact with other members of the TNF receptor superfamily help explain the pleiotropic actions of TNF-α. The TNF receptor family is divided into two large groups based on the adaptor proteins recruited in response to ligand binding. One major TNF-activated signaling pathway activates new gene transcription, whereas the other leads to cell death. Activation of the cell death pathway via the caspases 8 and 3 appears to be a rare physiological event because TNF-responsive gene products function to prevent cell death.

Both TNF receptors are cell surface receptors; they form trimeric complexes with TNF. The spatial distribution of the receptor and associated intracellular adaptor molecules is likely an important determinant of cellular specificity of action. Consequently, TNF activates signaling at multiple subcellular compartments, including the plasma membrane, mitochondria, and the nucleus. The ectodomains of both receptors are shed to form soluble receptors. The 55 kDa soluble TNF receptor is a constituent of normal cerebrospinal fluid, although its physiological role is unknown. However, given its effects on sleep and fatigue, it likely plays a role in sleep regulation.

TNF-α is expressed by microglia, astrocytes, and neurons and has a variety of biological actions in the brain, including a role in mediating both brain damage and neuroprotection. Whether TNF-α is protective or damaging may depend on the receptor type present – either the TNF 55 kDa or the TNF 75 kDa receptor – as well as the stimulus context and the presence or absence of substances that modify TNF-α activity. In addition to sleep, TNF-α has a role in thermoregulation, food intake, brain development, and neuronal connectivity. For instance, TNF-α potentiates AMPA-induced postsynaptic potentials,

AMPA-induced cytosolic Ca^{2+} increases, as well as several voltage-dependent calcium channels. TNF has a role in synaptic scaling, a process involved in maintaining synaptic diversity and plasticity.

Other NREMS Cytokine and Peptide Regulatory Substances

There is extensive evidence implicating both interleukin-1β (IL-1β) and GHRH in NREMS regulation that parallels that described previously for TNF-α. Thus, for example, inhibition of either GHRH or IL-1β inhibits spontaneous sleep. Mutant mice lacking functional GHRH receptors or mice lacking the IL-1β type I receptor have substantially less NREMS than respective strain controls. IL-1β induces growth hormone release via a hypothalamic mechanism that includes GHRH; anti-GHRH antibodies block IL-1β-induced growth hormone release. These antibodies also block IL-1β-induced NREMS. In fact, hypothalamic GABAergic neurons are receptive to both IL-1β and GHRH; both substances enhance intracellular calcium levels in these neurons. It is speculated that these neurons are the sleep-active hypothalamic neurons that increase their firing rates in response to IL-1β. In contrast, wake-active hypothalamic neurons decrease their firing rates in response to IL-1β. IL-1β and GHRH are related to TNF via the pathways outlined in Figure 1; collectively, it seems likely that these three substances form part of an NREMS regulatory network. Many other cytokines and members of the somatotropic axis can also affect sleep, but extensive knowledge concerning their roles in sleep regulation is lacking. They could in their own right be sleep regulatory substances or they may affect sleep via TNF-α, IL-1β, or GHRH.

Brain Organization of Sleep and TNF-α

Many investigations support the idea that sleep is regulated by specific brain circuits, such as the anterior hypothalamus. Perhaps the best evidence for this paradigm with regard to NREMS is that electrical, chemical, or thermal stimulation of the anterior hypothalamus induces NREMS. However, this paradigm inadequately addresses the issue of how the brain keeps track of its prior sleep–wake history over long periods of time. The transfer of cerebrospinal fluid from a sleep-deprived animal, but not a control animal, into a fully rested recipient enhances sleep in the recipient. This finding suggests that the homeostatic processes for sleep involve sleep regulatory substances.

There are also numerous results suggesting that sleep can be targeted to brain areas disproportionately activated during prior wakefulness. For instance, unilateral stimulation of the somatosensory cortex in awake humans produces asymmetry in EEG delta wave activity during subsequent NREMS. Similar results were obtained from rats and mice. Furthermore, dolphins only show EEG slow wave sleep on one side of the brain at a time. After a specific learning task, the subsequent EEG delta wave activity during sleep is enhanced in the area activated by the learning task. This finding reinforced previous work showing that either EEG activity or brain metabolism during sleep is regionally localized depending on prior use during wakefulness.

Our view of brain organization of sleep posits that sleep is initiated within neural assemblies as a function of prior cellular activity and this provides the mechanism for the localization and targeting of sleep, as well as for sleep homeostasis. In this view, for example, TNF-α is produced and released in response to neural and glial activity. These substances in turn are posited to be made and act locally in autocrine, paracrine, and juxtacrine ways to alter the input–output relationships of neural assemblies (e.g., cortical columns, barrels, or a cortical–thalamic–cortical loop) and thereby induce a functionally different state in these assemblies. Indeed, cortical TNF-α levels increase during prolonged wakefulness and during seizures – two conditions thought to be associated with enhanced cellular activity – and activity-dependent increases in TNF-α appear to be important for the developing nervous system. Furthermore, whisker stimulation upregulates TNF-α expression in neurons in the stimulated whisker's corresponding somatosensory barrel, but not in adjacent barrels, thereby directly demonstrating activity-dependent production of TNF-α.

Individual auditory and somatosensory cortical columns oscillate between functional states as defined by the amplitude of auditory- or whisker stimulation-induced surface evoked potentials. One of the functional states usually occurs simultaneously with whole animal sleep. This sleeplike state is dependent on its prior history in the sense that the probability of its occurrence is higher if, for the 15 min period prior to the measurement, it had been in the other functionally defined state. Furthermore, if two whiskers are stimulated, one at twice the rate of the other, the probability of the cortical column being in the sleep state is greater in the column receiving afferent input from the more rapidly stimulated whisker. If such changes in the functional state are dependent

Figure 2 TNF-α enhances the amplitude of surface evoked potentials induced by whisker stimulation. A rat with two-bilateral 12 electrode arrays plus a guide cannula was trained to accept the restraint associated with the recording apparatus and slept during recordings. If the rat was pretreated with TNF-α applied to the surface of the somatosensory cortex, surface evoked potentials were enhanced during quiet sleep compared to those occurring after heat-inactivated TNF-α (hiTNF). We propose that cytokines are driving neurons within cortical columns into a down state and thereby amplify surface evoked potentials. We also propose that the sleep functional state of the column is promoted by cytokines produced in response to cellular activity and is a function of the number of neurons in the down state.

on activity-dependent sleep regulatory substances such as TNF-α, then one would predict that direct application of TNF-α onto the surface of the cortex would drive the affected neural assemblies to simultaneously express the same functional state. Indeed, when TNF-α is applied in this manner, EEG delta power is enhanced unilaterally. Furthermore, if TNF-α is applied to the surface of the cortex and individual cortical columns are probed by whisker twitches, the probability of the column being in the sleeplike state increases (Figure 2). Such experiments strongly support the notion that sleep begins as a local process, being induced by the production of activity-dependent sleep regulatory substances such as TNF-α. Such a view has profound implications for our understanding of sleep regulation, sleep function, and unconsciousness.

Regulation of REMS by Prolactin and Related Molecules

The first anecdotal account implicating PRL in REMS regulation was from an experiment in which REMS was enhanced after systemic administration of PRL in hypophysectomized pontine cats. Subsequently it was shown that systemic PRL causes dose-dependent enhancements of REMS in rabbits. Thereafter, several lines of evidence implicated PRL in the regulation of REMS. The following were the major observations:

1. Injection of exogenous PRL stimulates REMS in cats, rabbits, and rats.
2. The increases in REMS develop slowly, over 2 or 3 h postinjection, and are maintained for several additional hours.
3. PRL-induced changes in sleep are selective for REMS.
4. PRL enhances REMS only during the light period in the rat.
5. In contrast, REMS is suppressed during the light period and is enhanced at night in mutant, PRL-deficient rats and PRL knockout mice.
6. Rats rendered chronically hyperprolactinemic by means of grafting pituitaries under the kidney capsule exhibit increases in REMS.
7. Both REMS and NREMS are enhanced in hyperprolactinemic pseudopregnant rats.
8. Restraint stress and ether stress are associated with enhanced circulating PRL and enhanced REMS. Restraint stress also enhances hypothalamic release of PRL, although stressor-induced release of pituitary PRL is thought to be responsible for the increases in REMS after stress.

Intracerebral administration of PRL or antibodies to PRL stimulates or inhibits REMS, respectively. The modulation of REMS is therefore a central action of PRL. PRL may come from two sources: it is produced by neurons in the hypothalamus and brain stem, and it is also released into the blood from the anterior pituitary. Circulating PRL is transported into the brain via specific receptor-mediated transport mechanisms residing in the choroid plexus. The REMS-promoting activity of blood-borne PRL is supported by the observation that REMS is enhanced in response to systemically injected PRL, excess PRL released from pituitary grafts, or stimulation of endogenous PRL secretion from the pituitary. Nevertheless, only slight decreases in REMS are observed when basal, nonstimulated blood PRL is suppressed by means of immunoneutralization. Although plasma PRL levels in humans are sleep related, being highest in the early morning hours, patients with PRL-producing adenoma fail to display changes in REMS; instead, their NREMS is increased. In summary, increases in blood PRL stimulate REMS in animal models, but circulating PRL at normal concentrations in the blood has only a minor effect on the regulation of REMS. The impact of the increased blood PRL concentrations on REMS is, in part, attributed to stimulation of the expression of PRL

receptors in the choroid plexus, whereby PRL enhances its own transport into the brain. It is thus posited that intracerebral PRL modulates REMS under normal conditions, whereas pituitary PRL provides additional stimulating influence when PRL secretion is high (e.g., during stress). PRL entering the brain from the systemic circulation acts on the same structures normally under the influence of intracerebral prolactinergic neurons.

Intracerebroventricular injections of hypothalamic peptides that cause pituitary release of PRL – vasoactive intestinal peptide (VIP) and pituitary adenyl cyclase activating peptide, both of which promote REMS – elicit expression of PRL mRNA in the hypothalamus and anti-PRL antibodies can block VIP-enhanced REMS responses. Another hypothalamic releasing factor for pituitary PRL, prolactin releasing peptide, also enhances REMS in rats if injected centrally.

The mechanism by which PRL increases REMS is unclear. PRL may modulate the circadian regulation of REMS at the level of the hypothalamus, or it may act in the brain stem structures generating REMS. The long (2 or 3 h) latency of the REMS response to exogenous PRL suggests that some metabolic actions mediate the sleep effects. Finally, growth hormone, which is structurally related to PRL, also stimulates REMS. Human growth hormone has a high affinity to PRL receptors and promotes REMS in both humans and rats.

The neuronal circuits responsible for the generation of REMS reside in the brain stem. The brain stem control of REMS involves the interactions between REMS-on neurons, which promote REMS, and REMS-off neurons, which inhibit REMS. Acetylcholine (ACh) is the best characterized neurotransmitter that promotes REMS. Cholinergic neurons localized in the laterodorsal tegmental nucleus (LDT) and the pedunculopontine tegmental nucleus (PPT) are involved in the generation of REMS signs such as EEG desynchronization, ponto-geniculo-occipital waves, and muscle atonia. Cholinergic neurons increase their firing rates approximately 20 s before the EEG signs of REMS and maintain higher activity levels during REMS than during NREMS, suggesting that these neurons participate in the initiation and maintenance of REMS. Numerous microinjection and microinfusion studies show that REMS is enhanced by cholinergic agonists and inhibited by cholinergic antagonists. Furthermore, kainate lesions of the PPT result in prolonged decreases in REMS. Anatomical data indicate that single cholinergic neurons in the LDT or PPT project to multiple brain regions that are responsible for the generation of individual signs of REMS. Therefore, these cholinergic neurons might be involved in the orchestration of different REMS signs to generate REMS.

A Proposed Mechanism for PRL-Enhanced REMS

REMS is influenced by metabolism. The length of the REMS cycles correlates with brain size and general metabolic activity. The brain primarily utilizes glucose as an energy source. Glucose is transported from the blood and into astrocytes through an active transport system and metabolized into pyruvate, the main fuel for neurons. In neurons, pyruvate may be metabolized into lactate by the enzyme lactate dehydrogenase in the absence of oxygen, or it may be metabolized into CO_2 and H_2O through the oxidative pathway which involves many enzyme actions, including pyruvate dehydrogenase (PDH). REMS is selectively suppressed during hypoxic hypoxia, whereas NREMS or waking may be enhanced. In contrast, an increase in oxygen availability induces a significant increase in REMS in chronic pontine cats kept at a fixed temperature. The high glucose and oxygen consumption levels during REMS compared to those during NREMS suggest that PDH activity is enhanced during REMS. It is suggested that glucose may be metabolized through the anaerobic pathways during wakefulness, converted to glycogen during NREMS, and metabolized through the aerobic pathways during REMS.

Stimulation of PDH in the mesencephalic/pontine cholinergic cells may serve as a final common pathway for various experimental interventions that promote REMS, such as REMS deprivation, immobilization stress, or administration of PRL. The connection between PRL and PDH was suggested by observations that PRL stimulated PDH activity in the prostate and the mammary gland. Increases in brain stem PDH activity occur in response to systemic injection of PRL.

The synthesis of ACh is critically dependent on the supply of acetyl-CoA, which in turn relies on the oxidation of pyruvate by the PDH complex during high glucose and oxygen consumption. PDH is particularly enriched in brain cholinergic neurons. Enhanced PDH activity results in increases in the concentration of acetyl-CoA and thereby stimulates the synthesis of ACh. Furthermore, brain cholinergic neurons are vulnerable to the deficiency of PDH. ACh levels are decreased by the PDH inhibitor 3-bromopyruvate

in brain homogenates or in the brain after local injection of this compound into the basal forebrain. Decreases in PDH activity elicited by experimental thiamine deficiency are also associated with the suppression of REMS.

Based on these observations, the proposed mechanism of the effects of PRL on sleep is as follows: PRL in the brain stimulates PDH and thereby energy production in neurons. This stimulation of PDH results in enhancement of ACh synthesis in cholinergic neurons because of an increased supply of acetyl-CoA. In our opinion, increased ACh production in itself does not trigger REMS. Due to the increased ACh pool, however, the quantity of ACh released increases whenever REMS spontaneously occurs. Therefore, PRL does not trigger REMS; instead, it facilitates spontaneous REMS. Furthermore, there is no evidence to suppose that PRL is specific to REMS-promoting cholinergic neurons. Cholinergic neurons also exist in the basal forebrain. These neurons are implicated in the mechanism of arousal, and their activities are associated with wakefulness. The importance of normal PDH activity has been demonstrated in the function of cholinergic neurons of the basal forebrain in experiments modeling the pathology of Alzheimer's disease. Stimulation of PDH in these neurons may explain the promotion of wakefulness by PRL during the dark period in rats. If further experiments substantiate that PRL acts via an increased synthesis of ACh due to enhanced activity of PDH, then PRL might be the first metabolic hormone whose effects on sleep can be linked to a distinct biochemical mechanism.

Conclusion

Our understanding of the biochemical regulation of sleep has progressed rapidly during the past 20 years. We now have a firm understanding of at least some of the humoral substances involved in sleep regulation. No doubt, other sleep regulatory substances will be described. Perhaps more important, these substances have already given insight into how the brain is organized to produce sleep. These mechanisms include a dynamic oscillation of states within neural assemblies coordinated into coherent whole animal states by sleep regulatory circuits and homeostatically driven by the accumulation of sleep regulatory substances.

The Molecular Correlates of Sleep May Offer Clues to Its Functions

All animal species studied to date sleep, and sleep may serve multiple functions, which may differ in different species. It is possible, however, that sleep also has a core function that is conserved from invertebrates to mammals. If this is the case, that function is most likely a cellular one because flies and humans share most pathways for intercellular and intracellular signaling, from membrane receptors and ion channels to nuclear transcription factors, but differ significantly in the number, anatomy, and complexity of brain circuits. The idea that the functions of sleep may ultimately relate to cellular and molecular aspects of neural function is not new. Giuseppe Moruzzi argued that "sleep concerns primarily not the whole cerebrum, nor even the entire neocortex, but only those neurons or synapses, and possibly glial cells, which during wakefulness are responsible for the brain functions concerned with conscious behavior." Moruzzi suggested that neural cells or synapses supporting waking conscious activity undergo plastic changes that make sleep necessary, although he did not speculate about the mechanisms. Others have suggested that sleep may help restore brain energy metabolism, may be needed to maintain the synaptic efficacy of the neural circuits not frequently used during wakefulness, or may favor a generalized synaptic downscaling following waking-induced synaptic potentiation. It has also been suggested that the rich spontaneous activity of neocortical neurons during slow-wave sleep may consolidate memory traces acquired during wakefulness. Several of these hypotheses are not mutually exclusive, and sleep may actually favor different cellular processes.

The analysis of the molecular correlates of sleep and wakefulness may help to understand the benefits that sleep brings at the cellular level. Specifically, the identification of the genes whose expression changes in the brain between sleep and wakefulness may clarify if, and why, brain cells need sleep and why their functions are impaired if they are prevented from doing so during sleep deprivation. In the past 15 years, subtractive hybridization, mRNA differential display, and microarrays have emerged as new powerful methods in transcriptomics, the study of the complete set of RNA transcripts produced by the genome at any one time. Microarrays are currently the most comprehensive and sensitive method to detect genome-wide expression changes, and they have allowed the identification of hundreds of transcripts whose expression is modulated by behavioral state. In addition, transcriptomics analysis has also identified functional categories of genes whose expression varies during sleep, wakefulness, and after different periods of sleep deprivation. At least some of these gene categories are conserved from invertebrates to mammals.

Table 1 lists the studies that have used transcriptomics approaches to identify genes whose transcript (mRNA) levels vary as a function of sleep, wakefulness, and/or sleep deprivation. It is clear from this table that the main focus has been on the cerebral cortex, although other brain regions have been studied, including cerebellum, hypothalamus, and brain stem. The cerebral cortex is of major interest because it is responsible for the cognitive defects observed after sleep deprivation, and it is at the center of most hypotheses concerning the functions of sleep.

The following general conclusions can be drawn from the studies listed in Table 1, and they are discussed further in this article:

- Hundreds of genes in the brain change their expression due to a change in behavioral state.
- Some genes increase their expression during sleep, whereas others do so during waking and sleep deprivation.
- Sleep and waking genes belong to different functional categories.
- Three functional categories of waking genes are conserved from flies to mammals.
- The noradrenergic system plays a role in the induction of some waking genes.
- The expression of several genes changes after chronic, but not acute, sleep loss.

Hundreds of Genes in the Brain Change Their Expression between Sleep and Waking

A first important finding of transcriptomics studies is that gene expression in the brain changes extensively as a function of behavioral states, sleep, spontaneous wakefulness, and short-term (a few hours) or long-term (several days) sleep deprivation.

Table 1 Studies that use transcriptomics approaches to identify molecular correlates of sleep (S), wakefulness (W), and sleep deprivation (SD)

Study[a]	*Method used/no. of tested transcripts*	*Experimental details*	*Major findings*
1	Subtractive hybridization (~4000 transcripts)	24 h SD (forced locomotion) vs. time-matched controls; rat forebrain	Four transcripts ↓ by SD, six transcripts ↑ by SD, all unknown
2	mRNA differential display (~9000 transcripts)	3 h S, W, SD (novel objects); rat cerebral cortex	One unknown transcript ↑ in S; 11 transcripts ↑ in W-SD, including *c-fos*, *NGFI-A*, and several mitochondrial genes
3	mRNA differential display (~9000 transcripts) + cDNA arrays (Clontech, 1176 transcripts)	8 h S, W, SD (novel objects); rat cerebral cortex	12 transcripts ↑ in S (all unknown except membrane protein E25); 44 transcripts ↑ in W-SD, including IEGs and heat shock proteins
4, 5	cDNA arrays (Clontech, 1176 + 588 +140 transcripts)	6 h SD (gentle handling), 6 h SD + 4 h recovery S vs. time-matched controls; mouse cerebral cortex (changes must be >100%); four array replicas	IEGs and heat shock proteins ↑ during SD Grp94 ↑ in recovery sleep
6	Affymetrix GeneChips, >24 000 probe sets, >15 000 reliably detected	8 h S, W, SD (novel objects); rat cerebral cortex (changes must be >20%); three to five array replicas; two statistical methods; qPCR; estimated false positives ~20%, based on qPCR confirmation of 52 transcripts (using independent groups of animals)	106 known transcripts and 155 ESTs ↑ in S; 95 known transcripts and 395 ESTs ↑ in W-SD
7	mRNA differential display (~5000 transcripts) + Affymetrix GeneChips, ~8000 probe sets, ~5000 reliably detected	8 h SD with or without prior LC lesion (DSP-4); rat cerebral cortex (changes must be >20%); three array replicas; two statistical methods; estimated false positives <20%, based on qPCR confirmation of 32 transcripts (using independent groups of animals)	20% (16/95) of the known transcripts ↑ in W-SD downregulated after cortical depletion of norepinephrine
8	Affymetrix GeneChips, 18 955 probe sets, ~9400 reliably detected	9 h S, W, SD (forced locomotion); fly head (changes must be >50% in two fly lines); four array replicas; one statistical method; estimated false positives <20%, based on qPCR confirmation of 19 transcripts (using independent groups of animals)	12 transcripts ↑ in S and 121 transcripts ↑ in W-SD
9	Affymetrix GeneChips, 1322 probe sets, ~600 reliably detected	6 h SD (gentle handling), 6 h SD + 2 h recovery S vs. time-matched controls; rat cerebral cortex, hypothalamus, basal forebrain (changes must be >50%); two array replicas	
10	Affymetrix GeneChips, 26 261 probe sets, ~17 000 reliably detected	1-week SD (disk-over-water method) compared to yoked controls, 9 h W, and 9 h SD; rat cerebral cortex (changes must be >20%); three to eight array replicas; one statistical method; estimated false positives <5%, based on qPCR confirmation of 15 transcripts (using independent groups of animals)	75 transcripts ↑ and 28 transcripts ↓ after long-term SD

ESTs, Expressed sequence tags; IEGs, immediate early genes.

Five percent or more of the transcripts tested in the brain show changes in gene expression according to behavioral state. Interestingly, a similar percentage of genes (1–10%) change because of differences in circadian time. In the cerebral cortex of rats, out of the 15 459 transcripts we tested, 808 (5.2%) were affected by time of day independently of behavioral state, and 752 (4.9%) were affected by sleep and wakefulness independently of time of day. These data indicate that, at least in the rat, day/nighttime and sleep/wakefulness influence gene expression in the cerebral cortex to a similar extent. Peripheral tissues such as liver and heart also show significant changes in gene expression as a function of circadian time. Whether this is also true for sleep-dependent and wakefulness-dependent genes is unknown because none of the array studies published so far has focused on peripheral tissues.

Some Genes Increase Their Expression during Sleep, Whereas Others Do So during Waking and Sleep Deprivation

We found that in the rat cerebral cortex, 95 known genes and 395 expressed sequence tags (ESTs; i.e., short transcribed sequences whose function is unknown) show higher expression after 8 h of spontaneous wakefulness or sleep deprivation, whereas 106 known genes and 155 ESTs show increased expression after 8 h of sleep. In the fly head, for which we used the same experimental protocol previously applied to rats (three experimental groups, including 8 h of sleep, 8 h of spontaneous wakefulness, and 8 h of total sleep deprivation), we identified 121 waking transcripts, including both known genes and ESTs, and 12 sleep transcripts, mostly unknown. Finally, we compared gene expression in the cerebral cortex of long-term sleep-deprived rats and sleeping controls and found that 226 transcripts are upregulated after long-term sleep deprivation and 113 after sleep. Thus, it seems that if all transcribed sequences are considered (including ESTs), there are more genes whose expression is upregulated during waking than during sleep. However, hundreds of genes are also upregulated during sleep, confirming the results of intracellular recording studies that show that sleep is far from being a quiescent state of global inactivity. In general, the largest fold changes are observed for waking genes. However, this is mainly due to the fact that waking increases the expression of transcription factors (e.g., c-fos) and effector genes (e.g., Arc) that behave as 'immediate early genes,' whose mRNA and protein levels may increase severalfold relative to sleep. Most waking and sleep genes, instead, change their expression by 20–50%, a fold change similar to that seen for most genes whose expression varies because of circadian time.

Sleep and Waking Genes Belong to Different Functional Categories

Sleep and waking transcripts belong to different functional categories and thus may favor different cellular processes. Most genes whose expression increases during wakefulness (or short-term sleep deprivation) code for proteins involved in energy metabolism, synaptic excitatory transmission, transcriptional activity, acquisition of new information, and the response to cellular stress. Sleep genes, instead, code for proteins involved in protein synthesis, synaptic downscaling and/or memory consolidation, lipid metabolism, and in membrane trafficking and maintenance.

Three Functional Categories of Waking Genes Are Conserved from Flies to Mammals

Three functional categories of genes are consistently induced in several animal species (fruit flies, mice, rats, and hamsters) during waking and short-term sleep deprivation relative to sleep. The first one includes genes involved in energy metabolism, including mitochondrial genes such as cytochrome oxidase (CO) I and IV. One study in rats also found an increase in CO enzymatic activity after 3 h of wakefulness. In mice, 6 h of sleep deprivation also affects the mRNA levels of genes involved in glycogen metabolism (glycogen synthase and glycogen phosphorylase) and increases the activity of glycogen synthase, possibly to counterbalance the rapid depletion, at the transition from sleep to wakefulness, of astrocytic glycogen stores. Eight hours of spontaneous waking or sleep deprivation also induces the expression in the rat cerebral cortex of *Glut1*, the gene coding for one of the more widely expressed glucose transporters in the central nervous system. The upregulation during waking of genes involved in energy metabolism is perhaps not surprising because glucose metabolism in many brain regions is higher in wakefulness than in non-rapid eye movement (NREM) sleep, and the brain relies almost exclusively on glucose as its energy substrate. These changes, however, do not seem to persist when sleep deprivation is protracted for 24 h or several days. This is consistent with imaging studies in animals, normal human subjects, and fatal familial insomnia patients showing no change or a decrease in cerebral metabolic rate after prolonged sleep loss relative to normal wakefulness.

Thus, the rapid upregulation of mitochondrial genes, *Glut1*, and glycogen-related genes may represent a mechanism by which the brain responds to the immediate increase in energy requirement during spontaneous waking or after a few hours of sleep deprivation, whereas prolonged sleep loss is associated with reduced energy demands.

A second group of genes consistently upregulated during wakefulness and downregulated during sleep includes heat shock proteins, chaperones, and, in general, genes involved in the response to cellular stress. Cellular stress is the cell's reaction to any adverse environmental condition that perturbs cellular homeostasis, with potential macromolecular damage (i.e., damage to proteins, DNA, RNA, and lipids). Wakefulness and short-term deprivation are associated with higher mRNA levels of small heat shock proteins with actin-stabilizing properties, such as HSP27 and αB crystallin; molecular chaperones (HSP70 and HSP60); and chaperones in the endoplasmic reticulum, such as BiP and Grp94. BiP (immunoglobulin heavy chain-binding protein) shows the largest and most consistent upregulation in the brain of awake animals, including mice, rats, hamsters, and sparrows, as well as in the head of fruit flies. BiP assists in the folding and assembly of newly synthesized glycoproteins and secretory polypeptides and increases in *BiP* expression have been classically described after heat shock and ischemia, when unfolded proteins accumulate in the endoplasmic reticulum. This unfolded protein response is also induced by other conditions that adversely affect the function of the endoplasmic reticulum, such as anoxia, glucose deprivation (BiP is also called glucose-regulated protein 78), and depletion of Ca^{2+} stores in the endoplasmic reticulum. Importantly, the unfolded protein response also triggers a slowing down of protein synthesis. In the rat cerebellum, 8 h of spontaneous wakefulness or sleep deprivation is associated with an increase in the mRNA levels of *PEK*. *PEK* codes for the EIF2a kinase that mediates the inhibition of protein synthesis during the unfolded protein response. Moreover, in the mouse cerebral cortex, 6 h of sleep deprivation is also associated with signs of slowing down of protein synthesis, as indicated by the phosphorylation of key components of the translational machinery and by changes in the ribosomal profile.

A third group of genes consistently upregulated during wakefulness and downregulated during sleep includes transcripts sensitive to membrane depolarization and synaptic activity. In the rat cerebral cortex, they include *RGS2*, *Homer/Vesl*, tissue-type plasminogen activator, casein kinase 2, cyclooxygenase 2, *cpg2*, and connexin 30. Moreover, several genes involved in activity-dependent neural plasticity and long-term potentiation, such as *Arc*, *BDNF*, *Homer/Vesl*, and *NGFI-A*, have been consistently found to be upregulated in the cerebral cortex of awake or short-term sleep-deprived rats. At least some of the same genes are induced during wakefulness and/or short-term sleep deprivation in mice, hamsters, and sparrows. In the fly head, many of the depolarization-sensitive genes involved in synaptic plasticity as identified by Guan et al. in 2005 are also waking-related genes, including *Astray*, *Kek2*, *stripe*, and *Hr38*. The fly wakefulness-related gene *stripe* is a member of the Egr family of transcription factors. In the rat brain, several members of this family, including *NGFI-A* (*Egr-1*), *krox 20* (*Egr-2*), and *NGFI-C* (*Egr-4*), are induced during wakefulness. *Hr38*, another fly wakefulness-related gene, is the *Drosophila* ortholog of the mammalian NGFI-B family of orphan nuclear receptors. *NGFI-B* is a wakefulness-related gene in the rat cerebral cortex. Thus, it seems that in both mammals and flies several plasticity-related genes involved in synaptic growth and potentiation are specifically induced during wakefulness.

The observation that genes involved in long-term potentiation and the acquisition of new memories are specifically induced during wakefulness should not be too surprising. After all, we learn when we are awake and able to adapt to the environment, and not when we are asleep. However, if sleep is not involved in learning, is there a role for it in other aspects of synaptic plasticity? Well-controlled experiments show that sleep may favor the performance of some, but not all, tasks. The strongest and more consistent data relate to procedural tasks and suggest an important role for NREM sleep or a combination of NREM and REM sleep. What remains unknown, however, are the mechanisms by which sleep may enhance performance. Animal and human studies have shown that brain circuits activated during the execution or the acquisition of certain tasks are 'reactivated' during the subsequent sleep period. The presence of this memory trace, as shown by electrophysiological recordings and imaging studies, could reflect the fact that sleep replays the waking experience, and by doing so it somehow allows the specific consolidation of the learned tasks. However, it is also possible that this trace is the inevitable consequence of the synaptic potentiation that occurs during learning, and that sleep enhances performance by actually allowing a generalized downscaling of synapses. The first and most important effect of this downscaling is thought to be the decrease in the metabolic cost of synaptic activity, which increases during waking due to synaptic potentiation. A second effect of the generalized but proportional decrease in synaptic weight is an increase in the signal-to-noise

ratio, which could improve the performance of some learned tasks.

If sleep is associated with a generalized depression of synaptic strength, molecular markers of synaptic depression should be increased during sleep relative to waking. Studies have identified and validated several specific and direct markers of synaptic strength, with the best established among them being the density, composition, and phosphorylation state of the GluR1 subunit of the glutamatergic AMPA receptors. We are currently measuring the number and phosphorylation state of synaptic GluR1 in the rat cerebral cortex after 6 h of sleep or sleep deprivation. Preliminary results show that in several cortical areas, sleep is associated with a relative dephosphorylation of GluR1 at serine 845, a finding consistent with the hypothesis that sleep is associated with synaptic downscaling.

The Noradrenergic System Plays a Role in the Induction of Some Waking Genes

One of the mechanisms that underlie the widespread changes in cortical gene expression between sleep and wakefulness is the activity of the noradrenergic system of the locus coeruleus (LC), whose neurons project diffusely over the entire brain. LC cells are tonically active during wakefulness, reduce their firing rate during NREM sleep, and cease firing during REM sleep. Moreover, LC activity increases phasically in response to salient events and in relation to the decision to act. In a series of experiments, rats were subjected to unilateral or bilateral LC lesions to deplete one or both sides of the brain of norepinephrine. In these animals, the raw electroencephalogram (EEG) and its power density spectrum were not significantly affected by the lesion. However, all cortical areas depleted of norepinephrine showed a marked decrease, during wakefulness, of the expression of plasticity-related genes such as *Arc*, *BDNF*, *NGFI-A*, and *P-CREB* as well as of stress response genes such as heat shock proteins and *BiP*. By contrast, the transcript for the translation elongation factor 2 was the only known sleep-related transcript whose expression increased after LC lesion (Figure 1). In a complementary experiment in mice, the activity of the LC of one side was increased using a conditional transgenic approach. This manipulation resulted in an increased ipsilateral expression of *NGFI-A* in cortical and subcortical target areas. Thus, LC activity during wakefulness modulates neuronal transcription to favor synaptic potentiation and memory acquisition and to counteract cellular stress, whereas LC inactivity during sleep may play a permissive role to enhance brain protein synthesis.

Figure 1 Schematic representation of the major functional categories of genes upregulated in the rat cerebral cortex after 3–8 h of spontaneous waking or sleep deprivation (acute sleep loss), 1 week of total sleep deprivation (chronic sleep loss), and 8 h of spontaneous sleep.

The Expression of Several Genes Changes after Chronic, but Not Acute, Sleep Loss

In an array study, we analyzed the expression of more than 26 000 transcripts in the cerebral cortex of long-term sleep-deprived rats. Animals were kept awake for 7 days using the disk-over-water method. This method uses minimal stimulation to enforce chronic sleep deprivation in the sleep-deprived rat, while it simultaneously applies to the control rat the same stimulation but without severely limiting its sleep. The sleep-deprived and the control rats are each housed on one side of a divided horizontal disk suspended over a shallow tray of 2 or 3 cm deep water. EEG and electromyogram are continuously recorded to detect sleep states. When the experimental rat falls asleep, the disk is automatically rotated at low speed, awakening the rat and forcing it to walk opposite to disk rotation to avoid being carried into the water. The yoked control rat receives the same physical stimulation because it is on the same disk. However, whereas sleep is severely reduced (by 70–80%) in the sleep-deprivation rat, the control rat can sleep whenever the sleep-deprived rat is spontaneously awake and eating, drinking, or grooming, and thus its sleep is reduced by only 25–40%.

We compared long-term sleep-deprived rats with rats spontaneously awake or sleep deprived for only 8 h and identified 75 transcripts upregulated and 28 transcripts downregulated after chronic sleep loss. Most transcripts specifically increased or decreased their expression due to the long-term sleep deprivation and not because of the disk stimulation, because they were not affected in the yoked controls. A large group

of genes upregulated after prolonged sleep loss codes for immunoglobulins, including two autoantibodies. Another group includes stress response genes such as the macrophage inhibitor factor-related- protein MRP14, expressed in microglia. Arylsulfotransferase, an enzyme involved in the catabolism of catecholamine, is also upregulated after chronic sleep deprivation. These genes are either not induced (antibodies and MRP14) or induced to a lesser extent (arylsulfotransferase) after acute sleep loss, suggesting that short-term and long-term sleep deprivation differ to some extent at the molecular level. We also compared long-term and short-term sleep deprivation to sleep and found that only a minority of genes were similarly up- or downregulated in the two sleep- deprivation conditions. Among the genes whose expression was most significantly downregulated in long-term sleep-deprived animals relative to sleeping animals were myelin constituents, including the most abundant structural protein component of myelin – the proteolipid protein. These findings suggest that sustained sleep loss may trigger a generalized inflammatory and stress response in the brain. Some glial cells (e.g., microglia) may help to protect neurons against this cellular insult, but others (e.g., oligodendrocytes) may also suffer some of its negative consequences. It will be important in the future to test whether sleep loss may be detrimental to the maintenance of cellular membranes and specifically to myelin.

Genes Upregulated during Sleep

Figure 1 shows the sleep-related transcripts identified so far in the rat cerebral cortex. Unfortunately, only one study in mammals was designed to identify genes upregulated after several (8) hours of sleep relative to both spontaneous waking and sleep deprivation to rule out effects of stress and circadian time. Another study in flies used the same experimental conditions used in rats, but for technical reasons the entire fly head, rather than the brain only, was used to hybridize the arrays. This most likely decreased the ability to detect state-dependent genes. Only 12 genes were identified as sleep-related in flies, and the function of most of them is unknown. Thus, the extent to which sleep genes are conserved across species is yet to be determined.

Two sleep genes in the rat cerebral cortex code for the translation elongation factor 2 and the initiation factor 4AII, and they are involved in protein synthesis. The mRNA levels of the elongation factor EF2 are also increased during sleep in the brain of Djungarian hamsters. A positive correlation between sleep and protein synthesis has been suggested by previous studies, and evidence suggests that waking and sleep deprivation are less conducive to protein synthesis than sleep. Whether sleep favors protein synthesis globally or whether it enhances the synthesis of specific classes of proteins is unclear.

Other sleep genes identified in the rat cerebral cortex are involved in the consolidation of long-term memory as well as in synaptic depression and depotentiation. Among them are calmodulin-dependent protein kinase IV, calcineurin, FK506 binding protein 12, inositol 1,4,5-trisphosphate receptor, and amphiphysin II. As mentioned previously, the mechanism by which sleep enhances memory and performance is still debated, but these molecular data are compatible with the idea that sleep benefits the brain by producing a global synaptic downscaling.

Another large group of sleep-related transcripts in the rat cerebral cortex is involved in membrane trafficking and maintenance. Some of these transcripts are important for the synthesis/maintenance of membranes in general and of myelin in particular, including oligodendrocytic genes coding for myelin structural proteins (e.g., *MOBP*, *MAG*, *plasmolipin*, and *CD9*), myelin-related receptors, and enzymes. Transcripts with higher expression in sleep also code for enzymes involved in the synthesis and transport of cholesterol, a major constituent of myelin and other membranes and an important factor in regulating synaptic efficacy. As mentioned previously, long-term sleep deprivation decreases the expression of the gene coding for proteolipid protein, a major myelin component. Intriguingly, among the few known sleep genes in *Drosophila* are the gene *anachronism* (*ana*) and three genes involved in lipid metabolism (*CG8756*, *CG9009*, and *CG11407*). Ana is a glycoprotein secreted by glial cells, and it controls the timing of neuroblast development. Whether *ana* plays any role in membrane trafficking and synaptic plasticity remains to be determined.

Conclusions

As it is apparent from the small number of studies in Table 1, transcriptomics analysis is still a work in progress, and it would be inappropriate to draw firm conclusions from what has been published to date. Continuous improvement in the array technology will certainly favor more progress in this area. For instance, the current arrays can assess the expression of 20 000–30 000 transcripts, but this is still far from a true 'whole genome' analysis. Low expression genes are often difficult to detect, especially in large and heterogeneous tissue samples such as most brain areas. Moreover, current arrays focus on the coding portion of the genome, but new 'tiling' arrays, in which probe sets are laid down at regular intervals

across the entire genome, are becoming commercially available. This will permit the identification of new transcriptionally active regions of the genome that have not been tested in more conventional arrays. Moreover, proteomics, the study of the complete repertoire of proteins that contribute to a cell's physiological phenotype, is a natural next step in the study of molecular correlates of behavioral states.

Introduction

Understanding how large groups of neurons interact across brain structures is important for understanding brain function. During both awake and asleep brain states there are structured interactions between groups of neurons (ensembles) in the hippocampus and groups of neurons in the neocortex. Ensembles fire together in predictable patterns during hippocampal theta and sharp waves in both the awake and sleeping brain, as well as during neocortical sleep spindles, delta waves, and slow oscillations. How are the ensemble patterns observed in the hippocampus related to ensemble patterns observed in the neocortex, and do they differ in the awake versus asleep brain?

Two prominent hippocampal activity patterns (theta and sharp waves) occur during specific behavioral states (Figure 1). The theta pattern occurs during active exploration of the environment, with a number of neurons throughout the hippocampal system discharging collectively every 50–100 ms. Theta is considered an 'online' state in which information about the 'world' is channeled from primary sensory pathways through the neocortical associative cortices (e.g., perirhinal and parahippocampal cortices) and then fed into the circuitry of the hippocampus. Theta pattern also occurs during rapid eye movement (REM) sleep.

During moments of immobility and quiet resting, sharp waves (SPWs) dominate the hippocampus, with large numbers of hippocampal neurons discharging in a fast-frequency (200 Hz) 'ripple' volley in relation to the slow (~100 ms) SPWs. Sharp waves are considered an output state, when the hippocampus reengages neocortical circuits, perhaps providing a comment, an index, or simply a replay about the content of prior theta-related input. This pattern has been suggested to serve an 'offline' consolidation process. Similar SPW patterns also dominate the hippocampus during slow-wave sleep (SWS). Do the ensemble firing patterns during SPWs in awake and sleep states support different functions? Defining the similarities and differences across awake and sleep states may shed light on their significance as well as on the function of distinct sleep states. More importantly, it is necessary to uncover the mechanism by which these 'replay' patterns are coordinated with the ongoing neocortical activity, to ensure information transfer between the two structures.

It has been often suggested that sleep and particular sleep stages (e.g., REM) play an important role in memory, perhaps consolidating important information or erasing trivial information gathered by the waking brain. According to several models, memory involves an initial encoding stage followed by a longer period of consolidation, with some models suggesting that ensemble interactions during REM and SWS contribute to memory consolidation. Several research groups have demonstrated that neurons within the hippocampus that fire together during exploration fire together and in temporally related sequences during both REM and SWS. Could these structured interactions during sleep support memory consolidation processes? What are the mechanisms that give rise to these interactions?

Information about the spatial extent and temporal synchronization of hippocampal and neocortical networks during both asleep and awake brain states may offer insight into the mechanism and function of large-scale integration and segregation of ensemble activity. Do the coordinated discharges of hippocampal neurons during SPWs actually influence neocortical neurons? What influence does the concerted action of neocortical neurons during sleep rhythms (spindles, delta waves, slow oscillation) have on hippocampal ensemble activity? Sleep spindles and delta waves reflect a concerted discharge of thalamic, thalamocortical, and neocortical neurons, and several findings now link the occurrence of SPWs to the synchronization of neocortical neurons during sleep spindles and delta waves. Thus, fairly large networks of hippocampal, thalamic, and neocortical neurons have the potential to synchronize their activity during SPWs. Do these coordinated interactions support the specific transfer of information between hippocampal and neocortical cell assemblies?

We suggest that structured interactions among neurons during awake and sleep serve as building blocks for systems-level functions. The dialogs between the hippocampus and neocortex during SPWs, during both awake and sleep states, may play an important role in consolidating hippocampal-dependent memory traces in neocortical stores. A protracted consolidation process, taking place over days/months, could then support the observation that hippocampal insults do not affect memories acquired at some point prior to insult (equally days/months/years). The logic and evidence in

Figure 1 Behavior-dependent macroscopic (electroencephalogram) states in the hippocampus. (a) Extracellular recordings from the CA1 stratum radiatum of the left (top) and right (bottom) hippocampus during the transition from exploration walking to being still. Note regular theta waves during walking, and large, negative sharp waves during immobility. Note also that sharp waves are bilaterally synchronous. (b) A single sharp wave with simultaneously recorded fast-field oscillation from the CA1 pyramidal layer at a faster time scale. support of a role for SPWs and neocortical oscillations in hippocampal-dependent memory, and their role in hippocampal–neocortical dialogs during SWS, are overviewed in the following sections.

The Basics: A Two-Stage Model of Memory Trace Formation

The neuronal activity of the hippocampal formation (hippocampus, subiculum, and entorhinal cortex) is organized around two population patterns, theta and SPW. Theta and SPW patterns seem to serve companion processes. The theta pattern occurs during exploratory behavior and REM sleep. During theta, hippocampal circuits receive rhythmic input from neurons within the entorhinal cortex. The entorhinal cortex transmits information from neocortical association areas (e.g., perirhinal, parahippocampal) to the hippocampus. Thus, theta synchronizes the input pathways into the hippocampus from the neocortex.

In contrast, SPWs occur during consummatory behavior and SWS. During SPWs, the output neurons of the hippocampal formation participate in organized population bursts. During each burst, SPW neurons in the CA1, subiculum, and deep layers of the entorhinal cortex fire fast-frequency population volleys at ~200 Hz. The fast-frequency discharge is accompanied by a fast-frequency (~200 Hz) field potential referred to as a 'ripple' near the perisomatic region. The ripple field potential reflects synchronized inhibitory input to the soma from local γ-aminobutyric acid (GABA)ergic neurons (e.g., basket cells).

Figure 2 Self-organized burst of activity in the hippocampal CA3 region produces a field potential in the dendritic layer of CA1 and a short-lived fast-frequency field oscillation (200-Hz ripple) within stratum pyramidale, as well as a phase-related discharge of the neurons. The hippocampal output, in turn, produces similar sharp wave–ripple complexes in the subiculum (Sub), parasubiculum (Para), and deep layers of the entorhinal cortex (EC). Adapted from Chrobak JJ and Buzsaki G (2005) Synaptic plasticity and self-organization in the hippocampus. *Nature Neuroscience* 11: 1560–1567, with permission.

Each SPW is a transient (40–100 ms) population volley that involves the discharge of roughly 40 000 to 80 000 neurons in the CA3–CA1–subicular complex–entorhinal cortex axis within a 50- to 200-ms time frame. Both SPWs and their associated fast-frequency ripples (Figure 2) are present in the hippocampus of

all mammals investigated, including humans. Several features of this fast-frequency population volley make this network pattern an excellent candidate for altering synaptic connectivity. First, the time window of the SPW population burst roughly corresponds to the time constant of the *N*-methyl-D-aspartate (NMDA) receptor, through which Ca^{2+}, the key ion for the induction of synaptic plasticity, enters the neuron. Second, the fast-frequency network output (~200 Hz) is the ideal frequency range for initiating long-term potentiation (LTP). Third, during the SPW burst there is a three- to fivefold gain of network excitability, creating an ideal condition for synaptic potentiation. Last, the SPW engages the neurons that make up the output network of the hippocampus (CA1, subiculum, and entorhinal cortex). This network logically would transfer information back to neocortical structures, and SPW-related discharge has been observed in a number of hippocampal/entorhinal target structures, including the perirhinal cortex, amygdala, ventral striatum, and prefrontal cortices.

Hippocampal Replay of Waking Patterns during Sleep

Neuronal activity during sleep may promote memory-related synaptic plasticity more effectively than does neuronal activity during awake states. Why? First, neurons, free from the influence of sensory-driven input, can discharge independently and perhaps randomly, thereby erasing synaptic modifications brought about by the awake brain. The expected result could be to refresh or wipe clean the synaptic modifications associated with previous experience. This would provide a fresh 'tabula rasa' every morning, ready for information from the new day. Alternatively, neuronal pathways used and modified in the awake brain could be replayed repeatedly, and the repeated activation could be used to enhance important/relevant synaptic modifications. The molecular processes supporting synaptic potentiation are quite protracted (hours/days), thus perhaps necessitating repeated instantiation of the patterns supporting potentiation.

Because SPWs occur during immobility, during consummatory behaviors, and, mostly, during SWS, it was inferred that SPWs during SWS could play an important role in memory consolidation. The repeated replay of ensemble patterns (representations) related to recent ensemble patterns could provide a dynamic network mechanism for the slow, offline, transfer of hippocampal computations to the neocortex. Some specific predictions of the model are that (1) neurons do not randomly participate in SPW volleys; (2) synaptic connectivity, firing rates, and population patterns during SWS remain similar unless specifically altered by awake experience; and (3) SPWs induce synaptic modifications in the output networks of the hippocampal formation.

Several physiological experiments support the conjectures and predictions of the two-stage model of memory consolidation. Ensembles of neurons discharging in spatial specific (place cells) environments continue to fire together at a high rate during subsequent SWS and REM sleep episodes (Figure 3). This replay of neuronal patterns has been observed in both rats and monkeys and has also been observed during SPWs during awake immobility as well as during SWS. Neurons 'tied' together by sensory experience(s) in the awake world tend to discharge together whenever the probability of their discharge is increased. In most of these studies, no specific 'learning' experience took place. Place (spatial)-specific neurons fired as a rat navigated on a linear track or circular environment, and subsequently discharged together some time later, during both awake states and during subsequent sleep (both REM sleep and SWS). Typically, the probability of two or more neurons discharging together is increased during sleep directly following an experience, as compared to sleep before spatial exploration. In addition to showing that neurons fire together, these experiments demonstrate that the specific sequence of place cells that discharge as a rat navigates an environment replay later in the same or related sequences. The degree to which these sequential patterns are maintained over time (hours to days)

Figure 3 Temporally compressed replay of learned neuronal sequences. Top: Spatiotemporal firing rate changes of 10 CA1 place units on an elevated track. Bottom: Representative examples of firing patterns of the same units during two ripple events of nonrapid eye movement sleep. Note the similarity between ripple-related spike sequences and the order of place-cell activation on the track. Adapted from Lee AK and Wilson MA (2002) Memory of sequential experience in the hippocampus during slow wave sleep. *Neuron* 36: 1183–1194, with permission from Elsevier.

has been somewhat equivocal and may vary as a function of experience and/or novelty.

The latter can be examined by comparing firing rates and coactivation of neuronal groups in sleep episodes interrupted by performance in a well-trained task, such as food foraging in an open field and running in a wheel. The discharge frequency of concurrently recorded pyramidal neurons remains remarkably stable across several sleep/wake cycles. Neurons with high firing rates during wheel running (associated with theta) continue to fire at a high rate during drinking or awake immobility. Similarly, fast-firing neurons in SWS sustain their relatively high rates during REM sleep. When firing rates of neuronal populations are compared in two sleep episodes, interrupted by a wheel-running session or foraging in an open field, discharge frequencies of individual cells are robustly correlated. Thus, coactivation patterns during sleep episodes preceding and following an awake session are very strongly correlated. Several studies suggest that an underlying anatomical or anatomical/physiological matrix governs the propensity of neurons to fire, and the probability that they fire together is simply altered by awake experience. Any recent alterations in the probability of firing are maintained across subsequent sleep episodes.

All told, these findings demonstrate that sensory-related firing patterns during awake states are correlated with similar patterns during subsequent periods of immobility and during sleep states. Do these correlated patterns demonstrate a unique role for sleep patterns in maintaining ensemble representations of prior events? No, they do not. The correlated patterns demonstrate that neurons that fire together in a relatively stable network generally fire together when any member of the ensemble discharges. Important caveat in these studies is that causality is derived from the difference between sleep sessions before and after exploration, while many studies demonstrate considerable nonspecific difference of network activity patterns between these seemingly equivalent states. While subtle modifications, small perturbations, in the stability of a relatively hard-wired network could support mnemonic representations and be used for recognition and retrieval of prior events, the described studies do not demonstrate that they do. One possible way to attribute causality to sleep–wake correlated patterns is to manipulate or perturb the system.

Novel Experience Alters Firing Patterns in Subsequent Sleep

Can synaptic change associated with a specific experience persist in such a way that changes could be detected in subsequent sleep? Few studies have examined the role of learning on ensemble firing patterns. Exposure to a novel situation can result in long-lasting changes in the firing patterns of hippocampal pyramidal neurons. The correlated firing rates of individual neurons during exploration of a novel environment and subsequent sleep episode are stronger than are the correlated rates between exploration and the preceding sleep episode. Importantly, firing rates observed in the sleep episodes before and after exposure to novelty are poorly correlated (**Figure 4**). Exploration in a novel environment has a similar effect on correlated activity among neurons, with neuronal pairs exhibiting high awake correlations continuing to display high correlation during subsequent sleep episodes.

A more direct support for the 'replay' of learned neuronal patterns comes from experiments in which, instead of two neurons firing together, three or more neurons (up to six) exhibit sequential temporal relationships during awake and subsequent sleep. Typically neurons involved in the sequences were both identical and replayed much faster during sleep than in the waking animal. The dynamics of each ripple indicate that tens of thousands of hippocampal output neurons discharge as a population volley at 200 Hz. In summary, specific neuronal sequences during SWS are determined by prior sensory experience and by the dynamics of the SPW ripple process.

Interactions between Neocortex and Hippocampus during Sleep

Though the hippocampus is critical to the encoding of new memories, it is fairly well understood that the hippocampus plays a time-limited role in memory consolidation. After an ill-defined time period (days, weeks, and months), most memories can be retrieved in the absence of the hippocampus. Thus, a gradual translation or translocation of neural patterns to neocortical targets is presumed to mediate 'long-term' memory storage. A number of models posit that the hippocampus plays a role in bringing ensembles of cortical neurons together to form a linked 'chain' of information related to a particular memory. The role of the hippocampus is to activate each link in the chain, allowing for memory retrieval, and/or to forge the links such that the entire chain can become hippocampal independent. In the absence of hippocampal input, as occurs in human temporal lobe amnesia or experimental animals, the links in the chain cannot readily be forged or retrieved. With an intact hippocampus, the repeated replay of hippocampal patterns during offline states, during REM or SPWs in SWS, may forge the neocortical links such that memories can eventually be retrieved without the hippocampus.

Figure 4 Comparison of discharge frequency of pyramidal cells in two successive slow-wave sleep (SWS) episodes, interrupted either (a) by a wheel running session (familiar) or (c) by novel exploration. Mean correlation values for 'sleep before' vs. 'sleep after' (S_B–S_A), 'awake' vs. 'sleep before' (A–S_B), and 'awake' vs. 'sleep after' (A–S_A) sessions in the well-trained running wheel task (b) and in the novel environment (d). Note high and low correlations between successive sleep sessions in the familiar and novel environments, respectively. Adapted from Hirase H, Leinekugel X, Czurko A, et al. (2001) Firing rates of hippocampal neurons are preserved during subsequent sleep episodes and modified by novel awake experiences. *Proceedings of the National Academy of Sciences of the United States of America* 98: 9386–9390, with permission.

The SPWs seem like an ideal candidate mechanism for the gradual offline strengthening of neocortical patterns related to memory, regardless of how the process is conceptualized.

Deep slow-wave sleep is characterized by widespread synchronized oscillatory patterns, defined primarily by spatially coherent delta waves during which spiking activity of nearly all principal cells and interneurons in the neocortex is suspended. The intervals between the silent periods define slow oscillations (0.3–1.5 Hz). The relatively abrupt shifts in population firing and silence states are reflected by the bimodal (depolarized and hyperpolarized or UP and DOWN) distribution of the membrane potential in neocortical, entorhinal, and subicular neurons. The UP state is often associated with K-complexes and thalamocortical sleep spindles (12–18 Hz).

Several studies have described a concurrence of hippocampal SPWs in association with neocortical sleep spindles and delta waves. The excitatory front of the UP cortical states can spread to the hippocampus via the entorhinal cortex, as reflected by the active sinks in the dentate molecular layer and stratum lacunosum-moleculare of the CA1 region, the main targets of the entorhinal cortex. As a result of the strong neocortical drive, dentate granule cells and other neurons of the dentate area fire coherently with the input from the entorhinal neurons during the slow oscillation. The rest of the hippocampus is less affected, mainly due to the strong feed-forward

inhibitory circuits between granule cells and CA3 pyramidal cells. Nevertheless, the majority of the output of CA1 pyramidal cells also increases their discharge rate in phase with the cortical UP state, likely driven by direct perforant path input. Important in the present context, a majority of SPW/ripple complexes are also associated with the enhanced neocortical activity during slow-wave sleep: the probability of occurrence of SPWs/ripples is highest at and after the onset of the cortical UP state. Furthermore, SPWs are modulated by single cycles by neocortical spindles (Figure 5), suggesting a more direct role for neocortical inputs in triggering SPWs.

In summary, cortical slow oscillations temporally coordinate the occurrence of K-complexes, thalamocortical spindles, and hippocampal SPWs. Such periodic 'rebooting' of neuronal activity in widespread neocortical, paleocortical, and hippocampal networks should have important functional consequences. Could specific subtle patterns of neocortical inputs 'select' the ensemble participants in each specific SPW? Is the neocortex querying the hippocampus about the relationship between ensemble members as instantiated in the neocortical input? The possible scenario of such a mechanism is as follows: After each DOWN state, the neocortex self-organizes its global activity from locally generated patterns. The DOWN–UP transition, perhaps involving thalamocortical spindle, triggers organized firing patterns of cortical neurons, which, in turn, can lead to activation of specific subpopulations of hippocampal neurons. As a result of the neocortex-biased selection, the activated hippocampal neurons can generate SPW-related synchronous output. Because the SPW is a punctuate event, whereas the UP state and sleep spindle are temporally protracted, the hippocampal output can be directed to the still-active neocortical assemblies. We hypothesize that the temporal coordination of neocortical and hippocampal strong bursting patterns favors the conditions in which the hippocampal output may assist in modifying neocortical synaptic connectivity.

Figure 5 Spread of neocortical activity into the hippocampus during slow-wave sleep. Current-source density and superimposed local field potential traces of simultaneously recorded events in the neocortex (NC; top) and the hippocampus (bottom). A delta wave, seen as the red source in layer 5 (LV; black arrow), is followed by a sleep spindle (black star). DOWN–UP state transition is indicated by the orange dashed line. In the hippocampus, the entorhinal cortex-mediated DOWN–UP transition is reflected by a phase reversal of the local field potential and a sink (blue) in the molecular layer (white arrow). The horizontal arrow denotes the neocortico-dentate time lag (~100 ms); gray star denotes sharp wave in CA1 stratum radiatum; o, stratum oriens; p, pyramidal layer; r, radiatum; l.m., lacunosum-moleculare; m.l., molecular layer; DG, dentate gyrus. (2006) Integration and segregation of activity in entorhinal-hippocampal subregions by neocortical slow oscillations. *Neuron* 52: 871–882, with permission from Elsevier.

Conclusions

The collective behavior of neurons (e.g., theta and gamma oscillations, SPWs and related 200 Hz ripples, and sleep spindles) offers a link between complex cognitive functions and behaviors governed by the brain and the biophysical, synaptic properties of individual neurons. Many of these collective behaviors can be observed in both the awake and sleeping brain. Understanding the differences between these collective patterns in the awake and sleeping brain should provide further insight into function. The current assumption about this function is that experience-initiated changes of synaptic connectivity are consolidated during sleep by way of transient, reciprocal, and strongly synchronous interactions between the neocortex and hippocampus.

Sleep and Sleep States: Histamine Role

H L Haas, O Selbach, and O A Sergeeva, Heinrich-Heine-Universität, Düsseldorf, Germany

© 2009 Elsevier Ltd. All rights reserved.

Overview

Histamine is a signaling molecule in the immune system, the skin, the stomach, and the brain of vertebrates. Histaminergic neurons are located exclusively in the posterior hypothalamus and extend their axons throughout the central nervous system (CNS) (Figure 1). They are active during the awake state but not during sleep. Three of the four known histamine receptors are widely expressed in the brain. Close mutual interactions between histaminergic and other aminergic (acetylcholine, norepinephrine, dopamine, serotonin) and peptidergic (orexins/hypocretins) systems form a network with basic homeostatic functions that are closely connected with the sleep–wake regulation. Because the fluorescence histochemistry techniques that have delivered complete pictures of the other aminergic systems for decades fail to make the histaminergic system visible, histamine has been a relatively neglected transmitter. Only after the discovery of antibodies against histamine and histidine decarboxylase did the existence of histamine gain general acceptance. Histaminergic neurons are now recognized as the major regulator of the waking center of the brain.

Histamine Metabolism

Histidine is taken up by histaminergic neurons through the L-amino acid transporter and is decarboxylated via the specific histidine decarboxylase to form histamine. This synthesis can be inhibited by α-fluoromethylhistidine (α-FMH) – a useful tool to study the histaminergic system functions. Histamine is carried by the vesicular monoamine transporter VMAT-2 into vesicles, from which it can be released upon arrival of action potentials. Inactivation in the extracellular space is achieved by methylation via histamine methyltransferase. Tele-methylhistamine undergoes oxidative deamination to tele-methylimidazoleacetic acid. Diamine oxidase leads directly to the production of imidazoleacetic acid, mainly in invertebrates; this effective γ-aminobutyric acid ($GABA_A$) receptor agonist does not seem to occur to a significant degree in mammalian tissues. The level of histamine in brain tissue is somewhat lower than that of other biogenic amines but its turnover is considerably faster (on the order of minutes) and varies with functional state. The synthesis of histamine is controlled by feedback through H3 autoreceptors.

Morphology and Location of Histaminergic Neurons

The histaminergic neurons, consisting of five subgroups, are located in the tuberomamillary nucleus. Many of the neurons lie close to the outer and inner (third ventricle) surfaces of the posterior hypothalamus. They are relatively large cells, with typically two or three thick major dendrites and an axon emanating from each cell at considerable distance from the soma. The dendrites contain vesicles with histamine, which is released to act as a feedback signal, reducing the firing of action potentials and the synthesis of histamine at the soma level. Histamine synthesis in and release from histaminergic endings, varicosit0ies on the multifold branching axons, is also reduced. These varicosities have been seen to form synaptic contacts with postsynaptic membranes, but a vast majority of the endings are located at some distance from the target membranes.

Several species have variable numbers of brain mast cells which contain and release histamine and can contribute substantially to the histamine content. A massive invasion of mast cells into the brain has been reported in doves during courting.

Physiology of Histaminergic Neurons

The histaminergic neurons display a rather regular firing pattern below 4 Hz and their membrane potential dwells at about −50 mV during waking (Figure 2). Their action potential displays a clear Ca^{2+} component, and two major opposing currents give the responses to current injection a very typical appearance, with a strong hyperpolarization-dependent inward rectification and marked outward rectification upon return to the membrane potential from more negative voltages. These conductances carry currents of the I_h- and the A-type, respectively. Ca^{2+}-dependent prepotentials in the dendrites and a tetrodotoxin-sensitive, noninactivating Na^+ current, together with a postspike K^+ current, create a pacemaker cycle. The actual firing rate is variable during waking and is dependent on behavioral state. A minimal polarization suffices to stop the firing as it occurs during sleep. This inhibition is attributed to the (GABA)ergic input mainly from the ventrolateral preoptic (VLPO) area, a known sleep active nucleus.

Local injections of GABA agonists in the tuberomamillary nucleus (TMN) cause sedation while GABA antagonists have the opposite effect.

The histaminergic neurons contain further transmitters with unknown specific functions. GABA and glutamic acid decarboxylase (GAD) are expressed in most TMN neurons, but so far no evidence for GABA release from the somata or the axon varicosities has been presented. Should GABA be released from a substantial fraction of such a projecting system the physiological impact would be expected to be significant and possibly opposite to the normal histamine release. Similarly, the inhibitory neuropeptide galanin is found in the TMN neurons and in the GABAergic afferents to them. Furthermore, enkephalins, thyrotropin-releasing hormone, and substance P are present in populations of the TMN neurons. The histamine neurons display a high level of expression of adenosine deaminase, which may be involved in a number of basic cellular functions.

Inputs to Histaminergic Neurons

Amino Acids

Sources for the inputs to histaminergic neurons are widespread: for example, glutamatergic fibers from the cortex and the hypothalamus are a source of glutamate, which excites histaminergic neurons, and the fibers carry both α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) receptors. Glycine inhibits a subpopulation of histaminergic neurons, but the role of glycinergic fibers is uncertain. Taurine, an osmolyte that can reach relevant concentrations in the extracellular space, gates strychnine-sensitive glycine receptors and $GABA_A$ receptors.

GABAergic inputs come from several mostly hypothalamic locations; functionally most prominent with respect to sleep–waking regulation is the innervation from the VLPO area, which fires high during sleep and thus suppresses the firing of histamine neurons. $GABA_A$ receptors are quite heterogeneous among histamine neurons; three groups with different GABA sensitivity have been identified, depending on the expression of the γ subunit of the ionotropic GABA receptor. The sedative component of general anesthetic effects (e.g., propofol) is attributed to an action on the TMN, with a key to this action being the low expression of the $GABA_A$ receptor ε subunit. Cessation of histaminergic neuron firing is associated with the loss of consciousness. The GABAergic inputs to the TMN are under feedback control of $GABA_B$ receptors.

Amines

All aminergic nuclei give rise to projections and they are all functionally excitatory, but use a variety of mechanisms. A nicotinic fast-desensitizing action occurs through α7-type receptors, but muscarinic actions have not been detected. Noradrenaline does not affect histaminergic neurons directly but

Figure 2 Properties of histaminergic neurons. (a) Spontaneous firing of a tuberomamillary neuron recorded *in vitro* at a membrane potential of −50 mV. Under superfusion with a histamine H3-receptor inverse agonist (thioperamide) the firing is markedly enhanced, indicating a tonic inhibition of the neuron through its autoreceptors. (b) Camera lucida drawing and recordings from a TM neuron. (Top) Response to negative current injection: a hyperpolarization-activated inward rectification (due to the current Ih, HCN1, and HCN3) and an outward rectification that delays the return to the membrane potential (due to A-type currents). (c) Voltage clamp recording (switch clamp) showing an inward Ca^{2+} current that is markedly reduced by a histamine H3-receptor agonist (R-alpha-methylhistamine). effectively controls GABAergic input through $\alpha 2$ receptors, mediating an inhibition of inhibitory postsynaptic currents (IPSCs). Dopamine excites histamine neurons through a yet undefined indirect action, whereas serotonin excites the histaminergic neurons through activation of Na^+–Ca^{2+} exchange (NCX). This electrogenic transporter has to let three Na^+ ions enter the cell to expel one Ca^{2+} ion; resulting in a depolarization and excitation in the absence of any conductance change.

Peptides

Galanin is expressed in histaminergic neurons and in the GABAergic inputs to them and it inhibits their firing. It is thus possible that galanin participates in both the autogenic (feedback) inhibition and in the extrinsic inhibition from the VLPO area. Neurons containing orexins (also called hypocretins) are neighbors of the histamine neurons; the nuclei intermingle partially. Both types of orexins (hypocretin-1 and -2) excite histamine neurons through the Hcrt2 receptor and largely via activation of NCX. This action is secondary to a rise in intracellular Ca^{2+} that probably depends on both extra- and intracellular sources of the Ca^{2+}. Hypocretin neurons also express dynorphin, which can contribute to the excitation of histaminergic neurons, as it suppresses GABAergic input. Leptin, the hormone from fat that controls food intake, has no obvious effect, but the appetite-stimulating ghrelin inhibits a potassium channel (Kir3). Nociceptin strongly inhibits TMN neurons at the postsynaptic level while morphine (μ receptors) excites them, probably through disinhibition.

Purines

The tuberomamillary nucleus displays a very strong expression of adenosine deaminase, which has led to the suggestion that it may also use adenosine as a

transmitter. So far such a role of adenosine is elusive, and there is no evidence for synaptic release of this nucleoside but it is sedative through A1 receptors. A2A adenosine receptors have also been implicated in sleep regulation, through enhancement of the inhibition of histamine neurons. Adenosine accumulates during wakefulness and is likely an endogenous sleep pressure substance. Interestingly, adenosine, which strongly inhibits many neurons in the brain, has no such effect on histamine neurons. In contrast, ATP excites histamine neurons through P_2Y_1 and P_2Y_4 receptors.

Histaminergic Pathways

Histaminergic fibers innervate virtually all parts of the CNS, from the spinal cord to the retina. A dense innervation is found in the hypothalamus, cortex, amygdala, and basal ganglia and more variably in the thalamus and hippocampus. The mutual innervation of aminergic systems forms a network that acts in concert to ensure vegetative, endocrine, metabolic, osmotic, and energetic homeostasis.

The waking action of histamine is attributed to projections to thalamus and cortex, as well as to other aminergic nuclei and their emanating axons. Relay cells in the thalamus are depolarized and thus are shifted to the regular firing mode, which represents an 'open door' for perception. In the absence of histaminergic tone these cells return to the burst firing mode, which closes the door to the cortex for sensory input. Most targets are depolarized and excited through a number of different mechanisms; it is only in the hippocampus that pyramidal cells are hyperpolarized and inhibited through intracellular Ca^{2+} increase, which activates a K^+ conductance. On the other hand, histamine can block Ca^{2+}-dependent K^+ conductance, and thus accommodate firing through another receptor (H2). Some hippocampal interneurons are rather strongly excited by H2 receptor activation, making the overall histamine action in this structure an inhibitory one.

Histamine Receptors

Histamine can activate Cl^- conductances in thalamus and hypothalamus: in the supraoptic nucleus this effect is blocked by picrotoxin and H2 receptor antagonists. In thalamic interneurons Cl^- conductance blocking is also H2 receptor mediated but is not picrotoxin sensitive. Histaminergic ionotropic receptors may play only a minor role, if any, in the vertebrate brain. In contrast, arthropod sensory neurons, the insect eye photoreceptor, and lobster olfactory neurons display synaptic transmission through histamine-gated Cl^- channels. Four metabotropic histamine receptors have been cloned; H1, H2, and H3 occur in the brain and H_4 receptors are mainly expressed in peripheral tissues such as blood, spleen, lung, and liver.

H1 Receptors

Histamine H1 receptors occur throughout the central nervous system, with a particularly high density in regions involved in arousal and waking, such as the thalamus and cortex and the cholinergic, noradrenergic, dopaminergic, and serotonergic nuclei (Figure 3). H1 receptor activation causes excitation in most brain regions (brain stem, thalamus, hypothalamus, cortex, amygdala, striatum) through G_{q11} protein and direct block of leak K^+ conductance or phospholipase C, inositol trisphosphate (IP_3), and diacylglycerol (DAG) mediation. IP_3 releases Ca^{2+} from internal stores and activates a number of Ca^{2+}-dependent processes, including the opening of a cation channel of the transient receptor potential canonical (TRPC) type or the stimulation of a Na^+–Ca^{2+}-exchanger. Furthermore, the elevated intracellular Ca^{2+} can stimulate NO synthase and consequently guanylate cyclase. On the other hand, Ca^{2+}-dependent K^+ channels can be opened, leading to hyperpolarization and inhibition, for instance, in hippocampal pyramidal neurons (Figures 4).

H1 receptor antagonists are classic antihistaminics and are widely prescribed for allergies. Their well-known sedative actions have prompted early suggestions for an involvement of endogenous

histamine in sleep–waking regulation. There is strong evidence for H1 receptors being the main mediators of histamine waking action. In H1 receptor knockout (KO) mice, however, the sleep–waking pattern is hardly changed, but the waking response to H3 receptor antagonists, which relieve the autoinhibition of histamine release, is abolished. Most antipsychotic and antidepressive pharmaceuticals occupy H1 receptors, but this is not part of the therapeutic effect. Genetic and molecular studies have recently attributed an important role in peripheral and central immunity to histamine receptors. The H1 receptor is identical to an autoimmune locus receptor (*Bordetella pertussis*-induced histamine sensitization; Bphs), with relevance to inflammatory brain diseases (e.g., multiple sclerosis). Through an action on astrocytes, histamine regulates the permeability of the blood–brain barrier and the immigration of immune cells in the otherwise privileged CNS. Histidine decarboxylase (HDC) KO mice, compared to wild type, produce more proinflammatory signals and display a particularly marked experimental autoimmune encephalitis.

H2 Receptors

Histamine from enterochromaffin-like cells in the stomach stimulates acid secretion by parietal cells, an action that is insensitive to the classic antihistamines (H1). Development of H2 receptor antagonists by Jim Black revolutionized the therapy of stomach ulcers. H2 receptors are also widespread in the brain, in particular in the basal ganglia, the hippocampus, and the amygdala. Activation of histamine (H2) as well as some β-adreno-, dopamine, serotonin, corticotropin-releasing hormone (CRH), and vasoactive intestinal peptide (VIP) receptors has similar actions on neuronal excitability: blockage of a Ca^{2+}-activated K^+ conductance (small K), which is responsible for the accommodation of

firing and a long-lasting (seconds) afterhyperpolarization following action potentials (Figure 5). The accommodation of firing determines the number of action potentials in response to a longer (~100 ms) depolarizing stimulus – that is, the number of action potentials in a burst, and the amount of Ca^{2+} inflow through high-voltage activated Ca^{2+} channels (HVACCs) or NMDA channels. This sets up a neuron state of readiness to respond. These actions are mediated by cyclic AMP and protein kinase A (PKA) and lead to phosphorylation of the transcription factor cAMP response element-binding protein (CREB; Figure 4). Cyclic AMP can also interact directly with another current, the hyperpolarization-activated cation current (I_h), by shifting its activation curve to more positive levels, leading to depolarization in thalamic and hippocampal neurons. Brief exposure of hippocampal slices to histamine, noradrenaline, or cyclic AMP causes long-term enhancements of CA1 population spikes and pyramidal neuron firing in the absence of high-frequency stimulation. Adenosine A1 receptors are negatively coupled to adenylyl cyclase and have effects opposite to those of histamine H2 receptor activation (i.e., increasing the long-lasting afterhyperpolarization and accommodation of firing). Adenosine has a sedative action (in contrast to the waking action of histamine) and is a major factor in sleep induction.

H3 Receptors

The histamine autoreceptor was termed H3 by the Paris group of J-C Schwartz, who first described it in 1983. H3 receptors are present on TMN somata, dendrites, and axons (Figure 3). They are coupled directly through a $G_{i/o}$ protein to Ca^{2+} channels, causing inhibition of TMN firing, histamine release from varicosities, and histamine synthesis. Adenylyl cyclase is depressed by H3 receptor activation. Importantly H3 receptors are found on many nonhistaminergic varicosities, such as those containing glutamate, acetylcholine (ACh), dopamine, noradrenaline, serotonin, GABA, and various peptides. Excitatory transmission in the glutamatergic perforant pathway from the entorhinal cortex to the dentate area is depressed by about 30% by histamine in rats, but not in mice. The glutamatergic corticostriatal pathway and the dopaminergic nigrostriatal pathway are also suppressed. In the substantia nigra, GABAergic potentials are reduced.

In contrast to the H1 and H2 receptor genes the H3 receptor gene features two or three introns. Alternative splicing yields a large number of H3 receptor isoforms with differential distribution and constitutive activity. The H3 receptors are thus highly promising targets for the development of selective

Figure 5 Electrophysiology of histamine actions. (a) H1-receptor: a depolarization of a pontine reticular formation neuron through block of a potassium conductance. (b) H2-receptor: block of the long-lasting afterhyperpolarization after Ca^{2+} inflow (Ca^{2+}-dependent potassium conductance, sK-channel) and block of the accommodation of action potential firing in a human hippocampal pyramidal cell *in vitro*. (c) H3-receptor: decrease of field excitatory postsynaptic potential (EPSP) in the dentate gyrus of the hippocampus evoked by perforant path stimulation. Histamine reduced release of the excitatory transmitter glutamate in these two pathways. Reproduced with permission from *Nature Reviews Neuroscience* 4: 121–130, Haas HL and Panula P, The role of histamine and the tuberomamillary nucleus in the nervous system, copyright 2003, Macmillan Magazines Ltd.

pharmaceuticals to treat neuropsychiatric disorders affecting sleep–waking regulation, feeding, mood, learning, and memory, as well as epilepsy, migraine, and inflammatory disorders. H3 receptor antagonists have, indeed, facilitatory actions on learning and memory, presumably in part by removal of a tonic inhibition of the release of other transmitters, such as glutamate and acetylcholine. In the light of the many possible actions on H3 heteroreceptors, the systemic effects of interference are difficult to predict.

Histamine and Synaptic Plasticity

Histamine (and hence the activity of the histaminergic neurons) can cause long-lasting changes in synaptic transmission in several structures by itself, and it can prime or modulate other forms of synaptic plasticity such as long-term potentiation (LTP) and long-term depression (LTD) (Figure 6). These phenomena represent coincidence detection and are associated with learning and memory. An important signal transduction pathway is the transient rise of intracellular Ca^{2+} and its binding to a Ca^{2+}/calmodulin kinase (CaMK).

Interference of the polyamine spermidine with early attempts to stain histamine neurons came to mind when direct interaction of the diamine histamine with the NMDA receptor on hippocampal pyramidal cells was first detected: this effect is similar to the potentiation by spermidine of the NMDA receptor (NR2B subunit) and opposite to the inhibitory action of protons. It is facilitated in slightly acidic conditions, such as occur in the CA3 region during synchronous discharges, with 'sharp waves' that evoke specifically distributed LTP in CA1 and that are likely a decisive element in memory trace formation. Histamine strongly promotes burst firing in the CA3 area, frequently leading to 200 Hz oscillations (ripples) during quiet waking or sleep. The replay of ripples during sleep has been proposed as critical for memory consolidation.

H1 receptor activation increases intracellular Ca^{2+} and potentiates the H2 effects that are proved proplasticity signals. H2 receptor activation stimulates adenylyl cyclase and controls a Ca^{2+}-dependent potassium current through CaM kinase II and the extent of firing in response to an excitatory stimulus. These mechanisms are deeply involved with triggering long-term potentiation and the cellular basis of learning and memory. Brief exposure of hippocampal slices to histamine causes LTP in the absence of any electrical stimulation. Adenosine A1 receptors are negatively coupled to adenylyl cyclase and have effects opposite to those of histamine on LTP. The histamine H3 receptor is an auto- and heteroreceptor with inhibitory action. The glutamatergic corticostriatal pathway undergoes long-term depression after H3 receptor stimulation.

Memory trace formation occurs in the hippocampus where a selected population of CA3 pyramidal cells produces a synchronous burst that is relayed to the CA1 area and acts as the natural trigger for long-term potentiation. Whether, and at which intensity, this burst is fired depends on the subcortical control by largely aminergic systems. Histamine interacts at all levels of this process.

Figure 6 Histamine and synaptic plasticity. (a) Histamine (H2-receptor activation) induces LTP of population spike in CA1 (Schaffer-collateral stimulation) in hippocampal slice. Inserted are population spikes at the times where they are shown and a slice. EC, entorhinal cortex; CA, cornu ammonis; DG, dentate gyrus. (b) Whole cell recording from hippocampal pyramidal cell. Neuron exposed to NMDA for 1 s displays inward current, which is larger in the presence of histamine. Histamine and Behavior

Histaminergic systems are phylogenetically old and are concerned with basic body functions of organisms in both the invertebrate and the vertebrate world. They are found in vertebrates in the hypothalamus, where feeding, drinking, osmoregulation, temperature control, energy administration, and the endocrinium are integrated with the sleep–waking and circadian rhythms. Histamine neurons fire exclusively during waking and particularly during attention. Excitation of the large cells in the supraoptic nucleus leads to antidiuresis. Injection of histamine into other hypothalamic sites induces drinking, and dehydration increases synthesis and release of histamine. Stimulation of oxytocin-containing cells and those releasing the prolactin-releasing hormone have far-reaching influences on mammalian reproduction. The suprachiasmatic nucleus, our circadian zeitgeber, receives strong histaminergic excitation. Locomotion is maintained by histaminergic activation and serves the basic function of feeding. $HDC^{-/-}$ mice display reduced exploratory activity, but normal habituation to novel environments, increased fear of heights, and superior motor coordination. H3 $receptor^{-/-}$ mice are lazy walkers, but H3 antagonists can cause hyperactivity. H1 $receptor^{-/-}$ mice display reduced ambulatory and exploratory activity and a reduced sensitivity to pain. Histamine activity on H2 receptors is an essential link in opioid receptor-mediated analgesia. In the periphery, histamine participates in the stimulation of nociceptors and itching, and the central histamine system is involved through both H1 and H2 receptors in pain perception.

Leptin-induced anorexia is mediated by the histaminergic system. Glucose-responsive neurons in the ventromedial nucleus are excited by histamine. In the anterior hypothalamus, H1 receptor activation lowers the set point of the hypothalamic thermostat; in the posterior hypothalamus, H2 receptors are involved with initiating heat loss mechanisms. The vegetative nervous system is under the control of the hypothalamus, with a significant contribution by histamine; this also includes cardiovascular control.

Control of Waking and Arousal

Sleep and awake states are closely correlated with essential body functions. Histaminergic neurons interact with the neighboring orexin/hypocretin-containing neurons to determine the right time for sleeping and waking. Loss-of-function of orexin/hypocretin neurons results in narcolepsy. Cataplexy, the major symptom of narcolepsy, is characterized by loss of muscle tone in the presence of consciousness. In contrast to other aminergic systems, histamine neurons are fully active during cataplexy. Thus histamine is mainly responsible for consciousness and noradrenaline is mainly responsible for muscle tone.

Destruction or inhibition of the tuberomamillary region causes somnolence, whereas activation evokes arousal. During the devastating influenza epidemic of 1918–1919, a significant number of patients suffered from sleep disturbances. Von Economo in Vienna investigated the brains of these patients and found posterior hypothalamic lesions in those who had suffered from hypersomnia (encephalitis lethargica) and anterior hypothalamic lesions in those who had suffered from insomnia. It is now clear that the first group must have lost their histamine neurons and probably the orexin/hypocretin neurons, whereas the insomnia patients displayed lesions in an area now known to be exceptionally active during slow-wave sleep (the VLPO area). The VLPO houses GABAergic neurons that project to wake-active aminergic neurons, specifically the histaminergic neurons, the firing of which is suppressed by the input. $GABA_A$ receptors display a large variability due to differential assembly of subunits in a receptor-channel complex. Depending on γ subunit expression, populations with different sensitivities to GABA have been identified – presumably reflecting an involvement in different aspects of the waking function.

The TMN is a major target of general anesthesia because it mediates the sedative component. $GABA_A$ receptor stimulation (local muscimol) is sedative whereas the local injection of a $GABA_A$ antagonist causes arousal. Systemic administration of general anesthetics that potentiate $GABA_A$ action increases activity of the sleep-active preoptic area and reduces activity of the TMN. Low-level expression of the $GABA_A$ receptor ε subunit in most TMN neurons (in contrast to the neighboring orexin/hypocretin neurons) may be key to the high sensitivity of the TMN to anesthetics.

Much of the more recent knowledge in this field comes from the rare, technically difficult recordings from identified histaminergic neurons over several hours in freely behaving animals, but results from experiments using local excitation, inhibition, or destruction all point in the same direction. In combination, measures of histamine release by microdialysis or c-fos activation and the selective, complete or reversible removal of the histamine system or its receptors have also given congruent evidence.

Hibernation, an adaptation to low external temperature and the lack of food, is a state of radically reduced physiological functions – brain activity, body temperature, heart rate, and metabolism – that highlights the link between feeding and sleeping. Interestingly, the turnover of histamine, the waking transmitter, is considerably enhanced during

hibernation. It seems to play a major role in regulating maintenance of and arousal from the hibernation state.

Learning and Memory

Correlation of synaptic plasticity with memory mechanisms is often claimed but the evidence is rarely convincing. The effects of histamine H1 and H2 receptor activation on principal cells in hippocampus, cortex, amygdala, or striatum are quite compatible with a positive influence on synaptic plasticity and memory. The excitatory action and the intracellular increase of Ca^{2+} ions (H1) are important mechanisms for maintaining wakefulness and attention and are a prerequisite for effective learning. Block of the accommodation of firing (H2) shifts target neurons toward a state of quiet readiness, characterized by little difference in membrane potential and spontaneous action potential firing, but a dramatically changed response to longer lasting (<100 ms) depolarizing signals. This is a response to compartmentalized Ca^{2+} signals. Classical conditioning (eye-blink reflex in rabbits) can reduce the amplitude and duration of the Ca^{2+}-dependent afterhyperpolarization in hippocampal pyramidal cells. These mechanisms are also of interest with respect to pathophysiological events leading to exaggerated activity and epilepsy. Contrary to expectation, histamine H1 antagonists (the classical antihistamines) are slightly epileptogenic. Two clues can be offered to explain this: (1) H1 receptor activation leads to hyperpolarization and inhibition of principal neuron firing in the (rodent) hippocampus through activation of Ca^{2+}-dependent K^+ channel opening; (2) interneurons in the hippocampus are strongly excited by H2 receptor activation. The same interneurons suffer a cutoff at high-frequency firing. Thus, the final action on a whole structure and its output cannot be predicted by studying principal cells alone and *in vitro*. H2 and H3 receptor blocking has revealed ambiguous results on learning paradigms. The histaminergic system can affect memory through at least two independent mechanisms, directly on the synaptic plasticity in hippocampus, striatum, and amygdala, and by an indirect inhibitory effect through the brain's reinforcement system. H1 receptor antagonists can act as reinforcers, alone or together with opiates, cocaine, or amphetamine.

H1 antagonists improve water maze performance but reduce radial maze performance. Locomotor activity and exploratory behavior are reduced, but learning and memory seem unaffected in H1 receptor knockout mice. H3 receptor$^{-/-}$ mice display enhanced spatial learning and reduced anxiety. Lesions of the histaminergic nucleus can lead to facilitation of learning, and pharmacological inactivation by posttrial injection of lidocaine leads to memory improvement. Such lesions or stimulations of the tuberomamillary nucleus are very difficult or impossible to perform without affecting neighboring structures or bypassing fibers.

Histidine decarboxylase KO mice cannot synthesize histamine. JS Lin has described an important defect in HDC$^{-/-}$ mice that is quite relevant for memory formation: their response to novelty is strongly impaired and they fall asleep rather than explore a new environment. JP Huston's group revealed a number of rather specific changes in HDC$^{-/-}$ mice: an improvement in negatively reinforced water maze performance but a defect in (nonreinforced) episodic object memory.

Histamine Pathophysiology

Hepatic encephalopathy (HE) develops as a result of high ammonia levels. Histidine and some other amino acids are significantly increased in the brains of HE patients. This leads to a higher synthesis of histamine, which does not cause alertness in these patients; instead, they suffer from sleepiness. Histamine turnover is not increased. Model rats with a portacaval anastomosis display defects in histamine-induced plasticity and are sleepy and uninterested in their environment; their histamine receptors may be desensitized or incorporated in the cells. In contrast to low levels of histamine, high levels inactivate NMDA receptors – in keeping with cognitive deficits.

Within the hypothalamus only the TMN neurons show tangles and degeneration in Alzheimer's disease and Down syndrome. In Parkinson's disease, histaminergic endings seem to take over the empty places left by degenerated dopaminergic axon varicosities. Histamine turnover is increased and H1 receptor binding is low in the frontal cortex of schizophrenic patients. H2 receptor antagonism can reduce negative symptoms in schizophrenia. Histamine receptor expression is altered in rats with ethanol preference. Finally, the histaminergic system has an antiepileptic influence; antihistamines (H1) can cause seizures and H3 receptor antagonists are anticonvulsive.

Conclusion

The brain histaminergic system is our major waking center and is deeply involved in many basic functions. It keeps the CNS alert and ready to react and is the gatekeeper of consciousness. H1 and H2 receptors mediate excitation and (long-term) potentiation of excitation, while the H3 autoreceptors provide a feedback control of synthesis, release, and electrical activity. As heteroreceptors, these receptors also control the varicosities of most other transmitter systems,

making them a prime target for pharmaceutical research and development.

Sleep and Sleep States: Hypothalamic Regulation

Introduction

The fact that the hypothalamus plays a central role in the regulation of sleep–wake behavior was first suggested in 1916 when the Viennese neurologist and psychiatrist, Baron Constantine von Economo, began to study patients with a viral encephalitis that profoundly affected sleep–wake regulation (i.e., encephalitis lethargica or von Economo's sleeping sickness). The preponderance of patients with von Economo's encephalitis lethargica slept excessively (some more than 20 h per day). Postmortem brain analysis revealed that these individuals had lesions at the junction of the midbrain and posterior hypothalamus, suggesting that this area of the brain contained wake-promoting circuitry. Interestingly, a small percentage of individuals afflicted with encephalitis lethargica became insomniacs, often sleeping only a few hours each day. These insomniacs had lesions involving not the midbrain–diencephalon junction but, rather, the basal forebrain (BF) and anterior hypothalamus, suggesting that these areas of the brain contained sleep-promoting circuitry. von Economo's observations in the lethargica victims were later recapitulated experimentally by Ranson (1939) through his demonstration of hypersomnolence in rhesus monkeys sustaining hypothalamic lesions and by Nauta (1946) in his findings of profound changes in sleep–wake behavior in rats following surgical ablation of preoptic and BF tissue. Remarkably, however, the key role of the hypothalamus in the regulation of sleep–wakefulness was obscured for almost a half century by the discovery of a brain stem 'ascending arousal system' in the late 1940s.

Electrocortical and Behavioral Arousal: The Ascending Reticular Activating System

During cortical arousal (i.e., the neurologically defined vigilance state of wakefulness), the cortical electroencephalogram (EEG) is desynchronized (i.e., high frequency/low amplitude), presumably reflecting differences in the timing of processing of cognitive, motor, and perceptual functions. The EEG directly reflects the collective synaptic potentials of inputs largely to pyramidal cells within the neocortex and hippocampus. In 1935, Bremer uncovered evidence of an ascending arousal system necessary for forebrain and cortical arousal when he demonstrated that transection of the brain stem at the pontomesencephalic level (but not the spinomedullary junction) produced coma in anesthetized cats. More than a decade later, Morruzi and Magoun provided additional support for the concept of an ascending arousal system when they demonstrated that electrical stimulation of the rostral pontine reticular formation produced a desynchronized EEG (an electrophysiological correlate of the conscious state) in anesthetized cats. It was subsequently shown that transections, electrolytic lesions, and infarcts of this same region (i.e., the putative ascending arousal system) produced coma, although it remained unclear whether this was a result of damage to fibers of passage or specific cell groups. Because these ascending arousal pathways traversed (or appeared to originate in) the midbrain reticular formation, the term 'ascending reticular activating system' (ARAS) was coined and the functional integrity of the ARAS was henceforth considered the *sine qua non* for cortical arousal and consciousness. What remained unresolved, however, was the neuroanatomical pathways and population of neurons by which the ARAS might control cortical activity. In the 1970s and 1980s, experiments revealed that, contrary to popular conception, the origin of the ARAS was not a functionally homogeneous mass of reticular tissue in the brain stem tegmentum but, rather, composed of discrete neuronal populations (and neurotransmitters) which can be parsed into two distinct anatomical branches. The first branch of the ARAS consists of cholinergic neurons originating in the pedunculopontine (PPT) and laterodorsal (LDT) tegmental nuclei of the mesopontine tegmentum. The PPT and LDT send excitatory cholinergic projections to the midline and intralaminar nuclei of the thalamus and play a critical gating role in thalamocortical transmission by preventing relay neurons from being hyperpolarized and entering into burst mode, thus clearing the way for thalamocortical sensory transmission.

Regarding thalamic oscillations during wake and sleep, thalamocortical neurons fire in one of two stereotypic modes. When their membrane potential is near threshold (as during wake), they respond to incoming stimuli by firing single spikes. However, when they are deeply hyperpolarized, a low-threshold calcium channel is de-inactivated. The resultant excitatory postsynaptic potentials now produce calcium spikes which are prolonged and produce a depolarized

plateau, from which the neuron fires a series or burst of action potentials (as during sleep). The increase in burst sequences inhibits thalamocortical sensory transmission, thus leading to deprivation of sensory signals from the environment. The state of these thalamocortical neurons is determined by inputs from the thalamic reticular nucleus, which surrounds the lateral surface of the thalamus. The reticular nucleus sends an inhibitory GABAergic projection to $GABA_B$ receptors on the thalamocortical neurons. These $GABA_B$ receptors are potassium channels that can deeply hyperpolarize the neuron sufficiently to de-inactivate the low-threshold calcium channels. Therefore, it is the state of the reticular nucleus that in turn determines the firing state of thalamocortical neurons.

Predictably then, neurons of the PPT and LDT fire most rapidly during wakefulness and rapid eye movement (REM) sleep, which is the stage of sleep associated with cortical activation, muscle atonia, and dreams. Historically, the thalamocortical system has been viewed as a critical component of the ARAS. In this view, the thalamus is thought to function as a major relay to the cortex for the ARAS, with the overall activity of the thalamocortical system forming the origin of the cortical EEG. Indeed, thalamic relay neurons fire in patterns that correlate with the cortical EEG. In turn, the overall activity in the thalamocortical system is thought to be regulated by the ARAS. Nevertheless, a critical role of the thalamocortical system in the ARAS has been challenged by studies demonstrating persistent cortical activation (i.e., desynchronized EEG) following thalamic lesions.

The second branch of the ARAS, which bypasses the thalamus and originates in the upper brain stem and caudal hypothalamus, consists of a series of wake-promoting monoaminergic cell groups that project to and activate neurons in the lateral hypothalamic area (LHA), BF, and cerebral cortex. The monoaminergic systems include the noradrenergic ventrolateral medulla and locus coeruleus, the dopaminergic neurons of the ventral periaqueductal gray matter, the serotoninergic dorsal and median raphe nuclei, and histaminergic neurons in the tuberomammillary nucleus. In general, neurons in all of these cell groups fire more during wakefulness than during non-rapid eye movement (NREM) sleep and show virtually no activity during REM sleep. Furthermore, of these monoaminergic cell groups, the dopaminergic neurons of the ventral periaqueductal gray appear to most potently influence arousal. More rostrally, the LHA, in addition to receiving input from these ascending monoaminergic systems, projects to the BF, cerebral cortex, and, in a reciprocal manner, components of the brain stem arousal systems. The LHA projection to the cortex is thought to augment the arousal system as lesions of the LHA produce profound sleepiness, stupor, or even coma in monkeys and rats. In fact, the LHA contains at least two distinct populations of neurons that are thought to contribute to the regulation of wakefulness. LHA neurons that contain orexin (also called hypocretin) are active during wakefulness and contribute to cortical arousal through ascending projections to the cortex and descending projections to neurons in the tuberomammillary nucleus, locus coeruleus, and dorsal raphe. Mice lacking orexin demonstrate narcolepsy-like symptoms, including profound behavioral state instability (e.g., frequent state transitions and cataplexy). putative glutamatergic LHA neurons that contain melanin-concentrating hormone have similar projections to the orexin neurons but are mostly active during REM sleep, during which time they are thought to inhibit the ascending monoaminergic systems. A third group of putative glutamatergic LHA neurons is also thought to be involved in arousal; however, this group remains unresolved.

Finally, the BF (including the nucleus basalis and magnocellular preoptic nucleus in the substantia innominata, and the medial septal nucleus and nucleus of the diagonal band of Broca) consists of cholinergic neurons intermixed with noncholinergic (largely GABAergic) neurons which project to the cortex, hippocampus, and, to a lesser extent, the thalamus and are implicated in waking and EEG desynchronization.

New Perspective on the ARAS

As previously described, the traditional model for the ARAS posits an origin in the upper brain stem monoaminergic and cholinergic cell groups and reticular formation, and it emphasizes the role of the thalamus as an obligate relay in cortical activation. However, cell-specific lesions using excitoxins (ibotenic acid and kainic acid) in these cell groups have caused relatively limited alteration of wakefulness in rats and cats. Hence, the origin of the arousing influence (i.e., the ARAS) has never been fully explained, and the source has been presumed to be the collective input from all of these structures so that lesions of any one of them will not cause loss of consciousness.

Experimental evidence has strongly suggested that the parabrachial nucleus (PB) and precoeruleus region (PC) of the dorsolateral pontine region, located caudal to the cholinergic PPT/LDT, are the likely neuroanatomical structures of origin for the ARAS, henceforth referred to as the 'ascending arousal system.' In general support of this concept are the findings that stimulation of the PB (in cats) produces marked electrophysiological activation of

the cortex and cell-specific lesions of the PB (in rats) produce profound coma with persistent sub-delta EEG. It has also been shown that the PB sends excitatory projections to the BF that, in turn, project to the cortex, presumably to maintain cortical arousal. In parallel with the PB–BF projection, the PC projects to the medial septum that, in turn, projects to the hippocampus and is presumably important in ascending control of hippocampal function. This hypothesis is supported by the observation that lesions of the PC selectively eliminate hippocampal theta activity during REM sleep. Thus, in this more contemporary view, the PB/PC, like the cholinergic PPT/LDT, is active during all states of cortical activation, including both wakefulness and REM sleep. In the presence of concomitant activation of the monoaminergic arousal systems, the cortical response to PB/PC–BF activation would be wakefulness; in the absence of monoaminergic stimulation, a state of REM sleep would prevail. This ascending arousal model differs fundamentally from the prevailing one in which the wake–sleep state is determined by the level of activation only of the monoaminergic and cholinergic arousal systems. In this alternate view, monoaminergic and cholinergic systems may modulate the activity of the PB/PC and can determine (via their cortical and thalamic projections) whether the PB/PC induces wakefulness versus REM sleep, but they cannot sustain a waking (or REM) state without the PB/PC. In essence, it appears that the loss of wakefulness caused by electrolytic or mechanical lesions in the midbrain reticular formation may be due mainly to disruption of the ascending projections to the BF (but not thalamus) from the PB/PC. Although many other cell groups, including the monoaminergic and cholinergic components of the arousal system, may play specific roles in modulating arousal, particularly under specific physiological circumstances, no other area has this property of being absolutely necessary to maintain a waking state.

As indicated previously, the functional integrity of the thalamus has been widely considered to be necessary for cortical arousal and the maintenance of consciousness. A well-entrenched role for the thalamus in the ARAS is further indicated by the explicit representation in contemporary neuroscience textbooks of the thalamocortical system as an obligate system/relay for maintaining cortical awareness (i.e., consciousness). It is indeed likely that the thalamus, which transmits a wide range of sensory inputs to the cerebral cortex, is necessary for its normal cognitive function. However, experiments dating back to Ranson's 1939 work have repeatedly shown that rodents, nonhuman primates, and humans lacking a thalamic relay and/or thalamocortical system demonstrate relatively normal sleep–wake EEG patterns and cortical arousal. Work has provided additional data supporting a limited role for the thalamic relay as well as the (reticulo thalamocortical pathway (originating in the LDT/PPT) in the overall level of arousal or cortical EEG activation during wakefulness. Again, however, these data do not deny the thalamus a potentially critical role in defining the content of cortical function during wakefulness.

The reported evidence that the integrity of the thalamus is not necessary to maintain an aroused cortical state strongly indicates that activating influences from the brain stem may reach the neocortex via an extrathalamic route. Experimental data have indicated a critical role for the BF in cortical arousal, suggesting the BF might function as the primary structural relay in the ARAS. Indeed, lesions of the BF produce coma (i.e., persistent sub-delta <1 Hz EEG intrinsically generated by cortical neurons) in experimental animals. Work has demonstrated that BF cholinergic and noncholinergic (likely GABAergic) neurons jointly control cortical arousal because loss of either the cholinergic or the noncholinergic neuronal populations (i.e., each lesion sparing one population) has minimal effects on cortical arousal, but combined lesions produce coma.

In summary, work has suggested that (1) the reticulothalamocortical pathway may play a very limited role in the regulation of the overall level of behavioral arousal or EEG activation during wakefulness, (2) the PB/PC–BF-cortical axis is a critical system for maintaining cortical arousal, and (3) cholinergic and noncholinergic (possibly GABAergic) BF neurons jointly contribute to cortical arousal.

Sleep – Turning the Ascending Arousal System Off

As outlined previously, projections from cholinergic neurons, monoaminergic cell groups, and orexin neurons act in a coordinated manner to produce arousal. But what turns off this arousal system to produce sleep? As indicated previously, von Economo proposed a putative sleep-promoting area in the BF/anterior hypothalamic area based on postmortem brain analysis of his insomniac patients. In the 1990s, von Economo's prediction was borne out experimentally by a series of studies which demonstrated a critical role for the ventrolateral preoptic nucleus (VLPO) in inhibiting these arousal circuits during sleep. Neurons of the VLPO are sleep active, contain the inhibitory neurotransmitters galanin and GABA, and receive afferents from each of the major monoaminergic systems. Consistent with a sleep-promoting function,

cell-specific lesion of the VLPO produces profound insomnia and sleep fragmentation. The VLPO contains two populations of neurons. The first is a cluster of neurons in the 'core' of the VLPO that projects most heavily to the tuberomammillary nucleus. A more diffusely distributed second population of VLPO neurons (i.e., the extended VLPO) project mainly to the locus coeruleus and the dorsal and median raphe nuclei and are thought to be important in gating REM sleep. The interaction between the VLPO and components of the arousal systems (e.g., tuberomammillary nucleus, dorsal raphe, and locus coeruleus) has been demonstrated to be mutually inhibitory and, as such, these pathways function analogously to an electronic 'flip-flop' switch/circuit (Figure 1). By virtue of the self-reinforcing nature of these switches (i.e., when each side is firing it reduces its own inhibitory feedback), the flip-flop switch is inherently stable in either end state but avoids intermediate states. The flip-flop design thus ensures stability of behavioral states and facilitates rapid switching between behavioral states. Within the framework of the flip-flop model, the VLPO represents the 'sleep side,' whereas the monoaminergic system represents the 'arousal side.' Importantly, it has not been determined if a mutually inhibitory relationship exists between the VLPO and the PB/PC (putative origin of the arousal system).

Flip-Flop Switch Stability and the Lateral Hypothalamic Area

Flip-flop switches also possess the, at times, undesirable property of abruptly undergoing unwanted state transitions. The frequency of unwanted state transitions may increase if one side of the switch is 'weakened' as the weakened side becomes less able to inhibit the other side, thereby biasing the switch more toward a midpoint where smaller perturbations may trigger a state transition. For example, it has been suggested that cell loss in the VLPO during aging may weaken the switch, ultimately manifesting in sleep fragmentation and daytime napping, both of which are frequent complaints in the elderly. This phenomenon is seen in rats with VLPO lesions, which demonstrate a significant decrease in total sleep time that is largely attributable to shortened sleep bouts. That is, rats with VLPO lesions can initiate but not maintain sleep because the switch is no longer balanced but, rather, biased toward the arousal side.

Figure 1 (a) The ascending arousal system consists of noradrenergic neurons of the ventrolateral medulla and locus coeruleus (LC), cholinergic neurons in the pedunculopontine (PPT) and laterodorsal tegmental (LDT) nuclei, serotoninergic neurons in the dorsal raphe nucleus, dopaminergic neurons of the ventral periaqueductal gray matter (vPAG), and histaminergic neurons of the tuberomammillary nucleus (TMN). These systems produce cortical arousal via two pathways: a dorsal route through the thalamus and a ventral route through the hypothalamus and basal forebrain (BF). The latter pathway receives contributions from the orexin and melanin-concentrating hormone (MCH) neurons of the lateral hypothalamic area (LHA) as well as from GABAergic or ACh neurons of the BF. (b) A schematic of the projections of the ventrolateral preoptic nucleus (VLPO; open circle) to the main components of the ascending arousal system. The VLPO neurons are primarily active during sleep and contain the inhibitory transmitters GABA and galanin.

Unwanted state transitions are a hallmark of narcolepsy. Patients with narcolepsy do not sleep more than normal people but experience profound fragmentation of sleep–wake behavior in the form of 'sleep attacks' during the day and frequent awakening during the night. In the late 1990s, two groups of investigators discovered that a lack of lateral hypothalamus (LH) orexin or their type 2 receptors can cause narcolepsy in experimental animals. It was subsequently demonstrated that humans with narcolepsy have few LH orexin neurons and low orexin levels in the cerebrospinal fluid. As indicated previously, orexin neurons are wake-active, and through their ascending projections to the cortex and descending projections to the monoaminergic and cholinergic system of the arousal system, they are thought to augment the ARAS in maintaining cortical arousal. These orexin neurons also project to the VLPO, although, curiously, the VLPO does not contain orexin receptors. This suggests that LH orexin neurons actively reinforce arousal tone as opposed to having a direct, mutually inhibitory relationship with the VLPO. Taken together, it has been hypothesized that LH orexin neurons and other, possibly glutamatergic neurons, are actually 'external' to the flip-flop switch but play an important stabilizing role for the switch. That is, the position of the orexin neurons outside the flip-flop switch permits them to stabilize behavioral state, thus reducing transitions during both sleep and wakefulness, whereas narcoleptic humans or animals lacking orexin have increased transitions in both states.

Homeostatic Regulation of Sleep

Although a teleological explanation for the function of sleep remains unresolved, it is clear that sleep has a restorative effect on the brain. This is perhaps best exemplified by the phenomenon of diminished cognitive and physical performance following sleep deprivation. Although the nature of 'sleep drive' is unknown, it has been conceptualized as a homeostatic pressure that builds during the waking period and is dissipated by sleep. This homeostatic process or 'sleep homeostat' thus represents the need for sleep (i.e., 'sleep propensity'). The cellular determinant of homeostatic sleep drive is unknown, although a putative endogenous somnogen, adenosine (AD), is thought to play a critical role. AD is a naturally occurring purine nucleoside that is hypothesized to accumulate during wake and, upon reaching sufficient concentrations, inhibits neural activity in wake-promoting circuitry of the BF and likely activates sleep-promoting VLPO neurons located adjacent to the BF. Consistent with this hypothesis are the observations that intracerebroventricular injections of AD promote sleep, extracellular concentrations of AD increase with prolonged waking and decline with sleep, administration of AD agonist near the VLPO increases sleep and induces Fos in VLPO neurons, and nonspecific AD antagonists (e.g., caffeine) potently increase waking and decrease sleep. However, data have demonstrated that accumulation of AD in the BF is not necessary for sleep drive, leaving the cellular basis of the sleep homeostat elusive.

Circadian Regulation of Sleep

Although a critical role of the circadian timing system (CTS) in providing temporal organization for behavioral states, including sleep–wakefulness, is well established, the role of the CTS in determining the duration, intensity, and propensity of sleep (and component sleep) is less clear. Nevertheless, regulation of sleep–wakefulness by the CTS is evident because the sleep–wake cycle continues on an approximately 24 h basis even when environmental conditions are constant (i.e., in the absence of environmental time cues). In addition, a clear circadian variation in sleep propensity and sleep structure has been demonstrated in humans by uncoupling the rest–activity cycle from the output of the circadian pacemaker (i.e., 'forced desynchrony protocol'). Circadian modulation of the cortical EEG during NREM sleep and REM sleep (i.e., independent of prior wake time) has also been demonstrated in humans. It has been hypothesized that this modulation of the cortical EEG, particularly REM sleep propensity, may occur through indirect projections from the suprachiasmatic nucleus (SCN) to the mesopontine tegmental nuclei involved in REM sleep generation. Rather strikingly, however, despite a demonstrated role for the circadian pacemaker in governing the timing of sleep, the SCN has only minimal monosynaptic outputs to sleep-regulatory centers, such as the VLPO and LHA orexin neurons, and none to brain stem arousal sites (**Figure 2**).

In 1982, Borbely proposed a two-process model of sleep regulation in which a homeostatic process (i.e., sleep drive) builds during the day and declines exponentially during sleep and interacts with a circadian process that is independent of sleep and waking. A further elaboration of Borbely's model for sleep–wake regulation, the 'opponent process' model, was proposed in 1993. Although conceptually similar to Borbely's two-process model, the opponent process model was the first to identify a role for the SCN in actively facilitating the initiation and maintenance of wakefulness and opposing homeostatic sleep tendency during the subjective day. Specifically, the

model predicted a wake-, but not sleep-, promoting role for the SCN in sleep–wake regulation – that is, an 'alerting' signal produced by the SCN that enhanced wakefulness and actively opposed the sleep homeostat. Human sleep studies, however, have yielded data largely consistent with both a wake- and a sleep-promoting role for the SCN in sleep–wake regulation. Dijk and Czeisler provided data supporting the concept that the primary role of the SCN in sleep–wake regulation is the generation of an alerting signal necessary for generating a consolidated bout of wakefulness. This circadian drive for wakefulness (i.e., the alerting signal) becomes gradually stronger during the waking period so as to oppose increasing homeostatic sleep drive. Similarly, consolidated sleep is achieved by having maximal circadian drive for sleep near the end of the sleep cycle when homeostatic sleep drive is minimal. The concept of a circadian 'hypnotic' signal subserving the circadian drive for sleep has also been proposed; however, no endogenous correlate of a hypnotic signal has been uncovered.

Hypothalamic Circadian Integrator for Sleep–Wake Regulation

As indicated previously, despite the widespread role of the SCN in shaping daily rhythms of behavior, physiology, and gene expression, SCN efferent projections to sleep systems (e.g., LHA orexin neurons and VLPO) are surprisingly limited (Figure 2). The densest projection from the SCN terminates dorsally and caudally in the adjacent subparaventricular zone (SPZ). Similar to the effects of SCN ablation, lesions that include the ventral SPZ abolish behavioral circadian rhythms, including rest–activity, sleep–wake cycles, and feeding. Surprisingly, lesions of the dorsal SPZ eliminate the circadian rhythms of body temperature but have little effect on the rhythms of locomotor activity or sleep. Thus, taken together, these observations suggest that neurons of the SPZ function as an obligate relay to maintain circadian rhythms of sleep and body temperature. Like the SCN, however, the SPZ has limited projections to the major components of the sleep–wake regulatory system. The SCN and ventral SPZ do however project densely to the dorsomedial hypothalamic nucleus (DMH). Lesions of the DMH also abolish circadian rhythms of locomotor activity, wake–sleep, feeding, and corticosteroid secretion, but not the rhythm of body temperature, which retains a normal circadian variation. These findings suggest that the principal neuronal output pathway that determines the timing of circadian behavior is mediated by a primary projection from the SCN to the SPZ, followed by a secondary projection to the DMH. Interestingly, the DMH sends

Figure 2 Hypothalamic integrator model for sleep–wake regulation. The suprachiasmatic nuclei (SCN) have relatively modest projections to sleep-regulatory networks, including the VLPO and orexin neurons. However, the bulk of its output goes to the ventral (vSPZ) and dorsal (dSPZ) subparaventricular zone and the dorsomedial hypothalamus (DMH). Lesions of the vSPZ disrupt the circadian rhythms of sleep–wakefulness and locomotor activity, whereas lesions of the dSPZ severely impair the circadian rhythms of body temperature. These findings suggest that vSPZ and dSPZ are obligate relays for the normal expression of the circadian rhythms of these functions. A major target of the SPZ is the DMH. Lesions of the DMH profoundly attenuate the circadian rhythms of sleep–wake, locomotor activity, corticosteroid secretion, and feeding. Interestingly, the DMH is one of the largest sources of input to the VLPO and lateral hypothalamic orexin neurons. This multistage regulation of circadian behavior in the hypothalamus allows for the integration of multiple time cues from the environment to shape daily patterns of sleep–wake.

a dense glutamatergic projection to the LHA orexin neurons as well as an intense GABAergic projection to the VLPO, suggesting a primary wake-promoting role for the DMH. Thus, these projections from the DMH neurons to sleep–wake centers of the hypothalamus provide a putative mechanism for the circadian regulation of sleep–wake cycles.

These findings raise the question of why circadian rhythms of behavior and physiology are regulated by a complex multisynaptic pathway in the hypothalamus rather than by a direct projection from the SCN to sleep–wake centers of the brain. In both diurnal and nocturnal species, the SCN is active during the light cycle, whereas the VLPO is always active during the sleep cycle (i.e., irrespective of circadian phenotype), suggesting an absolute requirement for additional (intervening) neural circuitry for organizing diurnal and nocturnal circadian programs despite identical clock input and sleep-control systems. In consideration of the fact that the timing of environmental pressures such as food availability and predation does not always track the solar day, and that the SCN normally remain phase-locked to the light–dark cycle, having flexibility in circadian organization may be extremely adaptive. Thus, for example, this series of multiple relays in the hypothalamus (SCN, SPZ, and DMH) could allow for the integration of light entrained circadian cues from the SCN with environmental time cues (e.g., feeding, temperature, and social cues) to sculpt patterns of rest–activity and sleep–wake cycles that are optimal for survival.

Corticolimbic Projections to the Hypothalamus – A New Frontier

In addition to the integration of external cues, these hypothalamic relays likely coordinate signals from visceral, emotional, and cognitive inputs which collectively influence arousal state. Although studies have demonstrated extensive corticolimbic (e.g., medial prefrontal cortex, infralimbic cortex, bed nucleus of the stria terminalis, and ventral subiculum) projections to the VLPO, SCN, and LHA, we still know very little about the mechanisms by which emotional or cognitive inputs interact with sleep–wake and arousal systems. Nevertheless, it has been hypothesized that during times of emergency these corticolimbic inputs (so-called 'allostatic load') may produce a state of hyperarousal that overrides the homeostatic and circadian drives for sleep, thereby enhancing cognitive and physical performance. Although the adaptive nature of this transient hyperarousal state is clear, chronic or inappropriate activity in corticolimbic sites secondary to psychological stress or depression may in fact be a primary contributing etiology to insomnia.

Summary

Approximately one century ago, von Economo proposed that sleep–wakefulness was governed by a waking influence arising from the midbrain and a sleep influence from the BF/anterior hypothalamic area. The remarkable accuracy of von Economo's predictions has been confirmed experimentally by the subsequent discovery of (1) a brain stem ascending arousal system that maintains consciousness and activates the forebrain both during wakefulness and during REM sleep and (2) the identification of a key hypothalamic switch that shuts off the arousal system to produce sleep. Work has further revealed the critical role of several additional hypothalamic nuclei in the circadian and homeostatic regulation of sleep–wakefulness. Despite this remarkable progress, significant gaps remain in our knowledge of how the arousal system and hypothalamic circuits interact to execute control of behavior state, including sleep–wake regulation.

Sleep and Sleep States: Network Reactivation

Introduction

The persistence of neural activity following a given stimulus or behavior is a widespread phenomenon in vertebrates. Simple introspection suffices to experience the phenomenon, which occurs during waking as well as during sleep. Network reactivation occurs, for instance, when a song heard by chance on the radio lingers in one's auditory imagination for days thereafter. Such reverberation seems to reflect a particularly robust encoding of the song memory, causing an involuntary recollection that runs on top of the heavy background of sensory interference that typically characterizes waking. When occurring during sleep, network reactivation gives rise to dreams as well as nonvivid thoughts ('mentation'), depending on the specific sleep state considered.

The Canadian psychologist Donald Hebb was probably the first to point out that patterns of neuronal activity present during memory encoding remain in the brain after stimulus cessation, maintaining the freshly acquired information 'alive' until structural cellular changes, able to transform a short-lived reverberatory trace into a long-lasting memory, have time to occur. In the past 20 years, evidence has accumulated suggesting that network reactivation is a critical step for learning, being related to many of its idiosyncrasies. It has also been demonstrated that network reactivation is enhanced during sleep, offering a plausible explanation for the beneficial role of sleep in memory consolidation. In addition, network reactivation elucidates the persistence of salient waking experiences during dreaming, a phenomenon labeled 'day residue' by Sigmund Freud. To date, network reactivation has been detected with a variety of techniques from the cellular to the systems level, including the transcriptional upregulation of activity-dependent genes, single neuron activity recorded with microwires, and large-scale neural activity measured by electroencephalographic waves and cerebral blood flow. This article reviews the properties and functions of network reactivation.

Feedback and Rhythms

The mechanistic investigation of network reactivation dates back to the pioneering studies conducted by Lorente de Nó on the dynamics of electrical excitation in hardwired neuronal loops. The famous disciple of Santiago Ramón y Cajal was interested in understanding how activity induced in a given neuron would be passed on to other cells so as to eventually return to the stimulus origin by way of recurrent connections. Based on much anatomy and some physiology, Lorente de Nó proposed that feedback loops comprising multiple neurons echo activation upon stimulation of a single neuron, creating depolarization cycles that only dissipate after several laps take place.

The notion of small-circuit network reactivation enthused neuroscientists in the twentieth century because recursive processes such as this could in principle implement clocks, pacemakers, and memory building blocks. This enthusiasm led to the discovery of specialized neuronal loops that generate recurrent traveling waves within and across brain structures. The combination of recursive architecture, local inhibitory neurons, and the modulatory input of different neurotransmitters (e.g., acetylcholine) gives rise to rhythms of variable duration which are characteristic of global brain states such as waking, sleep, and dreaming. Different substates occur within the major states, such as very long episodes of sustained regional oscillation, including theta rhythm (4–9 Hz in different species), which is composed of sinusoidal oscillations that strongly engage the hippocampus during alert waking as well as during rapid eye movement (REM) sleep, the dreaming phase of sleep in humans. Other rhythms include short-lived oscillations in the range of milliseconds to seconds, such as the cortical spindles (10–14 Hz) that are particularly abundant during stage 2 sleep, constituting its defining characteristic. Stage 2 sleep is one of the substates of slow-wave sleep (SWS), the nondreaming phase of sleep in humans.

The span of brain oscillations deemed behaviorally relevant goes from very slow, whole brain waves ($<$1 Hz) to very fast ripples ($\sim$200 Hz) that engage small groups of hippocampal neurons. All these oscillations depend on the interaction of specific neural circuits, such as the septohippocampal axis for theta rhythm, the thalamocortical loop for spindles, and intrahippocampal networks for ripples. Oscillations may coexist in time and space, phase locking at specific moments so as to optimize communication

among brain areas. For instance, slow oscillations of the membrane potential in the cerebral cortex constrain neurons to 'upstates' and 'downstates.' The slow oscillatory upstate represents the depolarizing phase of the slow oscillation, leading to discrete bursts of cortical activity that are followed by hippocampal sharp wave/ripples complexes, preferentially triggered by the upstate.

Reactivation, Reverberation, and Replay

Postulated by Donald Hebb more than 50 years ago, the term 'reverberation' was replaced in the past few decades by 'reactivation' and 'replay,' but neither term fully accounts for the general phenomenon in question. Although network reactivation decreases substantially during waking, it does not disappear completely when animals are awake. This was demonstrated by electrophysiological studies in rodents and can easily be verified by introspection. For most people, it suffices to remain quiet under reduced sensory stimulation in order for mnemonic images to appear. The available data indicate that salient experience causes sustained neural reverberation rather than discrete reactivation, in the sense that memory traces are continuously detectable during subsequent periods across all behavioral states in a state-dependent manner. Reverberating patterns of neural activity associated with past experience are largely, but not completely, masked during waking by incoming sensory inputs.

Another related term that became well known in the early 1990s is memory replay, which implies a high-fidelity repetition of past patterns of neural activity. However, the accuracy of neuronal reverberation is still controversial. In the rodent hippocampus, the path run by the animal during wakefulness can be very accurately re-created based on the spatiotemporal neuronal firing patterns observed during sleep. In contrast, researchers found low values for firing rate correlations among neurons in the cerebral cortex, suggesting that cortical reactivation implements a low-fidelity emulation of memories rather than a perfect replay. This is probably related to the fact that many portions of the mammalian cerebral cortex are dedicated to the joint representation of multiple perceptions or acts. As a consequence, single cells are recruited into many different neuronal groups, multiplexing information in a way that likely blurs the detectable network reactivation of any discrete engram. A notable counterpoint is found in songbirds: The nucleus RA, single output of the telencephalic song circuitry, displays a highly accurate replay of song-related firing patterns (**Figure 1(d)**). This remarkably rare case of high-fidelity replay derives from the very specialized neural processing carried out by this motor nucleus, namely the descending activation of a single, unique, and invariant sequential engram: the bird's own song.

A Link with Memory

Despite the importance of brain rhythms to explain major differences among behavioral states, nowadays it is recognized that the kind of network reactivation that underlies the recall of fine-grain memories arises from the interaction of much more complex neural circuits, in which the reverberation of neuronal activity does not derive trivially from a preexisting anatomical loop. Beginning in the 1970s, the investigation of primates performing working memory tasks showed that neurons in the prefrontal cortex show persistent firing rate changes during delay periods that separate stimulation from behavioral response. Currently, there is a consensus that network reactivation in the prefrontal cortex and other associative areas of intricate connectivity is directly implicated in the temporary storage of stimulus-related information required for correct behavioral responses. These so-called 'memory neurons' can remain active for many seconds after stimulus removal, keeping information about the past available for future decision making. In these cases, the experimental task shaped the neuronal behavior, uncovering neurons able to reverberate information on voluntary demand. This kind of delayed goal-directed reactivation is extremely important in nature for hunters and hunted alike. However, it does not account for all the time we spend in spontaneous network reactivation, either day- or night dreaming.

Network Reactivation Increases during Sleep

A major breakthrough in the search to identify the mechanisms underlying spontaneous network reactivation resulted from an experiment on the poststimulus sleep activity of hippocampal neurons performed by Constantine Pavlides and Jonathan Winson at the Rockefeller University in the late 1980s. Their elegant study took advantage of the fact that pyramidal hippocampal neurons in the rat tend to fire very selectively according to the spatial position of the animal in a given environment, hence the name 'place cells.' Using chronic electrode implants in the hippocampus, the experimenters first identified and recorded pairs of neurons with nonoverlapping place fields – that is, places in which the neurons fired the most. Then, rats were restricted from entering the place field of either cell overnight. Finally, animals were confined for 10–15 min within the place field of one of the cells so as to strongly stimulate one neuron while suppressing the activity of the yoked one. By

Figure 1 Neuronal reactivation in rats and birds. (a) Hippocampal place cells are reactivated during SWS and REM sleep after waking (WK) exposure to their corresponding place fields. $^*p < 0.05$. (b) For hippocampal place cells, pairwise neuronal correlations established during waking exposure to a circular maze (RUN) are preserved during subsequent SWS (POST), while being absent from prior SWS (PRE). In each circle, neurons are represented by dots over the perimeter, and correlations are represented as lines whose thickness is proportional to correlation strength. (c) SWS replays neuronal firing sequences observed during RUN in the hippocampus. Notice the temporal compression of the neuronal patterns during SWS. Shown are firing patterns during a single running lap on the left–right trajectory (left) or during an equivalent sleep 'frame' period (right). One neuron per row, one spike per tick. (d) Premotor neurons in nucleus RA of a zebra finch accurately replay singing-specific activity during sleep. Shown are raw traces of neuronal activity (900 ms) recorded during singing (premotor activity) and sleep (spontaneous activity). A color spectrograph of the song that the bird sang is shown on top, with horizontal bars indicating different song syllables. (e) To estimate similarity with past patterns of neuronal ensemble activity produced by the exploration of novel objects in rats, neuronal activity patterns were compared with extensive recordings of neuronal action potentials using a template-matching algorithm. As indicated by the white arrows, neuronal ensemble correlations increase gradually between waking (blue) and sleep (red for SWS and green for REM sleep). quantifying the neuronal firing rates during and after spatial confinement across the wake–sleep cycle, Pavlides and Winson found that changes in firing rates recorded during waking persist during ensuing SWS and REM sleep (Figure 1(a)). In other words, place cells exposed to their place fields prior to sleep showed increased firing rates during SWS and REM sleep compared to place cells that were not exposed to their place fields.

In 1994, Matthew Wilson and Bruce McNaughton showed that pairs of neurons recorded in the hippocampus carry into subsequent SWS the temporal firing relationships observed when animals run a circular path beforehand (Figure 1(b)). Follow-up of these discoveries by different research groups established that reactivation is strongest and most stable during SWS, becomes more variable during REM sleep, and decreases during waking. The difference between sleep states probably arises from the overall low activation of most of the brain during SWS, in contrast with the elevated neural activation that characterizes REM sleep, which is so high as to be considered waking-like, hence the alias 'paradoxical sleep' preferred by most European neuroscientists. Given the

consistent increase in network reactivation during SWS, its higher variance during REM sleep, and the short duration of total REM sleep in comparison with total SWS (~1:4 in rats and humans), one must conclude that SWS plays the major role in network reactivation, although dreaming sleep (i.e., REM sleep) also participates in the process.

Reactivation and Learning

The great importance ascribed to network reactivation by neuroscientists stems from its putative link with memory consolidation. Although the early breakthroughs in the field were mostly the result of electrophysiological investigation of rodent neurons, it was the survey of human brains with electroencephalography, positron emission topography, and functional magnetic resonance imaging that established a firm link between learning and network reactivation (Figure 2(a)). Postacquisition reverberation of regional brain activity during sleep has been shown to be proportional to memory acquisition and to quantitatively predict learning. Such reverberation is reflected in local increases of blood oxygenation as well as the amplitude of low-frequency electroencephalographic waves (delta band, <4 Hz) (Figure 2(b)). If learning coincides with an increase in slow oscillatory activity, the converse is also true: The application of 0.75 Hz pulses by transcranial magnetic stimulation during SWS enhances the retention of hippocampus-dependent memories in humans, but similar stimulation at 5 Hz does not produce the effect.

Network reactivation during sleep seems to favor the anatomical reorganization of memory traces, an increasingly recognized hallmark of memory consolidation. In the case of spatial memory tasks, which depend on the hippocampus for initial encoding, sleep favors a displacement of the activation elicited by task performance, from the hippocampus to striatal networks. Indeed, different lines of evidence suggest that network reactivation during sleep is directly implicated in the temporally graded propagation of memories from the hippocampus to cortical areas, a phenomenon made famous by patient H.M., who developed anterograde amnesia for declarative memories after bilateral removal of the hippocampus. Likewise, sleep may promote engram propagation in the case of implicit memory tasks, which initially involve the cerebellum but progressively engage the basal ganglia. To summarize, network reactivation during sleep seems to play a rather important role in the strengthening and relocation of memory traces within the brain.

Characterization of Reactivation Properties

One possible explanation for the increase in network reactivation during sleep is that endogenous brain activation, freed from sensory interference during

Figure 2 Regional brain reactivation in humans. (a) Brain regions reactivated during REM sleep in subjects previously trained in a visuomotor task. Shown are brain maps of regional cerebral blood flow as measured by positron emission tomography. The activated regions comprise the cuneus and adjacent striate striate cortex bilaterally, the left premotor cortex, and the mesencephalon. Maps show six different brain levels (from 16 mm below to 64 mm above the bicommissural plane), superimposed on the average MRI image of the sleeping subjects. (b) The amplitude of slow waves recorded with electroencephalography increases locally in subjects trained in a motor task. Shown is the topographic distribution of the percentage change in the amplitude of slow waves between the task condition and a control task, void of motor learning. White dots indicate the cluster of six electrodes showing increased amplitude of slow waves after motor learning. (a) Adapted from Maquet P, Laureys S, Peigneux P, et al. (2000) Experience-dependent changes in cerebral activation during human REM sleep. *Nature Neuroscience* 3(8): 831–836. (b) Adapted from Huber R, Ghilardi MF, Massimini M, and Tononi G (2004) Local sleep and learning. *Nature* 430: 78–81.

off-line states, flows preferentially through previously activated synapses. In principle, this would suffice to cause neuronal firing patterns originally produced during waking to reverberate significantly above chance levels during sleep. For instance, telencephalic reactivation may be driven by the pontine waves that are particularly abundant during REM sleep. To date, experience-dependent network reactivation during sleep has been observed in rodents, macaques, humans, and songbirds, indicating a very widespread biological phenomenon. Sleep promotes the coordinated reverberation of waking-acquired activity patterns across large groups of neurons in the hippocampus, primary sensory and associative cortices, basal ganglia, and even primary sensory thalamic relays. The synchronization of neuronal firing by slow cortical oscillations seems to generate discrete activity frames between the hippocampus and the cerebral cortex, promoting coordinating interactions across these brain regions during the membrane potential upstate (i.e., the depolarizing phase of the slow oscillation).

It is unclear whether reverberation is favored by novel stimuli, which are more salient for perception, or by well-trained stimuli/behaviors, which are deeply engrained by habit. Results favoring either option coexist in the literature. There is evidence that major changes in firing rate patterns last longer in the cerebral cortex than in the hippocampus, but more research is needed to elucidate this issue. The duration of network reactivation is also under intense debate. Whereas several studies point to fast-fading effects lasting less than 1 h, some experiments have detected signs of mnemonic reverberation for up to 48 h after stimulus removal.

It has been proposed that network reactivation during sleep occurs under different regimes of time compression or expansion, perhaps allowing for more efficient mnemonic processing. Some studies indicate that the experience-dependent reverberation of neuronal firing patterns is hastened during SWS, presumably because the activity bursts characteristic of that state (e.g., hippocampal ripples) promote the fast replay of entire neuronal firing sequences (Figure 1(c)). Similarly, there is some evidence suggesting that network reactivation is slowed during REM sleep, but a consensus regarding this issue is yet to be achieved. Another point of contention, with controversial evidence, is whether sleep also harbors antireverberation – that is, patterns of neuronal ensemble activity statistically more dissimilar from the waking reference patterns than expected by chance. In principle, the novelty-induced reverberation and antireverberation of neuronal firing patterns could play balancing roles in the delineation of specific memory traces, embossed in the synaptic landscape of the forebrain.

Reactivation at the Molecular Level

The very wide prevalence of network reactivation within the brain and across species suggests that it derives from extremely conserved elements of the vertebrate nervous system, such as the major anatomical connections and the molecular backbone shared by all neurons. As discussed previously, the overall plan of the vertebrate brain comprises several circuits prone to recursive activity, such as the thalamocortical loop. The conspicuous rhythms implemented by these circuits are ridden by finer-grain reactivation at the level of single neurons. Such neuronal reactivation, rather than large-scale rhythms, constitutes the most likely substrate for the recall of specific memories.

The acquisition of a single new memory involves activity-dependent molecular mechanisms able to store information at the synaptic level from many minutes to a few hours. Most of these mechanisms depend critically on the rise of calcium, either permeated through membrane channels (e.g., NMDA voltage-gated channels) or as a result of increased intracellular release. Elevated calcium levels activate phosphorylating enzymes (kinases) that trigger major changes in the internal biochemical milieu of the cell. Network reactivation immediately after memory acquisition seems to require, for instance, the phosphorylation of calcium/calmodulin kinase II (CaMKII), an autocatalytic enzyme that can by itself sustain local changes in synaptic strength. In this case, the substrate of reactivation is not an anatomical loop but, rather, a molecular one since CaMKII maintains memory by persistent self-phosphorylation.

Whereas the initial stabilization of recently acquired memories relies on spatially restricted synaptic mechanisms such as CaMKII activation, it is well established that the long-lasting persistence of mnemonic traces requires *de novo* protein synthesis. Indeed, calcium-dependent kinase activation triggers signaling cascades that couple membrane depolarization to genomic regulation inside the cell nucleus, leading to the transcriptional upregulation of several immediate early genes (IEGs) required for the long-term maintenance of memory. One of these genes is the activity-regulated cytoskeleton-associated protein (Arc), a calcium-dependent IEG that interacts with glutamatergic AMPA receptors, actin, and CaMKII to promote synaptic remodeling. Arc mRNA is transported to dendrites for local translation, leading to retrograde (presomatic) effects. Another activity-dependent gene regulated by calcium is zif-268 (also known as egr-1, krox-24, NGFI-A, and ZENK), which encodes a transcription factor with binding sites on the promoters of hundreds of different genes. The zif-268 protein is thought to modulate synaptic

remodeling by controlling the expression of genes directly involved in synaptic function, such as synapsins, the most abundant protein constituent of synapses, involved in the regulation of synaptic vesicle release. The transcriptional control of synapsin levels by the zif-268 protein illustrates how neuronal depolarization can prompt anterograde (postsomatic) synaptic remodeling. Such a mechanism could, in principle, disseminate synaptic changes downstream of long neuronal chains, effectively propagating memory traces across separate circuits.

The large-amplitude neural oscillations typical of SWS promote marked periodic fluctuations of calcium levels in activated synapses, as indicated by extracellular calcium measurements during sleep. As a consequence, it has been hypothesized that SWS is concomitant with the activation of multiple calcium-dependent kinases, with a role in memory formation. This would result in a pretranscriptional amplification of synaptic changes encoding novel memory traces during SWS, as suggested by recent data (Figure 1(e), white arrows). Although experimental evidence linking all the elements of these calcium-dependent metabolic cascades to sleep-dependent network reactivation is missing, results indicate that REM sleep triggers the activation/upregulation of several calcium-dependent molecules required for neuronal plasticity and memory formation, such as zif-268, arc, cyclic AMP response element-binding protein, and brain-derived nerve growth factor (Figure 3(a)). The sleep-dependent transcriptional upregulation of the zif-268 gene seems to also reveal memory trace relocation from the hippocampus to the cerebral cortex (Figure 3(b)). The activity-dependent anterograde response caused by the zif-268 gene represents a putative molecular mechanism for the propagation of synaptic changes across neuronal circuits, leading to memory relocation.

The fact that neuronal activity can be traced to molecular markers of plasticity establishes a strong parallel between the cellular and systems levels, offering support for the Hebbian notion that memory requires two consecutive and distinct steps, namely network reactivation for short-term recall and synaptic remodeling for long-term storage. The current results suggest that SWS and REM sleep play distinct and complementary roles in memory consolidation, with memory recall (network reactivation) occurring mainly during SWS and memory storage (plasticity-related gene) sparked off during REM sleep. Such a mechanism fulfills early conceptual notions of a two-step process for memory consolidation during sleep and is in line with evidence that SWS and REM sleep have synergistic effects on human procedural learning and developmental plasticity.

Figure 3 Molecular reactivation. (a) The mRNA levels of the activity-dependent gene *zif-268*, a transcription factor with an important role in memory consolidation, are upregulated during REM sleep in rats previously exposed to novel experience but not in control animals kept in their habitual home cages. Shown are autoradiograms of brain sections subjected to radioactive *in situ* hybridization. (b) The unilateral induction of hippocampal long-term potentiation during waking leads to marked unilateral gene upregulation in the hippocampus 30 min after high-frequency electrical stimulation (yellow arrow). Four hours later, during REM sleep, zif-268 is downregulated in the hippocampus but strongly induced in extrahippocampal regions such as the cerebral cortex and the amygdala, indicating that REM sleep disengages the hippocampus and engages extrahippocampal regions. Traces on the left represent hippocampal local field potentials typical of waking (top and middle) and REM sleep (bottom). (a) Reproduced from Ribeiro S, Goyal V, Mello CV, and Pavlides C (1999) Brain gene expression during REM sleep depends on prior waking experience. *Learning & Memory* 6(5): 500–508, with permission from Gold spring Harbor Laboratory press. (b) Adapted from Ribeiro S, Mello CV, Velho T, Gardner TJ, Jarvis ED, and Pavlides C (2002) Induction of hippocampal long-term potentiation during waking leads to increased extrahippocampal zif-268 expression during ensuing rapid-eye-movement sleep. *Journal of Neuroscience* 22(24): 10914–10923.

Dreams, Waking, and Sleep Mentation

In adult humans, REM sleep is almost always accompanied by dreaming, as can be easily demonstrated by waking experimental subjects during REM sleep and requesting dream reports. During human REM sleep, a selected set of forebrain areas are reactivated, including portions of the hypothalamus, amygdala, septum, and ventral striatum, as well as the anterior cingulate, orbitofrontal, entorhinal, and insular cortices. The dorsolateral prefrontal cortex, however, shows reduced activity. Given the role of prefrontal cortex activity in the executive control of behavior, its reduction during REM sleep has been proposed to underlie the poor logical concatenation and reduced self-awareness of dreaming in comparison with waking.

Dreams may have first evolved as a collateral effect of extended REM sleep, a characteristic mammalian trait. Pet owners know that cats and dogs seem to act out dreams during sleep. More controlled evidence of dreaming in nonhuman mammals was obtained by lesions of the brain stem nuclei that promote muscle atonia during REM sleep. Cats with such lesions sleep quietly through SWS, but upon entering REM sleep they become suddenly agitated by vigorous species-specific behaviors, such as meowing and pouncing. How are dreams generated, and what is their biological function?

As noted by Sigmund Freud, dreams often involve elements of the experience of the preceding day(s), the day residue. Although high-fidelity memory reactivation must be at the roots of the cognitive functions of sleep and dreams, it does not account entirely for the symbolic complexity that characterizes the oneiric narrative. After all, it is not common to dream about the exact repetition of waking scenes. On the contrary, most human dreams are characterized by the intrusion of illogical elements, leading to unforeseen associations. Human dreams are subjective narratives composed of familiar and unfamiliar beings, things, and places interacting around a self-representation of the dreamer that mostly observes an unfolding plot. Dreams vary in intensity, ranging from confused and faint impressions to complex time-evolving narratives with vivid imagery and surprising turns. Although dreams tend to be dominated by visual images, they can also involve combinations of auditory, olfactory, tactile, gustatory, motor, vestibular, and linguistic modalities. Dreams can sometimes be extremely pleasant or just the opposite, but they are usually characterized by a mix of emotions. Dreams are also hyperassociative, linking characters, places, and actions in bizarre ways. Dreams can also anticipate events of the coming day(s), particularly when subjects undergo extreme anxiety and expectation. A good example is provided by the dreams of students during the night before taking difficult exams; these dreams often contain detailed anticipatory simulations of the expected challenges, in content and/or context.

Freud also postulated that dream narratives fulfill wishes (or anti-wishes) of the awake subject, simulating the realization (or frustration) of specific desires. Whereas the prevalence of overt wish fulfillment in the dreams of normal adults is low, it is common in young children. Children living in war zones have a much higher incidence of nightmares, a result that has been interpreted as evidence that the function of dreams is to simulate environmental threats. Based on the existence of blissful dreams, other neuroscientists have expanded the threat-simulation theory to include the simulation of rewarded behaviors as a dream function. The notion of dreaming as behavior simulation leading to either reward or punishment is supported by the neuropsychological investigation of dreamless patients. These patients, who often conserve REM sleep, represent rare clinical cases with lesions of mesocorticolimbic pathways connecting reward centers with the thalamus, striatum, and cerebral cortex. Although REM sleep is spared in these cases, the loss of dreaming is accompanied by subjective reports of sleep disturbance, as assessed by qualitative interviews. This suggests a role for dreaming in sleep maintenance, which is another Freudian postulate.

The current evidence indicates that dreams reflect the intense and noisy network reactivation that takes place during extended REM sleep, with the cerebral cortex lightened up at high neuronal firing rates and oscillatory frequencies predominantly above 30 Hz (gamma band). The qualitative feeling of 'quasi-reality' in dreams derives from the fact that network reactivation during REM sleep occurs at an intensity and oscillatory spectrum comparable to those of waking. Such high levels of excitation cause the reverberating memories that comprise dreams to appear bright and vivid to the self-representation, and variations in neural activity levels explain the dynamic range of vividness that characterizes normal dreaming. Likewise, the simultaneous occurrence of neuronal reverberation in multiple forebrain sites during REM sleep explains the wide variation in dream 'sensory' modality. There is also a compelling relation between the higher variability of network reactivation during REM sleep and the fragmentation, condensation, and bizarreness of dreams. Far from being random, dream narratives highlight waking events according to how recent, novel, and behaviorally significant they were (i.e., dreams are directed by the anxieties and preoccupations of the dreamer). Dreams seldom occur during SWS. Instead,

the subjective experience of SWS consists of low-intensity but coherent thoughts resembling waking reasoning. The coherence of such 'mentation' likely reflects the high stability of neuronal reverberation during SWS. Similarly, the lack of intense imagery during SWS probably reflects the decreased cortical activity and slow oscillations that characterize network reactivation in this state.

Concluding Remarks

Network reactivation is a fundamental property of neuronal circuits that occurs at several levels, ranging from molecular and cellular mechanisms to the consequent systemic and behavioral manifestations. Reactivation is based on the existence of recurrent biological loops, from self-activating enzymes to large networks of correlated neurons distributed over multiple brain regions, with various degrees of duration. Although reactivation is favored by the interruption of sensory and motor interference provided by sleep, data suggest that it occurs nonstop during waking as well, spanning one's entire lifetime.

Introduction

Positron emission tomography (PET) shows the distribution in the body (or in the brain, in the context of neuroimaging) of compounds labeled with positron-emitting isotopes. In the field of sleep research, two compounds have mainly been used to assess the global and regional cerebral activity during the different sleep stages: [^{18}F]fluorodeoxygucose, which is a marker of glucose metabolism, and oxygen-15-labeled water ($H_2^{15}O$), which is an indirect marker of blood flow. In the framework of sleep research, PET images are acquired in combination with simultaneous recordings of brain electrical activity by electroencephalography for sleep staging. After data transformation and inter-individual standardization, statistical procedures allow the comparison of regional cerebral activity between two conditions (e.g., a specific sleep stage and wakefulness) or the examination of correlation patterns between regional activity distribution in a specific condition and measurements of relevant physiological events (e.g., sleep oscillations within a specific sleep stage). The resulting functional brain maps have contributed important information about human sleep physiology, assessed in the light of animal experimental data. Sleep functions have also been investigated with this technique. In particular, a role for sleep in learning and memory has been evidenced using PET recording during posttraining sleep associated with behavioral measurements.

Sleep Stages and Sleep Oscillations

PET studies have shown that global and regional patterns of brain activity during wakefulness are remarkably different from those obtained during sleep (i.e., rapid eye movement (REM) sleep and non-REM sleep).

Non-Rapid Eye Movement Sleep

Non-REM sleep is a state of synchronization of the electroencephalogram (EEG), along with the production of specific oscillations within thalamo-cortical networks: spindles, delta waves, and slow oscillations.

When compared to wakefulness and REM sleep, non-REM sleep is characterized by a decrease in global cerebral blood flow and regional cerebral blood flow (rCBF). The largest decreases in rCBF are observed in a set of subcortical and cortical areas, including the dorsal pons, mesencephalon, thalami, basal ganglia, basal forebrain, prefrontal cortex, anterior cingulate cortex, and precuneus (Figure 1(b)).

A lower activity in the brain stem and thalamus was expected from animal data of non-REM sleep-generation mechanisms; a decreased firing rate in the brain stem induces the sequential alternation of long hyperpolarization and short depolarization patterns in thalamic neurons, which leads to the formation of non-REM sleep rhythms (spindles, delta oscillations, and slow) among thalamocortical networks. Due to the low time resolution of the PET technique (i.e., one scan is the activity averaged over a period of time ranging from 40 to 90 s) and because the hemodynamic influences of hyperpolarization predominate over those of depolarization phases, brain areas where non-REM sleep rhythms are most expressed appear deactivated in PET studies.

At the cortical level, the pattern of deactivation is not homogeneously distributed. Indeed, the least active areas in non-REM sleep are located in associative cortices, especially the ventromedial prefrontal cortex (VMPF), which includes the orbitofrontal and anterior cingulate cortices. The VMPF is also one of the most active brain areas during the awake resting state and is involved in important cognitive processes such as action monitoring and decision making. In contrast, the primary cortices were the least deactivated cortical areas during non-REM sleep. This specific segregation of cortical activity remains poorly understood, although some hypotheses have been proposed, for instance, (1) that associative areas might be more profoundly influenced by non-REM sleep rhythms than primary cortices because they are the most active cerebral areas during wakefulness and (2) that sleep intensity is homeostatically related to prior waking activity at the regional level.

The precuneus is another cortical area that displays a reduced activity during non-REM sleep in PET studies. It is a region particularly active in wakefulness, during which it is involved in visual mental imagery processes, explicit memory retrieval, and consciousness. The precuneus is also deactivated during other states of decreased consciousness such as pharmacological sedation, hypnotic states, and vegetative states. The role of the precuneus during sleep still remains unclear. Its decreased activity during

Figure 1 Functional neuroanatomy of normal human non-REM sleep, as assessed by $H_2^{15}O$ PET: (a) brain areas in which rCBF decreases as a function of delta power during non-REM sleep (stages 2–4); (b) brain areas in which rCBF decreases during non-REM sleep as compared to wakefulness and REM sleep. In (a), image sections are displayed on different levels of the *z*-axis, as indicated at the top of each picture. The color scale indicates the range of *z*-values for the activated voxels, superimposed on a canonical T1-weighted MRI image. Displayed voxels are significant at $p < 0.05$ after correction for multiple comparisons. Note that different analyses (correlation (a) vs. subtraction (b)) gave rise to strikingly similar results in terms of the regional blood flow distribution. MRI, magnetic resonance imaging; PET, positron emission tomography; rCBF, regional cerebral blood flow; REM, rapid eye movement. Adapted from Maquet P, Degueldre C, Delfiore G, et al. (1997) Functional neuroanatomy of human slow wave sleep. *Journal of Neuroscience* 17(8): 2807–2812. Copyright 1997 by the Society for Neuroscience.

non-REM sleep might reflect a homeostatic compensation of a high waking activity.

The basal forebrain and the basal ganglia (mostly the striatum) have also been found to be consistently deactivated during non-REM sleep in PET sleep studies. The basal forebrain is a functionally and structurally heterogeneous structure in which a majority of neurons is involved in cortical activation during wakefulness and REM sleep. Its deactivation during non-REM sleep may therefore reflect a lower activity of these arousal-promoting neurons. The role of the basal ganglia, and especially the striatum, in sleep regulation remains speculative, however. Two hypotheses have been put forward. First, the striatum receives massive afferent inputs from the frontal cortex and the thalamus, which are also deactivated during non-REM sleep. These structures are most likely to participate to the formation of non-REM sleep rhythms by oscillating synchronously between long phases of hyperpolarization and bursts of discharges. Due to the fronto- and thalamo-striatal connections, basal ganglia neurons may likewise oscillate following these non-REM sleep-rhythm sequential patterns and, thus, appear deactivated at the macroscopic level. According to the second proposal, the striatum may also send projections to the pedunculopontine tegmental nucleus (PPT) in the brain stem and induce the disinhibition of this activating structure, subsequently leading to cortical arousal during wakefulness. In this perspective, the decreasing activity in the striatum during non-REM sleep may be related to a reduced propensity to arousal as well.

PET studies have not merely compared the activity between non-REM sleep and other stages of sleep or wakefulness. Another way to describe brain activity during this sleep stage was to search for the neural correlates of non-REM sleep oscillations (spindles and delta waves) by looking for brain areas in which rCBF values correlate with the EEG activity of interest (i.e., power density in the sigma or delta frequency band). Using this approach, spindle activity (12–15 Hz) has been shown to correlate negatively with rCBF in the thalamus, meaning that the higher the power density within the spindle frequency range on EEG recordings, the lower the thalamic activity. This result is in line with spindle-generation mechanisms in mammals, which are dominated by the cyclic repetition of hyperpolarization and spike bursts in the thalamic neurons. Delta activity (1.5–4 Hz) correlates negatively with rCBF in the VMPF, basal forebrain, striatum, and precuneus (Figure 1(a)). The resulting map is very similar to the brain map of the regions less activated during non-REM sleep compared to REM sleep and wakefulness (Figure 1(b)), which emphasizes the notion that delta activity is a prominent feature of non-REM sleep. A major difference,

however, is the absence of significant correlation between delta and thalamus activity, whereas the thalamus is markedly deactivated during non-REM sleep compared to other sleep stages or wakefulness. This discrepancy can be explained taking into account that two types of delta activity have been described in animals: a stereotyped delta rhythm, whose generation depends on intrinsic properties of thalamocortical neurons, and a cortical polymorphous delta rhythm, which persists after extensive thalamectomy. Therefore, the delta correlation map might preferentially reflect the brain areas involved in the generation of cortical delta waves during non-REM sleep. The physiology of these cortically generated delta oscillations, and their relationship with the slow rhythm, is still poorly understood.

It should be emphasized here that deactivation patterns found with PET studies do not imply that these brain areas remain idle during non-REM sleep. As already stated, non-REM sleep oscillations are produced by the recurrent and sequential alternation of hyperpolarization and depolarization phases in the thalamic and cortical neurons. The latter are characterized by bursts of neuronal firing temporally organized by the non-REM sleep slow oscillation. PET is insensitive to these bursts because it averages brain activity over long periods, during which the effects on regional brain function of prolonged hyperpolarization periods exceed those of shorter depolarization phases. This issue should be addressed in future studies using techniques with higher spatial and temporal resolution, such as combined EEG-functional magnetic resonance imaging (fMRI), that will provide activation patterns closer to the genuine non-REM sleep physiology, dominated by synchronous and low-frequency oscillations.

Rapid Eye Movement Sleep

REM sleep is characterized by a desynchronized EEG with high-frequency, low-amplitude activity, a major muscle atonia, spontaneous rapid eye movements, and an intense oneiric mentation. In contrast to non-REM sleep, PET studies showed that the global cerebral blood flow during REM sleep is sustained to a level comparable to wakefulness. At the regional level, several brain areas even display a higher rCBF during REM sleep compared to wakefulness and/or non-REM sleep: the pontine tegmentum, thalamus, amygdala, hippocampus, anterior cingulate cortex, temporal–occipital areas, and the basal forebrain. Conversely, regional decreases in activity are also found during REM sleep, in the dorsolateral prefrontal cortex (DLPF), posterior cingulate gyrus, precuneus, and inferior parietal cortex (Figure 2).

Activation of the pontine tegmentum, thalamic nuclei, and basal forebrain is in agreement with REM sleep-generation mechanisms in animals. REM sleep is generated by cholinergic processes arising from brain stem structures, located in the pedunculopontine tegmentum and laterodorsal tegmentum, which mediate widespread cortical activation via a dorsal pathway innervating the thalamus and a ventral pathway innervating the basal forebrain.

Consistent activations during REM sleep are also found in limbic and paralimbic structures, including the amygdaloid complexes, hippocampal formation, and anterior cingulate cortex. There is evidence that the amygdala plays a role in REM sleep modulation. For instance, carbachol (cholinergic agonist) injections in the central nucleus of amygdaloid complexes enhance REM sleep duration, and a shift from non-REM sleep to REM sleep is observed in rats after serotonin injection into the amygdala. The amygdala also appears to modulate important physiological features of REM sleep. For example, recent PET data suggest that the large variability in heart rate during REM sleep could be explained by a prominent influence of the amygdaloid complexes. Both amygdala and hippocampal formation are also critical for memory systems and may thus participate in the processing of memory traces during REM sleep.

PET studies showed higher rCBF values in temporal–occipital areas during REM sleep compared to wakefulness. These areas include the inferior temporal cortex and the fusiform gyrus, which are extrastriate cortices belonging to the ventral visual stream. Functional interactions between the primary visual cortex (striate cortex) and the extrastriate cortex during REM sleep were also assessed in a PET study. This study showed that extrastriate cortex activation is significantly correlated with striate cortex deactivation during REM sleep, whereas their activities are positively correlated during wakefulness. This result has been interpreted as supporting the hypothesis that REM sleep allows internal information processing (between extrastriate areas and their paralimbic projections, both activated during REM sleep) in a closed system dissociated from interactions with the environment (via striate cortex and prefrontal cortex, both deactivated during REM sleep).

Regional deactivations during REM sleep are mostly located in the DLPF (inferior and middle frontal gyrus), precuneus, posterior cingulate cortex, and a part of the parietal cortex (temporal–parietal region and inferior parietal lobule). In contrast, the activity in the superior parietal lobe and in the superior and medial prefrontal cortex is similar to waking level. The reasons of these cortical deactivations are still unclear. Animal data show that the cortical areas less

active during REM sleep (the inferior parietal and DLPF) receive only few inputs from the amygdala, whereas areas more active during REM sleep (the anterior cingulate and right parietal operculum) receive rich amygdalar inputs, suggesting that amygdala may modulate the pattern of cortical activity during REM sleep. This hypothesis is also supported by PET results showing that functional interactions between the amygdala and the temporal–occipital cortices are different in the context of REM sleep than in non-REM sleep or wakefulness. The amygdalo-cortical network during REM sleep might contribute, in particular, to the selective processing of emotionally relevant memories.

In animals, rapid eye movements during REM sleep are closely related to the occurrence of ponto-geniculo-occipital (PGO) waves. PGO waves are bioelectrical phasic potentials occurring during the transition from non-REM sleep to REM sleep or during REM sleep itself. They are observed in many parts of the animal brain, but they are most easily recorded in the pons, lateral geniculate bodies of the thalamus, and occipital cortex, hence their name. Animal data also suggest that PGO waves might have important functional roles, such as a facilitation of brain plasticity. In humans, a PET study found correlations during REM sleep, but not during wakefulness, between

spontaneous eye movements and rCBF in the occipital cortex and lateral geniculate bodies of the thalamus, supporting the hypothesis that PGO-like activities are present during REM sleep in humans as well as in animals.

Neuroimaging and Dreams

Dreaming is experienced every night by many humans as multisensory mental representations occurring spontaneously during sleep, often organized in a narrative manner. Dreams are more often associated with REM sleep (dream reports are present in 90% of the episodes in subjects awakened during a REM sleep period). Dream during REM sleep is classically considered the canonical dream with several characteristics: hallucinoid imagery, narrative structure, bizarreness, hyperemotionality, delusional acceptance, and deficient memory of its content. Dream reports are usually less organized, poorer, and shorter during non-REM sleep.

At the neuroimaging level, it has been proposed that the PET activation patterns during REM sleep might be interpreted in the light of dreams. Indeed, brain functional segregation during REM sleep, as already described, may account for several typical dreaming features (Figure 2). We present a few examples here.

Dream reports differentially involve the sensory modalities. Visual components are nearly always present, auditory components are present in 40–60% of dreams, movement and tactile sensations are present in 15–30%, and smell and taste components are present in less than 1%. The activation of the associative posterior (temporal–occipital) cortices may be related to these perceptual aspects of dreams, consistently dominated by visual and auditory elements. Accordingly, a cessation of visual dream imagery was reported in some patients with temporal–occipital lesions.

Dream content is also characterized by the prominence of emotions especially negative emotions such as fear and anxiety. Responses to threatening stimuli or stressful situations are known to be modulated by the amygdala during wakefulness. The high limbic, and especially amygdalar, activity during REM sleep may therefore underpin the emotional intensity occurring during dreams. Moreover, PET data have shown functional interactions between the amygdala and temporal–occipital cortices during REM sleep, and fMRI studies during wakefulness have found positive relationships between the emotional intensity of visual stimuli and both amygdalar and inferotemporal cortex activity. Together, these data suggest that emotional experience during dreams may engage specific brain networks encompassing the amygdala and temporal–occipital cortices rather than a single brain area.

The bizarreness of dream reports is another recurrent hallmark. The cortical patterns of hypoactivity during REM sleep may contribute to these aspects. Indeed, the prefrontal regions deactivated during REM sleep overlap with the areas involved in the selection of stimulus–response associations according to contextual signals, past events, and internal goals. The decreased activity of prefrontal regions consequently impairs the efficiency of this integrative system during REM sleep. This may, for instance, account for the inability of the dreamer to integrate information of a whole episode, leading to an oneiric content in which characters, times, and places are fused, incongruous, and discontinuous. It may also explain the decrease in volitional control and the dreamer's failure to organize mental representation toward a well-identified internal goal. Prefrontal inactivity during REM sleep may, then, explain why the dreamer is unable to control the flow of dream events.

These hypoactive areas also encompass frontal areas participating in the processing of episodic memory, that is, the ability to encode and recollect personally experienced events set in a particular spatiotemporal context. Prefrontal areas are involved in the monitoring of episodic memory retrieval by checking the accuracy and completeness of the processed information. The impairment of these areas during REM sleep might explain why, although 65% of dream reports contain residues of recent waking activity, only 1.4% of them are considered to represent a replay of full memory episodes. During dreams, episodic elements might be reactivated in a fragmented fashion, but the deactivation of the prefrontal cortex prevents the various details of past events from being integrated into an identifiable life episode. Impairment in these areas might also explain the well-known amnesia on awakening that prevents most people from accurately remembering the events experienced during the dream episode.

Overall, PET studies have brought interesting hypotheses about human dream organization. However, these assumptions remain largely speculative and partial, especially because combined dream and functional imaging data are still very sparse. In future studies, the use of scales to quantify and categorize the dream narrative in terms of different perceptual, emotional, or bizarre elements should provide crucial explanatory variables to model neuroimaging data. This combination of systematic neuropsychological assessments of dreams with neuroimaging data might greatly improve our insight into dreaming mechanisms by bringing genuine functional maps of the dreaming brain.

Sleep and Memory

The idea that sleep is involved in the processing of information that should be memorized dates back to the theory of memory consolidation a century ago. Consolidation here refers to the processing of memory traces during which the traces may be reactivated, analyzed, and gradually incorporated into long-term memory. In addition to anecdotic similarities between brain areas activated in canonical maps of normal human sleep and learning-related areas, other PET studies have supported a role for sleep in learning and memory. These studies suggest that neuronal activity patterns observed during a learning episode are reinstated during posttraining sleep. These reactivations allow for the adaptation of intercellular connection strengths between the elements of the network and the incorporation of the new experience into long-term memory. Both REM sleep and non-REM sleep are differentially involved in these processes.

During REM sleep, but not during non-REM sleep, the premotor and visual cortical areas engaged in the implicit learning of a procedural motor task are reactivated in subjects previously trained, compared to non-trained subjects. Such reactivations do not occur if the subjects are trained in a random version of the same task, showing that processing during sleep is not merely due to intense task exposure but rather relies on the sequential content of the material. These data speak for the reprocessing during REM sleep of procedural memory traces acquired during previous wakefulness.

During non-REM sleep, but not during REM sleep, the hippocampal areas activated during a spatial learning task are reactivated in subjects previously trained, compared to nontrained subjects. This result suggests a reprocessing during non-REM sleep of recent spatial memory traces acquired during previous wakefulness. Moreover, this study demonstrated a significant correlation between rCBF increases in the hippocampal areas during non-REM sleep and an overnight gain in behavioral performance, supporting the hypothesis that this offline reprocessing is related to plastic changes underlying a subsequent improvement in performance.

PET studies have thus contributed to a large amount of evidence supporting a role of sleep in learning and memory. These results are in agreement with behavioral data suggesting that REM sleep and non-REM sleep differentially modulate the consolidation of procedural and spatial/episodic memories, respectively, in the model called the dual process hypothesis. However, other behavioral data support, and brain-imaging results do not oppose to, the sequential hypothesis, in which the ordered succession of non-REM sleep and REM sleep are necessary for the consolidation of memory traces, whatever the memory system. Furthermore, memory systems and mechanisms are complex and heterogeneous, and it remains unclear whether sleep influences all memory systems. Behavioral data already suggest that not all memories need sleep to consolidate. More studies are needed to refine the characterization of the precise contribution of each sleep stage in the processing of the different categories of memory traces.

Conclusion and Perspectives

PET studies have contributed to the understanding of human sleep neurophysiology by describing the functional neuroanatomy of sleep stages, by proposing brain correlates of dreaming features, and by showing cerebral reactivations during sleep of regions involved in prior learning. Yet our knowledge about normal human sleep remains fragmentary. These seminal studies only pave the way for future works that will benefit from the development of multimodal techniques such as combined EEG-fMRI. This neuroimaging method is technically more challenging in sleep studies, but it also has a number of advantages, including better spatial and temporal resolutions. This should help in describing more accurately the dynamics of brain activity throughout the sleep–wake cycle and especially in relation to the sleep physiological events, such as sleep oscillations. Future studies should also continue to characterize the specific extent of sleep's contribution to the learning and memory processes, which remains a topic of intense debates. There is no doubt that functional neuroimaging studies bring us significant insights into sleep functions (e.g., the relationships between sleep and brain plasticity) and sleep physiology, which is a prerequisite to the investigation of sleep disorders.

Introduction

Sleep is a prominent yet enigmatic animal behavior. Despite the apparent ubiquity of sleep and associated vulnerability that (in part) defines sleep, the functions of sleep remain elusive. The seemingly simplest approach to determining sleep's functions would be to compare animals that sleep with those that do not and then determine whether a relationship exists between various traits thought to be functionally involved in sleep and the presence or absence of sleep. However all animals adequately studied sleep in one form or another making such comparisons currently impossible. Nevertheless, of the 30 or more animal phyla, detailed sleep information is known for only two: Chordata (includes vertebrates) and Arthropoda (includes insects). Thus, there is an opportunity for truly sleepless animals to be discovered in the future. For example, sponges (phylum: Porifera) are nearest to the base of the Metazoan phylogenetic tree and lack a nervous system. Based on the generally accepted belief that a plastic nervous system is the biological target benefiting from sleep, sponges should not sleep.

Determining whether sleep evolved many independent times or only once early in the evolution of animals is of fundamental importance in contemporary comparative sleep research. With the application of genetic approaches to the study of sleep, it has become important to establish homology between sleep in mammals and sleep in invertebrates, such as the fruit fly (*Drosophila melanogaster*), where genomes generally have less redundancy and are amenable to manipulation. Establishing homology between sleep in fruit flies and sleep in mammals would reinforce the usefulness of invertebrate models for determining the molecular correlates of human sleep. Even without homology at the molecular level, comparative studies can enhance our understanding of sleep. For instance, evolutionary convergence (i.e., distantly related species that independently evolved similar sleep-related traits) can provide insight into sleep by revealing overriding principles otherwise obscured by nonessential traits specific to one lineage.

The lack of a highly resolved cladogram of sleep across Animalia has not impeded comparative analyses of sleep. Indeed, many studies have tried to determine the relationships between the time species spend asleep and various constitutive, physiological, and ecological traits. Historically, this approach has been applied only in mammals, in which the electrophysiological correlates of sleep have been identified and quantified in a large number of species; however, a recent study provides insight into the correlates of sleep in birds as well. Although the strengths of functional hypotheses derived from comparative analyses are necessarily limited given the correlational nature of the data, the evolutionary patterns gleaned from such analyses, especially those that employ modern phylogenetic statistical techniques, provide a framework for the development of experimentally testable hypotheses.

As with comparing sleep among taxonomic groups, changes in sleep occurring during early development can provide insight into the functions of sleep. For example, changes in sleep duration, intensity, or the relative proportion of the two sleep states in mammals and birds over early ontogeny might be functionally linked to the concurrent development of the central nervous system. In this article, we review current knowledge of sleep in various taxonomic groups and over early ontogeny, and we relate important patterns to existing hypotheses for the functions of sleep. By doing so, we demonstrate the contribution that comparative sleep research has made to our greater understanding of why we sleep.

Behavioral Definition of Sleep

Sleep is foremost an animal behavior broadly characterized by quiescence with reduced responsiveness to stimuli. Sleep can be distinguished from other quiescent states (e.g., hibernation) by rapid reversibility to wakefulness with sufficient stimulation and homeostatic regulation; that is, sleep shows a compensatory increase in intensity or time following sleep loss. Sleeping animals often retreat to a species-specific location and assume a characteristic posture. Although the occurrence of concurrent sleep and swimming in some aquatic mammals is an exception to the quiescence criterion, these criteria apply to the vast majority of animals studied, ranging from insects to mammals and birds.

Mammalian Sleep

Behavioral sleep is associated with specific changes in brain activity. Placental and marsupial (or therian) mammals exhibit two basic states of sleep: slow-wave sleep (SWS), also known as non-rapid eye movement

(non-REM) sleep, and REM sleep. In nonhuman animals, the term SWS usually refers to all non-REM sleep, whereas SWS refers only to stages 3 and 4 of non-REM sleep in humans. SWS is characterized by an electroencephalogram (EEG) of low-frequency, high-amplitude activity arising from the large-scale synchronous slow oscillations of neurons in the neocortex. SWS is homeostatically regulated with SWS-related slow-wave activity (SWA) (typically 0.5–4.0 Hz EEG power density) reflecting the intensity of SWS, as arousal thresholds are correlated with the amount of SWA and SWA increases as a function of prior time awake. REM sleep is characterized by an EEG of high-frequency, low-amplitude activity similar to wakefulness, with a hippocampal theta rhythm (between 4 and 9 Hz or higher depending on the species) observed in some mammals, and an atonic electromyogram. Heart and respiratory rate are irregular during REM sleep, and thermoregulatory mechanisms that rely on motor control are diminished. REM sleep does not appear to have an intensity component, although the time spent in REM sleep can increase following sleep loss. In mammals that engage in extended periods of wakefulness, the time spent in SWS is the greatest and SWS-related SWA is the highest early in the subsequent sleep bout, whereas the proportion of time devoted to REM sleep increases toward the end of the sleep bout.

Figure 1 Cladogram for amniotes showing the evolutionary appearance of slow-wave sleep (SWS) and rapid eye movement (REM) sleep. Here, SWS and REM sleep arose independently in the most recent common ancestor to mammals and the most recent common ancestor to birds. However, in mammals, REM sleep first appeared in the common ancestor to all mammals as a heterogeneous state with neuronal activity in the brain stem indicative of REM sleep (+REM*) occurring concurrently with EEG activity indicative of SWS. In the most recent common ancestor to placental and marsupial mammals, REM sleep and SWS became segregated into two distinct states, with EEG activation occurring in conjunction with REM sleep-related brain stem activity. Evidence suggests that reptiles engage in SWS, but without the EEG slow-wave activity similar to that observed in mammals and birds.

Monotremes

The study of sleep in monotremes, an egg-laying order of mammals that are the closest extant relatives to therian mammals (Figure 1), may provide insight into sleep in the most recent common ancestor to therian mammals. An early study of the short-beaked echidna (*Tachyglossus aculeatus*) found only EEG activity indicative of SWS during sleep, thereby suggesting that REM sleep evolved after the appearance of the therian lineage. The electrophysiological correlates of sleep in the echidna were reexamined using a combination of EEG and brain stem neuronal recordings. As in the earlier study, REM sleep with cortical activation was not observed. However, during sleep with cortical slow waves, brain stem reticular neurons fired in an irregular pattern similar to that observed in placental mammals during REM sleep. This suggests that aspects of REM sleep in the brain stem and SWS in the cortex occur concurrently. Moreover, an EEG-based study of the duck-billed platypus (*Ornithorhynchus anatinus*) suggests that this mixed sleep state is typical of monotremes (Figure 1). Although neuronal activity in the brain stem was not recorded, the platypus showed frequent rapid eye movements and twitching of the head and bill, similar to that associated with REM sleep in therian mammals, whereas the cortex exhibited an EEG pattern indicative of SWS. Based on the incidence of twitches, the time spent in REM sleep was estimated at up to 8 h per day, the highest in any animal. A comparison of sleep times with therian mammals is difficult to interpret, however, given the heterogeneous nature of sleep and the absence of cortical correlates of REM sleep in monotremes.

Aquatic Mammals

Sleeping in the water poses a significant challenge for air-breathing mammals. Among Cetaceans, the electrophysiological correlates of sleep have been recorded only in the Odontocetes (dolphins and porpoises). Dolphins and porpoises exhibit unihemispheric SWS (USWS), a mixed state in which one cerebral hemisphere shows EEG activity characteristic of deep SWS while the other shows a pattern indistinguishable from wakefulness (Figure 2). Although the lighter stages of SWS can occur concurrently in both hemispheres, deep SWS occurs only unihemispherically. Evidence suggests that SWS is homeostatically regulated independently in the two hemispheres, which is an example of regional use-dependent SWS homeostasis, a phenomenon discovered only recently in terrestrial mammals including humans. Dolphins and porpoises swim and

Figure 2 Examples of unihemispheric slow-wave sleep in the bottle-nosed dolphin (*Tursiops truncatus*). The EEG was recorded from the anterior, medial, and posterior neocortex. Note the high-amplitude, low-frequency activity indicative of slow-wave sleep (blue) in only the left (a) or the right (b) hemisphere concurrent with low-amplitude, high-frequency activity indicative of wakefulness (red) in the other hemisphere. Reproduced from Mukhameotv LM, Supin AY, and Polyakova IG (1977) Interhemispheric asymmetry of electroencephalographic sleep patterns in dolphins. *Brain Research* 134: 581–584, with permission from Elsevier.

surface to breath during USWS, but they can also float at the surface or rest motionless underwater. Given that the eye opposite the awake hemisphere remains open, USWS may allow dolphins and porpoises to monitor the environment for conspecifics and predators during sleep. Although behavioral signs of REM sleep (e.g., twitching and rapid eye movements) have been observed infrequently in quiescent Cetaceans, unequivocal REM sleep has not been recorded electrophysiologically, suggesting that Cetaceans have lost REM sleep secondarily. Nevertheless, REM sleep could occur in very small amounts or in a modified form in Cetaceans. Interestingly, manatees (order: Sirenia) also exhibit USWS and small amounts of REM sleep. Unlike Cetaceans and manatees, seals can sleep in the water and on the land. Seals in the family Phocidae hold their breath during periods of bilateral SWS and REM sleep underwater, whereas seals in the family Otariidae show interhemispheric asymmetries in the intensity of SWS while sleeping on the surface of the water.

Early Ontogeny of Mammalian Sleep

The time spent asleep changes greatly over early development. In mammals, newborns generally sleep the longest. This high amount of sleep declines over early ontogeny until it stabilizes at a species-specific level similar to that seen in adults. Sleep homeostasis

has been demonstrated in postnatal day 5 rats, before SWS and REM sleep appear in the EEG as differentiated states. Evidence suggests that SWS and REM sleep actually differentiate before the EEG shows sleep-related changes in cortical activity. The proportion of total sleep time devoted to REM sleep (%REM sleep) and SWS also changes greatly during the first postnatal weeks. Interestingly, the magnitude of these changes appears to be influenced by the degree of precociality at birth (Figure 3). Altricial mammals (those that are relatively more dependent on their parents at birth for food, warmth, and protection; e.g., rats and cats) show a marked reduction in %REM sleep through the first postnatal weeks (Figure 3) and show more exaggerated behavioral characteristics of REM sleep, such as rapid eye movements and twitches. Conversely, newborn precocial mammals (e.g., guinea pigs) are more developed relative to altricial mammals, and they exhibit a %REM sleep comparable with that of adults (Figure 3). These observations led (in part) to the hypothesis that REM sleep provides endogenous stimulation necessary for the early development of the central nervous system, particularly that related to the visual system. Indeed, experimental evidence implicates REM sleep in maturational processes of the visual system during early ontogeny. As discussed later, phylogenetic comparative analyses also support the idea that REM sleep facilitates early brain development.

Figure 3 Changes in the percentage of total sleep time devoted to rapid eye movement (%REM) sleep across early development in the rat, cat, and guinea pig. In the altricial rat and cat, REM sleep constitutes most of total sleep time and decreases to levels close to that of adults approximately 1 month after birth. Conversely, %REM sleep in the precocial guinea pig is relatively stable over early ontogeny and into adulthood. Note, however, that even as adults, altricial species have higher %REM sleep than more precocial species. Reprinted Jouvet-Mounier D, Astic L, and Lacote D (1970) Ontogenesis of the states of sleep in rat, cat, and guinea pig during the first postnatal month. *Developmental Psychobiology* 2: 216–239, with permission from John Wiley & Sons, Inc.

Unlike newborn terrestrial mammals, newborn Cetacean calves are continuously active, swimming alongside their mothers during the first few weeks postpartum. Although electrophysiological recordings have not been obtained during this period of activity, the calves close one eye intermittently while swimming underwater and, therefore, might be engaging in USWS. However, calves are unlikely to be engaging in REM sleep if REM sleep is incompatible with swimming. The possible absence of REM sleep in newborn calves during their first weeks of life seemingly challenges theories for a functional role of REM sleep in brain development; however, given that Cetacean calves are extremely precocial, REM sleep could nonetheless play a role in brain development *in utero*.

Avian Sleep

Birds are a particularly interesting taxonomic group in which to study sleep. Birds have brains comparable in relative size to those of mammals and cognitive abilities that include vocal learning and tool making; however, much of the avian forebrain is organized in a manner markedly different from mammals. Although the dorsal two-thirds of the avian forebrain (a region formerly thought to be primarily striatal) is derived from the same embryonic neural tissue (the pallium) that gives rise to the mammalian neocortex, the avian pallium is arranged in a nuclear manner that lacks the true laminar organization of the neocortex (Figure 4). Interestingly, despite this difference in pallial organization, birds are the only nonmammalian taxonomic group to show unequivocal SWS and REM sleep (Figure 1).

Like mammalian SWS, avian SWS is characterized by an EEG of low-frequency, high-amplitude activity. Birds that sleep predominantly at night (e.g., domestic hens, *Gallus domesticus*; European blackbirds, *Turdus merula*; nonmigrating white-crowned sparrows, *Zonotrichia leucophrys gambelii*) show slow-wave activity during SWS that is greatest early in the night and gradually declines thereafter in a manner suggestive of mammalian-like SWS homeostasis. Indeed, we recently demonstrated that pigeons (*Columba livia*) show a compensatory increase in SWS-related low-frequency EEG power density following short-term sleep deprivation, suggesting that mammalian and avian sleep is regulated in a similar manner.

Avian REM sleep also shares several features in common with mammals. REM sleep is associated with closure of both eyes, rapid eye movements, occasional bill movements, and behavioral signs of reduced muscle tone such as dropping of the head. However, muscle atonia has been observed only in

Figure 4 Modern consensus view of avian and mammalian brain relationships. Historically, much of the avian telencephalon was thought to be homologous to the mammalian striatum. However, converging lines of evidence demonstrate that the dorsal two-thirds of the avian telencephalon is actually derived from the pallium (green), the same neural tissue that gives rise to the mammalian neocortex. The new nomenclature reflecting this fundamental change in our understanding of brain evolution is depicted in the sagittal view of a zebra finch (left) and human (right) brain. Ac, accumbens; B, basorostralis; Cd, caudate nucleus; CDL, dorsal lateral corticoid area; E, entopallium; GP, globus pallidus (i, internal segment; e, external segment); HA, hyperpallium apicale; Hp, hippocampus; MV, mesopallium ventrale; IHA, interstitial hyperpallium apicale; L2, field L2; LPO, lobus parolfactorius; OB, olfactory bulb; Pt, putamen; TuO, olfactory tubercle. The several large, white regions are axon pathways (i.e., white matter) in the cerebrum. Lamina (cell-sparse zones separating brain subdivisions) are marked as solid white lines, primary sensory neuron populations are distinguished from neighboring regions by dashed white lines, and regions differing in cell density or size are demarcated by dashed gray lines. birds that can securely rest their head on the back. As in mammals, thermoregulatory responses are diminished during REM sleep. During REM sleep, the EEG reverts to a pattern similar to wakefulness, but often with lower amplitude. Unlike mammalian REM sleep, however, a hippocampal theta rhythm has not been found in birds. Episodes of REM sleep typically last 2–10 s and occur in clusters. The short duration of REM sleep episodes does not appear to be related to a need to maintain balance because REM sleep episodes are equally short when birds are sitting with their heads supported on their backs. In many birds, REM sleep increases throughout the night, in a manner similar to humans. In pigeons, this reflects an increase in the incidence and the duration of REM sleep episodes across the night. The proportion of total sleep time devoted to REM sleep appears to be lower in bird species (mean, 8%) than in mammalian species (mean, 17%). As in mammals, the time spent in REM sleep increases following sleep deprivation. Finally, since REM sleep and SWS have been recorded in every avian species investigated, both states were likely present in the most recent common dinosaur ancestor to birds (Figure 1).

Like aquatic mammals, birds often sleep with one eye open, a behavioral state associated with SWS in the hemisphere opposite the closed eye and EEG activity intermediate between wakefulness and SWS in the hemisphere opposite the open eye. Birds have the ability to switch from sleeping with both eyes closed to sleeping with one eye open in response to a perceived increase in the risk of predation. Here, birds direct the open eye toward the potential threat and are able to respond to threatening stimuli presented to the open eye. In contrast to mammals, where unihemispheric SWS occurs only in aquatic mammals, such interhemispheric asymmetries in slow-wave activity are common in birds and may be an ancestral trait. As in Cetaceans that swim in a coordinated manner during unihemispheric SWS, sleeping with one eye open and half the brain awake may allow birds to sleep during flight. Although there is strong evidence showing that birds, such as common swifts (*Apus apus*) and frigatebirds (*Fregata* sp.), spend periods lasting days to weeks or longer in constant flight, sleep in flight has not been confirmed with electrophysiological recordings.

Early Ontogeny of Avian Sleep

The ontogenetic development of avian sleep has been studied in relatively few species. In precocial chickens (*Gallus gallus*), the EEG correlates of SWS and REM sleep can be distinguished 1 day before hatching, whereas in the altricial pigeon (*Columba livia*) EEG activity is absent at hatching and does not resemble that of adults until 14 days later. Although it is

unclear whether chicken chicks show more or less REM sleep than adults shortly after hatching, the proportion of sleep allocated to REM sleep seems to reach adult levels within the first week post-hatch. Among altricial birds, the ontogeny of SWS and REM sleep has only been examined in magpies (*Pica pica*), in which juveniles sleep longer and have more REM sleep than adults. Additional studies on early sleep ontogenesis in species of greater taxonomic diversity are needed to determine whether the ontogenetic changes in sleep in altricial and precocial birds parallel those observed in mammals. Interestingly, chicken chicks that imprint on a moving object on the day of hatching exhibit more REM sleep during the first 3 h following imprinting than nonimprinted control chicks, suggesting that REM sleep may play a role in this acute form of learning. Sleep also appears to play a role in song learning in juvenile zebra finches (*Taeniopygia guttata*).

Sleep in Reptiles

The presence of SWS and REM sleep in all mammalian and avian species investigated suggests that either these states were present in the most recent common ancestor to extant mammals, birds, and reptiles or they evolved independently in mammals and birds. Several studies have attempted to distinguish between these alternatives by examining the electrophysiological correlates of sleep behavior in reptiles and, to a lesser extent, amphibians and fish. Unlike mammals and birds, however, where largely similar results have been obtained across species and laboratories, the results from reptiles have been less consistent and therefore subject to more diverse interpretations. Although some controversy persists, the EEG during reptilian sleep behavior typically shows intermittent high-voltage spikes arising from a background pattern similar to or slightly reduced in amplitude compared to quiet wakefulness. Because the incidence of spikes is correlated with arousal thresholds and increases following sleep deprivation, spikes appear to reflect sleep intensity. Studies have shown that these spikes originate in the reptilian hippocampus, thereby corroborating earlier pharmacological evidence indicating that reptilian spikes are comparable to similar spikes occurring in the mammalian hippocampus during SWS. Despite this similarity at the level of the hippocampus, however, the reptilian dorsal cortex does not generate concurrent high-amplitude slow waves typical of SWS in mammals and birds.

REM sleep has been reported in reptiles and fish based on the presence of eye, head, and limb movements during sleep. However, it remains unclear whether these behaviors truly reflect REM sleep-related twitching similar to that observed in mammals and birds or partial arousals from sleep. Although the presence of brain stem neural activity suggestive of REM sleep in sleeping echidnas raised the possibility that reptiles also exhibit REM sleep at the level of the brain stem, no sign of REM sleep was detected in the brain stem of sleeping turtles, despite the presence of neural structures involved in generating REM sleep in mammals. The presence of unequivocal SWS and REM sleep in mammals and birds, but not in reptiles, amphibians, or fish, suggests that these sleep states arose independently in the mammalian and avian lineages through convergent evolution (**Figure 1**).

Corticocortical Connectivity and SWS

Historically, the absence of slow waves in the EEG of sleeping reptiles has been attributed to the lack of a thick cortex similar to that which generates slow waves in mammals. However, the presence of slow waves in sleeping birds, despite the absence of a neocortex (**Figure 4**), demonstrates that the neocortex is not essential for the genesis of EEG slow waves. Instead, the extent of connections within the mammalian neocortex, avian hyperpallium, and reptilian dorsal cortex may explain why slow waves are present during sleep in mammals and birds but not reptiles (**Figure 5**). In mammals, corticocortical connections in layers II and III play an integral role in synchronizing the slow oscillation of neurons in a manner sufficient to generate slow waves in the EEG. In accord with the absence of slow waves in sleeping reptiles, the three-layered reptilian dorsal cortex lacks layers II and III, and it shows limited corticocortical connectivity (**Figure 5**). Furthermore, although birds lack a true neocortex, the hyperpallium shows extensive interconnectivity (**Figure 5**). Thus, the occurrence of sleep-related slow-wave activity in amniotes seems to be related to the extent of interconnectivity in the neocortex, hyperpallium, and dorsal cortex, although additional factors may also play a role.

A persistent question in sleep research is whether the EEG correlates of sleep are involved in the functions of sleep or simply reflect an epiphenomenon of the state. For example, the presence of slow waves in the EEG of sleeping mammals and birds may simply be an emergent property of a heavily interconnected neocortex and hyperpallium. Alternatively, as suggested by experimental work in mammals, the corticocortical connections that give rise to slow waves may also depend on slow waves to maintain the level of connectivity at an energetically and functionally adaptive level. Experimental evidence indicates that slow waves may also be involved in sleep-dependent memory processing and plasticity. Additional studies are needed, however, to determine whether slow

waves evolved independently in mammals and birds (and not in reptiles) to maintain their heavily interconnected brains and associated cognitive abilities, or whether similar processes occur during reptilian sleep in a manner undetectable in the EEG. As indicated by the presence of hippocampal spikes during sleep, at least some of the neural correlates of SWS seem to be present in reptiles (Figure 1). A comparison of sleep-related gene expression among mammals, birds, and reptiles may clarify the evolutionary history of SWS and REM sleep.

Comparative Perspectives on the Functions of Sleep

More is known about sleep in mammals than in any other group of animals. Electrophysiological sleep data exist for just less than 100 mammalian species. An examination of this comparative data set reveals that the time spent in SWS and REM sleep varies greatly across Mammalia. Many studies have tried to identify the evolutionary determinants responsible for maintaining such interspecific variation in the structure of sleep. The identification of significant predictors of sleep times may help shed light on the functions of SWS and REM sleep. For example, species with a higher mass-specific basal metabolic rate (i.e., basal metabolic rate per gram of body mass) were once thought to engage in more SWS, a relationship that could support an energy conservation role for SWS, because metabolic rates are lower during SWS. Additionally, it was once thought that species with greater encephalization allocated a lower proportion of time spent sleeping to REM sleep, seemingly refuting a neurophysiological role for REM sleep, such as memory processing and plasticity. However, excluding our own analysis, all comparative studies of sleep treated each species (or, in one case, family) as a statistically independent unit. Independence is a basic assumption of all statistical analyses, but species cannot be considered independent because they are related to one another through common

ancestry. Phylogenetic comparative methods (e.g., independent contrasts) were developed by evolutionary biologists to deal with such interspecific relatedness in comparative studies; however, until recently, these procedures had not been used in comparative sleep research.

In our analysis, we controlled for shared evolutionary history among species using independent contrasts and analyzed our phylogenetically controlled data using a multivariate analysis that incorporated hypotheses for the functions of SWS and REM sleep. Many of our results were different from those in previous studies. Unlike all previous studies, we found that species with greater encephalization (i.e., brain mass controlling for body mass using regression) allocate a greater proportion of time asleep to REM sleep, thus providing the first comparative support for a neurophysiological role for REM sleep. Although no relationship was found between encephalization and the time spent in SWS, cumulative slow-wave activity may be the more accurate measure of SWS. Contrary to some comparative studies and expectations under the energy conservation hypothesis, we found that species with a higher residual basal metabolic rate (BMR) engage in less SWS and sleep less altogether. These relationships might reflect increased foraging demands associated with higher residual BMR and thus less time available for sleep. Nevertheless, mammals with higher residual BMRs may obtain functionally comparable amounts of SWS by engaging in more intense SWS, although such intensity data are largely unavailable. Alternatively, the restorative processes occurring during sleep could be achieved more quickly with higher residual BMR and thus take less time to accomplish.

Predation risk should be among the strongest selection pressures influencing how to structure sleep and how long to sleep because sleeping is dangerous. Interestingly, the vulnerability associated with sleep may depend on the sleep state. For example, due to high arousal thresholds, deep SWS and REM sleep may be particularly dangerous sleep states from an antipredator standpoint. Indeed, in the context of our multivariate models, we found that species sleeping at relatively exposed or risky locations in the wild engage in less REM sleep and allocate a lower proportion of sleep time to REM sleep in the laboratory. Although the time spent in SWS was largely independent of predation risk, once again, SWS intensity may respond more strongly to the risk of predation. As per previous studies, we found that species more precocial at birth engage in less REM sleep as adults, a relationship that was not mediated strongly by predation risk because precocial species did not generally sleep in more vulnerable locations than relatively altricial species. The degree of precociality as a predictor of REM sleep time in adults may reflect an extension of the ontogenetic changes in REM sleep shown in **Figure 3**, which supports the idea that REM sleep is particularly important in early brain development. However, why high levels of REM sleep during early ontogeny should persist in adults remains enigmatic.

Correlates of Avian SWS and REM Sleep

As discussed previously, the electrophysiological correlates of avian sleep are remarkably similar to those observed in mammals. In addition to these similarities, there is also great variation in the time avian species spend in SWS and REM sleep. Thus, an obvious question is whether birds share the same evolutionary determinants of SWS and REM sleep as mammals? We addressed this question by conducting the first electrophysiologically based comparative analysis of avian sleep architecture using the same phylogenetically controlled variables as in our mammalian analysis. Overall, we found that birds that sleep at relatively exposed sites in the wild engage in less SWS in the laboratory, but this was the only significant relationship identified. Thus, if relationships identified in mammals reflect functional aspects of sleep architecture, then the same functions may not apply broadly to birds.

Sleep in Invertebrates

More than 97% of all animal life is invertebrates, of which 80% are arthropods, the taxonomic group which includes insects. Surprisingly, however, of the 30 or more animal phyla, sleep has been studied in only 2: Chordata (includes vertebrates) and Arthropoda (includes insects), with much work having been focused on the fruit fly (*Drosophila melanogaster*) and the honeybee (*Apis mellifera*). Sleep in honeybees is characterized as a sustained period of quiescence accompanied by increased arousal thresholds and specific postures (e.g., antennal immobility). Optomotor interneurons in the optic lobes of forager honeybees show lowered sensitivity during the subjective night, when forager bees are often quiescent, than during the subjective day. Sleep in honeybees was shown to be homeostatically regulated as antennal immobility increased following 12 h of sleep deprivation. Sleep has also been demonstrated in scorpions (*Heterometrus* and *Pandinus* spp.), cockroaches (*Blaberus giganteus* and *Leucophaea maderae*), and crayfish (*Procambarus clarkii*). Also, preliminary work suggests that sleep is present in three additional animal phyla: Nematoda (*Caenorhabditis elegans*), cephalopods (*Octopus vulgaris* and *Sepia pharaonis*) in the phylum Mollusca, and box jellyfish (*Chironex fleckeri*) in the phylum Cnidaria.

Conclusions

Our understanding of how and why we sleep has been enhanced by studies examining the evolution and ontogeny of sleep. The presence of SWS and REM sleep in all avian and mammalian species studied, and their apparent absence in reptiles, suggests that these states arose independently twice: once in the ancestor to birds and once in the ancestor to mammals (Figure 1). A comparison of neurocytoarchitecture among homeotherms suggests that the degree of corticocortical (or palliopallial) connectivity is responsible for EEG slow-wave activity in mammals and birds. Interestingly, REM sleep-related cortical activation evolved independently in the ancestor to therian mammals and the ancestor to birds (Figure 1). The similarity in the electrophysiological correlates of behavioral sleep in homeotherms suggests similarities in functions, possibly related to having heavily interconnected brains and associated cognitive abilities. However, in phylogenetically controlled comparative analyses, the evolutionary determinants of sleep times in birds were markedly different from those identified in mammals. Identifying the reasons for these differences is a promising area for future work.

Our understanding of the evolution, ontogeny, and functions of sleep would benefit greatly from studies in species representing broader phylogenetic diversity. Here, the study of species nearest the base of the Metazoan phylogenetic tree would be most revealing. A systematic approach to selecting taxa for study should be employed that takes into consideration neuroanatomy, neurophysiology, and phylogenetic position in the context of current hypotheses for the functions of sleep. Future work should also expand existing genetic work on fruit flies and rats to nonmammalian vertebrate taxa and to nonarthropod invertebrate taxa. The success of these endeavors will depend on the broad collaboration of animal behaviorists, evolutionary biologists, geneticists, and neurophysiologists, but will do much to aid our greater understanding of sleep.

Introduction

During slow-wave sleep, brain activity is dominated by oscillations, such as delta oscillations and slower oscillations. The thalamus, together with the cortex, participates in generating and sustaining these oscillations. Delta waves were observed in the isolated cortex *in vivo* by Frost and colleagues in 1966, and delta-wave activity has been found in the isolated thalamus as well in thalamic slices, although these are more regular than delta waves *in vivo*. The latter studies demonstrated that this form of delta-wave activity is generated intrinsically by the interplay of I_T and I_h currents in thalamocortical (TC) neurons. Slow oscillations (<1 Hz) can be generated by the cortex; they were observed in cortical slices by Sanchez-Vives and McCormick in 2000. A similar type of oscillation has also been observed by the group of V Crunelli to be an intrinsic property of thalamic neurons when metabotropic receptors are stimulated.

Spindle oscillations, which are mostly visible in the early stages of sleep (stage II in humans), are the best-studied sleep oscillation and are generated by thalamic circuits under physiological conditions. In contrast to delta and slow oscillations, for which cortical generators also exist, spindles are generated exclusively in the thalamus. We focus here on sleep spindles, their genesis by thalamic networks, how these oscillations are distributed across the entire TC system, and how they are modulated.

In the human electroencephalogram (EEG), spindle oscillations are grouped in short 1–3 s periods of 7–14 Hz oscillations, organized within a waxing-and-waning envelope, that recur periodically every 10–20 s. In cats and rodents, spindle waves of similar characteristics appear during slow-wave sleep and are typically more prominent at sleep onset. They are enhanced by some anesthetics, such as barbiturates, which, when administered at an appropriate dose, generate an EEG dominated by spindles. In ferret thalamic slices, spindle oscillations occur spontaneously. This *in vitro* model of spindle waves has made it possible to precisely characterize the ionic mechanisms underlying spindle oscillations.

The first indication that spindles could originate outside the cerebral cortex was from Bishop in 1936, who showed that rhythmical activity was suppressed in the cerebral cortex following destruction of its connections with the thalamus. In 1938, Bremer showed that rhythmical activity is still present in the white matter following destruction of the cortical mantle. Later, Adrian in 1941 and Morison and Bassett in 1945 observed that spindle oscillations persist in the thalamus on removal of the cortex, providing firm experimental evidence that these oscillations originate in the thalamus. These experiments led to the development of the thalamic pacemaker hypothesis, according to which rhythmic activity is generated in the thalamus and communicated to the cortex, where it entrains cortical neurons and is responsible for the rhythmical activity observed in the EEG.

Thalamic Pacemakers for Sleep Spindle Oscillations

The first cellular mechanism for the genesis of spindle oscillations was proposed by Andersen and Eccles in 1962. From intracellular recordings from TC relay neurons during spindles, they reported that TC cells fired bursts of action potentials interleaved with inhibitory postsynaptic potentials (IPSPs). They suggested that TC cells fire in response to IPSPs (postinhibitory rebound), which was later demonstrated to be a characteristic electrophysiological feature of thalamic cells by Jahnsen and Llinas. Andersen and Eccles suggested that the oscillations arise from the reciprocal interactions between TC cells and inhibitory local-circuit interneurons. This mechanism was later incorporated into a computational model that provided a phenomenological description of the inhibitory rebound.

The mechanism proposed by Andersen and Eccles was seminal but not entirely correct because reciprocal connections between TC cells and thalamic interneurons have never been observed in anatomical studies. It was later found by Scheibel and Scheibel that the thalamic reticular (RE) nucleus, a sheetlike structure of inhibitory neurons surrounding the thalamus, could provide the inhibition of TC cells and that TC-RE loops could underlie the recruitment phenomena and spindle oscillations. They predicted that the output of the RE nucleus should be inhibitory and that the inhibitory feedback from RE cells onto TC cells should be critical for the genesis of thalamic rhythmicity. This hypothesis was supported by the observation that the pattern of firing of RE neurons was tightly correlated with IPSPs in TC neurons.

Several critical experiments by the group of Steriade firmly established the involvement of the RE nucleus in the generation of spindles in cats *in vivo*. The typical intracellular features of spindle oscillations in the two thalamic cell types is shown in Figure 1(a). By using intracellular or extracellular experiments, it was shown that (1) cortically projecting thalamic nuclei lose their ability to generate spindle oscillations if deprived of input from the RE nucleus and (2) the isolated RE nucleus can itself generate rhythmicity in the spindle frequency range.

Thus, thalamic rhythmicity can be explained by three different mechanisms: the TC interneuron loops of Andersen and Eccles, the TC-RE loops of Scheibel and Scheibel, and the RE pacemaker hypothesis of Steriade (although Steriade's work also demonstrated the importance of the cortex; see the section titled 'Dialog between thalamus and cortex: emergence of large-scale synchrony'). The introduction of an *in vitro* model of spindle waves in ferrets by McCormick's group (Figure 1(b)) supported the second of these mechanisms. Slices of the visual thalamus that contain the dorsal (lateral geniculate nucleus (LGN)) and reticular nuclei (perigeniculate nucleus (PGN)) as well as the interconnections between them generated spindles spontaneously, confirming earlier experimental evidence for the genesis of spindles in the thalamus.

The *in vitro* preparation allowed detailed pharmacological investigation of the ionic currents and synaptic receptors underlying the spindle oscillations. The spindle waves disappeared after the connections between TC and RE cells were severed, consistent with the mechanism based on intrathalamic TC-RE loops proposed by Scheibel and Scheibel. This *in vitro* experiment also confirmed the observation that the input from RE neurons is necessary to generate spindles, as found by Steriade's group in 1985. However, the RE nucleus maintained *in vitro* did not generate oscillations without connections with TC cells, in contrast with the observation of spindle rhythmicity in the isolated RE nucleus *in vivo* by Steriade's group in 1987.

Thus, *in vitro* experiments appear to support a mechanism by which oscillations are generated by the TC-RE loop, in contrast with the RE pacemaker hypothesis. Computational models suggested a way to

Figure 1 Spindle oscillations in thalamic circuits: (a) *in vivo* intracellular experiments in cats under barbiturate anesthesia, showing the activity of thalamocortical (TC) and thalamic reticular (RE) cells during spindle waves; (b) *in vitro* intracellular experiments in ferret visual thalamic slices, showing the activity of the same type of thalamic neurons during spindle waves; (c) computational model of spindle waves generated by TC-RE interactions. The left drawing in (c) shows a simple circuit, consisting of two TC and two RE cells interconnected with glutamatergic (AMPA) and GABAergic receptors (GABA$_A$ and GABA$_B$). The right drawing in (c) shows the activity of two model neurons during simulated spindle waves. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; GABA, γ-aminobutyric acid. reconcile these apparently contradictory experimental observations. Models showed that both types of rhythmicities are possible and suggested ways to reconcile the experiments. First, different modeling studies found that oscillations very similar to isolated RE preparation *in vivo* could be generated by networks of RE cells. The oscillations were generated by the interaction between the rebound properties of RE cells, as provided by the T-type Ca^{2+} current I*T*, and γ-aminobutyric acid (GABA)-mediated IPSPs, consistent with experiments. Second, several modeling studies found that spindle oscillations with characteristics identical to those in the *in vitro* preparation could be generated from TC-RE loops (Figure 1(c)). In this case, the oscillations were dependent on I*T*-mediated rebound properties in the TC cells and GABA-mediated IPSPs, together with excitatory postsynaptic potential (EPSP)-evoked bursts in RE cells. Third, it has been proposed that the differences observed between spindles *in vitro* and *in vivo* could be explained by the limited connectivity between the RE neurons in the slice and/or insufficient levels of neuromodulation in the slice needed to maintain isolated RE oscillations.

Dialog between the Thalamus and Cortex: Emergence of Large-Scale Synchrony

The initiation and distribution of spindle oscillations in large circuits was investigated more recently by using multiple recordings *in vivo* and *in vitro* (Figures 2(a) and 2(c)). Spindle oscillations *in vitro* show traveling wave patterns, with the oscillation typically starting on one side of the slice and propagating

Figure 2 Control of spindle oscillations by the cerebral cortex: (a) multisite extracellular recordings *in vitro* showing the propagating activity of spindle waves in the visual thalamic slice; (b) model of propagating spindle wave activity in thalamic networks with topographic connectivity; (c) multisite extracellular recordings in the thalamus of cats *in vivo* showing the large-scale synchrony of spindle waves in the intact thalamocortical (TC) system; (d) model of the TC network showing large-scale synchrony. to the other side at a constant propagation velocity (Figure 2(a)). In contrast to thalamic slices, the intact TC system *in vivo* does not display such clear-cut propagation, but spindle oscillations are remarkably synchronized over extended thalamic regions and show very limited traveling-wave activity (Figure 2 (c)), in agreement with early observations. Moreover, a study by Contreras and colleagues in 1996 showed that large-scale synchrony was lost when the cortex was removed, suggesting that, although the oscillation is generated by the thalamus, its synchrony depends on the cortex. However, cutting intracortical connections has no effect on large-scale synchrony, so cortical connections are not responsible for organizing the synchrony of sleep spindles.

The mechanisms for large-scale synchrony were investigated by computational models by first simulating the propagating properties found in slices (Figure 2(b)). These models assumed a topographic connectivity between TC and RE layers and could generate traveling spindle waves consistent with *in vitro* data. Second, a model by Destexhe and colleagues in 1998 simulated TC networks with bidirectional interactions between the cortex and thalamus and showed that all experiments could be reproduced under the assumption that the cortex recruited TC cells primarily through inhibition. This inhibitory-dominant cortical feedback to the thalamus is consistently observed experimentally and can explain large-scale synchrony by the mutual recruitment of thalamic and cortical networks (Figure 2(d)). The same mechanism can also explain the genesis of absence-type of epileptic seizures when the excitability of cortical neurons is too high. The concept of cortical control of thalamic spindle oscillations can be generalized to other oscillation types, and it was proposed by Steriade that the slow oscillation organizes spindle oscillations, delta oscillations, and more complex patterns such as K-complexes.

Control of Sleep Oscillations by Neuromodulators

Neuromodulators such as acetylcholine (ACh), norepinephrine, (NE), serotonin, (5-HT), histamine (HA), and glutamate abolish the low-frequency rhythms in TC systems during sleep. In the thalamus, where both the relay neurons and the reticular thalamic cells are hyperpolarized during sleep, the activation of the neuromodulatory systems depolarizes the thalamic cells by 5–20 mV, inactivating the low threshold Ca^{2+} current and inhibiting bursting. The transition to tonic firing enhances the participation of sensorimotor processing, which is blocked during sleep.

Conclusion

The thalamus shifts during sleep from a tonic mode, suitable for relaying information from the periphery to the cortex, to a rhythmic mode that generates activity and produces highly spatially and temporally coherent states through interactions with the cortex. During sleep, the feedback connections from the cortex to the thalamus become highly effective in globally coordinating activity in the thalamus. Thus, the thalamus becomes a mirror during sleep, linking distant parts of the cortex. This could be important for maintaining and adjusting the overall balance of activity in the cortex.

The Molecular Correlates of Sleep May Offer Clues to Its Functions

All animal species studied so far sleep, and sleep may serve multiple functions, which may differ in different species. It is possible, however, that sleep also has a core function that is conserved from invertebrates to mammals. If this is the case, that function is most likely a cellular one, because flies and humans share most pathways for intercellular and intracellular signaling, from membrane receptors and ion channels to nuclear transcription factors, but differ significantly in the number, anatomy, and complexity of brain circuits. The idea that the functions of sleep may ultimately relate to cellular and molecular aspects of neural function is not new. Giuseppe Moruzzi argued that "... sleep concerns primarily not the whole cerebrum, nor even the entire neocortex, but only those neurons or synapses, and possibly glial cells, which during wakefulness are responsible for the brain functions concerned with conscious behavior...." (Moruzzi, 1972). Moruzzi suggested that neural cells or synapses supporting waking conscious activity undergo plastic changes that make sleep necessary, although he did not speculate about the mechanisms. Others have suggested that sleep may help in restoring brain energy metabolism, may be needed to maintain the synaptic efficacy of the neural circuits not frequently used during wakefulness, or may favor a generalized synaptic downscaling following waking-induced synaptic potentiation. It has also been suggested that the rich spontaneous activity of neocortical neurons during slow-wave sleep may consolidate memory traces acquired during wakefulness. Several of these hypotheses are not mutually exclusive, and sleep may actually favor different cellular processes.

The analysis of the molecular correlates of sleep and wakefulness may help to understand the benefits that sleep brings at the cellular level. More specifically, the identification of the genes whose expression changes in the brain between sleep and wakefulness may clarify if, and why, brain cells need sleep and why their functions are impaired if they are prevented from doing so during sleep deprivation. In the last 15 years, subtractive hybridization, mRNA differential display, and microarrays have emerged as new powerful methods in transcriptomics, the study of the complete set of RNA transcripts produced by the genome at any one time. Microarrays are currently the most comprehensive and sensitive method to detect genome-wide expression changes, and have allowed the identification of hundreds of transcripts whose expression is modulated by behavioral state. In addition, transcriptomics analysis has also identified functional categories of genes whose expression varies during sleep, wakefulness, and after different periods of sleep deprivation. At least some of these gene categories are conserved from invertebrates to mammals.

Table 1 lists the studies that used transcriptomics approaches to identify genes whose transcript (mRNA) levels vary as a function of sleep, wakefulness, and/or sleep deprivation. It is clear from the table that the main focus has been so far on the cerebral cortex, although other brain regions have recently been studied, including cerebellum, hypothalamus, and brain stem. The cerebral cortex is of major interest because it is responsible for the cognitive defects observed after sleep deprivation, and it is at the center of most hypotheses concerning the functions of sleep.

Several general conclusions can be drawn from the studies listed in Table 1. Each of them is further discussed below.

1. Hundreds of genes in the brain change their expression due to a change in behavioral state.
2. Some genes increase their expression during sleep, others during waking and sleep deprivation.
3. Sleep and waking genes belong to different functional categories.
4. Three functional categories of waking genes are conserved from flies to mammals.
5. The noradrenergic system plays a role in the induction of some waking genes.
6. The expression of several genes changes after chronic, but not acute sleep loss.

Hundreds of Genes in the Brain Change Their Expression between Sleep and Waking

A first important finding of the recent transcriptomics studies is that gene expression in the brain changes extensively as a function of behavioral states, sleep, spontaneous wakefulness, short-term (a few hours) or long-term (several days) sleep deprivation. Five percent or more of the transcripts tested in the brain show changes in gene expression according to behavioral state. Interestingly, a similar percentage of genes (from 1% to 10%) changes because of differences in

IEGs, immediate early genes; ESTs, expressed sequence tags.

circadian time. In the cerebral cortex of rats, out of the 15 459 transcripts we tested, 808 (5.2%) were affected by time of day, independently of behavioral state, and 752 (4.9%) were affected by sleep and wakefulness independently of time of day. These data indicate that, at least in the rat, day/night time and sleep/wakefulness influence gene expression in the cerebral cortex to a similar extent. Peripheral tissues such as liver and heart also show significant changes in gene expression as a function of circadian time. Whether this is also true for sleep-dependent and wakefulness-dependent genes is currently unknown, because none of the array studies published so far has focused on peripheral tissues.

Some Genes Increase Their Expression during Sleep, Others during Waking and Sleep Deprivation

We found that in the rat cerebral cortex 95 known genes and 395 expressed sequence tags (ESTs) (i.e., short transcribed sequences whose function is still unknown) show higher expression after 8 h of spontaneous wakefulness or sleep deprivation, while 106 known genes and 155 ESTs show increased expression after 8 h of sleep. In the fly head, in which we used the same experimental protocol previously applied to rats (three experimental groups, including 8 h of sleep, 8 h of spontaneous wakefulness, and 8 h of total sleep deprivation), we identified 121 waking transcripts, including both known genes and ESTs, and 12 sleep transcripts, mostly unknown. Finally, we recently compared gene expression in the cerebral cortex of long-term sleep deprived rats and sleeping controls, and found that 226 transcripts are upregulated after long-term sleep deprivation, and 113 after sleep. Thus, it seems that if all transcribed sequences are considered (including ESTs), there are more genes whose expression is upregulated during waking than during sleep. However, hundreds of genes are also upregulated during sleep, confirming the results of intracellular recording studies that show that sleep is far from being a quiescent state of global inactivity. In general, the largest fold changes are observed for waking genes. However, this is mainly due to the fact that waking increases the expression of transcription factors (e.g., c-fos) and effector genes (e.g., Arc) that behave as 'immediate early genes,' whose mRNA and protein levels may increase several folds relative to sleep. Most waking and sleep genes, instead, change their expression by 20–50%, a fold change similar to that seen for most genes whose expression varies because of circadian time.

Sleep and Waking Genes Belong to Different Functional Categories

Sleep and waking transcripts belong to different functional categories, and thus may favor different cellular processes. Most genes whose expression increases during wakefulness (or short-term sleep deprivation) code for proteins involved in energy metabolism, synaptic excitatory transmission, transcriptional activity, acquisition of new information, and the response to cellular stress. Sleep genes, instead, code for proteins involved in protein synthesis, synaptic downscaling and/or memory consolidation, lipid metabolism, and in membrane trafficking and maintenance.

Three Functional Categories of Waking Genes Are Conserved from Flies to Mammals

Three functional categories of genes are consistently induced in several animal species (fruit flies, mice, rats, hamsters) during waking and short-term sleep deprivation relative to sleep. The first one includes genes involved in energy metabolism, including mitochondrial genes such as cytochrome oxidase (CO) I and IV. One study in rats also found an increase in CO enzymatic activity after 3 h of wakefulness. In mice, 6 h of sleep deprivation also affect the mRNA levels of genes involved in glycogen metabolism (glycogen synthase and glycogen phosphorylase), and increase the activity of glycogen synthase, possibly to counterbalance the rapid depletion, at the transition from sleep to wakefulness, of astrocytic glycogen stores. Eight hours of spontaneous waking or sleep deprivation also induce the expression in the rat cerebral cortex of *Glut1*, the gene coding for one of the more widely expressed glucose transporter in the CNS. The upregulation during waking of genes involved in energy metabolism is perhaps not surprising, because glucose metabolism in many brain regions is higher in wakefulness than in non-rapid eye movement (NREM) sleep, and the brain relies almost exclusively on glucose as its energy substrate. These changes, however, do not seem to persist when sleep deprivation is protracted for 24 h or several days. This is consistent with imaging studies in animals, normal human subjects, and fatal familial insomnia patients, showing no change or a decrease in cerebral metabolic rate after prolonged sleep loss relative to normal wakefulness. Thus, the rapid upregulation of mitochondrial genes, *Glut1*, and glycogen-related genes may represent a mechanism by which the brain responds to the immediate increase in energy requirement during spontaneous waking or after a few hours of sleep deprivation,

while prolonged sleep loss is associated with reduced energy demands.

A second group of genes consistently upregulated during wakefulness and downregulated during sleep includes heat shock proteins, chaperones, and, in general, genes involved in the response to cellular stress. Cellular stress is the cell's reaction to any adverse environmental condition that perturbs cellular homeostasis, with potential macromolecular damage, that is, damage to proteins, DNA, RNA, and lipids. Wakefulness and short-term deprivation are associated with higher mRNA levels of small heat shock proteins with actin-stabilizing properties, such as HSP27 and alpha-B crystallin, molecular chaperones (HSP70, HSP60), and chaperones in the endoplasmic reticulum, such as BiP and Grp94. BiP (immunoglobulin heavy chain-binding protein) shows the largest and most consistent upregulation in the brain of awake animals, including mice, rats, hamsters and sparrows (Cirelli et al., unpublished observations), as well as in the head of fruit flies. BiP assists in the folding and assembly of newly synthesized glycoproteins and secretory polypeptides and increases in *BiP* expression have been classically described after heat shock and ischemia, when unfolded proteins accumulate in the endoplasmic reticulum. This unfolded protein response is also induced by other conditions that adversely affect the function of the endoplasmic reticulum, such as anoxia, glucose deprivation (BiP is also called glucose-regulated protein 78), and depletion of Ca^{2+} stores in the endoplasmic reticulum. Importantly, the unfolded protein response also triggers a slowing down of protein synthesis. In the rat cerebellum, 8 h of spontaneous wakefulness or sleep deprivation are associated with an increase in the mRNA levels of *PEK*. *PEK* codes for the EIF2a kinase that mediates the inhibition of protein synthesis during the unfolded protein response. Moreover, in the mouse cerebral cortex, 6 h of sleep deprivation are also associated with signs of slowing down of protein synthesis, as indicated by the phosphorylation of the key component of the translational machinery and by changes in the ribosomal profile.

A third group of genes consistently upregulated during wakefulness and downregulated during sleep include transcripts sensitive to membrane depolarization and synaptic activity. In the rat cerebral cortex, they include *RGS2*, *Homer/Vesl*, *tissue-type plasminogen activator*, *casein kinase 2*, *cyclooxygenase 2*, *cpg2*, and *connexin 30*. Moreover, several genes involved in activity-dependent neural plasticity and long term potentiation, such as *Arc*, *BDNF*, *Homer/Vesl*, and *NGFI-A*, have been consistently found to be upregulated in the cerebral cortex of awake or short-term sleep deprived rats. At least some of the same genes are induced during wakefulness and/or short-term sleep deprivation in mice, hamsters, and sparrows (Cirelli et al., unpublished results). In the fly head, many of the depolarization-sensitive genes involved in synaptic plasticity as identified in Guan et al. are also waking-related genes, including *Astray*, *Kek2*, *stripe*, and *Hr38*. The fly wakefulness-related gene *stripe* is a member of the Egr family of transcription factors. In the rat brain several members of this family, including *NGFI-A* (*Egr-1*), *krox 20* (*Egr-2*), and *NGFI-C* (*Egr-4*), are induced during wakefulness. *Hr38*, another fly wakefulness-related gene, is the *Drosophila* ortholog of the mammalian NGFI-B family of orphan nuclear receptors. *NGFI-B* is a wakefulness-related gene in the rat cerebral cortex. Thus, it seems that in both mammals and flies several plasticity-related genes involved in synaptic growth and potentiation are specifically induced during wakefulness.

The observation that genes involved in long-term potentiation and the acquisition of new memories are specifically induced during wakefulness should not be too surprising. After all, we learn when we are awake and able to adapt to the environment, and not when we are asleep. But if sleep is not involved in learning, is there a role for it in other aspects of synaptic plasticity? Well-controlled new experiments show that sleep may favor the performance of some, but not all, tasks. The strongest and more consistent data relate to procedural tasks, and suggest an important role for NREM sleep or a combination of NREM and REM sleep. What remains unknown, however, are the mechanisms by which sleep may enhance performance. Animal and human studies have shown that brain circuits activated during the execution or the acquisition of certain tasks are 'reactivated' during the subsequent sleep period. The presence of this memory trace, as shown by electrophysiological recordings and imaging studies, could reflect the fact that sleep replays the waking experience, and by doing so somehow allows the specific consolidation of the learned tasks. However, it is also possible that this trace is the inevitable consequence of the synaptic potentiation occurred during learning, and that sleep enhances performance by actually allowing a generalized downscaling of synapses. The first and most important effect of this downscaling is thought to be the decrease in the metabolic cost of synaptic activity, which increases during waking due to synaptic potentiation. A second effect of the generalized but proportional decrease in synaptic weight is an increase in the signal to noise ratio, which could improve the performance of some learned tasks.

If sleep is associated with a generalized depression of synaptic strength, molecular markers of synaptic depression should be increased during sleep relative to waking. Recent studies have identified and validated several specific and direct markers of synaptic strength, the best established among them being the density, composition, and phosphorylation state of the GluR1 subunit of the glutamatergic AMPA receptors. We are currently measuring the number and phosphorylation state of synaptic GluR1 in the rat cerebral cortex after 6 h of sleep or sleep deprivation. Preliminary results show that in several cortical areas, sleep is associated with a relative dephosphorylation of GluR1 at serine 845, a finding consistent with the hypothesis that sleep is associated with synaptic downscaling.

The Noradrenergic System Plays a Role in the Induction of Some Waking Genes

One of the mechanisms that underlie the widespread changes in cortical gene expression between sleep and wakefulness is the activity of the noradrenergic system of the locus coerulues (LC), whose neurons project diffusely over the entire brain. LC cells are tonically active during wakefulness, reduce their firing rate during NREM sleep, and cease firing during REM sleep. Moreover, LC activity increases phasically in response to salient events and in relation to the decision to act. In a series of experiments rats were subjected to unilateral or bilateral LC lesions to deplete one or both sides of the brain of norepinephrine. In these animals the raw EEG and its power density spectrum were not significantly affected by the lesion. However, all cortical areas depleted of norepinephrine showed a marked decrease, during wakefulness, of the expression of plasticity-related genes such as *Arc*, *BDNF*, *NGFI-A*, and *P-CREB*, as well as of stress response genes such as heat shock proteins and *BiP*. By contrast, the transcript for the translation elongation factor 2 was the only known sleep-related transcript whose expression increased after LC lesion (Figure 1). In a complementary experiment in mice the activity of the LC of one side was increased using a conditional transgenic approach. This manipulation resulted in an increased ipsilateral expression of *NGFI-A* in cortical and subcortical target areas. Thus, LC activity during wakefulness modulates neuronal transcription to favor synaptic potentiation and memory acquisition and to counteract cellular stress, while LC inactivity during sleep may play a permissive role to enhance brain protein synthesis.

Figure 1 Schematic representation of the major functional categories of genes upregulated in the rat cerebral cortex after 3–8 h of spontaneous waking or sleep deprivation (acute sleep loss), 1 week of total sleep deprivation (chronic sleep loss), and 8 h of spontaneous sleep.

The Expression of Several Genes Changes after Chronic, but Not Acute Sleep Loss

In a recent array study we analyzed the expression of >26 000 transcripts in the cerebral cortex of long-term sleep deprived rats. Animals were kept awake for 7 days using the disk-over-water method (DOW). This method uses minimal stimulation to enforce chronic sleep deprivation in the sleep-deprived rat, while it simultaneously applies to the control rat the same stimulation, but without severely limiting its sleep. The sleep-deprived and the control rat are housed each on one side of a divided horizontal disk suspended over a shallow tray of 2–3 cm deep water. EEG and EMG are continuously recorded to detect sleep states. When the experimental rat falls asleep, the disk is automatically rotated at low speed, awakening the rat and forcing it to walk opposite to disk rotation to avoid being carried into the water. The yoked control rat receives the same physical stimulation because it is on the same disk. However, while sleep is severely reduced (by 70–80%) in the sleep deprivation rat, the control rat can sleep whenever the sleep deprived rat is spontaneously awake and eating, drinking, or grooming and thus its sleep is only reduced by 25–40%.

We compared long-term sleep deprived rats with rats spontaneously awake or sleep deprived for only 8 h, and identified 75 transcripts upregulated, and 28 transcripts downregulated after chronic sleep loss. Most transcripts specifically increased or decreased their expression due to the long-term sleep deprivation and not because of the disk stimulation, because they were not affected in the yoked controls. A large

group of genes upregulated after prolonged sleep loss codes for immunoglobulins, including two autoantibodies. Another group includes stress response genes such as the macrophage inhibitor factor-related-protein MRP14, expressed in microglia. Aryl-sulfotransferase, an enzyme involved in the catabolism of catecholamine, is also upregulated after chronic sleep deprivation. These genes are either not induced (antibodies, MRP14), or induced to a lesser extent (aryl-sulfotransferase) after acute sleep loss, suggesting that short-term and long-term sleep deprivation differ to some extent at the molecular level. We also compared long-term and short-term sleep deprivation to sleep, and found that only a minority of genes were similarly up- or downregulated in the two sleep deprivation conditions. Among the genes whose expression was most significantly downregulated in long-term sleep deprived animals relative to sleeping animals were myelin constituents, including the most abundant structural protein component of myelin, the proteolipid protein. These findings suggest that sustained sleep loss may trigger a generalized inflammatory and stress response in the brain. Some glial cells (e.g., microglia) may help to protect neurons against this cellular insult, but others (e.g., oligodendrocytes) may also suffer some of its negative consequences. It will be important in the future to test whether sleep loss may be detrimental to the maintenance of cellular membranes and more specifically to myelin.

Genes Upregulated during Sleep

Figure 1 shows the sleep-related transcripts identified so far in the rat cerebral cortex . Unfortunately, so far only one study in mammals was designed to identify genes upregulated after several (8) hours of sleep relative to both spontaneous waking and sleep deprivation, to rule out effects of stress and of circadian time. Another study in flies used the same experimental conditions used in rats, but for technical reasons the entire fly head, rather than the brain only, was used to hybridize the arrays. This most likely decreased the ability to detect state-dependent genes. Only 12 genes were identified as sleep related in flies, and the function of most of them is currently unknown. Thus, the extent to which sleep genes are conserved across species is yet to be determined.

Two sleep genes in the rat cerebral cortex code for the translation elongation factor 2 and the initiation factor 4AII, and are involved in protein synthesis. The mRNA levels of the elongation factor EF2 are also increased during sleep in the brain of Djungarian hamsters (Cirelli et al., unpublished results). A positive correlation between sleep and protein synthesis has been suggested by previous studies, and recent evidence suggests that waking and sleep deprivation are less conducive to protein synthesis than sleep. Whether sleep favors protein synthesis globally, or whether it enhances the synthesis of specific classes of proteins is still unclear.

Other sleep genes identified in the rat cerebral cortex are involved in the consolidation of long-term memory, as well as in synaptic depression and depotentiation. Among them are *calmodulin-dependent protein kinase IV*, *calcineurin*, *FK506 binding protein 12*, *inositol 1,4,5-trisphosphate receptor*, and *amphiphysin II*. As mentioned above, the mechanism by which sleep enhances memory and performance is still debated, but these molecular data are compatible with the idea that sleep benefits the brain by producing a global synaptic downscaling.

Another large group of sleep-related transcripts in the rat cerebral cortex is involved in membrane trafficking and maintenance. Some of these transcripts are important for the synthesis/maintenance of membranes in general and of myelin in particular, including oligodendrocytic genes coding for myelin structural proteins (e.g., *MOBP*, *MAG*, *plasmolipin*, *CD9*), myelin-related receptors and enzymes. Transcripts with higher expression in sleep also code for enzymes involved in the synthesis and transport of cholesterol, a major constituent of myelin and other membranes and an important factor in regulating synaptic efficacy. As mentioned above, long-term sleep deprivation decreases the expression of the gene coding for proteolipid protein, a major myelin component. Intriguingly, among the few known sleep genes in *Drosophila* is the gene *anachronism* (*ana*), as well as three genes involved in lipid metabolism (*CG8756*, *CG9009*, *CG11407*). Ana is a glycoprotein secreted by glial cells, and controls the timing of neuroblast development. Whether *ana* plays any role in membrane trafficking and synaptic plasticity remains to be determined.

Conclusions

As it is apparent from the small number of studies in Table 1, transcriptomics analysis is still a work in progress, and it would be inappropriate to draw firm conclusions from what has been published so far. Continuous improvement in the array technology will certainly favor more progress in this area. For instance, the current arrays can assess the expression of 20 000–30 000 transcripts, but this is still far from been a true 'whole-genome' analysis. Low-expression genes are often difficult to detect, especially in large and heterogeneous tissue samples such as most brain areas. Moreover, current arrays focus on the coding portion of the genome, but new 'tiling' arrays, in

which probe sets are laid down at regular intervals across the entire genome, are becoming commercially available. This will permit the identification of new transcriptionally active regions of the genome that have currently not been tested in more conventional arrays. Moreover, proteomics, the study of the complete repertoire of proteins that contribute to a cell's physiological phenotype, is a natural next step in the study of molecular correlates of behavioral states.

Sleep Apnea

Sleep Apneas Are Neurally Mediated

Distinguishing the types of sleep-disordered breathing events and sleep apnea syndromes is of utmost importance in gauging patient risk and guiding optimal therapy. The term apnea is defined in the adult as cessation in ventilatory airflow for 10 s or longer. In children, cessation of airflow for any duration qualifies as an apnea. Sleep apnea syndromes have been divided into two categories: obstructive and central sleep apnea. This terminology has led to confusion because it implies neural and mechanical processes for central and obstructive apneas, respectively. Indeed, a common misperception is that obstructive sleep apnea (OSA) has a primarily physical etiology (a fixed obstruction in the upper airway), whereas central sleep apnea (CSA) involves alterations in neural input. It is essential to understand, however, that all sleep-disordered breathing syndromes, including OSA, occur only during sleep and thus involve sleep-dependent changes in neural drive to various ventilatory and airway stabilizer muscles. During wakefulness, individuals with OSA have normal ventilation and no significant upper airway obstruction. In wakefulness, these individuals effectively use upper airway muscle to stent open the upper airway. A normal consequence of sleep is reduced neural drive to many muscle groups, including upper airway dilator muscles (e.g., muscles of the tongue and soft palate reduce muscle activity). The termination of an obstructive apnea typically requires wakefulness with resumption of upper airway muscle activity. In other words, the obstructive process in OSA is dynamic and neurally mediated. The neural mechanisms by which OSA occurs may differ for nonrapid eye movement (NREM) and rapid eye movement (REM) sleep. There are differences in neurochmeical drive to the upper airway dilator motor neurons in NREM and REM sleep, and subsets of individuals with OSA are affected differentially in the two distinct sleep states. Specifically, a fraction of patients with OSA have apneas exclusively in REM sleep, whereas others have events in both sleep states but may have more frequent events in NREM sleep than in REM sleep. In most patients, reductions in arterial oxygen levels induced by apneas are more pronounced in REM sleep because REM sleep atonia of chest wall muscles compromises lung volume and oxygenation.

Individuals with CSA do not have increased collapsibility of the upper airway and therefore do not rely on upper airway muscles to maintain patency. There are two major neural mechanisms underlying central apneas. First, in one group of individuals with CSA, ventilatory drive is markedly less in sleep than in wakefulness, and thus a transition into sleep can induce an apnea. These patients are most likely to have apneic events in stages 1 and 2 NREM sleep, when a sigh at the termination of one apnea can lower the $PaCO_2$ sufficiently to initiate the next apnea. In the second group of patients with CSA, there is a reliance on respiratory muscles other than the diaphragm for ventilation. In NREM sleep, these accessory muscles are somewhat suppressed, and in REM sleep the muscles may have atonia. Thus, in these individuals, CSA is expected to be most pronounced in REM sleep.

A second basic concept regarding sleep apnea and its terminology is that not all significant sleep-disordered breathing events are apneas. This concept is most relevant for OSA, for which epidemiological studies justify inclusion of other ventilatory disruptions. In fact, a partial reduction in ventilation occurring with a drop in the oxyhemoglobin desaturation or with an arousal may result in as much sleepiness as apnea events of the same frequency. Clinically significant OSA events occur along a spectrum from what is termed respiratory effort-related arousals (an airflow limitation with an arousal but normal ventilation) to hypopneas (commonly defined as 30–90% reductions in ventilation, measured as airflow, with a 4% decline in the oxyhemoglobin saturation) to apneas (as defined previously). These clinical definitions are relevant because respiratory effort-related arousals and hypopneas can cause significant sleepiness, whereas hypopneas may contribute to cardiovascular disease. These types of disordered breathing events are categorized and defined in Figure 1. Disease severity for OSA is defined by the frequency of apnea and hypopnea events per hour of sleep. The American Academy of Sleep Medicine defines mild, moderate, and severe sleep apnea as 5–15, 16–30, and more than 30 apneas and/or hypopneas per hour, respectively. The mathematical modeling for OSA disease severity and morbidity risk, however, is not complete, and it is anticipated that future definitions of severity of OSA will include a factor for the magnitude of oxygenation changes, the time spent hypoxic, and/or the degree to which sleep is fragmented, as described later.

Figure 1 Delineation of sleep apnea syndromes and definitions of sleep-disordered breathing events.

Epidemiology and Genetics of Sleep Apnea

Beyond the common mechanistic theme of sleep-related reductions in neural drive to ventilatory muscles, the pathogeneses for OSA and CSA are remarkably distinct. Consequently, the various sleep apnea syndromes have minimal overlap in epidemiology and genetic bases.

Obstructive Sleep Apnea

The prevalence and/or severity of OSA vary with gender, age, family history, and ethnicity. Specifically, the prevalence of symptomatic OSA (OSA with sleepiness or fatigue) in adults in North America, Europe, and in select regions of Asia is 4–7% for males and 2% or 3% for females. In prepubertal children, there are no apparent gender differences. Prevalence increases with age, rising to more than 40% in elderly individuals. Although some studies have shown increased prevalence of OSA in females after menopause, longitudinal studies are needed to better delineate hormonal and aging effects on OSA. The prevalence of OSA in subjects in the Sleep Heart Health Study appears not to vary with race. However, it is clear that the severity of OSA is greater in age-matched African American versus Caucasian individuals, and overall, OSA develops at an earlier age in African Americans than in Caucasian adults. Familial aggregation is clear for OSA. Approximately 40% of the variance in the apnea hypopnea frequency may be explained by familial factors, and a positive family history increases the relative risk by two- to fourfold. Craniofacial anomalies that compromise upper airway space and stability provide additional risk factors for OSA. At least two endocrine conditions predispose to OSA: hypothyroidism and acromegaly. The most significant risk factor for OSA, however, is obesity, which is best characterized using the body mass index (kg m^{-2}) and/or the neck circumference. With the prevalence of obesity increasing in North America, prevalence rates determined 10 years ago will soon require reexamination. In children, the major risk factor has been adenoid and tonsil hypertrophy, although the increase in obesity in children is threatening to make it a major risk factor. A small number of patients diagnosed with OSA are thin. In this group, chronic nasal obstruction from allergies or septal deviation, retrognathia, or chronically enlarged tonsils may predispose patients to increased collapsibility of the upper airway and OSA. In summary, the most important risk factors for OSA appear to be obesity (body mass index and neck circumference), age, family history of OSA, male gender, craniofacial and/or upper airway soft tissue anomalies, hypothyroidism, and acromegaly. However, because OSA is so prevalent, it is essential that the possibility of OSA is considered in all individuals presenting with fatigue and/or unrefreshed sleep.

Although it is clear that OSA has a significant genetic basis, it is less clear whether the genetic basis rests entirely with the intermediate phenotypes (e.g., obesity and craniofacial morphology) or whether there are also genes that determine the severity of OSA and the clinical sequelae of the disease severity. It is important to acknowledge that the many risk factors for OSA and the varied clinical

presentations and comorbidities render this syndrome a complex disorder, determined not only by numerous genetic factors but also by environmental and cultural factors. The relative importance of body mass index versus craniofacial structure influences is expected to vary substantially across races with craniofacial differences. Genetics of OSA will require reexamination in large populations in India and China, where obesity may increase with economic expansion. Although there are many candidate genes for the intermediate phenotypes and for ventilatory control, very few have been explored and fewer still in large-scale clinical studies. In adults with OSA, polymorphisms of angiotensin converting enzyme, APOε4, and tumor necrosis factor-α have been identified. Whether these have a direct role in OSA risk or in the severity of comorbidities will require further investigation. Several studies on nonhuman mammals support genetic variation in apnea and hypoxia responses. These studies suggest that genetics may play a very important role in individual susceptibility to complications of OSA.

Central Sleep Apnea

It is estimated that CSA represents just 4% of the sleep apnea diagnoses made in clinical sleep laboratories. CSA occurs in many vastly different conditions. These CSA predispositions may be classified as disorders associated with (1) heightened ventilatory drive, (2) reduced ventilatory drive, and (3) insufficient and abnormal ventilatory pump function. Because of these diverse predispositions, the prevalences of CSA and for many of its subtypes are not known. However, it is estimated that 25–40% of individuals with congestive heart failure with systolic dysfunction may have CSA, and many of these individuals will have Cheyne–Stokes respiration. An additional risk factor for CSA associated with heightened respiratory drive includes periodic breathing or CSA associated with ascent to high altitude (acute hypoxia-induced increased ventilatory drive). The predisposition to CSA at altitude is associated with several angiotensin converting enzyme polymorphisms. Neuromuscular disorders with pump muscle weakness also predispose to CSA. Thus, CSA may be observed in individuals with Duchenne's or myotonic muscular dystrophy or amyotropic lateral sclerosis, myasthenia gravis, multiple sclerosis, and other disorders involving lower ventilatory pump muscle function. In this collection of neuromuscular disorders, the predisposition to sleep-disordered breathing arises from reliance on pump muscles other than the diaphragm. These accessory pump muscles normally have greater reductions in activity in both NREM and REM sleep compared to the diaphragm. Thus, when these accessory muscles are required for normal ventilation, it is expected that CSA will be present. A very rare form of CSA is congenital central hypoventilation syndrome (CCHS), with apneas occurring in 1 of every 200 000 births. Mutations in the *Phox2B* gene occur in most, if not all, individuals with CCHS. This gene is essential in the development of the autonomic nervous system. Sleep and breathing studies in mice with transgenic absence of the gene have confirmed the importance of the *Phox2B* gene in the development of autonomic ventilatory control and CSA by demonstrating impaired autonomic neuronal development CSA in mice lacking this gene. Whether specific mutations in *Phox2B* or in other gene mutations identified in children with CCHS (e.g., *Ret*, *Mash-1*, and *hash-1*) may contribute to adult forms of idiopathic CSA is not known.

Pathophysiology

Obstructive Sleep Apnea

Three decades ago, Sauerland and Harper measured the electromyographic activity of a major upper airway dilator muscle, the genioglossus, across sleep in subjects with OSA. Coincident with each apneic event, they observed reductions in genioglossus muscle activity, and upon arousal they observed resumption of genioglossus activity and resolution of the apnea. These landmark observations set the stage for further elucidation of mechanisms underlying the pathogenesis of OSA. People with OSA may have normal or reduced upper airway dimensions in wakefulness and may have increased soft tissue surrounding the upper airway, but the universal feature of OSA is increased collapsibility of the upper airway, particularly when upper airway muscle activity is reduced.

Collapse of the upper airway is a dynamic process. Inspiration creates negative pressures in the upper airway. Counterpressure must be generated to prevent collapse of the upper airway in individuals with severe OSA. Collapsibility of the upper airway in snorers is greater than collapsibility in individuals without sleep-disordered breathing but far less than in people with OSA. This increased collapsibility parallels the severity of sleep-disordered breathing events, where the most collapsible airways are present in individuals with OSA who have predominantly apneas.

With the understanding that sleep-dependent reductions in upper airway muscle activity are central to the collapse of the upper airway in OSA, a significant effort has been put forth to determine the neurochemical mechanisms underlying reduced muscle activity. It is now evident that sleep-dependent reductions in serotonin and noradrenaline and increases in GABA

delivery to motor neurons innervating the genioglossus contribute to the reduced muscle activity in sleep. It is unfortunate that serotonergic and noradrenergic receptor subtypes on upper airway motor neurons do not represent safe pharmacological targets. It is hoped that novel G-protein-coupled receptors will be identified on upper airway motor neurons and that these may be pharmacotherapeutic targets.

Central Sleep Apnea

As a condition with diverse causes, including congestive heart failure, CCHS, and many neuromuscular disorders, the pathophysiology of CSA varies with the cause of the condition. In deep NREM sleep (stages 3 and 4), ventilation is controlled almost exclusively by autonomic factors and is therefore extremely regular. In lighter NREM sleep (stages 1 and 2), there are major differences between the ventilatory response to low $PaCO_2$. A low $PaCO_2$ in wakefulness will not result in a cessation of ventilation. In contrast, a low $PaCO_2$ in light NREM sleep can suppress ventilation, causing an apnea until the $PaCO_2$ rises enough to stimulate ventilation. Typically, there is an overshoot so that upon arousal, the ventilatory response is so robust that the $PaCO_2$ falls again to a level that induces an apnea if the patient falls quickly back to sleep. This principle underlies the pathophysiology in several forms of CSA. If ventilatory drive is high in waking and subjects enter into NREM sleep with a sufficiently low $PaCO_2$, below the apneic threshold in NREM sleep, apnea will ensue until the CO_2 rises sufficiently to augment ventilatory drive in sleep or induce an arousal. Through this same sleep-dependent reduced ventilatory drive mechanism, a healthy individual may have a post-sigh apnea in NREM sleep. High-altitude periodic breathing also occurs through a similar change in ventilatory drive. At high altitude, there is some hypoxic drive to increase ventilation and sufficiently lower $PaCO_2$. Upon entering sleep, again if the $PaCO_2$ is below the apnea threshold, an apnea will occur until an increased $PaCO_2$ is detected resulting in an arousal that, in turn, greatly augments ventilation, blowing the $PaCO_2$ back down below the apnea threshold, where the process repeats itself throughout the night.

This same sleep-dependent change in ventilatory response to $PaCO_2$ underlies Cheyne–Stokes breathing. In this condition, the heightened ventilatory drive in wakefulness is, in part, a consequence of increased sympathetic drive that drives down the wake $PaCO_2$. Cheyne–Stokes respiration has been successfully treated pharmacologically with adrenergic blockade.

The remainder of conditions predisposing to CSA are those with impaired neuromuscular function. Individuals with neuromuscular weakness may have impaired diaphragm function yet can have normal waking ventilation by using accessory muscles (e.g., the sternocleidomastoid or internal intercostals and abdominal muscles). Sleep-related central apneas occur when sleep-dependent reductions in accessory muscle activity occur. In these conditions, sleep apnea will be worse in REM sleep when atonia is present in all accessory muscles of ventilation.

Clinical Features of Sleep Apnea

Obstructive Sleep Apnea

The clinical presentation of OSA varies across subsets of individuals. Adults with severe OSA, particularly obese males, present with a remarkably consistent constellation of: loud snoring, witnessed pauses in breathing at night, unrefreshed sleep, and daytime sleepiness or fatigue. Dyspepsia, rhinitis, and nocturia are also commonly associated symptoms. Many individuals with severe OSA will also report clumsiness, poor concentration, and impaired dexterity and/or memory impairments. Recognition of mild to moderate OSA in thin males, premenopausal females, and children presents a greater challenge. Patients with less severe OSA are more likely to have complaints of insomnia, fatigue, and quiet or minimal snoring. Therefore, of significant concern is the potential for underdiagnosis. Somatic complaints may predominate and may be attributed to chronic fatigue syndrome, depression, and fibromyalgia. The presentation in children differs greatly from the presentation in adults. Specifically, parents and other caregivers of children with OSA may recognize increased distractibility, labile mood, and hyperactivity in these children, without appreciating sleepiness, sleep disturbances, or even snoring.

The physical exam in many, but not all, cases will provide clues of upper airway compromise, such as a large tongue, a large neck circumference (>17 in. in adult males or >15 in. in adult females), a low-lying soft palate, a posteriorly displaced soft palate (1–4 mm anterior–posterior velopharyngeal space), large tonsils, a small mandible, and, rarely, a high arched palate. However, it is possible to have a normal head and neck exam and yet have enlarged lingual tonsils or collapse of the pharynx that is evident only in sleep. The physical exam should also always include an exploration for signs of hypothyroidism and acromegaly because these would be treated differently, as indicated later.

Central Sleep Apnea

The clinical presentation in CSA varies with the underlying cause, and as with the different

pathophysiologies, depending on the cause, the clinical presentation may be classified into two categories: individuals with lower arterial $PaCO_2$ values in wakefulness and those with normal or increased arterial $PaCO_2$. Individuals with CSA and low arterial $PaCO_2$ values may describe sleep as disturbed and unrefreshing, or they may have daytime hypersomnolence or fatigue. Increased fatigue with sedentary behaviors compared to exertional behaviors should alert physicians to examine the possibility of sleep-disordered breathing. Some patients may present with paroxysmal nocturnal dyspnea or may present with quiet snoring and witnessed apneas. However, the witnessed apneas and snoring are less obvious than events witnessed in people with severe OSA. Individuals with normal to increased $PaCO_2$ may present with clinical features more consistent with chronic hypoxemia and hypoventilation: polycythemia, cor pulmonale, or morning headaches.

Diagnosis

The gold standard for diagnosing both CSA and OSA has been overnight polysomnography. Recording sleep in parallel with ventilatory pump effort and nasal and oral airflow, the full spectrum of snoring, hypopnea, and apnea events can be examined. In addition, the effects of sleep-disordered breathing events on sleep quality and on arterial oxygenation may be determined. Together, this information distinguishes CSA and OSA and the severity of OSA can be determined. In OSA, night-to-night variability can be high, particularly in individuals with mild to moderate disease. Thus, when clinical suspicion is high and the first polysomnogram does not show OSA, it may be necessary to repeat the study. In females and in people with mild OSA, events may cluster in REM sleep. Thus, it is essential to examine sufficient REM sleep in individuals before excluding the possibility of OSA. Also in these patient populations, it is important to search for frequent arousals (>15 h) associated with increased ventilatory effort. With CSA, polysomnographic features may be instrumental in elucidating causes of sleep-disordered breathing. For example, Cheyne–Stokes presents with a very characteristic crescendo–decrescendo pattern in ventilation, with the arousal occurring at the peak of ventilation. Congenital central hypoventilation syndrome, which has rarely been identified in adults, manifests with most severe apneas occurring in slow-wave sleep. In contrast, because ventilatory motor neuron suppression is most pronounced in REM sleep, many patients with pulmonary disease or neuromuscular disorders (those that rely on accessory muscles for ventilation) will have more severe sleep-disordered breathing in REM sleep, when these muscle have atonia. Neither the sensitivity of polysomnography for the diagnosis of CSA nor the night-to-night variability in CSA has been established. Thus, if clinical suspicion is high, repeated polysomnography may be indicated in the hypersomnolent patient.

Of significance, OSA progresses with age and weight gain; thus, reconsideration of the severity of disease and its treatments is required periodically.

Therapies

Obstructive Sleep Apnea

The frontline therapy for moderate to severe OSA is the application of positive airway pressure (PAP) to the upper airway to prevent collapse. The pressure must be titrated individually to a level that prevents obstruction (apneas, hypopneas, and snores with arousals) in both NREM and REM sleep and yet is not so high as to interfere with sleep. Levels typically vary between 5 and 15 cm H_2O. Although remarkably effective for OSA, the therapy is an air pump connected to a relatively airtight mask or nasal interface, and as such this system can be cumbersome and uncomfortable. Consequently, less than half of the individuals prescribed PAP regularly use this therapy. Nonetheless, every effort should be made to encourage use of PAP regularly because this is the only therapy for OSA shown to lessen cardiovascular and neurobehavioral morbidity, even in mild to moderate OSA. Masks and nasal interfaces are more comfortable than the first equipment designed, and many patients who thought they could never tolerate a PAP mask are now able to comply with newer interfaces. Patients with claustrophobia and mask intolerance may undergo behavioral therapy for PAP desensitization. Developments in PAP therapy include machines that can self-adjust the level of PAP based on airflow patterns, gradually increasing pressure as needed across sleep stages and different sleeping positions.

Other therapies for OSA should be considered in young individuals with mild sleep apnea and in individuals with mild disease and inability to desensitize to PAP. These alternative therapies include surgical procedures to shorten the soft palate and reduce collapsibility of the pharynx (uvulopalatoplasty), reduce the tongue volume (genioglossectomy), or advance the genioglossus forward (genioglossus advancement hyoid myotomy) as initial surgical therapies and, if clinically indicated, a second phase of surgery to more dramatically increase pharyngeal space (maxillary advancement or maxillary and mandibular osteotomy). Laser-assisted uvulopalatoplasty is not as effective as surgical uvulopalatoplasty

for treating sleep apnea. Clinical indications for use of temperature-controlled radio frequency are still being determined. Some patients who do not tolerate PAP or in whom OSA is mild may benefit from oral appliances for sleep-disordered breathing. Although well tolerated, therapy takes weeks to months to reach optimal effectiveness. Factors predicting success with oral appliances include female gender, non-obese body habitus, young age, and positional OSA with more events in the supine position.

Weight loss should be recommended for all obese individuals with sleep-disordered breathing. Dietary counseling should be the first step taken, and all patients should understand that reduced caloric intake is the primary principle for most, if not all, successful weight loss programs. Exercise may help maintain weight, but in most nonathletic individuals, healthy caloric restriction should be the primary strategy for weight loss. Bariatric surgery is typically reserved for individuals with morbid obesity because there is a 10% chance of significant perioperative adverse events and a 1% chance of mortality in the postoperative period. The majority of individuals who have substantial weight loss after bariatric surgery will experience marked reductions in OSA, if not reversal of the disease. Treatment of endocrine disorders and OSA (hypothyroidism and acromegaly) should begin with PAP therapy, but across the treatment of the underlying endocrine disorder, the PAP may need adjusting. Several medical therapies for OSA may be considered as second-line therapies for mild OSA. There may be subsets of individuals who respond to supplemental oxygen, positional therapy, and, rarely, pharmacotherapies such as selective serotonin reuptake drugs in individuals with mild REM sleep-predominant apnea. Because these therapies are only rarely effective, treatment success should be determined with repeated polysomnography during treatment.

Central Sleep Apnea

Treatment of CSA varies with the cause of sleep apnea. PAP initially appeared promising for treating Cheyne–Stokes respiration in heart failure, but with newer medical therapy including treatment of the sympathetic overdrive, indications for PAP are less clear. High-altitude CSA may be treated with descent, acetazolamide, and medications reducing the hypoxia–angiotensin response or with supplemental oxygen. For other forms of CSA, ventilation must be augmented in sleep, and this may be achieved with PAP that assists ventilation rather than acts as an air splint. This bilevel PAP may be delivered with a mask as in OSA or, rarely, by tracheostomy tube if the noninvasive delivery fails.

Morbidities and Disease Interactions

One of the most significant advances during the past decade regarding OSA has been the identification of OSA as a risk factor for numerous and diverse morbidities. OSA is a major risk factor for excessive sleepiness and sleepiness-related impaired performances. Indeed, OSA is an independent risk factor for motor vehicle crashes, raising the relative risk by 2.5-fold. A direct link is supported by the reduction in car crash risk with successful treatment of sleep apnea. Several reports suggest that OSA is an independent risk factor for insulin resistance. This risk remains after controlling for obesity. As with motor vehicle accidents, further support for this disease interaction comes from studies showing improvement in glucose control with successful use of PAP therapy. It will be exciting to determine whether long-term PAP therapy reduces the occurrence of complications of diabetes. Several reports suggest that OSA may impair liver function and might contribute to nonalcoholic fatty liver disease, a major risk factor for liver failure in developed countries. Perhaps the most impressive observation in individuals with OSA has been the elucidation of OSA as an independent risk factor for several cardiovascular diseases, including hypertension, congestive heart failure, and stroke. Here again, obesity was controlled for. Importantly, the relative risk for hypertension increases even at levels of mild OSA (5–15 events per hour). The rates of significant cardiovascular events during 10-year follow-up in a large European trial also increased with mild to moderate OSA, but to a far greater extent (fourfold increase) in individuals with severe untreated OSA. This risk in individuals with severe OSA declines almost to baseline when treated effectively with PAP across the duration of follow-up. The risk of cardiovascular death is also reduced with PAP therapy in people with severe OSA. In light of the seriousness of morbidities and the disease interactions associated with OSA, every effort to improve PAP therapy acceptance and use should be made.

Future Directions

This area of research is extremely vibrant, and consequently significant progress has been made in understanding the pathophysiology, epidemiology, genetics, therapies, and disease interactions of sleep apnea. In light of the serious morbidities associated with OSA, future directions should emphasize disease prevention, improved detection of mild disease, early disease intervention, and development of novel well-tolerated effective therapies. As disorders with diverse systemic

effects, furthering of multidisciplinary approaches to patient care will be ever more important in the future.

Human Sleep

Human sleep is a behavioral state that alternates with waking, relative to which it is characterized by a heightened threshold to sensory input, attenuation of motor output, characteristic changes in central and peripheral physiology, and diminished conscious awareness. It is during this state of altered consciousness that dreaming occurs. Two major types of sleep, rapid eye movement (REM) and non-rapid eye movement (NREM), are characteristic of all mammals and alternate with regular, species-specific periods, indicating that they are timed by a reliable oscillator. In adult humans, this period is 90–120 min, resulting in approximately four or five cycles per night, as shown in Figure 1.

Polysomnographic Recording of Sleep

Since the late 1960s, sleep stages have been visually scored using the standardized electroencephalographic (EEG), electrooculographic (EOG), and electromyographic (EMG) criteria of the 1968 manual developed by Alan Rechtschaffen and Anthony Kales. EEG, EOG, and EMG are collectively termed polysomnography (PSG). Figure 2 shows the sites of placement of electrodes for recording these three measures, which constitute oscillating field potentials from the underlying cortex (EEG), relative distance of the electronegative retina from the electrode (EOG), and muscle tone (EMG). In recent years, these electrophysiological descriptors of sleep stage have been expanded to include results from functional neuroimaging (e.g., functional magnetic resonance imaging), quantitative EEG (e.g., spectral analysis), and magnetoencephalography (MEG). Although these new technologies are rapidly expanding our understanding of sleep neurophysiology, the PSG criteria of Rechtschaffen and Kales remain the gold standard by which the progression of sleep stages (or 'sleep architecture') is routinely characterized in clinical and research sleep labs. (Note, however, that the American Academy of Sleep Medicine published a substantive update of the Rechtschaffen and Kales manual in 2007.) The following sections first characterize sleep architecture in terms of the traditional PSG measures and then describe cellular neurophysiology relevant to the control of the sleep–wake and REM–NREM cycles and, lastly, findings on regional brain activation in sleep.

Sleep Architecture

Before commencing with a description of sleep architecture, it is important to define three terms used to characterize the EEG: frequency, amplitude, and morphology. EEG measures changes in electrical potential on the scalp that, in turn, reflect fluctuation of membrane potentials integrated across large numbers of cortical neurons beneath the recording electrodes. Such fluctuations or 'brain waves' are rhythmic, and their features reflect varying degrees of synchrony in membrane potential changes among neurons in these large aggregates. Frequency refers to the rapidity of fluctuation in electrical potential between successive peaks (or successive troughs) of measured EEG brain waves and is measured in cycles per second or Hertz (Hz). Amplitude refers to the magnitude of electrical potential change between such waves' peaks and troughs and is measured in (micro) volts. Morphology refers to the shape of a particular EEG wave or group of waves, reflecting both their frequency and amplitude, which can assume characteristic forms such as the sleep spindle or K-complex described later.

The initiation of NREM sleep is gradual and is characterized by a slowing in frequency of brain waves in the EEG from predominance of beta (14–25 Hz) and gamma (25–80 Hz) frequencies seen with eyes open (Figure 3(a)) to alpha (8–13 Hz) with eyes closed (Figure 3(b)) and finally to a predominance of theta rhythm (4–7 Hz) in stage 1 NREM sleep (Figure 3 (c)). The subsequent increasing depth of NREM sleep through stages 2–4 can be generally characterized as a progressive decrease in the predominant EEG frequency along with a progressive increase in average wave amplitude (Figures 3(d), (e) and (g)). In stage 1 NREM, characteristic slow eye movements are recorded in the EOG and muscle tone (EMG) is diminished relative to waking (Figure 4). Stage 1 is succeeded by stage 2 sleep, with an EEG characterized by further decreased mean frequency and increased amplitude of brain waves (Figure 3(d)). Stage 2 EEG is also characterized by two distinctive wave forms: sleep spindles, which are intermittent clusters of spikes at sigma frequency (12–14 Hz) with characteristic waxing and waning morphology, and the K-complex, which is a large negative (upward) deflection followed by a positive (downward) deflection (Figure 3(d)). In stage 3 sleep, sleep spindles decrease, EEG frequency further slows, and the amplitude of brain waves increases.

Figure 1 A night of sleep shown in the form of a 'hypnogram' in which the vertical axis shows depth of NREM sleep, red bars show REM, and the 90–120 min periodicity of each sleep cycle can be estimated as the duration from the end of one REM period to the end of the next one. Note that early in the night NREM is deeper and occupies more of the sleep cycle, whereas toward the end of the night, NREM sleep is lighter and more time is spent in REM. Adapted from Pace-Schott EF and Hobson JA (2002) The neurobiology of sleep: Genetic mechanisms, cellular neurophysiology and subcortical networks. *Nature Reviews Neuroscience* 3: 591–605, with permission.

Figure 2 Placement of electrodes for polysomnography (PSG) that includes electroencephalography (EEG), electrooculography (EOG), and electromyography (EMG).

Very high-amplitude delta waves (1–3 Hz) occur in the deepest NREM sleep, stages 3 and 4, which are also known as slow-wave sleep (SWS) or delta sleep. A slower oscillatory rhythm of less than 1 Hz, the 'slow oscillation,' has been described in cats and humans. In healthy young adults between ages 20 and 40 years, stage 1 NREM occupies approximately 2–5% of total sleep, stage 2 occupies 45–55%, stage 3 occupies 3–8%, and stage 4 occupies 10–15%.

REM sleep, discovered in 1953 by Eugene Aserinsky and Nathaniel Kleitman, has also been termed 'paradoxical' sleep because, by contrast with NREM, frequencies in the EEG resemble those of waking but muscle tone reaches its minimum level (Figure 3(f)). This EMG minimum in REM results from central, brain-stem-mediated inhibition of spinal alpha motor neurons ('REM atonia'). Because of its wake-like EEG (Figures 3(f) and 3(g)), REM has also been termed 'active' sleep. Also, because of its low-amplitude, high mixed-frequency waves, it has been termed 'desynchronized' sleep, in contrast with NREM (especially SWS), in which high-amplitude waves reflect synchronous activity of cortical neurons. As its name suggests, saccadic rapid eye movements (REMs) occur during REM sleep (Figure 4). These REMs, which occur in singlets and clusters, reflect the fact that unlike skeletal muscles, oculomotor muscles are not atonic in REM. REMs are believed to reflect underlying, central phasic (brief) neural events that can also be measured as peripheral muscle twitches (that briefly overcome REM atonia), middle-ear muscle movements, and periorbital potentials. Such events, in humans, are likely related to ponto-geniculo-occipital waves – phasic potentials recorded sequentially in the pons, thalamic lateral geniculate body, and the occipital cortex that are a characteristic electrophysiological feature of REM in the cat. Unlike REM's phasic events, its tonic (persisting), wake-like EEG is believed to reflect cortical activation by the cholinergic ascending arousal systems described later. An additional EEG feature of REM sleep, the 'sawtooth wave,' is illustrated in Figure 3(f).

Figure 3 Depth of sleep is characterized by the frequency and amplitude of EEG waveforms with slower frequency and higher amplitude indicative of greater depth. The dominant EEG frequencies waking and sleep stages: (a) waking with eyes open (beta); (b) waking with eyes closed (alpha); (c) stage 1 NREM sleep (theta); (d) stage 2 NREM sleep (theta frequency with sleep spindle and K-complex wave forms); (e) stages 3 and 4 NREM sleep collectively termed 'slow-wave sleep' (delta); (f) REM sleep (wake-like EEG, characteristic saw-tooth waves); (g) a single sleep cycle from early in the night showing the complete series of stages from waking to NREM stages 1–4 and back through these stages to REM. Autonomic and Peripheral Physiological Changes in Sleep

In NREM sleep relative to waking, heart rate, blood pressure, and respiration rate decline (Figure 5), sympathetic outflow of the autonomic nervous system decreases, and parasympathetic activity increases. Parasympathetic activity, as measured by heart rate variability indices, becomes closely linked to changes in the delta power band. In REM, heart rate, blood pressure, and respiration rate again rise but, as noted previously, muscle tone remains actively suppressed. In REM, homeostatic responses are attenuated. For example, respiration becomes insensitive to blood CO_2 and thermoregulation is largely absent. Additional peripheral features of REM include penile erections and clitoral engorgement. In the transition from NREM to REM sleep, sympathetic activity increases and parasympathetic activity decreases, but the parasympathetic:sympathetic ratio remains high as evidenced by pupillary miosis.

Neurophysiological Basis of Sleep Stage Changes

Control of sleep onset from the waking state is believed to be a function of the hypothalamus. Clifford Saper and colleagues have shown that there is a population of neurons in the anterior hypothalamus that, unlike much of the brain, shows increased metabolic activity during sleep (Figure 6). These neurons are concentrated in the ventrolateral preoptic area (VLPO) and produce both the inhibitory amino acid γ-aminobutyric acid (GABA) and the inhibitory neuropeptide galanin. At sleep onset, these neurons become active and inhibit ascending arousal systems of the brain stem, posterior hypothalamus, and basal forebrain (described later), thereby effecting the transition from the waking state to NREM sleep.

Once NREM is initiated, its delta and slow (<1 Hz) oscillatory rhythms, as well as its spindle and K-complex wave forms are generated by reciprocally interconnected thalamic and cortical neural circuits that have been extensively investigated and described by the late Mircea Steriade and colleagues. When the influence of subcortical ascending arousal systems decreases following sleep onset, thalamocortical circuits shift into an oscillatory mode during which transmission of sensory information to the cortex is blocked. Intrinsic oscillations of NREM represent the combined influence of two neuronal mechanisms: (1) the inhibitory influence of neurons of the thalamic reticular nucleus – a thin sheet of GABAergic neurons surrounding the thalamic periphery – on thalamic neurons projecting to the cortex, and (2) an oscillation within cortical neurons involving alternation between a prolonged hyperpolarization phase and a shorter depolarized phase with rapidly repeated spiking. This latter rhythm, generated within cortical networks, is the neuronal basis of the <1 Hz slow oscillation in the EEG and has been shown in animal models to exert an organizing or grouping influence on other intrinsic NREM sleep rhythms such as sleep spindles and the K-complex.

During waking, NREM oscillatory rhythms are prevented due to neuromodulation of thalamocortical circuits and cortex by ascending projections >from arousal-promoting systems of the brain stem, hypothalamus, and basal forebrain (Figure 6). Such neuromodulators include (1) acetylcholine from the midbrain–pons (mesopontine) junction in the brain stem, as well as from the basal forebrain (e.g., nucleus basalis); (2) the monoamines including norepinephrine (NE) and serotonin (5-HT) from the locus coeruleus and dorsal raphe, respectively, in the mesopontine brain stem dopamine from the midbrain periaqueductal gray, and histamine from the posterior hypothalamus; and (3) the neuropeptide orexin from the lateral hypothalamus. In contrast, during REM sleep, the intrinsic rhythms of NREM are prevented mainly by influence on the thalamus and basal forebrain from the cholinergic (acetylcholine) subcomponent of these systems originating in the mesopontine brain stem, including the laterodorsal tegmental and pedunculopontine nuclei.

Figure 5 Peripheral physiological changes accompanying one sleep cycle. The EM trace shows the number of rapid eye movements per minute indicating the occurrence of REM sleep. The EEG trace is a hypnogram as in **Figure 1**. The SBP trace is systolic blood pressure, the Resp trace is respiration rate, the Pulse trace is heart rate, and the BM trace is the number of body movements per minute (movements increase at the beginning and end of REM). Reproduced from Hobson JA and Pace-Schott EF (2003) Sleep, dreaming, and wakefulness. In: Squire L, Bloom F, McConnell S, Roberts J, Spitzer N, and Zigmond M (eds.) *Fundamental Neuroscience*, 2nd edn. San Diego: Academic Press, with permission from Elsevier.

Homeostatic and Circadian Control of Sleep Onset

A two-process model of sleep propensity, proposed by Alexander Borbely, suggests that homeostatic mechanisms (process S) interact with circadian factors (process C) to bring about sleep–wake transitions. Process S refers to a drive to sleep that increases as a function of the duration spent awake, whereas process C refers to sleep propensity varying as a function of time of day. The physiological basis of process S is believed to be substances that build up in the brain as a function of time awake ('endogenous somnogens'), and the purine nucleoside adenosine is currently the most widely suggested candidate for such a substance, although others have also been proposed (e.g., interleukin-1, prostaglandin D1, and growth hormone releasing hormone). Robert McCarley and colleagues have suggested that the specific site at which adenosine acts to promote sleep is in the basal forebrain, although its somnogenic effects have been reported at other subcortical sites as well.

Sleep propensity due to process C is an example of a wide variety of physiological circadian rhythms whose 'master clock' resides in the suprachiasmatic nucleus (SCN) of the anterior hypothalamus. Cells of the SCN contain molecular clocks that maintain a near-perfect 24-h periodicity via interlocking positive and negative feedback control of transcription and translation of circadian genes. These SCN cells can become entrained to the ambient photoperiod by light impinging on retinal ganglion cells that contain photoreceptive pigments such as melanopsin and which communicate monosynaptically with the SCN via the retinohypothalamic tract. Clifford Saper and colleagues have shown that the SCN, in turn, projects to various hypothalamic nuclei with circuits through subparaventricular and dorsomedial nuclei able to influence sleep–wake transitions via projections to the VLPO. Secretion of the pineal sleep hormone melatonin is also controlled by the SCN via a multisynaptic pathway and provides an internal signal of circadian time, as well as feedback to the SCN via its melatonin receptors.

Recent Discoveries Regarding the Brain in Sleep

The advent of new technologies in brain imaging has resulted in a greatly increased understanding of the behavioral and electroencephalographic features of human sleep. Positron emission tomography (PET) studies indicate that global cerebral oxygen utilization (detected using $H_2^{15}O$) and glucose metabolism (detected using ^{18}fluorodeoxyglucose) is decreased during NREM sleep compared to waking. Relative to waking, glucose metabolism is decreased by approximately 11% in stage 2 NREM and approximately 40% in SWS. fMRI studies have shown similar declines with deepening NREM sleep in the cerebral blood oxygen level-dependent signal that is measured using this technique. In contrast, during

Figure 6 Major components of sleep inducing and wake-inducing neuromodulatory systems. To induce sleep, projections from the gamma-aminobutyric acid (GABA) and galanin (gal) producing cells of the ventrolateral preoptic nucleus (VLPO) of the anterior hypothalamus send inhibitory signals to each of the ascending arousal systems of the brain stem, basal forebrain, and hypothalamus. These arousal systems include: the tuberomammillary nucleus (TMN) of the posterior hypothalamus that produce histamine (HIST), serotonin (5-HT) producing cells of the dorsal raphe (Raphe), acetylcholine (ACh) producing cells of the laterodorsal tegmental (LDT) and pedunculopontine tegmental (PPT) nuclei and norepinephrine (NA) producing cells of the locus coeruleus (LC). Other ascending arousal systems not shown include the perifornical lateral hypothalamus that produces orexin, dopamine producing cells of the midbrain periaqueductal gray, and cholinergic projections from the basal forebrain (nucleus basalis, diagonal band of Broca, medial septum) to the limbic system and the cortex. Reproduced from Saper CB, Chou TC, and Scammell TE (2001) The sleep switch: Hypothalamic control of sleep and wakefulness. *Trends in Neurosciences* 24: 726–731, with permission from Elsevier.

REM, global cerebral energy metabolism increases so that it is equal to or even greater than that of waking.

Deactivation of frontal cortices is one of the first physiological signs of human sleep. This has been observed whether activation is measured by EEG, MEG, PET, or fMRI. Functional imaging studies have also shown deactivation of the thalamus to be an early event in sleep onset. As NREM sleep deepens, more posterior cortices also decrease their neuronal activity, as do subcortical areas including the hypothalamus, basal ganglia, and hippocampus. In addition to their earlier deactivation in NREM, frontal areas may also display a greater need for recovery sleep than more posterior regions. Alexander Borbely and colleagues have shown that slow-wave activity (SWA), measured as the spectral power in delta frequencies, can serve as a marker of homeostatic sleep pressure. SWA is inversely related to cortical activation, is greater in frontal than in parietal and occipital regions in the first NREM episode of the night, and spreads in a frontal to posterior direction within the cortex. In addition to being the first part of the cortex to 'go to sleep,' frontal areas also appear to be the last part to wake up because their reactivation lags behind that of the rest of the brain.

After the transition from NREM to REM, much of the lateral frontal cortex remains less active than during waking. However, PET studies have shown that blood flow and glucose metabolism increase during REM in subcortical brain regions such as the pons, midbrain, thalamus, amygdala, hypothalamus, and basal ganglia, as well as limbic-related cortices such as parahippocampal cortex, temporal pole, anterior insula, caudal orbitofrontal cortex, subcallosal anterior cingulate, and medial prefrontal cortex (e.g., Brodmann areas 24, 32, and 10). Eric Nofzinger and colleagues have termed these midline structures an 'anterior paralimbic REM activation area' and have shown that their reactivation during REM following low activity in NREM can be as great or greater than their activation during waking.

Summary

Sleep, consisting of alternating REM and NREM states, is a universal behavior of all mammals. In humans, this cycle has a periodicity of 90–120 min and consists of characteristic substages of NREM characterized by brain waves of increasing amplitude and decreasing frequency as NREM deepens. The oscillating EEG patterns of NREM reflect synchronous activity in thalamocortical circuits. REM sleep is characterized by a unique, paradoxical combination of a fast, wake-like EEG but the least muscle tone of any stage. Characteristic peripheral and autonomic changes accompany stages of the sleep cycle with higher, more variable respiration, pulse, and blood pressure during REM than during NREM. Sleep propensity is determined by the interaction of a circadian rhythm ('process C') that is controlled, like other such rhythms, by the biological clock in the suprachiasmatic nucleus and a sleep homeostatic 'process S' that increasingly drives the need for sleep the longer one is awake. Waking is maintained by the ascending arousal systems of the brain stem, hypothalamus, and basal forebrain that send projections containing wake-promoting neuromodulators such as serotonin, norepinephrine, acetylcholine, histamine, orexin, and dopamine to the thalamus, limbic system, and cerebral cortex. During sleep, inhibitory projections from sleep-active sites in the anterior hypothalamus suppress these same arousal systems. In REM, mainly one component of these wake-active systems, that of

acetylcholine, activates the forebrain. Functional neuroimaging studies have revealed that NREM sleep is associated with widespread cortical deactivation relative to waking that is particularly pronounced in frontal areas. During REM, midline limbic and paralimbic areas are selectively activated while much of the lateral cortex remains in the less activated state characteristic of NREM.

Introduction

The behavioral and cognitive consequences of sleep deprivation have been the subject of scientific investigation for over 100 years, since the pioneering work of Patrick and Gilbert in 1896. In general, sleep deprivation produces neurobehavioral deficits in experimental tasks of alertness, attention, memory, cognition, learning, and motor responses, as well as performance deficits in operational settings (e.g., on the highway and in the factory). Despite the wealth of knowledge concerning the behavioral effects of sleep loss, much less work has examined the neurophysiological effects of sleep loss. This article discusses what we have learned about the effects of sleep deprivation on brain function from the perspective of functional neuroimaging studies. First, the definitions of sleep deprivation and brain function are covered. Then we review the literature in which functional neuroimaging is used to study sleep deprivation. Because the widespread application of functional neuroimaging techniques is still relatively new, there are fewer than 20 such studies published. However, rather than providing a detailed review of each one, we highlight the common findings and provide details only when they are illustrative or of particular interest. Finally, we provide a synthesis of the various findings.

Definitions

Sleep deprivation in humans can be broadly classified into three categories: total sleep deprivation (TSD), partial sleep deprivation (PSD), and sleep fragmentation. TSD is the complete lack of sleep for at least one night and often longer. PSD involves restricted sleep for multiple nights, that is, individuals obtaining an inadequate amount of sleep for several consecutive nights. Sleep fragmentation is repeated awakenings from sleep throughout the night. This results in a decreased amount of sleep but a normal time spent in bed. This article focuses on the research on TSD because all published neuroimaging studies in healthy adults to date have used this paradigm.

The term 'brain function' can be used to describe activity ranging from the cellular level (e.g., production of neurotransmitters) to the systems level (e.g., interactions among several brain regions). Functional neuroimaging refers to a set of technologies that allow researchers to examine brain activity with various spatial and temporal resolutions and relate that activity to behavior. Here we focus on two aspects of brain function typically examined in functional neuroimaging studies: (1) that cognitive performance is a behavioral measure often conceptualized as the output of brain function and (2) that functional neuroimaging techniques all provide some measure of brain metabolism. The two functional neuroimaging techniques that have been used most commonly to understand the effects of sleep deprivation are positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). The specific PET technique used measures glucose metabolism over the course of 45 min (although the signal is dominated by activity in the first 20 min). The measure of brain function obtained in the fMRI studies is a complex signal called the blood oxygen-dependent (BOLD) signal. When neurons in a local area increase firing rates (e.g., in response to a cognitive demand), blood flow and blood volume in that area increase. These, in turn, increase oxygen delivery to the area. However, more extra oxygen is delivered than is needed, and the net result is an elevated level of oxyhemoglobin in the local region of activity. It is this elevated level of oxyhemoglobin that produces the BOLD signal. fMRI has a temporal resolution on the order of seconds. Both techniques allow investigators to examine the regions of the brain that are involved in processing a cognitive task being performed by a subject. Brain regions showing positive signal changes when an individual performs the task are said to be activated.

Functional Neuroimaging Studies of Sleep Deprivation

This section reviews the findings from the PET and fMRI studies examining sleep deprivation in healthy young adults. The various reports are categorized by the type of cognitive task examined. Not surprisingly, the type of task has a tremendous influence not only on the brain regions activated when the

subject is well rested but also on how brain activation changes with sleep deprivation.

Attention Tasks

There are many types of attention (e.g., sustained, selective, spatial, and divided), but functional neuroimaging studies have examined only sustained attention and short-term visual attention. Sustained attention is the ability to focus on a single task for an extended period of time. Visual attention refers to the need to process a short stream of visual stimuli and respond to a specific target. In well-rested individuals, sustained attention relies on the right middle frontal gyrus and inferior parietal lobe and, to a lesser extent, on the left inferior parietal lobe and bilateral thalamus. Shorter-term visual attention tasks rely more heavily on the extrastriate cortex, as well as the fusiform, lingual, and superior parietal regions, depending on the specific target of attention.

The first study to use neuroimaging to examine TSD was a PET study involving a sustained attention task in which individuals pressed a button every 3 s for 45 min. Along with a decrease in alertness, this study showed decreased whole-brain metabolism of glucose following approximately 32 h of TSD. In addition, the frontal and temporal lobes showed a decrease in absolute metabolic rates, whereas the parietal lobes showed an increase and the occipital lobes showed no change. The largest decreases, however, were seen in the thalamus, basal ganglia, and cerebellum. These findings are consistent with a later PET study of sustained attention in which subjects performed a serial addition task for 45 min. That study showed a significant drop in cerebral metabolic rates in most brain regions after 24 h of TSD, which continued throughout 72 h of TSD. Both these studies used very long tasks and only examined brain function averaged across the entire task.

Two other studies used fMRI to examine attention after TSD on a finer temporal scale. The first measured visual attention over 40 s and found that increased activation in the ventrolateral thalamus supports intact attention after TSD. The final study used an even finer temporal scale to examine performance on the psychomotor vigilance task (PVT), which measures sustained attention and arousal lability. In this task, an individual presses a button as soon as a millisecond counter starts, which begins randomly within a predetermined interval. The task lasts 10 min and requires sustained attention. Within a testing session, performance on the PVT has been thought to reflect state instability (the variability (waxing and waning) in performance produced by the increased sleep drive during TSD). Findings showed that the frontoparietal sustained attention network supported fast reaction times whether the subjects were well rested or sleep deprived. These brain regions did not respond during slow reaction times under normal sleep conditions (which is probably why those reaction times were slow). Interestingly, however, these same regions showed increased responses immediately following slow reaction times after TSD. This was thought to reflect individuals reengaging in the task following a slow response because they received feedback regarding this slow reaction time. In essence, then, a slow reaction time prompts compensatory effort from an individual, and this compensatory response is captured in fMRI as an increase in activation in the frontoparietal sustained attention network following the slowest reaction times. A final noteworthy finding is that the study also suggests that the mechanism underlying poor performance after TSD is either (1) the impaired ability of the brain to appropriately allocate resources to task-specific brain regions or (2) the inability to inhibit activation within brain regions that actively interfere with performance.

Overall, it appears that TSD results in decreased brain responses in regions underlying sustained attention demands, as well as diminished performance on sustained attention tasks. Nonetheless, it appears that sleep-deprived individuals can indeed engage these attention regions for brief periods while sleep deprived, but only when accompanied by compensatory activation within the thalamus. This brief engagement allows for intermittent normal levels of performance, despite the fact that average performance across the entire task is diminished with TSD. This set of findings illustrates the importance of the temporal scale at which brain function is measured during TSD.

Learning Tasks

Learning is an essential task for humans, and there are multiple types of learning and memory that rely on various brain systems. Verbal learning (i.e., memorization of language-based material) is the only type of learning studied with functional neuroimaging techniques in the context of sleep deprivation. Studies of TSD have examined brain function during the encoding of verbal material, but none has directly studied recall or recognition of learning materials. Cortical regions associated with verbal encoding are almost exclusively in the left hemisphere and include the medial temporal structures, inferior frontal gyrus, premotor areas, middle temporal gyrus, and cerebellum.

Unlike sustained attention tasks, in which brain function generally decreases with TSD, verbal encoding tasks elicit increased activation in several brain

regions after TSD. The most reliable increases are seen in the left and right inferior frontal gyri, as well as the left-hemisphere inferior and superior parietal lobes. This increased activation is typically associated with intact, or only minimally impacted, performance on the learning tasks. In fact, the increased activation within the parietal lobes is directly related to performance after TSD; individuals showing the greatest activation within the left inferior parietal regions after TSD show the best learning performance after TSD.

In addition, the difficulty level of the verbal learning task also influences brain function with TSD. This was demonstrated in a study comparing learning an easy word list versus learning a hard word list. During the memorization of easy words, brain activation did not differ between well rested and TSD states. Memorization of hard words, however, elicited strong increases in brain activation after TSD, and those increases were directly related to performance. The influence of task difficulty in verbal learning has also been examined by employing a distracter task to interfere with learning. That study showed a similar result, with the learning-plus-distraction condition showing greater cerebral responses after TSD than after a normal night of sleep. Once again, the greater the increase in activation with TSD, the better the subjects performed on the learning task. Interestingly, in all the studies that examined verbal learning, the left parietal lobes showed increased activation following TSD and individuals showing the greatest increases in this region also showed the best performance after TSD. This suggests that the left inferior parietal lobe plays a key role in maintaining verbal learning performance during TSD.

Finally, one recent study examined cerebral responses during a verbal learning task from a network perspective using functional connectivity analyses. This study showed that memorization of easy words and hard words each activated the same brain regions (the left and right inferior frontal gyrus and left inferior and superior parietal lobes) but that the interconnections among those regions differed. Following TSD, this study found that the interactions among brain regions within these networks changes. Specifically, in both cases, the interhemispheric connection within the frontal lobe weakened, whereas the intrahemispheric connection between the inferior and superior parietal lobes increased. Thus, this study suggests that changes, positive or negative, in cerebral activation with TSD may reflect alterations in communication among brain regions rather than simply increased or decreased activation within discrete brain regions.

Working Memory

Working memory, also called executive function, has long been a popular cognitive domain in TSD research. This is because (1) working memory tasks typically rely, at least in part, on brain function within the prefrontal cortex; (2) the prefrontal cortex has traditionally been thought of as the brain region most vulnerable to TSD; and (3) electroencephalography (EEG) studies have consistently demonstrated that changes in the frontal lobes following TSD contribute to cognitive performance deficits. The term 'working memory' refers to a large number of cognitive functions, however. It is likely that the specific aspect of working memory examined in any given study influences the measured effect of TSD on brain function. The types of working memory tasks used in functional neuroimaging studies of TSD include those requiring arithmetic, maintenance of information, and manipulation of information.

Arithmetic working memory relies on activation within the bilateral dorsolateral prefrontal cortex, anterior cingulate gyrus, and bilateral parietal lobes. Two studies examined arithmetic working memory following TSD. One of those is the PET study previously discussed in the section on attention tasks. This study showed widespread decreases in glucose metabolism during task performance starting after 24 h of TSD. However, activation in this study was confounded by the sustained attention demands of the task. The second study was an fMRI study examining serial subtraction after 35 h of TSD. Even though this study measured brain activation over 40 s intervals (thereby reducing the sustained attention demands), it confirmed the decreased responses within task-related brain regions following TSD. In both studies, subjects showed diminished performance with TSD.

Tasks requiring maintenance of information in working memory elicit bilateral activation in the prefrontal, precentral, and inferior parietal regions, as well as in the insula and thalamus. Tasks requiring the manipulation of information in working memory show more extensive activation in those same areas, reflecting the fact that manipulation requires more cognitive resources than simple maintenance. The studies examining brain function after TSD during tasks requiring maintenance and/or manipulation of information in working memory have reported both increased and decreased activation with TSD. Some of that inconsistency can be attributed to the task difficulty, similar to the verbal learning studies. More specifically, tasks requiring only the maintenance of information in working memory are more likely to show deceased activation, whereas those requiring the manipulation of information are more

likely to show increased activation with TSD. Furthermore, increasing the difficulty level within either a maintenance or manipulation task also results in greater activation during TSD. This is evident from a study that used a grammatical transformation task to manipulate task difficulty and found a stronger modulation of activation in task-related regions as difficulty increased following TSD, compared to the degree of modulation after normal sleep.

Overall, the effect of TSD on the cerebral response to working memory demands remains unclear. It appears that arithmetic demands (at least those not overlearned) produce decreased activation after TSD. The brain response to other working memory tasks probably depends on the specific nature of the task demands and the specific subregions with the prefrontal cortex underlying performance of those specific demands.

Visuospatial Functioning

Visuospatial functioning refers to those cognitive processes involved in visual perception of spatial relationships among objects. One example of visuospatial functioning involves the recognition of objects, such as circular line configurations, that have no verbal properties. In imaging experiments using recognition of nonverbal objects, visual association areas in the ventral visual stream are commonly activated along with the precuneus, an area associated with the dorsal visual stream. As with working memory tasks, studies using visuospatial tasks have shown both increases and decreases in cerebral activation following TSD. Most commonly, activation in the visual association cortex and precuneus decreases after TSD, and this correlates with decreased behavioral performance. Regions showing increased activation during recognition of nonverbal objects after TSD include the basal ganglia and insula. Interestingly, the one study that attempted to use a more real-world spatial navigation task (a piloting task) found exclusively increased activation after TSD, including in both visuospatial processing regions and dorsolateral executive controls regions.

Summary and Conclusion

Research using functional neuroimaging techniques to better understand the effects of sleep deprivation on brain function is still in the early stages. Most studies have taken a relatively descriptive approach; they administered various tasks to examine the differences in brain function after normal sleep and after TSD. A few studies have used more sophisticated manipulations such as parametrically manipulating task demands or functional connectivity analyses. Despite the fairly small number of studies in this area, some generalizations can be made about the results. There appear to be two distinct brain responses to cognitive challenges during TSD. The first is characterized by decreased activation relative to the well-rested state and diminished performance; this can be thought of as an impaired brain response. The second type of response is characterized by increased activation and relatively intact performance; this has been interpreted as a compensatory recruitment response.

Compensatory Recruitment Hypothesis

The compensatory recruitment hypothesis states that the brain has the ability to recruit additional cognitive resources during task performance following TSD that it typically does not recruit to perform the same task when the subject is well rested. These resources are then engaged in performing the task, and the more an individual engages these cognitive resources following TSD, the better the individual performs the task. It is this correlation between recruitment (measured as activation) and performance that makes the process compensatory. Clearly, however, such recruitment does not always occur because several studies reported decreased activation with TSD. Three broad classes of factors are thought to influence whether, and where in the brain, recruitment occurs following TSD: (1) cognitive task-related factors (What is the subject asking the brain do to?); (2) the length and type of sleep deprivation; and (3) individual difference variables (i.e., some individuals are able to recruit new resources and others are less able).

The studies reviewed here suggest that cognitive task factors certainly play a role in brain function following TSD. For example, sustained attention tasks seem to show impaired brain responses following TSD, whereas verbal learning tasks consistently show increased activation. In addition, each study that systematically manipulated the task difficulty showed that increasing the task difficulty facilitated the compensatory recruitment response. We might think that there is a functional limit to this difficulty-influenced recruitment; however, no study to date has effectively demonstrated such a limit. A similar argument could be made with respect to the length of sleep deprivation. After enough sleep loss, even the verbal learning tasks that consistently show recruitment with TSD should show decreased activation; however, only one published study took functional neuroimaging measurements at multiple time points during TSD. This was the PET study showing decreased glucose metabolism after 24, 48, and 72 h of TSD. Because

this study did not even show recruitment at the first time point, it cannot serve as a test of this aspect of the hypothesis. Likewise, no study has examined any length of PSD. The final factor thought to affect recruitment is individual differences, which has only been investigated in a few preliminary studies and, thus, also remains largely untested.

Future Directions

Clearly, much work needs to be done before we will fully understand the impact of sleep deprivation on brain function. All three factors proposed to affect cerebral activation following TSD need more research. Cognitive task-related factors are the most well-studied area. Nonetheless, we need to design cognitive tasks better so as to focus on very specific aspects of cognition rather than on general domains of cognition. For example, instead of examining working memory generically, investigators should employ event-related designs to examine the various components of working memory (e.g., attention, working memory buffer, manipulation, and encoding/retrieval). To the extent this has been done already, the results suggest that some components are more sensitive to TSD than others. Furthermore, future studies should use more real-world tasks when possible. For the second factor, models of PSD need investigation. This is a more realistic model of sleep loss in day-to-day life. Behavioral studies have suggested that a week of 4 or 6 h in bed per night produces cognitive deficits on some tasks similar to 24 or 48 h, respectively, of TSD. However, the time course of the deterioration and whether the brain can show compensatory recruitment during PSD remain unknown. Finally, behavioral data show that some individuals are relatively resilient to the effects of TSD on specific tasks, whereas others are more vulnerable. Understanding the source of those differences could lead to important advances in job selection, safety training, and effective countermeasures to sleep deprivation. Currently, we do not even know if demographic measures such as age, education, IQ, and gender play a role in the brain's response to TSD. Other variables to consider include the subject's mastery of a given task, genomic and gene expression differences, and prior experience with sleep deprivation. Work in this area is growing exponentially. The promise is that a better understanding of the consequences of sleep deprivation, and the factors that protect against the negative consequences, will help us better understand the function of sleep itself.

Sleep Deprivation: Neurobehavioral Changes

J D Minkel, S Banks, and D F Dinges, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Sleep restriction is common in modern society, not only as a result of medical and psychiatric disorders but also because of sociocultural influences including occupational and domestic responsibilities. Artificial lighting and around-the-clock services have facilitated lifestyles that do not allow for adequate levels of sleep. The resulting 'sleep debt' is associated with significant daytime performance deficits that carry considerable social, financial, and personal cost. The most well-documented changes in behavior resulting from sleep deprivation include microsleeps intruding into wakefulness and resulting in lapses in cognitive functions that are indicative of state instability. Sleep deprivation experiments have also found deleterious effects on mood, cognitive performance, and motor function due to an increasing sleep propensity and destabilization of the wake state. Vigilant and executive attention, working memory, and divergent higher cognitive functions are particularly vulnerable to sleep loss. These effects have been demonstrated in studies of total sleep deprivation (i.e., those that allow no sleep opportunity) and in studies of chronic partial sleep deprivation.

History of Sleep Research

Although observations on the effects of sleep loss can be found throughout recorded human history, the first systematic investigation of the effects of sleep loss in humans was conducted more than a century ago at the University of Iowa. Observations of three adults across 90 h of sustained wakefulness showed a general decrease in sensory acuity, slowing of reaction times and motor speed, and problems with memorization relative to performance after recovery sleep. This nineteenth-century study identified microsleeps, hypnagogic reverie, lapsing, circadian variation, and recovery sleep depth, all of which have withstood the test of time as behavioral consequences of sleep deprivation in humans.

The first systematic sleep studies were conducted by Dr. Nathaniel Kleitman beginning in the 1920s. He noted that subjects often seemed to increase their motivation during sleep deprivation to perform as well as they did prior to the sleep loss and that on some tasks, performance appeared normal at the beginning of the test but deteriorated as the test duration increased. These results demonstrated that sleep deprivation did not produce a 'lesion' in performance, which was the conventional wisdom at the time, but reduced neurocognitive capacity and performance.

The next major insight into the consequences of sleep deprivation occurred in the 1930s when Neil Warren and Brant Clark found that performance during sleep deprivation became more variable, despite little change in measures of central tendency of performance. This observation – namely that variability in behavioral output characterized the neurobehavioral performance of sleep-deprived healthy adults – offered a way of reconciling conflicting results among sleep deprivation studies without invoking motivation and duration of measurement. Modern experiments have confirmed the original observation that sleep deprivation increases performance variability rather than simply or solely decreasing average performance.

The physiological basis for the effects of sleep deprivation was first investigated in the late 1940s by Bo Bjerner, who demonstrated that sleep deprivation-induced lapses in performance (which contributed to greater variability) were associated with changes in the human scalp-recorded electroencephalogram (EEG). Specifically, it was observed that alpha-wave (8–12 Hz) depression and high-amplitude slow-wave activity accompanied delayed actions (lapses) on a performance task during deprivation. This EEG profile had been documented 10 years earlier to co-occur with subjective drowsiness.

Thus, by 1950 some of the most fundamental features of performance changes during sleep deprivation had been identified. However, the disparate findings had not yet been integrated into a theoretical model of how sleeplessness affected neurobehavioral functions. Moreover, the behavioral effects of sleep deprivation had not yet been understood relative to the homeostatic drive for sleep. Only in the past 10 years has the full range of consequences from sleep deprivation begun to be understood and a theory that attempts to systematically integrate findings from the neurobiology of sleep deprivation with data on cognitive and neurobehavioral performance changes been developed.

Functional Consequences of Sleep Deprivation

Sleep Deprivation and Accident Risk

Accidents involving sleep-deprived operators have been estimated to have an annual economic impact of \$43–\$56 billion. Motor vehicle crashes due to drowsy driving contribute substantially to these estimates. Drowsiness markedly increases the risk of crashing, and motor vehicle accidents related to sleep loss are particularly common. Length of time awake, nocturnal circadian phase, reduced sleep duration, prolonged driving duration, and use of sedative–hypnotic medications have all been found to contribute to the occurrence of drowsy-driving and fatigue-related motor vehicle crashes. Studies of shift workers, truck drivers, medical residents, and airline pilots show an increased risk of crashes or near misses due to sleep deprivation. Table 1 shows the results of a nationwide study of the increased motor vehicle crash risks posed by sleep deprivation from the common practice of scheduling medical residents for extended work shifts of 30 h or more. Sleepiness-related motor vehicle crashes have a fatality rate and injury severity level similar to those of alcohol-related crashes.

Sleep deprivation poses a risk to safety in all modes of transportation and to performance in many other safety-sensitive occupations. For example, studies of interns working prolonged shifts in intensive care units demonstrated that they made 35% more serious medical errors during work schedules that allowed the current practice of $\geq$30-h shifts compared to work shifts limited to 16 h. Limiting the prolonged shifts also resulted in the interns sleeping 5.8 h more per week, and they had less than half the rate of attentional failures while working during on-call nights. Thus, sleep deprivation is a preventable cause of accidents in most people.

Sleep Deprivation and the Propensity to Fall Asleep

Under normal conditions, humans experience either stable sleep or wakefulness with relatively little time spent transitioning from one state to another. When sleep is resisted, however, the stability of the sleep–wake system begins to break down. Intrusions of sleep into wakefulness and goal-directed performance become evident through increases in a variety of neurobehavioral phenomena: performance lapses, microsleeps and sleep attacks (i.e., involuntary naps), voluntary naps, shortened sleep latency, slow eyelid closures, and slow rolling eye movements. Wake state instability from inadequate sleep duration or timing can occur while people engage in virtually any type of motivated behavior. In fact, sleep deprivation has been shown to produce psychomotor impairments equivalent to those induced by alcohol consumption at or above the legal limit.

As sleep deprivation increases, the biological initiation of sleep occurs more often and sooner, as evident in sleep propensity/latency tests, which use polysomnography to measure physiological transitions from wake to sleep. Sleep deprivation results in not only a reduction in the latency to sleep onset during the Multiple Sleep Latency Test but also a reduction in latencies from lighter stages of nonrapid eye movement (REM) sleep to deeper slow-wave sleep (SWS). Such rapid transitions from waking to physiologically

No. reported	1971	1156
No. of commutes	54 121	180 289
Rate (per 1000 commutes)	36.42	6.41
Odds ratio (95% CI)	5.9 (5.4–6.3)	1.0

A within-person case-crossover analysis was used to assess the risks of motor vehicle crashes and near-miss incidents among interns during commutes after extended shifts compared with nonextended shifts. A two-by-two table was constructed for each intern who reported either a crash or a near-miss incident, consisting of the number of crashes or near-miss incidents after an extended shift, the number of crashes or near-miss incidents after a nonextended shift, the number of extended shifts that did not precede a crash or a near-miss incident, and the number of nonextended shifts that did not precede a crash or a near-miss incident. CI, confidence interval. Reproduced from Barger LK, Cade BE, Ayas N, et al. (2005) Extended work shifts and the risk of motor vehicle crashes among interns. *New England Journal of Medicine* 352: 125–134.

deeper stages of sleep reveal the increased neurobiological drive for sleep when wakefulness has been sustained too long, sleep duration has been too brief, and/or sleep consolidation has been abnormal, disrupted, or fragmented.

Whereas the Multiple Sleep Latency Test involves instructing subjects to try to fall asleep while supine in a sleep-conducive environment, the Maintenance of Wakefulness Test involves instructing subjects to remain awake rather than fall asleep in a non-sleep-conducive environment. Like the Multiple Sleep Latency Test, the Maintenance of Wakefulness Test shows reduced sleep latency in response to sleep deprivation. Thus, whether attempting to fall asleep or resist sleep, the latency from waking to sleeping is reduced by sleep deprivation. Although there is some controversy regarding the interpretation of sleep latency measures relative to actual cognitive performance measures during sleep deprivation, sleep latency tends to reflect subjective reports of daytime sleep tendency and the duration of nighttime sleep in the general population.

Microsleeps, Lapses, and Errors

Sleep deprivation not only reduces latencies to enter into normal sleep but also produces microsleeps (i.e., brief episodes of sleep that occur during waking performance). These intrusions result in behavioral lapses or errors of omission (i.e., failure to respond in a timely manner during cognitive performance demands). Lapses contribute to increased moment-to-moment variability in cognitive performance in sleep-deprived adults. Sleep deprivation can also increase errors of commission (i.e., response when no stimulus is present or to the wrong stimulus). Although lapses generally exceed the number of errors of commission on tasks in which the sleep-deprived subject controls the rate of performance, the opposite can be the case when the pace of the cognitive task permits only a very limited time for a response (i.e., tasks done under time pressure). In the latter circumstances, both types of errors are common in sleepy subjects.

Wake State Instability

The consequences of sleep deprivation on human performance were previously understood by the 'lapse hypothesis', which asserted that performance was relatively unchanged except during brief periods of low arousal. Although partially correct, this hypothesis does not explain some of the most robust cognitive changes associated with sleep deprivation, including a general slowing of cognition and reaction time, increased variability in performance, and potentiated decline in performance as time on task increases. To accommodate these effects of sleep deprivation, the wake state instability theory was developed. Rather than suggesting that sleep deprivation simply produces brief periods of impairment in otherwise normal performance, this theory posits that variability in neurocognitive performance increases as homeostatic sleep-initiating mechanisms become progressively more dysregulated with sleep loss. Thus, the theory posits that the co-occurrence of sleep and waking neurobiologies destabilizes performance, making it more erratic, less predictable, and poorly executed toward goal attainment. Not only do behavioral lapses result from sleep deprivation but also even optimal responses can be slowed or made less effective by sleep loss. Higher-order cognitive functions are adversely affected via the impact of sleep loss on basic attention and memory functions, as well as through direct effects on the areas of the cerebrum that mediate executive functions.

Wake state instability is theorized to occur when the brain's capacity to maintain alertness is hindered by the activation of sleep initiation from cortical and subcortical 'sleep switch' mechanisms. In such circumstances, behavioral state instability occurs when sleep pressure is elevated in the presence of goal-directed waking behavior. This conceptualization integrates the neurocognitive effects of sleep deprivation with what is known neurobiologically about sleep–wake regulation. When state instability is high, neurocognitive performance of the sleep-deprived individual is unpredictable and a product of interactive, reciprocally inhibiting neurobiological systems mediating sleep initiation and wake maintenance.

Sleep Deprivation and Basic Cognitive and Psychomotor Performance

Attentional networks, one of the basic building blocks of all cognitive activity, appear to be especially vulnerable to disruption by sleep deprivation. Therefore, any cognitive performance task that relies on stable vigilance and sustained attention with timely responses (e.g., driving) is at risk for deficits induced by sleep loss. Lapses of attention increase in both frequency and duration with increasing sleep deprivation, resulting in a progressive shift toward attentional lability. Individuals who are motivated to remain awake while sleep deprived can temporarily mask their impairment by engaging in compensatory behaviors (e.g., standing, walking, and talking), but the masking effects are typically short-lived. Ultimately, the compensatory effort to resist sleep cannot prevent intrusions of sleep initiation into wakefulness, as evidenced by Kleitman's observations

of sleep-deprived subjects 'semi-dreaming' while engaged in verbal cognitive tasks and by first-person reports of sleep-deprived people falling asleep while ambulating in dangerous environments.

There are hundreds of published studies on the cognitive deficits induced by sleep deprivation in humans. Sleep deprivation induces a wide range of effects on cognitive functions, although cognitive tasks vary considerably in their sensitivity to sleep loss. In general, regardless of the task, cognitive performance deteriorates more rapidly in sleep-deprived subjects than in well-rested controls; this is the classic 'fatigue' effect that is exacerbated by sleep loss. However, even performance on very brief cognitive tasks that precisely measure speed of cognitive throughput, and other aspects of attention and memory, consistently has been found to be sensitive to sleep deprivation. In this sense, sleep deprivation adversely affects the cognitive building blocks of attention and memory, on which higher-order cognition depends.

Two often overlooked confounding factors that can obscure the effects of sleep loss on many cognitive tasks are intersubject variability (e.g., aptitude on a task) and intrasubject variability (e.g., rate of learning a task). For example, one person's poorest performance during sleep deprivation may be superior to the best performance of a non-sleep-deprived person. Similarly, someone may be cognitively diminished by sleep loss but continue to improve when measured over time due to continued learning. Moreover, a failure to understand that sleep deprivation increases variability within subjects and between subjects and/or a failure to measure behavior at a frequent rate can result in the effects of sleep deprivation being missed in cognitive measures because less sensitive metrics or inappropriate data analyses are used.

Sleep Deprivation and Higher Cognitive Functions

More complex tasks involving higher cognitive functions have often been reported to be insensitive to sleep deprivation. In general, convergent rule-based deduction and critical thinking (e.g., logic-based tasks) show little change in accuracy during sleep deprivation, although they will reflect cognitive slowing. When tasks are made more divergent, such as multitasking and flexible thinking, sleep deprivation appears to have adverse effects on problem-solving performance. Divergent skills involved in decision making that appear to be affected by sleep loss include assimilation of changing information, updating strategies based on new information, lateral thinking, innovation, risk assessment, maintaining interest in outcomes, insight, communication, and temporal memory skills.

Implicit to divergent thinking abilities is a reliance on executive functions subserved by the prefrontal cortex. Executive function can be defined as the ability to plan and coordinate a willful action in the face of alternatives, monitor and update action as necessary, and suppress distracting material by focusing attention on the task at hand. Many tasks thought to engage different aspects of executive function have been used in studies of sleep-deprived individuals. These tasks also rely on working memory and executive attention, and most show some adverse effects of sleep loss.

Sleep Deprivation and Working Memory

Working memory involves the ability to hold and manipulate information and can involve multiple sensorimotor modalities. Deficits in neurocognitive performance requiring working memory result in difficulty determining the scope of a problem due to changing or distracting information, impairment in remembering temporal order of information, difficulty maintaining focus on relevant cues, taking inappropriate risks, difficulty maintaining flexible thinking, demonstrating poor insight into performance deficits, perseverating on thoughts and actions, and problems making behavioral modifications based on new information. It can therefore be concluded that sleep deprivation adversely affects prefrontal cortex-related executive attention and working memory abilities. Although both neurobehavioral and neuroimaging experiments confirm that sleep deprivation adversely affects neurocognitive functions involving the prefrontal cortex, there is also increasing evidence that subcortical systems involved in sleep initiation – especially hypothalamic, thalamic, and brain stem nuclei – have an important role in altering prefrontal cortical activity during sleep deprivation.

Sleep Deprivation, Mood, and Emotion

In comparison to the effects of sleep deprivation on cognition and performance, relatively little is known about the effects of sleep deprivation on emotional processes, with the exception of subjective mood states. Experimental data have clearly shown that virtually all forms of sleep deprivation result in increased negative mood states, especially feelings of fatigue, loss of vigor, sleepiness, and confusion. These data are limited, however, in that they were obtained without systematic mood induction procedures or other experimental probes designed to influence mood. It is not known if there are systematic differences in how specific events influence mood in sleepy versus rested subjects.

Sleep deprivation is widely believed to be associated with impaired emotional functioning as well. Field studies of sleep deprivation in military and medical personnel have found that reduced sleep is associated with increased negative and decreased positive emotional responses to specific events, but the uncontrolled nature of these studies allows for multiple interpretations of the findings. Other than simple subjective self-report measures of affect, there are few laboratory-based studies on affective responses in sleep-deprived humans. A controlled experiment in rats, however, found that sleep deprivation was associated with increases in aggression and risk-taking behavior. Although data are somewhat limited, the available evidence suggests that emotional processes are sensitive to sleep loss.

Effects of Chronic Partial Sleep Deprivation

Although acute total sleep deprivation is commonly used in research, chronic partial sleep restriction is more frequently experienced in real-world settings. Medical conditions (e.g., pain), sleep disorders (e.g., apnea), work demands (e.g., night shift work), and social and domestic responsibilities generally reduce the amount and quality of sleep that people are able to achieve but rarely eliminate sleep time entirely. Despite the pervasiveness of partial sleep restriction relative to acute total sleep deprivation, only recently has there been substantial experimental focus on its effects.

Daytime Sleep Propensity during Chronic Sleep Restriction

Basic questions concerning how much sleep is required for normal functioning, whether or not there is a cumulative cost to chronically restricted sleep, and to what extent individuals differ in sleep need have only recently been addressed experimentally. Few experiments have studied the cognitive effects of chronic sleep restriction over more than 7 days in a controlled laboratory setting to ensure participants only obtained the sleep durations they were assigned, and that they used no stimulants (e.g., caffeine and nicotine) or other techniques to reduce sleepiness. The two most extensive investigations found adverse effects of chronic sleep restriction on measures of vigilant attention, reaction time, cognitive throughput, and working memory. In one study, truck drivers were randomized to seven nights of 3, 5, 7, or 9 h time in bed for sleep per night. Only the 9-h time in bed condition showed no cognitive impairments across days. In an even larger experiment in which healthy young adults had their sleep duration restricted to 4, 6, or 8 h time in bed for 14 nights, only the 8-h time in bed condition showed no cognitive impairments across days. Three discoveries in these two experiments were seminal. First, both studies found dose–response cumulative adverse effects of sleep restriction on cognitive functions. That is, deficits in neurocognitive performance accumulated across consecutive days of sleep restriction when time in bed for sleep was chronically reduced below 7 h per night, and the accumulation was more rapid as sleep time became shorter. Second, the cognitive deficits induced by chronic sleep restriction accumulated to levels of impairment equivalent to those observed after one or two nights of acute total sleep deprivation. Figure 1 illustrates these phenomena for psychomotor vigilance task lapses from the two experiments.

Attenuated Subjective Effects of Chronic Sleep Restriction

The third major finding from the two large-scale controlled dose–response experiments on chronic sleep restriction concerned effects on subjective estimates of sleepiness. Although it is commonly assumed that people know when they are tired from inadequate sleep and can therefore correctly anticipate their ability to perform safely, these and other laboratory studies do not support this assumption. Subjective reports of sleepiness during periods of chronic sleep restriction showed an immediate modest elevation after the first one or two nights of sleep restriction, but this response reached a plateau after a few days and did not demonstrate the cumulative increases that were evident in cognitive performance deficits. Thus, as chronic sleep restriction progressed, subjective perception of alertness became increasingly dissociated from the reality of neurocognitive ability. Subjects often reported that they had adjusted to the reduced sleep durations, but objective performance measures clearly indicated that they had not. This suggests that people frequently underestimate the cognitive impact of sleep restriction and overestimate their performance readiness when sleep deprived.

Polysomnography and Waking EEG and Electrooculography Effects of Chronic Sleep Restriction

Waking EEG changes have also been observed during chronic sleep restriction. These typically involve shifts toward slower EEG frequencies in the theta (4–8 Hz) and delta range (3.75–4.5 Hz). Chronic sleep restriction to 3 or 4 h time in bed has been reported to lead to a decrease in saccadic velocity and slow eye movements (via electrooculography).

Figure 1 Lapses of attention during a psychomotor vigilance test from two experiments of chronic sleep restriction. (a) In this experiment, sleep was restricted for 14 consecutive nights in 36 healthy adults. Subjects were randomized to 4 h (n = 13), 6 h (n= 13), or 8 h (n = 9) sleep opportunities at night. Performance was assessed every 2 h from 7:30 a.m. to 11:30 p.m. The graph shows cumulative increases in lapses of attention during the psychomotor vigilance task (PVT) per test bout across days. The horizontal dotted line shows the level of lapsing found in a separate experiment when subjects had been awake continuously for 64–88 h. (b) In this experiment, sleep was restricted for seven consecutive nights in 66 healthy adults (mean age, 48 years). Subjects were randomized to 3 h (n = 13), 5 h (n = 13), 7 h (n = 13), or 9 h (n = 16) sleep opportunities at night. Performance was assessed 4 times each day from 9 a.m. to 9 p.m. As in a, the graphs show cumulative increases in PVT lapses per test bout across days within the 3 h and 5 h groups (p = 0.001). The horizontal dotted line shows the level of lapsing found in a separate experiment by Van Dongen et al. when subjects had been awake continuously for 64–88 h. (a) Adapted from Van Dongen HP, Maislin G, Mullington JM, and Dinges DF (2003) The cumulative cost of additional wakefulness: Dose–response effects on neurobehavioral functions and sleep physiology from chronic sleep restriction and total sleep deprivation. *Sleep* 26: 117–126. (b) Adapted from Belenky G, Wesensten NJ, Thorne DR, et al. (2003) Patterns of performance degradation and restoration during sleep restriction and subsequent recovery: A sleep dose–response study. *Journal of Sleep Research* 12: 1–12. Reprinted from Opp MR (ed.) (2005) *SRS Basics of Sleep Guide*. Westchester, IL: Sleep Research Society.

Slow eyelid closures (which are associated with vigilance lapses) have also been shown to increase with sleep loss and have been found to be a sign of drowsiness while driving.

In addition to affecting Multiple Sleep Latency Test and Maintenance of Wakefulness Test sleep propensity measures, sleep restriction can affect sleep physiology. Following acute total sleep deprivation, rebound increases in non-REM SWS and non-REM EEG slow-wave activity (SWA) – the putative marker of sleep homeostasis – are commonly observed, but these EEG slow-wave rebounds are much less marked in chronic sleep restriction. When sleep duration is 4 h or more, there appears to be modest loss of SWA but marked reductions of stage 2 non-REM and REM sleep time. Consequently, it appears that deficits in SWS and non-REM SWA are not the basis for the cumulative cognitive performance deficits observed during chronic sleep restriction to 4–7 h per night, although they may be more closely related to subjective sleepiness. Other aspects of sleep must be critical to maintaining waking cognitive functions. Total sleep time, rather than non-REM

EEG SWA, therefore remained the major predictor of waking cognitive functions.

Sleep Debt Hypothesis versus Wake Extension Hypothesis

In the chronic sleep restriction experiment involving sleep limited to 4, 6, or 8 h time in bed for 14 consecutive nights, physiological sleep responses to sleep reduction did not mirror waking neurobehavioral responses, but cumulative wakefulness in excess of 15.84 h predicted performance lapses across all sleep deprivation conditions. This suggested that the concept of 'sleep debt' (or cumulative lost sleep) accounting for the cumulative waking neurobehavioral deficits was perhaps a misnomer since it was the additional wake time in excess of 15.84 h per day that appeared to accumulate and have a neurobiological 'cost' over days of sleep restriction. Thus, it is possible that the cumulative cognitive deficits during chronic sleep restriction were not caused by reduction of sleep time *per se* but, rather, by excessive wakefulness beyond a maximum period during which stable neurobehavioral functioning could be maintained. Viewed this way, cumulative wake extension (i.e., excess wakefulness), rather than cumulative loss of sleep (i.e., sleep debt), may be the primary cause of progressively reduced behavioral alertness both across days of chronic sleep restriction and across days of total sleep deprivation. This hypothesis awaits a neurobiological explanation. There has been little basic research published on possible neurobiological mechanisms for the effects of chronic sleep loss on waking cognitive performance, but it has been proposed that an increase in A_1 adenosine receptors in the basal forebrain in response to initial sleep loss may sensitize the brain to subsequent sleep loss.

Physiological Effects of Sleep Deprivation

Endocrine and Metabolic Effects of Chronic Sleep Restriction

Sleep restriction has also been found to affect metabolic responses. Restriction of sleep to 4 h time in bed per night for six nights, compared to extension of sleep to 12 h time in bed per night for six nights, has been associated with elevation in evening cortisol, increased sympathetic activation, decreased thyrotropin activity, and decreased glucose tolerance. Leptin levels have been observed to decrease following sleep restriction to 4 h time in bed. It is believed that these endocrine changes contribute to altered signaling of hunger and appetite, which may promote increased weight gain and obesity. Support for this hypothesis comes from epidemiological evidence of a U-shaped curvilinear association between sleep duration and body mass index (BMI). Those who slept less than 8 h had increased BMI proportional to decreased sleep. In addition, short sleep (5 vs. 8 h) was associated with low leptin (an adipocyte-derived hormone that suppresses appetite) and high ghrelin (predominantly a stomach-derived peptide that stimulates appetite), independent of BMI. The association of sleep duration, especially reduced sleep time, with obesity had also been observed in other epidemiological studies.

Cardiovascular Effects of Chronic Sleep Restriction

An increase in cardiovascular morbidity has been associated with sleep duration in a number of epidemiological studies. For example, there is epidemiological evidence of hypertension and increased risk of coronary events in women reporting less than 7 h of sleep or more than 9 h sleep per day. Similar findings have also been observed in studies examining cardiovascular health in shift workers, who typically experience chronic reductions in sleep duration in addition to circadian disruption. The mechanism underlying the link between chronic sleep restriction and increased cardiovascular risk is unknown. One potential mechanism, however, may be activation of inflammatory processes during sleep loss, which has been reported to occur in laboratory studies of healthy sleep-deprived adults.

Immune and Inflammatory Effects of Chronic Sleep Restriction

A single night of total or partial sleep deprivation can alter natural killer cell activity and circulating levels of leukocytes and cytokines (interleukin-6 and tumor necrosis factor-α) in healthy humans. Although there have been few controlled experiments, it appears that restriction of sleep to 4 h time in bed for six nights acutely reduced antibody titers to influenza vaccination. Attenuation in the febrile response to an endotoxin (*Escherichia coli*) challenge in subjects undergoing chronic sleep restriction to 4 h time in bed for 10 nights has also been observed. The basic mechanisms by which these acute effects of sleep deprivation on immune responses occur remain to be identified, and their clinical significance is unknown.

Differential Neurobehavioral Vulnerability to Sleep Loss

Sleep deprivation (both acute total and partial chronic) not only increases neurobehavioral variability within subjects (i.e., state instability) but also

reveals marked cognitive performance differences between subjects. As sleep pressure accumulates over time, intersubject differences also increase markedly. Although most people suffer neurobehavioral deficits when sleep deprived, there are individuals with extreme reactions at both ends of this spectrum. Some people experience very severe impairments even with modest sleep loss, whereas others show few, if any, cognitive deficits until sleep deprivation is very severe. Studies have shown that these responses to sleep deprivation are stable and reliable across subjects, suggesting that they are traitlike and likely genetic rather than the result of situational variability or 'noise'. Thus, some people are much more vulnerable to the neurocognitive effects of sleep deprivation than others. The biological basis of the differential vulnerability to neurocognitive deficits from sleep loss is not known.

Summary

For more than a century, experiments on the effects of total and chronic partial sleep deprivation in healthy human subjects have revealed that sleep cannot be deprived without immediate and often profound changes to neurobehavioral functions, especially those involving attention and memory. In addition to the brain being sensitive to sleep loss, experiments indicate that endocrine, metabolic, immunologic, and inflammatory processes are also affected by sleep deprivation. Despite evidence of the behavioral and physiological risks posed by sleep deprivation, time devoted to sleep has declined in industrialized societies, especially in the past 20 years. Instead of protecting sleep time, there is a tendency in modern cultures to spend resources on ways to safely reduce sleep time to accommodate 24-h operations. These efforts have met with modest success. There is as yet no substitute for sleep, and sleep duration remains the most reliable predictor of wake state stability and neurobehavioral functioning.

Sleep in Adolescents

L Tarokh, Brown University, Providence, RI, USA
M A Carskadon, Brown University, Providence, RI, USA; and E. P. Bradley Hospital, Providence, RI, USA

Sleep behavior and sleep physiology manifest dramatic changes across adolescent development. Certain sleep pattern changes arise from psychological and societal sources, such as a growing sense of independence, increasing access to electronic apparatus in the bedroom, greater academic obligations, and more social opportunities. Some have noted that emergent changes in affect regulation and social affiliation, including 'first love,' can have striking influences on sleep patterns.

Certain hormonal changes that herald and accompany puberty are sleep related, such as the pulsatile sleep-dependent release of luteinizing hormone (LH), which leads to subsequent sleep-related release of sex steroids. Whether these hormonal changes have a direct effect on sleep is unknown; that sleep changes substantially in the pubertal transition is well established. As discussed later, maturation of the central nervous system (CNS) affects the phenomenology of sleep as well as the underlying intrinsic regulatory processes.

In addition to CNS changes, adolescent maturation is associated with new physical attributes and reproductive development. A common method to gauge pubertal development in humans is Tanner staging, which relies on identifying benchmarks in secondary sexual characteristics. Thus, in boys genital development and the growth and distribution of pubic hair are evaluated, and in girls breast development and pubic hair growth and distribution are evaluated. Tanner stage 1 is assigned if no signs of development are identified, Tanner stages 2–4 designate intermediate pubertal stages based on achieving developmental criteria, and Tanner stage 5 requires achievement of all the benchmarks identifying full maturation of secondary sexual characteristics. Note that central signs of puberty (e.g., nocturnal LH release and likely CNS changes) occur earlier than the external physical attributes of puberty.

Adolescent Development and the Brain

The behavioral, emotional, and cognitive changes of adolescence are accompanied by large-scale remodeling of the brain that provides a biological basis for many features of adolescent development. *In vivo* longitudinal studies of the developing human brain using magnetic resonance imaging (MRI) show that gray matter volume increases during preadolescence and declines postadolescence. This inverted U-shape change in gray matter volume corresponds on a cellular level with a marked proliferation of axons/synapses in early puberty and synaptic pruning in later adolescence. Positron emission tomography studies have shown a similar inverted U-shape increase and then decrease in waking cerebral glucose metabolic rates. These cross-sectional studies demonstrate a peak in absolute cerebral glucose metabolism at the age of 9 or 10 years followed by a steady decline until the ages of 16–18 years, at which point levels reach adult values. Not surprisingly, there is a strong correspondence between the developmental curve for blood glucose metabolism, gray matter volume, and synaptogenesis. The combined results from these studies provide strong evidence that adolescence is a time of major neural reorganization.

Adolescent Development and the Waking Electroencephalogram

The changes in gray matter volume, glucose metabolism, and synaptogenesis parallel the decline of electroencephalographic (EEG) power across adolescent development. The EEG signal is thought to arise from synchronous synaptic activity at the cortex; therefore, a reduction in the number of cortical synapses would logically result in dampened EEG power. Although gray matter volume and EEG power decline across adolescence, white matter volume – an index of myelination – increases in a linear manner. Adolescent development is also accompanied by greater functional connectivity between distant cortical regions (i.e., connections between frontal and occipital lobes), as inferred from EEG coherence. Cross-sectional studies of waking EEG coherence show a pattern of increasing inter- and intrahemispheric coherence before and during adolescence.

Along with waking EEG power and coherence changes, the frequency of the dominant posterior rhythm (alpha rhythm) increases as the brain matures. This rhythm is associated with a relaxed waking state and increases in amplitude with eye closure. The dominant posterior rhythm is seen during eye closure in infants as young as a few months old and increases in frequency from approximately 4 Hz in infancy to approximately 8 Hz in mid-childhood, reaching adult frequencies (8–12 Hz) by adolescence.

Adolescent Development and the Sleeping EEG

The EEG is a central measure of sleep, and indeed, EEG patterns are a defining characteristic of sleep in mammals. Typically measured along with electrooculogram and electromyogram, the EEG in humans contributes to defining sleep states (nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep) and four sleep stages within NREM sleep. As outlined previously, a significant amount is known about the maturation of the waking EEG. Less is known about adolescent development of the sleeping EEG, although a number of characteristic changes have been identified. As with waking, for example, the age-related decrease in EEG power is strikingly apparent during sleep, particularly in the lower frequencies.

Figure 1 illustrates a number of changes of nocturnal sleep that accompany adolescent maturation by displaying the sleep hypnogram of a representative 10-year-old Tanner stage 1 child and a 15-year-old Tanner stage 5 adolescent. When sleep quantity is held constant at approximately 9 or 10 h, adolescent development is accompanied by a profound decline of approximately 40–50% in the quantity of NREM sleep stages 3 and 4, commonly referred to as slow-wave sleep (SWS). The dampening of EEG amplitude consequent to cortical synaptic pruning may account for the developmental reduction of SWS. At the same time, stage 2 NREM sleep, the definition of which involves EEG features unrelated to amplitude (i.e., sleep spindles and K complexes), increases. Another impressive developmental feature of sleep is the advance of REM sleep to an earlier point in sleep, from a latency of approximately 150–180 min to a latency of approximately 100 min in most studies.

Figure 2 illustrates the marked reduction of EEG amplitude for NREM sleep stages 2 and 4 and REM sleep across adolescence. The sleep EEG amplitudes are notably lower in the more mature adolescent. This EEG amplitude decline appears to be non-state-dependent because it is seen in wakefulness and NREM and REM sleep, although definitive longitudinal assessments have not been carried out. Figure 3 emphasizes this point by displaying the absolute EEG power spectra across the entire night for the pre- and postpubertal youngsters. Warmer colors (designating greater power) in the Tanner stage 1 child versus the Tanner stage 5 child are evident across frequencies and states. The differences are especially clear for low frequencies (1–4 Hz), particularly early in the night.

Figure 1 Sleep hypnograms of two boys, one at pubertal Tanner stage 1 (top) and the other at Tanner stage 5 (bottom). The *y*-axis designates stage/state, and the *x*-axis indicates elapsed time from lights out. REM episodes are underlined with a red bar. Stages were determined by visual scoring of 30 s epochs according to standard staging criteria. Significantly greater stage 4 sleep is typical of prepubertal adolescents compared to postpubertal adolescents. The decreased stage 4 sleep in more mature adolescents is accompanied by increased stage 2 sleep. Note also that REM sleep episodes increase in duration over the course of the night. Of note is the delayed onset of the first REM episode in the Tanner 1 preadolescent. Indeed, the first REM episode is often 'skipped' in Tanner 1 preadolescents.

Figure 2 Comparison of Tanner stage 1 (top) and Tanner stage 5 (bottom) EEG tracings of NREM sleep stage 2, stage 4, and REM sleep from the same children and nights as in Figure 1. The calibrations designate the voltage and timescale of all tracings. The diminished EEG amplitude in the more mature adolescent is obvious from these tracings and is most evident in stage 4 sleep; however, this developmental change is not stage specific and occurs in all sleep stages and in the waking EEG. The reduction of EEG amplitude during early adolescence is believed to result from cortical synaptic pruning that occurs during this developmental stage.

This EEG balance of power toward the less mature brain is also clear for the sigma frequencies (approximately 14 Hz). Note that the sigma 'stripe' in these plots is evident only for NREM sleep and disappears during REM episodes.

Sleep Regulation and Adolescent Development

Homeostatic Process (Process S)

In the two-process model of sleep regulation, independent homeostatic (process S) and circadian (process C) processes operate interactively to regulate the amount and timing of sleep. Process S, which can be characterized colloquially as sleep pressure, has been modeled using the NREM sleep EEG slow-wave activity (0.5–4.5 Hz; SWA). As waking is extended, NREM EEG SWA power increases during subsequent sleep and is modeled using a saturating exponential function. With sleep, NREM EEG SWA spectral power manifests an exponential decay across the sleep episode.

The substantial decline in absolute SWA EEG power across adolescence raises the additional question of whether the homeostatic regulatory process is altered and perhaps secondarily accounts for certain expressed sleep behaviors in adolescents. The Brown University group examined this issue in several ways using cross-sectional data sets. First, they examined the dynamics of the decay of SWA across the sleep episode of Tanner stage 1 and Tanner stage 5 adolescents. As Figure 4 illustrates, the exponential fits were overlapping functions, and the mean decay time constant for Tanner stage 1 subjects was 143.2 min (range, 87.0–195.5) and that for Tanner stage 5 subjects was 128.2 min (range, 80.4–176.9). This finding indicates that the nocturnal recovery process is similar for adolescents across this developmental phase, with an implication that neither sleep intensity nor sleep need change with adolescence.

On the other hand, when the accumulating function of process S is examined in the context of extended wakefulness, the data indicate the presence of a maturational change. One approach examined sleep pressure by assessing the speed of falling asleep

Figure 3 Time–frequency plot of the same nights and children depicted in the hypnograms displayed in **Figure 1**. The figure is derived from fast Fourier transform analysis of the C3/A2 EEG signal. The plots depict how the frequency content of the EEG signal changes over the course of the night. The *y*-axis is the frequency and the *x*-axis shows hours since lights out. EEG power is indicated by the color, in which warmer colors (reds and yellows) indicate higher power and cooler colors (aqua and blue) indicate lower power. During NREM sleep, the power of the signal at frequencies below 4 Hz is maximal, particularly early in the night, ebbing in strength across the sleep episode. Note also that the power in these slow frequencies is markedly greater for the younger boy. NREM episodes are also marked by high power in the spindle frequency range (12–16 Hz). In contrast, during REM episodes, the power in the lower frequency and spindle bins is diminished. The characteristic cycle-by-cycle nature of the sleep EEG is apparent in these plots. Overall EEG power differences between the Tanner 1 and Tanner 5 participants are readily apparent at all frequency bins.

in adolescents at Tanner stage 1 and Tanner stage 5. This study found that after approximately 14.5, 16.5, and 18.5 h awake, the less mature youngsters fell asleep significantly faster than the more mature group. A second approach modeled process S using SWA in a sleep deprivation study and found fitted functions for the exponential saturating function with a time constant of 15.4 ± 2.5 h for the mature Tanner stage 5 adolescents compared to 8.9 ± 1.2 h for a group of pre-/early pubertal (Tanner stages 1/2) children. These two findings indicate that the more mature adolescents, although they exhibit the same sleep recovery pattern, may find it easier to remain awake longer than the less mature adolescents. This developmental alteration may contribute to the later timing of sleep that emerges across adolescence.

Circadian Timing (Process C)

Maturational changes in the circadian timing system (CTS) also appear to contribute to the behavioral changes in adolescent sleep patterns. The master 'clock' in mammals has been localized to a small paired nucleus in the hypothalamus, the suprachiasmatic nuclei (SCN). A direct pathway from the retina, particularly the light-sensitive melanopsin-containing retinal ganglion cells, carries light input directly to the SCN, where the light signals affect the molecular machinery of the CTS within SCN neurons.

Figure 4 Dynamics of slow-wave activity (SWA; 0.6–4.6 Hz) across the sleep episode in eight prepubertal (solid circles) and eight mature (open circles) adolescents. SWA power for each NREM sleep cycle is shown as a percentage of the individual child's average overnight NREM sleep, and each symbol represents this value plotted at the midpoint of the time relative to the onset of sleep. The lines show exponential functions fitted to the Tanner 1 (thick line) and Tanner 5 (thin line) data. (Both fits achieved r^2 values of 0.83.) These data indicate that the dissipation of SWA, and inferentially of process S, does not change with pubertal development, although the power of the EEG SWA signal is markedly changed as shown in **Figure 3**. Reproduced from Jenni OG and Carskadon MA (2004) Spectral analysis of the sleep electroencephalogram during adolescence. *Sleep* 27: 774–783.

One of the first findings implicating the CTS in the adolescent delay of sleep timing was an association between self-reports of phase preference (e.g., morningness vs. eveningness) and puberty in sixth-grade girls: Girls who rated themselves more mature also rated themselves with greater evening-type phase preference. Subsequent studies examined these phenomena using better measures, such as Tanner staging and circadian phase measured using the dim light melatonin onset (DLMO) phase. DLMO is a reliable and noninvasive assessment of circadian phase acquired from serial plasma or saliva samples collected under dim light (less than approximately 40 lux) conditions. Because melatonin levels are low during the biological daytime and rise during the biological night, the circadian phase can be measured by assessing the onset phase of melatonin release. In adolescents, saliva is collected approximately every 30 min in dimly lit conditions during the participants' usual evening hours.

A major feature of the CTS is its sensitivity to environmental light. Effects of light on the CTS are phase dependent; to wit, light impinging on the clock in the early nighttime produces phase delays (later timing) and light occurring in the early morning produces phase advances (earlier timing). Because of this phase-dependent light sensitivity, mature adolescents living in their normal circumstances will inevitably express later circadian phase positions because their delayed sleep pattern exposes them to light at a later time. Therefore, to determine whether the internal process undergoes developmental change, light exposure needs to be controlled, for example, by controlling sleep (dark) schedules. In such controlled circumstances, the DLMO phase is positively correlated with Tanner stage, whereby more mature adolescents have a later DLMO phase. This circadian phase delay across adolescence may affect the ability of older adolescents to fall asleep easily in the evening since the CTS favors wakefulness in the early circadian night, sometimes called the forbidden zone for sleep. In addition to humans, a pubertal delay of sleep behavior has been reported in rhesus monkeys and in the octodon degus, a small diurnal mammal with a relatively protracted developmental course from birth to reproductive maturity.

Attempts have been made to identify the underlying mechanism for this adolescent phase delay. One hypothesis holds that the intrinsic period of the circadian timing system may slow from prepubertal to postpubertal adolescence, thus delaying circadian phase. Studies that permit assessment of internal circadian period are both difficult and time-consuming and have not established the validity of this hypothesis. One study, however, has shown that the period is longer on average in adolescents than in adults. Another theory for the developmental change in circadian phase posits that the phase-dependent sensitivity to light's phase shifting effects may favor phase delays either through strengthening the delay response to evening light or through weakening the phase advance to morning light. Attempts to demonstrate this phenomenon have not been successful to date, although none has used the most circadian-sensitive shortwave (blue) light sources to examine the possibility of a maturational change in light sensitivity.

Thus, the circadian timing system does manifest a phase delay associated with pubertal/adolescent development; however, the mechanism for the delay is unknown. Unlike the sleep system in which the adolescent decline in EEG amplitude can be attributed directly to cortical synaptic pruning, no molecular, cellular, or systems basis has been identified to explain the maturation of the CTS across adolescence.

Interaction of Process S and Process C

As noted previously, the circadian timing system favors waking in the biological evening. Indeed, the strength of the arousing signal from the circadian timing system increases from the usual time of morning arousal until about the time of usual bedtime and

decreases across the typical nighttime window. On the other hand, the homeostatic sleep–wake process builds as waking is extended, only to dissipate during sleep. Either process on its own is untenable for supporting our usual sleeping and waking patterns; however, the interaction provides an arousing circadian signal later in the day to support alertness when the homeostatic pressure would otherwise favor sleep. Conversely, the circadian arousing signal wanes during the night. As morning comes, with circadian arousal at its nadir, wakefulness is underwritten by the restorative function of sleep.

In the case of adolescent development, this interaction plays out in several important ways. When daytime alertness is evaluated in children keeping an optimizing sleep schedule (10 h per night from 10:00 p.m. to 8:00 a.m.), the interaction of processes S and C manifests as maximal alertness from rising until bedtime. With the onset of puberty, however, the pattern shifts to one that augments midday sleepiness. In the experimental paradigm that showed this phenomenon, young people were followed annually across several years with summertime assessments on the optimized sleep schedule and sleepiness measured with the Multiple Sleep Latency Test (MSLT), a standardized measure of the speed of falling asleep (sleep propensity) at 2 h intervals across the day. In prepuberty, the youngsters maintained alertness near the ceiling of this measure throughout the day; at midpuberty, the pattern changed to exhibit faster sleep onsets on tests given in the middle of the afternoon. Subsequent evaluation of these data indicated that the phase delay of pubertal development resulted in a reorganization of the phase relationship between sleep and the circadian timing system. With this reorganization, the circadian buffering of accumulating sleep pressure across the waking day did not occur until a later phase, and thus midday sleepiness emerged.

In normal circumstances, however, adolescents do not live with optimal sleep. As outlined below, sleep occurs later and is shorter in older adolescents. This pattern results in chronic insufficient sleep on school nights that is not recuperated fully by nighttime sleep. In these circumstances, morning alertness specifically is impaired since adolescents wake with elevated homeostatic pressure and also at a circadian phase that does not support alertness.

One study examined the consequences of this mismatch in students attending the 10th grade of high school in the United States. These students were required to attend school beginning at 7:20 a.m. When followed on their normal sleep schedule for 2 weeks, the students obtained approximately 7.5 h of sleep each night, going to bed on average at approximately 10:30 p.m. and waking at approximately 6:00 a.m. When their alertness was measured using the MSLT, these adolescents were sleepiest at 8:30 a.m. (average speed of falling asleep was 5 min), and alertness improved in the late morning and early afternoon, presumably due to the alerting effects of the circadian timing system. Thus, the speed of falling asleep at 2:30 p.m. was 11 min. Of greater note in this study, however, was the appearance of an abnormal pattern of sleep in nearly 50% of the young people on the MSLTs: They had at least one test (usually at 8:30 a.m.) in which they fell directly into REM sleep rather than NREM sleep (i.e., sleep-onset REM episodes). Furthermore, the speed of falling asleep in this group was even faster at 8:30 a.m. – 3.4 min on average. A distinguishing feature of this group was that the phase of DLMO was later, and the investigators concluded that they woke at a much earlier circadian phase than the other students, at a time favoring sleeping over waking and REM sleep over NREM sleep. The MSLT results in these young people looked more like those of patients with a serious sleep disorder – narcolepsy – than healthy teens.

Sleep Habits and Adolescent Development

As mentioned previously, sleep patterns undergo major alterations across adolescent development – changes that have been confirmed in many surveys of young people on every continent (except Antarctica). In each case, the timing of sleep is later overall in older adolescents. In societal circumstances requiring early morning awakening – for example, with early starting time for school as found in many communities in the United States – sleep quantity also is reduced, at least on school days. Indeed, the difference between school day and weekend schedules becomes greater during adolescence. At age 9 or 10 years, for example, children may delay weekend bedtime slightly but tend not to delay or extend sleep as much on weekend mornings. By age 14 or 15 years, on the other hand, bedtime is much later on school nights, delayed by 1–3 h on weekends, and weekend sleep can be several hours longer than on school days. These weekday–weekend differences express both the pressure for sleep to delay during adolescence and the compensatory need for sleep on weekends due to insufficient sleep on school nights in the older adolescents.

The 2006 Sleep in America poll of the National Sleep Foundation surveyed approximately 1600 adolescents and caregivers. Data from this poll provide a contemporary perspective of adolescent sleep. Although this article has emphasized the biological bases of sleep pattern alterations across adolescence,

the influence of environmental factors is undeniable. Furthermore, the interactions among sleep regulatory changes and social/environmental influences and constraints can lead to troubling outcomes in susceptible youngsters. As the Sleep Foundation poll data show, school night sleep time reported by sixth-grade students in the United States is approximately 8.4 h and it is only 6.9 h in 12th-grade students, which by general consensus is significantly below the sleep need of teens.

The starting time for school plays an important role in setting the stage for short sleep in many adolescents. Thus, although teens' bedtimes delay significantly across adolescence, rising time on school days does not delay and indeed may actually become earlier (Figure 5). Later bedtimes fit well with the intrinsic maturational changes; earlier rising times, however, do not arise from a natural tendency on the part of adolescents but in direct response to waking in time for school. The result is truncated sleep time. In cases in which school begins later in the day, as shown by a number of ongoing studies of students in Brazil, Croatia, and the United States, teens sleep later and longer. One US study that examined sleep patterns of high school students before and after imposition of a later school schedule found that bedtimes did not change significantly; however, rising times were later and, consequently, youngsters slept more.

A newly emerging consensus also credits access to contemporary technologies as contributing to adolescent sleep patterns. For example, Belgian adolescents who report using electronic media to help them fall asleep in fact sleep less than other teens and report themselves as more tired. Furthermore, the National Sleep Foundation's 2006 Sleep in America Poll found

Figure 5 Adolescent self-reported sleep patterns taken from surveys performed in the 1990s with children living in the United States. Girls are represented by closed symbols and boys by solid symbols. Weekend bedtimes (top) and rise times (bottom) are shown with dotted lines; weekday (school day) schedules are indicated by solid lines. The sample included children ages 10–17 years who were enrolled in school at the time of the survey. Times on the *y*-axes are indicated using 24 h clock hours. Reproduced from Jenni OJ and Carskadon MA (2005) Infants to adolescents. In: *SRS Basics of Sleep Guide*, pp. 11–20. Westchester, IL: Sleep Research Society.

that compared to younger teens, older teens have increased numbers of technological devices (e.g., telephone, instant messaging, MP3 player, electronic games, television, computer, and Internet connection) accessible to them in their bedrooms. In addition, teens who reported having four or more such devices in the bedroom also reported sleeping 30 min less on average each night than those with fewer devices.

Consequences of Chronic Insufficient and Ill-Timed Sleep in Adolescents

The association of maturational changes of the intrinsic regulatory systems with the seductive nocturnal lifestyle options available to teenagers makes for a synergistic drive toward later timing of sleeping and waking for most teens. When confronted with the inevitability of an early school bell, a pattern emerges that comprises late, short, and irregular sleep. As noted previously, for some teens the combination results in extreme morning sleepiness and sleep-onset REM episodes. For others, the combination can be deadly. For example, in car crashes attributed to the driver having fallen asleep, the age of the driver is 16–25 years in more than 50% of cases.

Consequences of insufficient, irregular, and ill-timed sleep also include potential problems with mood regulation and depression, learning and memory, weight regulation, substance use or abuse, school tardiness and absenteeism, along with impulsivity and risk taking. Many of these behavioral tendencies are thought to be endemic problems of adolescence, yet the contributions of poor sleep may be involved. Serious consideration and scientific examination of these issues is needed. Trends point to continued deterioration of adolescent sleep patterns and at younger ages. Thus, whether adolescent sleep may affect the maturation of neurons, neural circuitry, or neurochemistry is in urgent need of study.

Sleep in Aging

M Rissling and S Ancoli-Israel, University of California at San Diego, San Diego, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Background

Sleep is one of many biological processes that invariably undergoes change with age. Older adults may experience an increase in sleep disturbance as the homeostatic and circadian rhythm processes regulating the sleep cycle become more fragile. Sleep is also affected by the many complications associated with physical and mental illness that often accompany aging. It is important to understand the distinction between expected changes in sleep associated with aging and those likely to arise from pathology unrelated to aging *per se*. This article reviews both.

Changes in Sleep with Age

It is generally well accepted that aging results in an overall decrease in slow-wave sleep (SWS). The amplitude of slow-wave delta waves is attenuated, and the percentage of SWS observed is markedly decreased. This process is gradual and begins in young adulthood, at around 20 years of age, but stabilizes by about age 60, with no further reduction in SWS. There is evidence of a gender difference, with men showing greater decreases in SWS than women. Latency to rapid eye movement (REM) sleep is also decreased in the older adult and is considered to be a direct consequence of the circadian phase advancement that occurs with aging.

The largest overall change observed in older adults is an increase in stage shifts, with more time spent awake in bed following sleep onset. The disruptions are often characterized by early morning awakenings and an inability to fall back to sleep and may be due to a number of sleep disturbances (such as insomnia or other specific sleep disorders) rather than to aging. The result is marked decreases in sleep efficiency (defined by the percentage of sleep that occurs while in bed) and consequently increases in daytime sleepiness. Stage 1 sleep is slightly increased in association with such arousals; stage 2 sleep appears to be more or less constant throughout the life span.

The need for sleep, or the sleep drive, however, does not diminish with age. Rather, it is the ability to satisfy the sleep drive that becomes impaired. Therefore, although the need for sleep remains the same, nighttime sleep is curtailed, with the remaining sleep drive redistributed to the daytime. The decreased ability to maintain nighttime sleep is most often attributed to changes in circadian rhythms, insomnia comorbid with medical or psychiatric illnesses and medication use, and the presence of other specific sleep disorders, such as periodic limb movements in sleep or restless leg syndrome (RLS), REM behavior disorder, and sleep-disordered breathing.

Changes in Circadian Rhythm

Circadian rhythms, such as hormone secretion, body temperature, and the sleep–wake cycle, fluctuate every 24 h. In humans, the sleep–wake cycle is regulated by the combined effect of an endogenous pacemaker and exogenous stimuli. The hypothalamic suprachiasmatic nucleus (SCN) is considered the endogenous clock of the brain and is believed to be the primary mediator of circadian rhythms. Circadian rhythms maintained by the SCN are naturally entrained by exogenous stimuli, or zeitgebers (time cues). The most significant zeitgeber is light, but other factors, such as physical activity, the timing of meals, and social interactions, have also been shown to be important regulators.

As people age, their circadian rhythms become weaker, desynchronize, and lose amplitude. It is hypothesized that the progressive deterioration of the SCN and its subsequent weakened functioning contribute to the disruption of circadian rhythms in older adults. The most common desynchronized pattern often seen in older adults is an advancement of the sleep phase.

Older adults with advancement of the sleep phase have increased numbers of early morning awakenings and difficulty maintaining sleep. They typically experience an increased drive for sleep between 7 p.m. and 9 p.m. and a drive to wake up between 3 a.m. and 5 a.m. Despite being sleepy earlier in the evening, they will often try to stay up later because of societal pressure, resulting in fewer hours spent in bed sleeping. The decreased total sleep time at night then results in daytime sleepiness and napping. Some older adults take inadvertent evening naps in front of the television or while reading early in the evening and then have difficulty falling asleep when they go to bed later in the evening; yet they still wake up early in the morning. This pattern gets interpreted as a complaint of insomnia, that is, difficulty falling asleep, difficulty staying asleep, and daytime sleepiness.

Treatment of Circadian Rhythm Disturbances

The most common treatment for circadian rhythm disturbances is bright light therapy. An advanced circadian rhythm can be delayed and the sleep–wake

cycle strengthened with evening light exposure. As the sun is the strongest source of bright light, older adults with advanced rhythms should spend more time outdoors during the late afternoon or early evening and avoid bright light in the morning hours (as morning light would advance their rhythms even more). Studies have also shown that exposure to artificial light via a bright light box in the early evening has a similar effect and can improve sleep continuity in both healthy and institutionalized older adults. Adherence to a regular sleep schedule will promote a more robust sleep–wake cycle. Physical activity has also been shown to improve nighttime sleep quality. Such therapies are without adverse effects, and each has been shown to improve mood, performance, and quality of life and to reduce fatigue.

While melatonin has been shown to be safe, the efficacy for circadian rhythm disturbances has not been established. There is little consensus on the recommended dose or timing of administration, and melatonin purity and composition are currently not regulated in the United States by the Food and Drug Administration (FDA).

Insomnia

Insomnia is defined as difficulty falling asleep or staying asleep or nonrestorative sleep which results in daytime consequences. Insomnia is found in 30–50% of those more than 60 years old. Gender differences exist as well, with older women being more likely to complain of insomnia than older men. In older adults, sleep maintenance insomnia (an inability to maintain sleep throughout the night) and early morning or terminal insomnia (awakening early in the morning, with difficulty returning to sleep) are the most common complaints. Insomnia in the older adult is most often comorbid with medical and psychiatric illness or the medications used to treat those illnesses. Insomnia may also be a complaint in patients with specific sleep disorders, such as RLS or periodic limb movements in sleep.

Consequences of Insomnia

The consequences of disturbed sleep are well known and may include difficulty sustaining attention, slowed response time, difficulty with memory, and decreased performance. These consequences can be more pronounced in older adults and may even be misinterpreted as symptoms of dementia. Insomnia disrupts the sleep of 64% of bed partners of both healthy and demented older adults and 84% of caregivers (i.e., who may sleep in separate rooms). Nighttime restlessness secondary to insomnia is often cited as the primary reason for institutionalizing a demented relative.

Untreated insomnia is associated with a nearly 500% increase in the general risk for serious accidents and injuries, including car accidents due to daytime sleepiness and hip fractures due to falls. In the older adult, insomnia is most often comorbid with medical and psychiatric disorders and the medications used to treat them.

Medical and Psychiatric Illness and Insomnia

Older adults are the most susceptible to comorbid insomnia as they are more likely to have multiple medical conditions. Data from the National Sleep Foundation 2003 poll on sleep in older adults showed that those with three or four medical conditions, including cardiac disease, pulmonary disease, stroke, and depression, reported significantly more sleep complaints than did those with none, one, or two conditions.

Medical and psychiatric illnesses most commonly associated with insomnia include pain resulting from osteoarthritis or malignancies, chronic obstructive pulmonary disease, congestive heart failure, nocturia (e.g., due to enlarged prostate) and incontinence, neurological deficits (e.g., stroke, Parkinson's disease, and dementia), gastroesophageal reflux, depression, and anxiety disorder. Difficulty falling asleep has a prevalence rate of 31% for patients with osteoarthritis and 66% for those with chronic pain conditions. In addition, 81% of arthritis patients, 85% of chronic pain patients, and 33% of diabetes patients report difficulty staying asleep.

Two additional conditions that are associated with aging and contribute to poor sleep are nocturia and menopause. Nocturia or frequent voluntary voiding of urine during the night and nocturnal polyuria, the production of an abnormally large volume of urine during sleep, are common causes of awakenings and disruption of nighttime sleep. Although nocturia is often perceived as causing nocturnal awakenings, it has been hypothesized that the fragmented sleep experienced by the older adult leads to more awareness of the need to void. The circadian rhythm of urine excretion is also altered with age such that there is a fall of renal concentrating ability, sodium conservation, and secretion of renin–angiotensin–aldosterone, and arginine vasopressin secretion and an increase of atrial natriuretic hormone. The bladder's ability to store urine decreases with age, and age-related lower urinary tract problems, such as detrusor overactivity, can affect frequency and urgency.

Menopause is associated with hormonal, physiologic, and psychological changes that affect sleep and may play a critical role in modulating both the presence and the degree of sleep disruption. Menopausal

vasomotor symptoms or hot flashes are known to lower sleep efficiency and cause multiple arousals during the night. Insomnia is a common symptom of menopause and may be partially related to psychological factors such as depression and anxiety.

In fact, insomnia can be prognostic or indicative of depression. While depressed mood may predict insomnia, unresolved insomnia also places adults at greater risk for developing depression, anxiety, and substance abuse. Studies in younger adults have suggested that treating the insomnia may improve depression.

Medication Use and Insomnia

Alerting or stimulating drugs, such as central nervous system stimulants, beta-blockers, bronchodilators, calcium channel blockers, corticosteroids, decongestants, stimulating antidepressants, stimulating antihistamines, and thyroid hormones are known to cause difficultly falling asleep when taken late in the day. Sedating drugs, such as sedative antihistamines, antihypertensives, and sedative antidepressants, may cause excessive daytime sleepiness when taken early in the day and contribute to daytime napping behavior and consequently delay nighttime sleep onset. Adjusting the dose or the time of day of administration often improves the insomnia.

Treatment of Insomnia

Effective treatments for insomnia in older adults include cognitive behavioral therapy (CBT) and pharmacological therapy.

CBT CBT is a combination of cognitive restructuring and behavioral modification for insomnia. The cognitive portion deals with misconceptions or unrealistic expectations about sleep (i.e., absolute requirement of 8 h or more of sleep), amplification of the consequences of not getting enough sleep, incorrect thinking about the cause of insomnia, and misunderstandings about healthy sleep practices. The behavioral component of CBT involves a combination of sleep restriction therapy, stimulus control therapy, and good sleep hygiene practices. Tables 1–3 list the rules for each of these, respectively.

A recent National Institutes of Health (NIH) State-of-the-Science Conference on Insomnia concluded that CBT is as effective as prescription medications for the treatment of chronic insomnia and that there are indications that the beneficial effects of CBT may last well beyond the termination of treatment. If pharmacologic treatment is initiated, it is most effective when combined with CBT.

Table 1 Stimulus control therapy

Stimulus control is a behavioral therapy that seeks to remove the association of sleeplessness with the bed. The following steps reflect the principles of stimulus control:
Step 1. Go to bed only when sleepy.
Step 2. Use the bed only for sleeping – do not read, watch television, or eat in bed.
Step 3. If unable to fall asleep within about 20 min (don't watch the clock), move to another room. Stay up until really sleepy. The goal is to associate the bed with falling sleep quickly.
Step 4. If you are awake at night for more than about 20 min, get out of bed.
Step 5. Repeat Step 4 as often as necessary.
Step 6. Awaken at the same time every morning regardless of total sleep time.
Step 7. Avoid naps.

From Bootzin RR, Epstein D, and Wood JM (1991) Stimulus control instructions. In: Hauri PJ (ed.) *Case Studies in Insomnia*, pp. 19–28. New York: Plenum; Bootzin RR and Epstein D (2000) Stimulus control. In: Lichstein KL and Morin CM (eds.) *Treatment of Late-Life Insomnia*, pp. 167–184. Thousand Oaks, CA: Sage and Morin C (2005) Psychological and behavioral treatments for primary insomnia. In: Kryger MH, Roth T, and Dement WC (eds.) *Principles and Practice of Sleep Medicine*, 4th edn., pp. 726–748. Philadelphia: Elsevier/Saunders.

Table 2 Sleep restriction therapy

Sleep restriction therapy that seeks to keep patients from spending excessive time in bed. The following steps reflect the principles of sleep restriction therapy:
Step 1: Cut bedtime to actual amount patient reports sleeping but not less than 4 h per night.
Step 2: Prohibit sleep outside these hours.
Step 3: Get up at the same time each morning.
Step 4: Have patient report daily the amount of sleep obtained.
Step 5: Compute sleep efficiency (SE); based on moving average of five nights; when SE is >85%, increase bedtime by15 min.
Step 6: Compute sleep efficiency (SE); when SE is > 80%, increase time in bed by going to bed 15 min earlier. Continue to get up at same time each morning.

From Glovinsky PB and Spielman AJ (1991) Sleep restriction therapy. In: Hauri PJ (ed.) *Case Studies in Insomnia*, pp. 49–63. New York: Plenum; Morin C (2005) Psychological and behavioral treatments for primary insomnia. In: Kryger MH, Roth T, and Dement WC (eds.) *Principles and Practice of Sleep Medicine*, 4th edn., pp. 726–748. Philadelphia: Elsevier/Saunders; and Spielman AJ, Saskin P, and Thorpy MJ (1987) Treatment of chronic insomnia by restriction of time in bed. *Sleep* 10: 45–56.

Pharmacological therapy There are several classes of medications used to treat insomnia in older adults, in particular benzodiazepine receptor agonists (benzodiazepines and nonbenzodiazepines), melatonin receptor agonists, antidepressants, antipsychotics, and anticonvulsants. In addition, over-the-counter

Table 3 Sleep hygiene rules for older adults

1. Maintain a consistent bedtime and uptime.
2. Use the bed only for sleep and satisfying sex. Avoid watching television, eating, or discussing stressful issues while in bed.
3. Minimize noise and temperature extremes.
4. Keep the bedroom environment as dark as possible. Minimize the exposure to bright light if you get out of bed during the night. Use the dimmest night-light possible.
5. Avoid naps if you have difficulty falling asleep at night. If must nap, restrict napping to 30 min or less in the early afternoon.
6. Avoid nicotine near bedtime and during night awakenings.
7. Avoid all forms of caffeine for 4–6 h before bedtime.
8. Although alcohol may help you fall asleep, metabolism of alcohol will cause awakenings.
9. Avoid eating heavy meals and large amounts of protein close to bedtime. A light meal of carbohydrates or dairy products (particularly milk) is preferable.
10. Avoid vigorous exercise just before bedtime.
11. Avoid having pets in bed at nighttime.

Table 4 Does and half-life of US Food and Drug Administration-approved agents for insomnia

Generic agent (trade name)	*Dose (mg)*[a]	*Half-life (h)*
Benzodiazepine receptor agonists: benzodiazepines		
Flurazepam HCL (Dalmane)	15, 30	47–100
Quazepam (Doral)	7.5, 15	39–73
Estazolam (ProSom)	0.5, 1, 2	10–24
Temazepam (Restoril)	7.5, 15, 30	3.5–18.4
Triazolam (Halcion)	0.125, 0.25	1.5–5.5
Benzodiazepine receptor agonists: nonbenzodiazepines		
Eszopiclone (Lunesta)	1, 2, 3	6
Zaleplon (Sonata)	5, 10, 20	1
Zolpidem (Ambien)	5, 10	1.4–4.5
Zolpidem MR (Ambien CR)	6.25, 12.5	2.8–2.9
Melatonin receptor agonist		
Ramelteon (Rozerem)	8	2–5

[a]The lowest dose is generally recommended as the starting dose for older people.

medications such as antihistamines (diphrenhydramine) and nutritional or herbal supplements are often used. The NIH conference concluded that there is no systematic evidence for the effectiveness of antidepressants, antipsychotics, anticonvulsants, antihistamines, or herbal preparations in the treatment of insomnia. The panel also expressed significant concerns about the risks associated with the use of these medications, particularly in older adults.

The NIH panel also concluded that the benzodiazepine receptor agonists and in particular the newer nonbenzodiazepines have been shown to be the most effective and safest of the sedative hypnotics (at the time of the conference, the melatonin receptor agonist remelteon had not yet been approved by the FDA). The key to successful pharmacologic treatment of insomnia lies in choosing the sedative or hypnotic with the characteristics that best fit the patient's complaints. (It is important to note that only ten agents have been approved by the FDA for the treatment of insomnia. It is important to note that there are only 10 agents approved by the FDA for the treatment of insomnia, listed in Table 4 with the recommended dose and half-life. Table 5 lists the indications for the five newer nonbenzodiazepine receptor agonists and the melatonin receptor agonist.)

If sedatives or hypnotics are presecribed, the potential side effects must be taken into account. The administration of long-acting benzodiazepines can cause adverse daytime effects such as excessive daytime sleepiness and poor motor coordination, which may lead to injuries. In older adults, the risk of falls, cognitive impairment, and respiratory depression are of particular concern, although recent data suggest that insomnia *per se*, and not hypnotics, might increase the risk of falls. Chronic use of long-acting benzodiazepines can lead to tolerance and withdrawal symptoms if they are abruptly discontinued. In addition, the potential for exacerbating coexisting

medical conditions such as severe hepatic or renal disorders exists when some of these medications are used. The newer nonbenzodiazepine agents have been shown to be effective with a lower propensity for causing clinical residual effects, withdrawal, dependence, or tolerance.

Specific Sleep Disorders

There are also specific sleep disorders which are quite common in the older adult and which contribute to poor sleep. These would include sleep-disordered breathing (SDB), RLS and periodic limb movements in sleep, and REM behavior disorder.

SDB

SDB, also called sleep apnea, is a disorder in which the patient periodically stops breathing during sleep. Each apnea (complete cessation in respiration) or hypopnea (partial decrease in respiration) lasts a minimum of 10 s and generally ends with an arousal. This results in fragmented sleep and nocturnal hypoxemia. The total number of apneas plus hypopneas per hour of sleep is called the apnea–hypopnea index (AHI) or respiratory disturbance index (RDI). Depending on the laboratory, an AHI or RDI greater than or equal to 5–10 is required for the diagnosis of SDB.

The prevalence of SDB in older adults has been estimated to be between 30% and 60%, substantially higher than in younger adults. Cross-sectional studies have shown that there is a small increase in prevalence of SDB with increasing 10-year age groups. In the longest longitudinal study, older adults followed for 18 years showed changes in AHI only when associated with changes in body mass index.

There are two main types of SDB. The first, central sleep apnea, occurs when the respiratory centers in the brain shut down during sleep, and there is no attempt to breathe. Central sleep apnea is most common in congestive heart failure and is often associated with Cheyne–Stokes breathing. The second, obstructive sleep apnea (OSA), is the more common and occurs when the muscles of the airway collapse. The two main symptoms of OSA are loud snoring and excessive daytime sleepiness (EDS). EDS, which results from the recurrent nighttime arousals and sleep fragmentation, may manifest as unintentional napping or falling asleep at inappropriate times during the day. EDS can cause reduced vigilance and is associated with cognitive deficits, which may be particularly serious in older adults who may already have some cognitive impairment at baseline.

In addition to the cognitive deficits that may occur as a result of SDB, there is some evidence that many of the progressive dementias (e.g., Alzheimer's and Parkinson's disease) involve degeneration in areas of the brain stem responsible for the regulation of respiration and other autonomic functions relevant to sleep maintenance, thus placing the patient at increased risk for SDB.

Patients with SDB are at greater risk for hypertension, cardiac arrhythmias, congestive heart failure, myocardial infarction, and stroke. Most of the research, however, has not focused on older adults, so the relationship between SDB and some of these various morbidities remains unknown in the older population. Research that has targeted older adults has reported an association between SDB and the risk of developing cardiovascular disease, including coronary artery disease and stroke.

Treatment of SDB Treatment of SDB in older adults should be guided not only by the severity of the SDB but by the significance of the patient's symptoms. Patients with more severe SDB (AHI > 20) deserve a trial of treatment. For those with milder SDB (AHI < 20), treatment should be considered if comorbid conditions such as hypertension, cognitive dysfunction, or EDS are present. Treatment should never be withheld because of age or because of assumed noncompliance.

The gold standard for treating SDB is continuous positive airway pressure (CPAP), a device which provides continuous positive pressure via the nasal passages or oral airway, thus creating a pneumatic splint to keep the airway open during inspiration. If used appropriately, CPAP has been shown to be safe and efficacious. Alternative treatments include oral appliances, weight loss (although most older adults with SDB are not obese), and surgery; however, no other treatments have been shown to be as effective as CPAP.

Significance of SDB in development The presentation of sleep apnea in the older adult is not necessarily the same as in the younger adult. This has led to the idea that OSA in older adults might be a different disorder from OSA in younger adults. Two questions that arise are whether OSA is pathological in older adults and whether OSA in the older patient should be treated, and if so, when?

From a clinical standpoint, does it matter what is causing SDB in the older adult? Does it matter if the SDB in the older adult is the same as or different from the SDB seen in the younger adult? Probably not. What matters is whether SDB in the older adult has negative consequences. Most studies suggest that SDB does not increase the risk of mortality in the older adult, but that older adults with SDB are excessively sleepy and that SDB may contribute to decreased

quality of life, increased cognitive impairment, and greater risk of nocturia, hypertension, and cardiovascular disease. In addition, older adults with both insomnia and SDB have more functional impairment than those with just insomnia.

Any patient, no matter the age, who presents with symptoms of impairment as well as with a history of traffic accidents and repeated falls, should be evaluated for a sleep disturbance. Treatment of a symptomatic older patient should not be withheld on the basis of age, as the consequence of SDB can be just as serious in older as in younger patients. The bottom line is that if the sleep apnea is associated with clinical symptoms (e.g., hypertension, cognitive dysfunction, nocturia, high levels of sleep-disordered breathing, cardiac disease), then it should be treated, regardless of the age of the patient.

Periodic Limb Movements and RLS

The condition known as periodic limb movements in sleep (PLMS) is characterized by repetitive leg movements during sleep, occurring every 20–40 s and recurring several hundred times over the course of the night, each causing a brief awakening, which results in sleep fragmentation. Patients with PLMS may complain of EDS and/or insomnia. The number of limb movements per hour of sleep is called the periodic limb movement index, with ten or more limb movements per hour needed for a clinical diagnosis. A diagnosis of PLMS therefore must be made with an overnight sleep study that records leg movements. The etiology of PLMS is unknown. PLMS can be seen in patients with fibromyalgia and in conjunction with other primary sleep disorders, including SDB and narcolepsy.

While the prevalence of PLMS in adults is estimated to be 5–6%, the rate increases dramatically with age, with reported prevalence rates of up to 45% in community-dwelling people over the age of 65.

RLS, a condition strongly linked to PLMS, is characterized by leg dysesthesia, often described as 'a creepy crawling' or 'restless' sensation, occurring in the relaxed awake state. The uncomfortable sensations can be relieved only by movement. The diagnosis of RLS is made on the basis of history alone, often with the question, When you try to relax in the evening or sleep at night, do you ever have unpleasant, restless feelings in your legs that can be relieved by walking or movement? Patients may have no knowledge that they kick, so interviewing the patient's bed partner may be helpful in elucidating the history of both RLS and PLMS. Patients with symptoms of RLS should also be assessed for anemia, uremia, and peripheral neuropathy as each of these conditions can cause or exacerbate RLS.

Treatment of PLMS and RLS RLS and PLMS are treated primarily with dopamine agonists, which reduce the number of kicks and associated arousals. At this time, only ropinirole and pramipexole have been FDA-approved for the treatment of RLS.

REM Behavior Disorder

REM behavior disorder (RBD) is characterized by the intermittent absence of normal skeletal muscle atonia during REM sleep, resulting in patients' acting out their dreams. RBD generally occurs during the last third of the night, when REM sleep is more common. The movements during RBD may be violent and potentially harmful to patient and bed partner. Vivid dreams, consistent with the patient's aggressive and/or violent behavior, may be recalled on waking.

The prevalence of RBD is unknown, but it has been shown to be most common in older men. The etiology of RBD is also unknown, but there is a strong association between idiopathic RBD and neurodegenerative diseases, including Parkinson's disease, multiple system atrophy, and Lewy bodies dementia, with the RBD often preceding the other disorders by years. Data suggest that close to half of RBD patients develop Parkinson's disease within several years of the RBD diagnosis. The onset of acute RBD has been associated with stress disorders and the use of monoamine oxidase inhibitors and fluoxetine as well as withdrawal of REM-suppressing agents (e.g., alcohol, tricyclic antidepressants, amphetamines, and cocaine).

Treatment of RBD Treatment of RBD with clonazepam, a long-acting benzodiazepine, results in partial or complete cessation of abnormal nocturnal motor movements in 90% of patients. However, because of the long half-life, many patients report residual sleepiness in the morning and during the day. Recently, melatonin has also been shown to be an effective treatment. In addition to the pharmacologic treatment, other aspects of treatment should include good sleep hygiene and education for the patient and bed partner. The bedroom should be made safer by removing heavy or breakable or potentially injurious objects from the bed's vicinity. Heavy curtains should be placed on bedroom windows and doors, and windows should be locked at night. Finally, to avoid falling out of bed, patients may consider sleeping on a mattress on the floor.

Conclusion

The ability to have restful sleep decreases with age but is likely independent of age itself. Medical and psychiatric disorders, medication, circadian rhythm changes, and primary sleep disorders (such as SDB,

RLS or PLMS, and RBD) contribute to older adults' decreased ability to maintain a full night's sleep. Each of these conditions is treatable, and health care professionals should never withhold treatment because of age or because of assumed noncompliance.

Sleep Mentation in REM and NREM: A Neurocognitive Perspective

J S Antrobus, The City College of New York, New York, NY, USA
E J Wamsley, Harvard Medical School, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Dreaming in Rapid Eye Movement Sleep

The neurocognitive study of sleep mentation began when Aserinsky, in the first all-night electroencephalograph (EEG) study of sleep, observed periodic intervals of rapid eye movements (REMs) associated with reports of long, visually vivid, and often bizarre dreams. Although Aserinsky quite plausibly assumed that sleepers were scanning their dream imagery, this assumption has not been confirmed. Relative to periods of non-REM (NREM) sleep, REMs occur during periods of low-voltage, high-frequency EEGs so similar to that of waking that European scientists called it 'paradoxical' sleep. The first REM period typically follows about 90 min of NREM sleep and lasts about 10 min. Subsequent REM periods increase in duration and make up a total of 21% of sleep time. Although REMs are most frequent at the onset of each REM period, and are associated with the most visually vivid dream reports, vivid dreaming is reported throughout the period, even after intervals of REM quiescence. Sleepers report some content from about 80% of REM awakenings, as compared to 50% of NREM awakenings. REM reports are, on average, more vivid, emotional, storylike, and bizarre than are NREM reports. Relative to these REM reports, NREM reports are generally shorter and thoughtlike, more often consisting of isolated, static images.

Although the association between REM sleep and dreaming is one of the strongest, nonpathological, neurocognitive associations ever discovered, in 1953 what was known about waking neurophysiological processes was insufficient to instruct a model of dreaming sleep. Consequently, neurological models of dreaming initially emphasized the pontine processes that produced the alternation between REM and NREM sleep, at the expense of describing how cortical structures might generate the thought and imagery of those states. REM/NREM models were also silent about the fact that 6% of NREM reports were more dreamlike than were REM reports, matched by sleeper and time of night, and about the rather dramatic increase in the dreamlike quality of both REM and NREM reports in the late morning.

The Activation–Synthesis Model

Though the study of reported sleep mentation is necessarily limited to humans, the first brain models of REM/NREM sleep were based on the cat. Hobson, McCarley, and their colleagues solved the puzzle of the paradoxical wakelike EEG pattern of REM sleep when they showed that it is produced by reticular–thalamic–cortical circuits similar to those that Moruzzi and Magoun had previously shown to produce general wakefulness. The 90-min periodic alternation between REM and NREM sleep is controlled by pontine circuits. The primary distinction between waking and REM sleep is that the pontine-initiated REM activation process strongly inhibits both afferent input, from the sensory pathways, and efferent motor output. In short, it produces an active brain, with high sensory thresholds and, except for the oculomotor system, motor paralysis. In REM sleep, the dreamer can attempt to run, but efferent commands from the motor cortex are inhibited and the afferents that normally confirm feedback of movement, both kinesthetic and visual, are not received. The dreamer may interpret this to mean that he/she is 'stuck.'

But how, in the absence of sensory input, does the brain produce imagery and thought? In their activation–synthesis model (1977), Hobson and McCarley proposed that the 'input' is oculomotor information initiated in the pons and transmitted via pontogeniculooccipital (PGO) circuits to the cortex. In the attempt to 'synthesize' this information, the cortex creates a semicoherent visual story (i.e., the dream).

The large amplitude of the PGO spikes during REM sleep in cats suggested that they might interrupt the cortical EEG and thereby the coherence of the ongoing story sequence, producing the bizarre characteristics of the dream. But this assumption has yet to receive empirical support. Because of the pontine origin of this circuit, Hobson further argued that the Freudian assumption of a cortical (i.e., higher order) origin of dream process was without merit. The synthesis portion of the model is based on the quite reasonable neurocognitive isomorphic assumption that the cortex interprets subcortical processes similarly during sleep and waking. Thus, a command from the lateral geniculate nucleus to move the eyes rightward in waking should be interpreted similarly in REM sleep. However, the geniculooculomotor left–right orientation pattern of waking is not sustained, at least consistently, in REM sleep – the isomorphism assumption does not hold in this particular case.

Synthesis and Dream 'Incorporation'

The stimulus–response experimental procedures that are so effective in waking cognitive neuroscience are almost useless in sleep, since processing a stimulus generally drives the sleeper out of the biological state being studied. Nevertheless, once it was established that REM sleep is the time when the likelihood of dreaming is high, investigators began to systematically study how the dreamer 'incorporates' external stimuli into the dream. Although a fine spray of water or a soft bell presented during sleep generally elicit a short interval of EEG alpha, sleep often returns quickly to the prior REM state. Using this procedure, Dement showed that the time interval between stimulus presentation and awakening was similar to the length of the subsequently reported dream experience – which discredited the theory that dreams occurred in the momentary transition between sleep and waking.

The content of such incorporations, while fascinating, provided little information about the processes by which they were produced. Their salient characteristic was that they rapidly made remarkably good sense out of one or more features of the external stimulus – within the apparently prior context of the ongoing dream episode. For example, Dement found that spraying individuals with water during REM sleep led one dreamer to report that his children had spilled water on him while he was reading a book, whereas another dreamer reported that while watching an actress walk on stage ahead of him, it began to rain through the ceiling, so the actress immediately opened her umbrella. These quick, apparent 'interpretations' by the sleepers, in response to their wet skin, are remarkably similar to the left-brain interpretations of right-brain input later reported by Gazzaniga in split-brain patients.

Activated Cortex as an Attractor Landscape

A neural network attractor is essentially a network with recurrent connectivity that represents a well-learned feature, object, person, or event. Attractors that share many features ('wet face,' 'wet clothes,' 'rain,' 'shower') lie closer together than do attractors that represent dissimilar objects. A large array of attractors can be represented in an attractor landscape in which each attractor is a basin within a large plane; attractors with similar features are neighbors within a common attractor valley. When information reaches the landscape, it is cycled recurrently until it 'settles' into (i.e., recognizes) one particular attractor. Cortical regions that process different classes of features or events may be represented as different, but interconnected, landscapes. Several characteristics of attractors make them particularly useful for representing the brain processes that generate dreaming and other forms of sleep mentation. Even when information is extremely 'noisy,' it can settle into the basin of an attractor. Second, the settling process can be strongly biased by prior context, whether the context is the preceding dream narrative, the events of the preceding day, or chronic life stressors. Biases may be represented as temporary deepening of attractor basins – neurally by long-term potentiation (LTP) of the synapses that form their neural networks, particularly in the hippocampal system. Finally, the patterns of regional cortical activation that distinguish REM, NREM, and waking states can be represented by leveling or deepening the basins across different regional attractor landscapes.

The pontine–reticular–cortical activation network described by Hobson and his colleagues provides a basis for amplifying a large cortical attractor network during REM sleep. Other sources of activation capable of supporting attractor networks, thereby sleep mentation, even in NREM sleep, will be described in the following sections. This attractor model is nicely supported by the 'incorporation' studies, whereby a single feature of an external stimulus is attracted to a basin that has previously been deepened by the context of the prior dream. For example, if the dream is located in the living room close to the telephone, when the experimenter, Dement, rings a buzzer, the attractor landscape 'interprets' the sound as the telephone, and the dreamer gets up to answer it.

Incorporation studies of sleep mentation imply that external input is the origin of the sleep mentation content. A neural network attractor model, however, can 'recognize' and produce well-learned sequences of activity even when the input is sheer neural noise (i.e., possesses no information). This suggests that an activated cortical region can produce the same type of output that it was trained to do in the waking state, even when there is no concurrent external stimulus input. It further implies that the higher the level of regional activation, the deeper the attractor basins, and therefore the greater the likelihood that any noisy information will settle into one of the basins of attraction (i.e., produce mentation).

Characteristics of Sleep Mentation

Hallucinatory Quality

The ability of activated cortical attractors to produce vivid, even bizarre, imaginal sequences is characteristic not only of REM sleep but also of waking mentation, under conditions of mild sensory deprivation. The truly unique characteristic of the REM dream is its hallucinatory quality. Because inhibition of sensory

input allows minimal processing of external stimuli, the constructed imaginal world is experienced as veridical perception. The dreamer imaginally interacts with the imaginal perceptions. By contrast, though waking daydreams in a dark room may be similarly vivid, the daydreamer reports them as imaginal. We assume that the hippocampal system tends to maintain a background representation of the daydreamer's external environment even when the daydreamer is not actively attending to those stimuli.

Lucid Dreaming

Opposing this hallucinatory, defining characteristic of REM dreams is the relatively infrequent phenomenon of 'lucid' dreams, whereby the 'sleeper' reports being aware that he/she is dreaming, and in some cases is able to deliberately modify the events of his/her ongoing dream. Lucid dreams are commonly reported from the final hours of morning sleep. The phenomenon suggests that the hallucinatory characteristic of dreamlike mentation may have a neurological basis different from that of other properties. Circadian-driven reticular formation/cortical circuits may not produce the deafferentation associated with the REM/NREM cycles, so that sensory, including proprioceptive, thresholds are lower than in earlier REM periods. These lower thresholds may allow the lucid dreamer to process stimuli that identify the external world and distinguish it from the internal dream experience, thereby producing the experience of 'knowing' that one is dreaming.

Personal Motives, Values, and Emotions

Night terrors are associated with the most violent emotions in sleep. These experiences occur upon sudden arousal from what is otherwise the deepest stage of NREM sleep (stage 4), and continue into a sustained hallucination of being attacked. The cry of terror and motor escape from the imagined attacker is preceded by only a few seconds of autonomic arousal, more intense than is seen in waking. The 'cause' is thought to be the loss of normal parasympathetic inhibition of the sympathetic system.

By contrast, emotions reported from REM sleep are more modest and tend not to awaken the sleeper or produce an autonomic response. We assume that the inhibitory afferent–efferent processes that protect sleep during the REM period extend to the autonomic system. Reported emotions provide us with an index of the motives that are active during sleep. This index suggests that emotions are stronger in REM than in NREM sleep, and that negative emotions are more prevalent than positive. Nevertheless, REM reports, especially in the early night, often describe without emotion events that in the waking state would elicit a strong emotional response.

The abstract nature of motives and the difficulty of determining whether a motive or emotion precedes a visual dream event, or is elicited in response to it, make the study of motivation in sleep very difficult. Fortunately, an increasing understanding of how the amygdala, medial prefrontal, and frontal cortices represent goal or motive structures in the waking state provides us with a neurological basis for exploring how these structures may participate in the production of sleep mentation.

Positron emission tomography (PET) studies show that the amygdala is unusually active in REM sleep, relative to NREM and waking, providing a neural basis for the negative emotions characteristic of that sleep stage. That the amygdala is associated with the experience of fear and pain in the waking state suggests that it plays a similar role in REM dreaming. Following the amygdala–fear model of LeDoux, we suggest that the imaginal events continuously generated by the cortex in REM sleep are also continuously evaluated by the amygdala, via their links to the medial prefrontal cortex, for their potential imagined threat to the dreamer. Positive emotions are reported less frequently than are negative emotions in REM mentation, but, with the exception of night terrors, both are reported less frequently in NREM mentation. We note that this description of affect in REM dreams is inconsistent with the long, vivid, emotional dreams that define most people's experience of their dreams. The latter tend to be produced while sleeping late on a weekend morning, and their neural generators are circadian and homeostatic processes that amplify the generation of mentation in REM and NREM sleep.

Analyzing brain-lesioned patients, Solms demonstrated that forebrain regions with limbic connections – which, in the waking state, participate in estimating the value of stimuli – are in sleep critical for dreaming in both REM and NREM sleep. Arguing against the activation–synthesis model, he finds that dreaming can persist even in the face of massive lesioning of the pontine brain stem mechanisms responsible for REM sleep. By contrast, dreaming can be entirely eliminated by forebrain lesions, particularly in the ventromesial quadrant of the frontal lobes, an area which connects frontal and limbic structures with dopaminergic cells in the ventral tegmentum. This forebrain circuit is often referred to as the 'seeking' or 'wanting' center of the human brain. Administration of L-dopa, stimulating this area, results in excessive and intense dreaming (in addition to psychotic symptoms). Conversely, inhibition of this circuit with haloperidol inhibits dreaming. Solms therefore hypothesizes that dreaming is controlled, not by the cholinergic brain

stem mechanisms described by Hobson but rather by this dopaminergic forebrain motivational system. In summary, the construction of sleep mentation is strongly influenced by neural processes that, in waking, determine the value of stimuli.

Bizarreness

There are two primary classes of bizarre mentation. The most common in laboratory reports are sudden changes in scene or location. The second, the juxtaposition of features, objects, or persons that would be improbable or impossible in the waking state, is the hallmark of the popular conception of dreaming, but is relatively infrequent in both REM and NREM sleep, especially in the early night. The neural basis for both classes is a matter of speculation. Certainly, the characteristics of attractors that make sense out of noisy input mitigate against bizarre patterns. Densely connected attractors in the same feature neighborhood tend to actively inhibit features that rarely occur together (i.e., they prevent bizarre juxtaposition). For example, in waking, a person cannot be recognized simultaneously as a boy and a girl. Yet one dreamer reported that "it was my brother," but "he was a girl" in the dream. We assume that the sense of knowing the relationship – "it was my brother" – was accomplished in an attractor field other than the field that saw his visual features as "a girl." Many dreamers do not recognize these incongruities until they awaken, at which time the normal communication between these cortical processing regions is restored. PET and transcranial magnetic stimulation studies have shown that cortical regions tend to be less effectively interconnected during sleep, as compared to wakefulness. Transcollosal communication may be especially impaired during REM sleep. We suggest that this lack of connectivity in sleep allows attractors that normally constrain one another in the waking state to produce bizarre combinations of visual objects, conversation, meanings, and responses, which would otherwise mutually inhibit one another.

The neural basis of sudden changes of topic or scene is even less well understood. We speculate that all thought, sleep or waking, is sustained by the value assigned to it by the amygdala and other limbic structures. We assume that the continuity that we, correctly or not, attribute to waking thought is due largely to the stability of our external environment. Lacking this external basis for continuity in sleep, each dream scenario simply fades away and is replaced by a new scene of significance to the dreamer.

Visual and Auditory Imagery

Visual imagery is much brighter and clearer in REM than in NREM periods (reported as being about 70% of the magnitude of brightness and clarity of waking perception). Although we assume that most of this imagery is generated in the occipital and right parietal cortex, heightened activity in extrastriate visual areas during REM sleep is accompanied by substantial decreases in blood flow to primary visual cortex. Sleepers who have been blind from birth report surprisingly normal dreams, which are apparently constructed from spatial coordinates learned in the waking state from auditory, tactile, and motor cues. Reported auditory imagery in REM sleep is also more frequent than in NREM, as are reports of conversation and the meanings of those conversations. Reports of tactile or pain imagery in sleep are extremely rare.

Total Reported Information

Given that REM reports exceed NREM on almost any variable on which they are compared, one must ask whether the cortical regions that generate mentation simply generate more information in REM sleep. With the exception of emotional intensity, after the effect of total reported information is partialled out, no other variable contributes to the qualitative difference in REM versus NREM mentation. REM reports, for example, tend to contain more bizarreness than NREM reports do, simply by virtue of their greater length. This suggests that aside from the more vivid visual imagery, which we attribute to right parietal cortex activation in REM sleep, the remaining characteristics of REM mentation may be attributed to a widespread increase in cortical activation. The active regions simply do what they were trained to do in the waking state, except that with high sensory thresholds, their processing sequences are not responsive to external stimuli, and decreased connectivity between regions results in less mutual constraint than is operative in waking perception. Many investigators have claimed, and continue to claim, that the unique pattern of cortical activation in REM must produce a unique pattern of mentation, but few have statistically corrected for the total amount of reported information, and some have even discarded reports with no content.

Circadian Influences on Sleep Mentation

Report length, and with it most characteristics of sleep mentation, tends to increase during the final hours of sleep. It is this longer, more dramatic imagery and emotion that people typically remember and identify as dreaming. Because REM periods also increase in length across the night, it has been generally assumed that these longer, more dramatic late-morning dreams are the result of a more active REM

process. However, increases in report length and dreamlike quality across the night occur in NREM as well as in REM sleep, correlated with the rising phase of a circadian cortical activation cycle, roughly correlated with the core body temperature rhythm. Propensity for REM sleep, which increases across the night, is controlled by the endogenous circadian clock, as is spindle frequency activity in stage 2 and alpha activity in REM sleep. Levels of the wake-promoting neuromodulator cortisol also rise as the sleeper moves toward morning wakefulness. Each of these activation-related physiological changes depends not on the number of hours of prior wakefulness or sleep, but rather on internal clocklike mechanisms. Although circadian-driven changes in cortical activation are difficult to measure directly, core body temperature is known to begin rising about 2 h before the time of normal waking. Inasmuch as circadian-driven cortical activation does not include the inhibition of sensory input characteristic of the REM generator, REM mentation produced during this late-morning interval may sometimes tend to be lucid in the sense described earlier. The size of the circadian effect on report length can be quite large, equaling the strength of the REM/NREM effect on propensity to report dreaming.

Joint and Unique Patterns of REM and Circadian-Based Mentation

That both REM and circadian generators are associated with increased mentation reporting and dreaming places us in a better position to ask what patterns of sleep mentation are unique to, or common to, the two generators. We note that the late-morning circadian increase in NREM (as well as REM) dreaming accounts, at least in part, for the often disputed source of dreaming in NREM sleep. Consistent with the heightened amygdala activation specific to REM sleep, a study from our lab recently found that circadian-driven activation amplified the emotional intensity of late-morning REM reports, but did not effect emotion in NREM sleep.

Bizarreness Revisited

That bizarreness increases with the active phases of both the circadian and the REM cycles suggests that bizarreness is not produced by an activation process unique to REM sleep and its pontine generator. We suggest that as cortical activation increases, more objects and events are produced, and if the regions that generate these objects and events are weakly interconnected, failing to mutually constrain one another, each will be regarded as improbable in the context of the other upon awakening.

Homeostatic-Driven Processes, Naps, and Dreaming

Circadian-driven cortical activation would be expected to increase steadily throughout the morning hours and into the afternoon. The joint effect of the circadian and REM/NREM generators should therefore produce intense dreaming at this time, compared to during the night. However, these activation effects appear to be opposed by the familiar, but poorly understood, 'sleep need' process. This homeostatic process, commonly measured by propensity for slow-wave activity in the EEG, accumulates as an exponentially saturating function of time awake, and then discharges during sleep according to an exponentially decaying function. It follows that even a short period of waking might suppress the activating effects of the rising phase of the circadian rhythm. Supporting this assumption, a recent study in our laboratory found that NREM reports from early-afternoon naps, when circadian activation is presumably high, yielded less total information than did late-morning NREM reports preceded by sustained sleep. Ultimately, the generators and suppressors of cortical activation responsible for mentation can only be isolated by further studies that employ forced desynchrony protocols in which individuals sleep at various phases of the circadian rhythm.

Sleep State Ambiguity and Mentation Features

Although the vernacular labels 'wake' and 'sleep' imply that the two states are discretely different, the father of sleep research, Nathaniel Kleitman, showed that biological characteristics of the two states can be dissociated. Inasmuch as the feature patterns of night terrors and lucid dreaming, discussed earlier, are incompatible with the defining characteristics of either waking or sleep, it would obfuscate our understanding of those phenomena if we were to force them into one category or the other. This dilemma raises the question of how much weight to give to an individual's own classification of his/her sleep/wake state when it conflicts with neurological and behavioral criteria. Sleep scientists traditionally distinguished sleep from waking by EEG criteria. However, these criteria were brought into question when it was found that many normal sleepers reported having been awake when interrupted from stage 2 NREM sleep during the first 2 h of the night. Interestingly, the latency of some of these 'awake' responses was sometimes over 30 s. One systematic study of this issue found that people use the subjective quality of their preinterruption mentation to make the judgment as to whether they were awake or asleep.

Thus, if mentation were an internal subvocal monolog common in the waking state, the stage 2 sleeper might say, "I was awake," whereas streams of vivid imagery common to REM dreaming would elicit the judgment of being asleep.

Sleep Oscillations

Introduction

The discovery that the brain oscillates during sleep is almost as old as the discovery of the electroencephalogram (EEG). The first human EEG recordings reported oscillations, the type, frequency, and amplitude of which highly depend on behavioral state. In an alert, awake subject, the EEG is dominated by low-amplitude fast activity ('desynchronized EEG') with high-frequency oscillations (beta, gamma), whereas during slow-wave sleep, the EEG shifts to large-amplitude, slow oscillations. The early stage of slow-wave sleep is associated with EEG spindle waves, which occur at a frequency of 7–14 Hz. As sleep deepens, waves with slower frequencies (0.3–4 Hz), including delta waves and slow oscillations, appear and progressively dominate the EEG. During paradoxical sleep, also called rapid eye movement sleep, EEG activities resemble those of wakefulness.

The cellular bases of slow-wave sleep oscillations have been investigated since the first extracellular and intracellular recordings in mammals. The major brain regions identified are the thalamus and cerebral cortex, which are intimately linked by means of reciprocal projections. The activities of thalamic and cortical neurons during sleep have been largely documented by electrophysiological studies. The cellular mechanisms underlying these oscillations depend on many factors, such as the connectivity and intrinsic properties of the different types of thalamic and cortical neurons. To determine these cellular mechanisms, it is necessary to use computational models, which are based on experimental data, and to suggest mechanisms and, if possible, predictions to test them. This type of interaction has been quite successful in the (still ongoing) exploration of the mechanisms of sleep oscillations, which this article attempts to summarize.

Sleep Spindle Oscillations

Sleep spindles are found during the early stages of sleep (sleep stage 2 in humans) and constitute an electrographic landmark for the transition from waking to sleep. Spindle oscillations consist of 7–14 Hz waxing and waning potentials, grouped in sequences lasting 1–3 s and recurring every 3–10 s. Spindle oscillations constitute an interesting and well-constrained problem to investigate by computational models for several reasons. First, these oscillations are generated in the thalamus, which is a well-known structure anatomically, with well-defined connectivity between the different cell types (see circuit in Figure 1(a)). Second, spindles are remarkably well documented experimentally and have been extensively characterized both *in vivo* and *in vitro*. Third, this oscillation is generated by an interplay of complex cellular properties (schematized in Figure 1(b), left), such as burst firing, and synaptic interactions via multiple types of postsynaptic receptors (see Figure 1(b), right). Computational models are needed to understand this complex interplay.

The typical electrophysiological features of spindle oscillations are shown in Figure 1(c). The two cell types involved, thalamocortical (TC) and thalamic reticular (RE) neurons, oscillate synchronously and display burst discharges according to a mirror image: RE cells display bursts following excitatory postsynaptic potentials while TC cells burst following inhibitory postsynaptic potentials. While RE cells tend to burst at every cycle of the oscillation, TC cells produce bursts only once every few cycles. These features are typical of spindles recorded in thalamic neurons in different mammals.

Several hypotheses for the genesis of oscillations by thalamic circuits have been proposed. These involve reciprocal synaptic interactions between TC neurons and local inhibitory interneurons, loops between TC and RE neurons, or loops within the RE nucleus. The involvement of the RE nucleus was firmly demonstrated in a series of experiments by Steriade's group. In particular, the deafferented RE nucleus *in vivo* can exhibit spindle rhythmicity in extracellular recordings. In contrast, the RE nucleus does not display autonomous oscillations *in vitro*, but spindles have been observed in thalamic slices based on TC–RE interactions. These *in vitro* spindles display the same intracellular features as *in vivo* (Figure 1(c)).

To attempt clarifying these contrasting results, the genesis of spindle oscillations was investigated with computational models. First, models investigated whether the RE nucleus is capable of displaying oscillations consistent with experiments. Models found that RE neurons interacting through γ-aminobutyricacidergic (GABAergic) synapses can generate spindle rhythmicity and suggested different mechanisms. GABAergic interactions between RE neurons can make them oscillate synchronously through mutual inhibitory rebound interactions, either with slow GABAergic synapses or with fast ($GABA_A$ receptor-mediated) GABAergic synapses with extended connectivity. Synchronized oscillations can also be generated

from RE neurons connected with depolarizing GABA-ergic synapses. The presence of gap junctions in the reticular nucleus was also incorporated in models and also reinforced its propensity to oscillate in the spindle frequency range. Thus, models suggest that the intrinsic properties of thalamic RE neurons, combined with their synaptic or electrical interactions, support the RE pacemaker hypothesis.

Second, models including TC and RE cells showed that spindle oscillations can also be obtained from TC–RE loops. This TC–RE loop model is shown in Figure 1(d). Neurons were modeled using Hodgkin–Huxley type representations of Na^+, K^+, and Ca^{2+} voltage-dependent currents, which were based on voltage-clamp data on thalamic neurons. These models reproduced the most salient intrinsic properties of thalamic neurons, such as the production of bursts of action potentials (Figure 1(b)). Synaptic interactions were modeled with conductance-based kinetic models, which were used to simulate the main receptor types (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), $GABA_A$, and $GABA_B$) identified in thalamic circuits (Figure 1(b), right). Under these conditions, the circuit generated 7–14 Hz spindle oscillations with the typical features identified intracellularly in the different thalamic neuron types. The model reproduced the typical mirror image between TC and RE cells during spindles, as well as the phase relations between cells (see Figure 1(d)). In particular, TC cells produced bursts once every two or three cycles, a feature consistently observed experimentally (compare with Figure 1(c)). More-irregular behavior, similar to the experiments, was obtained in larger networks (Figure 1(e)) or in the presence of the cortex (see the section titled 'Propagation or large-scale synchrony'). The oscillations also showed the typical waxing-and-waning envelope of spindles; this property was due in the model to Ca^{2+}-mediated slow regulation of the hyperpolarization-activated current, a prediction that was verified experimentally.

Thus, models show that the complex bursting properties of thalamic neurons, combined with their interactions through well-defined types of synaptic receptors, account for both RE pacemaker oscillations and spindle oscillations arising from TC–RE loops without assuming pacemaker activity in the RE nucleus. How may such an apparent inconsistency be resolved? This question was addressed by a computational model of the RE nucleus which took into account the action of neuromodulators (such as noradrenaline) in depolarizing RE cells. This model produced oscillations only when a sufficient level of neuromodulator was present. The difference between *in vivo* and *in vitro* preparations may therefore be explained by the limited connectivity between the RE neurons in the slice and/or by the fact that slices lack the necessary level of neuromodulation to maintain isolated RE oscillations. The main prediction from this model is that applying neuromodulators to slices of the RE nucleus should induce oscillations similar to those observed *in vivo*. This prediction still awaits testing.

Propagation or Large-Scale Synchrony?

How spindle oscillations are initiated and distributed in large circuits was investigated with multiple recordings *in vivo* and *in vitro*. Spindle oscillations *in vitro* showed traveling wave patterns, with the oscillation typically starting on one side of the slice and propagating to the other side, at a constant propagation velocity. Traveling spindle waves were simulated by computational models of networks of interconnected TC and RE cells (one-dimensional extensions of the circuit shown in Figure 1), in two independent modeling studies. These models were similar in spirit to the circuit shown in Figure 1(a) but assumed that there was a topographic connectivity between TC and RE layers, consistent with anatomical data. Under these conditions, the models generated traveling waves consistent with *in vitro* data.

However, in contrast to thalamic slices, the intact TC system *in vivo* does not display clear-cut propagation, but spindle oscillations are synchronized over extended thalamic regions and show little signs for traveling wave activity (Figure 2(a)). This large-scale synchrony was lost when the cortex was removed, suggesting that although the oscillation is generated by the thalamus, its synchrony depends on the cortex. To investigate the mechanism underlying large-scale synchrony, a TC network model was developed by combining the previous model of thalamic slices with a model of deep cortical layers. The principal prediction of this model was that, in order to generate large-scale coherent oscillations, the powerful action of cortex on thalamus (via corticothalamic fibers) must be included, and most important, the cortex had to recruit the thalamus primarily through the RE nucleus. Because of the powerful inhibitory action of RE cells, the action of corticothalamic input is 'inhibitory dominant' on TC cells, a property essential to maintain large-scale synchrony by synchronizing the rebound bursts of TC cells. This property of inhibitory dominance is generally observed intracellularly in thalamic neurons when the cortex is stimulated. In these conditions, the same model was capable of generating large-scale synchrony in the presence of the cortex, as well as traveling wave activity in the isolated thalamus (Figure 2(b)). Consistent with these models, propagating activity has indeed been observed in the thalamus of decorticated cats *in vivo*.

Figure 2 Modeling the large-scale synchrony of spindle oscillations. (a) Multiple extracellular field potential recordings (Th1 . . . Th8) in the thalamus of cats *in vivo*. In the intact thalamocortical system (Intact), the oscillations were synchronized over large distances (7 mm between Th1 and Th8). After removal of the cortex (Decorticated), the large-scale synchrony was largely abolished. (b) Computational models of thalamocortical networks displaying large-scale synchrony when cortex was present (left) and local synchrony with traveling-wave activity in the isolated thalamus (right). (a) Adapted from Contreras D, Destexhe A, Sejnowski TJ, and Steriade M (1996) Control of spatiotemporal coherence of a thalamic oscillation by corticothalamic feedback. *Science* 274: 771–774. (b) Adapted from Destexhe A, Contreras D, and Steriade M (1998) Mechanisms underlying the synchronizing action of corticothalamic feedback through inhibition of thalamic relay cells. *Journal of Neurophysiology* 79: 999–1016.

The cortical control of thalamic relay cells through dominant inhibitory mechanisms has important consequences, not only for explaining large-scale synchrony, but also for explaining pathological situations such as absence epileptic seizures. As a result of inhibitory dominance, a too strong corticothalamic feedback can overactivate thalamic $GABA_B$ receptors and entrain the physiologically intact thalamus into hypersynchronous rhythms at ~3 Hz. This scheme may explain the genesis of absence seizures, which are hypersynchronous ~3 Hz rhythms that appear suddenly in the TC system. These seizures can be provoked experimentally by increasing cortical excitability in a physiologically intact thalamus. The TC model accounts for those experiments and can simulate seizures based on inhibitory-dominant corticothalamic feedback. This model directly predicted that manipulating corticothalamic feedback should entrain intact thalamic circuits to generate hypersynchronous rhythms at ~3 Hz, a prediction verified by two independent studies. A similar mechanism, with a different balance between $GABA_A$ and $GABA_B$ receptors, can also generate faster hypersynchronous rhythms (around 5–10 Hz), as observed in rat or mouse experimental models of absence seizures.

Slow-Wave Oscillations

During the deepest phases of sleep (stages 3 and 4 in humans), as well as for some anesthetized states, cortical activity is dominated by delta and slow oscillations, in a frequency range of 0.3–4 Hz. The intracellular

correlate of these slow waves is the alternation between depolarized states (up states) and hyperpolarized states (down states), which occurs in perfect synchrony with the EEG (Figure 3(c)). Thus, entire cortical regions are simultaneously switching between up and down states, as also shown by multiple extracellular studies. The origin of these oscillations seems to be cortical because they survive extensive thalamic lesions, and they are also observed in cortical slices.

One of the interesting features of up states is that this activity is very similar to that during the awake state. This is supported by several observations. First, during the up state, the EEG is of low amplitude, and fast activity is similar to desynchronized EEG. Second, extracellular recordings have shown that the up states obey the same dynamics of firing, have similar local correlations, and display similar relations between EEG and unit firing as wakefulness does. Third, simulating nuclei participating in the ascending arousal system induces periods of desynchronized EEG corresponding intracellularly to prolonged up states. Fourth, conductance measurements from intracellular recordings in anesthetized or EEG-activated states show similar conductance patterns during both states. The absolute conductance is lower in activated states than in up states, but both states are characterized by similar ratios between excitatory and inhibitory conductances. Fifth, computational models of up/down states and of activated states in cortical circuits suggest that both can be generated by similar mechanisms.

Computational models have investigated the genesis of slow-wave oscillations and the associated up- or down-state patterns. These models were based on recurrent circuits of excitatory and inhibitory cortical neurons (Figure 3(a)). The two main electrophysiological types of cortical neurons were considered, as well as their synaptic interactions through glutamate (AMPA) and GABAergic ($GABA_A$) receptors (Figure 3(b)). These models showed that up states can be generated by recurrent excitatory and inhibitory connections, which self-sustain the activity (Figure 3(d)). Different exact mechanisms by which up states begin and terminate have been proposed. Up states can start either by the interaction between subthreshold Na currents (persistent Na current) and miniature excitatory synaptic potentials. Another possible mechanism is spontaneously active cells that would initiate the wave of activity in the network. In either case, none of the mechanisms has been verified experimentally. The termination of the up state is apparently due to a progressive run down of synaptic activity, as indicated by conductance measurements. What causes this run down could be either an intrinsic property, such as the progressive buildup of a slow potassium conductance, or simply depression of excitatory synapses. Both hypotheses are supported by experimental data and are also consistent with the refractoriness of the up states found in slices (this refractoriness could be due to the potassium conductance, or recovery from synaptic depression).

Another property of up/down states is that the duration of the down state is proportional to network size. Down states are typically short *in vivo* (a few hundred milliseconds) whereas they can last up to 20 s in slices. Cutting cortical slabs of different sizes *in vivo* confirmed that the down-state duration varies inversely in proportion to slab size. Here again, this property is consistent with the two mechanisms of initiation outlined above as they both depend on coincident activation of either miniature or spontaneously active cells, both of which will occur more often in large networks.

Models were also used to simulate the transition to the sustained and irregular firing activity during wakefulness. Self-sustained irregular states similar to activated states have been simulated by various models. Only a few models, however, provided the transition from up/down states to activated states. For all such models, up states and activated states are very similar and differ only by the level of excitability of the neurons (mostly by downregulating potassium conductances). Some of these models were confronted to input resistance or conductance measurements and reproduced qualitatively the values measured experimentally. The fact that up states and activated states can be simulated with few differences by the same models is another indication that those two states stem from similar network activity.

A final property of slow waves is that the up states clearly show propagating properties *in vitro*. This propagation can be reproduced by computational models (Figure 3(e)), assuming that synaptic connections are made locally in the cortical network. In contrast, there is evidence that up states are highly synchronized *in vivo*, because the local EEG is always phase locked with intracellular activity (Figure 3(a)). Multiple extracellular recordings in natural sleep also demonstrated that the up states of slow waves are highly synchronized across distances up to 7 mm in cortex. A detailed investigation of this synchrony, and the conditions under which up states can propagate *in vivo*, as well as the modeling of such phenomena, still await.

What Is the Role of Slow-Wave Sleep Oscillations?

As mentioned above, the up states during slow waves share many different features of the sustained activity during wakefulness, and thus, up states can be viewed

Figure 3 Computational models of slow-wave oscillations in cerebral cortex. (a) *In vivo* recordings of a morphologically identified pyramidal neuron during slow waves. as brief periods of activity in which network dynamics are very similar to the dynamics during wakefulness. This is consistent with the fact that up states would represent 'replayed' events that have occurred previously during the wake state. There is abundant experimental evidence, from birds to higher mammals, for such a replay during sleep.

Why would such a replay occur during sleep and not during wakefulness? There is presently no clear answer to this question, but it was proposed that another type of sleep oscillation, sleep spindles, may be implicated in gating of long-term plasticity mechanisms (for example, permanent changes that require protein synthesis). Computational models of reconstructed pyramidal neurons, combined with intracellular measurements of thalamic inputs during spindles, have shown that the pattern of synaptic bombardment during spindles in the cortex is a strong excitatory-driven depolarization in dendrites, with an equally strong inhibition around the soma, preventing the cell from excessive firing. This pattern is likely to induce massive calcium entry at around 10 Hz in the dendrites, which is an ideal signal to activate molecular gates, such as protein kinase A. Sleep spindles would therefore provide a physiological signal similar to the repeated tetanus used to induce long-term synaptic changes in slices. However, instead of inducing potentiation directly, spindles may in fact provide a 'priming' signal, opening a gate that allows permanent changes to subsequent inputs ('replayed' events mentioned earlier) following the sleep spindles.

Taking those two observations together leads to the following scenario for how these different mechanisms may contribute to memory consolidation during sleep. During conscious experience, latent memories are formed throughout the cortex, together with links to the hippocampal formation that allow top-down retrieval to occur. During the early stages of sleep, spindle oscillations would mobilize the molecular machinery needed for memory consolidation in cortex. In the deeper phases of slow-wave sleep, during the brief periods of wakelike activities (up states), the hippocampal formation would activate latent memories stored in the neocortex ('replay') and induce permanent changes in intrinsic or synaptic conductances. This hypothetical mechanism of memory consolidation during sleep is consistent with all electrophysiological characteristics of sleep oscillations, and it predicts that special correlations between hippocampal and cortical activities should occur during the up states of slow waves. Such correlations have been found recently between cortical slow waves (up states) and hippocampal sharp waves. No computational model has been proposed to date to explain these observations, and certainly they constitute one of the most exciting directions to pursue toward exploring the role of sleep oscillations.

Behavioral and Electrographic Signs of Sleep Stages

Sleep Onset

The popular view that behavioral quiescence is the sign that heralds sleep may be valid for the full-blown state of sleep but not for the preparatory period during which many animal species display complex motor behaviors directed to find a safe home for sleep. The defining signs of the period when one falls asleep are changes in brain electrical activity (electroencephalogram (EEG)) that are associated with long periods of inhibition in neurons located in the thalamus, a deep structure in the brain and a gateway for most sensory signals in their route to the cerebral cortex. The consequence is that the incoming messages are blocked in the thalamus and the cerebral cortex is deprived of information from the outside world.

In contrast with the rapid awakening from sleep, the period of falling asleep is quite long. Thus, sleep onset may not be exclusively attributable to neuronal mechanisms, which operate on short timescales. It is conceivable that the mechanisms of falling sleep will only be revealed with concerted studies on sleep humoral factors (acting on longer timescale) and on their actions on neurons in critical brain areas. Currently, little is known about the effects of sleep-promoting chemical substances on neurons. The list of putative sleep humoral factors is quite long. Some of them are (1) adenosine, which exerts a tonic inhibitory control on both upper brain stem and basal forebrain cholinergic activating (awakening) neurons; (2) muramyl peptides, which have a chemical structure that is similar to that of serotonin, a neurotransmitter that was implicated in the generation of early sleep stages; and (3) prostaglandin D_2, whose receptors are found in the anterior hypothalamus, thought to be a critical zone for promoting sleep.

The concepts postulating that sleep is a passive phenomenon due to closure of cerebral gates leading to brain deafferentation or, alternatively, an active phenomenon promoted by inhibitory mechanisms arising in some cerebral areas have long been considered as opposing views. However, neurons with inhibitory influences (located in the anterior hypothalamus) act on neurons that exert excitatory influences on the brain (located in the posterior hypothalamus and upper brain stem reticular core), and the final outcome of these relations is the disconnection of the forebrain. Therefore, the two mechanisms (active and passive) of sleep onset are probably successive steps within a chain of events, and they are complementary rather than opposed.

Slow-Wave and Rapid Eye Movement Sleep

Sleep consists of an alternation between two distinct stages. The early stage is characterized by large-scale synchronization of low-frequency EEG activity (0.5–15 Hz), which is generated by the cerebral cortex and thalamus. Synchronization is a state in which two or more oscillators display the same frequency because of mutual influences. The notion of synchronization supposes the coactivation as well as concerted inhibitory processes in a large number of neurons. The summation of neuronal activities is sufficiently large to be recorded with gross electrodes, such as scalp electrodes when recording the human EEG. Because of the prevalent low-frequency waves, this stage is termed slow-wave sleep. This electrophysiological feature is associated with behavioral quiescence and suspension of conscious processes related to the external world because the transmission of signals is inhibited in the thalamus, even before these signals reach the cerebral cortex, the highest site of consciousness. However, not all mental processes are obliterated during slow-wave sleep because the brain oscillations that occur during this stage give rise to synaptic plasticity that underlies processes through which information is stored, such as consolidation of memory traces acquired during the state of wakefulness. Also, a peculiar form of dreaming mentation is present during slow-wave sleep.

The second stage of sleep is associated with rapid eye movements (REMs) and the sign that distinguishes it from the other two states of vigilance (slow-wave sleep and waking) is the largely suppressed motor output (muscular atonia) due to inhibition of spinal motor neurons. In addition, spiky potentials (ponto-geniculo-occipital (PGO) waves), related to ocular saccades, can be recorded from the thalamus and cortex and are regarded as the physiological correlate of dreaming. This state was also termed active because the level of brain alertness is similar to, or even higher than, the state of wakefulness. (This should not imply, however, that slow-wave sleep is inactive from the standpoint of brain functions since neuronal recordings have shown that cortical neurons fire during this stage at almost the same level as during waking.) Thus, REM sleep is a brain-active state associated with paralysis of limbs' muscles. In other words, motor commands from a highly excitable cerebral

cortex cannot be executed because of the inhibition of motor neurons in the spinal cord. Although REM sleep seems very similar to wakefulness because of intense brain activity, some differences also exist between these two states, mainly due to more effective inhibitory processes in waking and the virtual silence of monoaminergic neurons. This might explain the psychological differences between the logical thought in waking and the bizarre, illogical, and emotional content of dreaming in REM sleep.

Sleep Oscillations: Sites of Generation and Cellular Mechanisms

Three Major Oscillations Define Slow-Wave Sleep

The brain rhythms that characterize slow-wave sleep are the slow oscillation (0.5–1 Hz) that appears from the onset of full-blown sleep; spindles (7–15 Hz), whose amplitudes are highest during stage 2 of slow-wave sleep; and delta waves (1–4 Hz), which appear in stages 3 and 4, when their great amplitudes may obscure spindles.

The slow oscillation was first described using intracellular recordings from different neuronal types in anesthetized animals and, in the same article, was also detected in EEG recordings during natural slow-wave sleep in humans in which cyclic groups of delta waves at 1–4 Hz recurred with a slow periodicity of 0.4 or 0.5 Hz. The distinctness between delta and slow oscillations also came from human studies showing that the typical decline in delta activity (1–4 Hz) from the first to the second sleep episode was not present at frequencies characteristic for the slow oscillation (range, 0.55–0.95 Hz). The cortical nature of the slow oscillation was demonstrated by its survival in the cerebral cortex after large thalamic lesions and its absence in the thalamus of decorticated animals. This rhythm was recorded in all major types of neocortical neurons, including pyramidal-shaped and local circuit inhibitory neurons. The slow oscillation is composed of a prolonged depolarizing ('up') phase followed by a long-lasting hyperpolarizing ('down') phase. The hyperpolarizations of cortical neurons occur from the onset of sleep and distinguish sleep from the steady depolarization seen during waking (Figure 1). The depolarizing phase consists of excitatory postsynaptic potentials (EPSPs), some intrinsic excitatory currents, and also inhibitory postsynaptic potentials (IPSPs) that reflect the action of synaptically coupled local

Figure 1 The slow oscillation marks the difference between waking and slow-wave sleep (SWS). Intracellular recording of regular-spiking neuron from left cortical area 21 of chronically implanted cat, together with depth EEG from left areas 4 and 21, electrooculogram (EOG), and electromyogram (EMG). Transition from waking to SWS. Two epochs, one in waking and the other in SWS, are marked by horizontal traces (below EOG) and expanded below (arrows). Note the occurrence of episodic cyclic hyperpolarizations of the slow oscillation since the very onset of SWS, as indicated by EEG.

circuit GABAergic neurons. The hyperpolarizing (silent) phase is not produced by inhibitory interneurons but is due to disfacilitation (removal of synaptic, mainly excitatory, inputs) in intracortical and thalamocortical networks and also to some K^+ currents.

Sleep spindles are waxing-and-waning waves, grouped in sequences that recur every 2–5 s. They are generated in the thalamus, even in the absence of the cerebral cortex, but corticothalamic neurons have a decisive role in the near simultaneity of spindles over widespread thalamic and cortical territories. The pacemaker of spindles is the thalamic reticular nucleus, which consists exclusively of inhibitory (GABAergic) neurons. In the absence of this nucleus, spindles are not seen in the remaining thalamus and cortex, but this oscillation is present in the deafferented reticular nucleus. The cellular mechanisms underlying spindles are as follows. At each spindle wave, thalamic reticular neurons fire spike bursts that impose IPSPs on their targets, thalamocortical neurons. Following IPSPs, thalamocortical neurons discharge postinhibitory rebound spike bursts that are transmitted to cortex, where they rhythmically excite cortical neurons and thus give rise to spindles. The rebound is an intrinsic property of thalamic neurons and depends on a Ca^{2+}-mediated conductance, which is inactive during waking and REM sleep when neurons are depolarized and is de-inactivated (uncovered) during slow-wave sleep when thalamocortical neurons are hyperpolarized.

Some delta waves arise in the cortex without thalamic participation. Another type of delta potentials is generated in thalamocortical neurons through interplay between two of their intrinsic properties.

Coalescence of low-frequency corticothalamic rhythms by the slow oscillation Unlike rhythms that appear within distinct frequency bands and are generated in restricted neuronal circuits of simplified experimental preparations (e.g., isolated thalamic or cortical slices maintained *in vitro* and decorticated or thalamectomized animals *in vivo*), the normal brain does not generally display separate oscillations during slow-wave sleep. Rather, it displays a coalescence of the slow oscillation with other sleep rhythms (spindles and delta) as well as with faster (beta and gamma) rhythms that are superimposed on the depolarizing phase of the slow oscillation (Figure 2). The circuitry and neuronal mechanisms that account for the grouping of low-frequency and fast-frequency rhythms by the slow oscillation are discussed later.

During the depolarizing phase of the slow oscillation, the synchronous firing of neocortical neurons impinges upon thalamic reticular pacemaking neurons, thus creating conditions for formation of spindles, which are transferred to thalamocortical neurons and up to cortex, at which level spindles shape the tail of the slowly oscillatory cycle (Figure 2, middle panel in 'slow + spindle'). This connectivity explains why a cycle of the slow oscillation is followed by a brief sequence of spindles in thalamocortical neurons and in the cortical EEG (Figure 2, left panel in 'slow + spindle'), as seen with intracellular recordings in animal studies as well as with EEG recordings in human slow-wave sleep. The sequence of grapho-elements consisting of an ample surface-positive transient, corresponding to the excitation in deeply lying cortical neurons, followed by a slower, surface-negative component and eventually a few spindle waves, represents the combination between the slow and spindle oscillations. It is termed the K-complex and is a reliable sign for stage 2 of human sleep, but it is apparent in all stages of slow-wave sleep. These investigations indicate that K-complexes are the expression of the spontaneously occurring, cortically generated slow oscillation, although K-complexes can also be evoked by sensory stimuli during sleep.

Why fast rhythms are also observed during slow-wave sleep The unexpected association between a slow sleep rhythm and fast oscillations that are conventionally regarded as defining the electrical activity of waking and REM sleep is explained by the voltage dependency of fast oscillations. Indeed, cortical and thalamic neurons generate beta and gamma oscillations at relatively depolarized values of the membrane potential. Thus, fast rhythms are sustained during the steady depolarization of cortical neurons during waking and REM sleep, selectively appear over the depolarizing phase of the slow sleep oscillation, and are absent during the hyperpolarizing phase of the slow oscillation (Figure 2). The association between slow oscillation and fast rhythms has also been reported in human sleep.

Fast Oscillations during REM Sleep and Wakefulness

Beta and gamma waves (20–80 Hz) occur spontaneously during REM sleep and waking and are evoked by intense attention, conditioned responses, tasks requiring fine movements, or sensory stimuli. Beta and gamma rhythms can interchangeably be termed fast because neurons may pass from beta to gamma oscillation in very short periods of time (0.5–1 s), with slight depolarization of cortical neurons. Studies in humans have also shown that there is no precise cutoff between the beta and gamma bands since these activities may fluctuate simultaneously, as indicated by increased activities within both beta and gamma frequency bands (20–40 Hz) during cognitive processes implicating memory. The synchronized fast

Figure 2 Coalescence of slow oscillation with spindle and gamma rhythms. Intracellular recordings from cortical and thalamic neurons in cats. Slow + spindle, combined slow oscillation and spindle. (Left) Depth EEG from cortical area 4 and intracellular recording of thalamocortical neuron from ventrolateral (VL) nucleus. The excitatory component (negative depth EEG wave, downward deflection) of the slow cortical oscillation (0.9 Hz) is followed by a sequence of spindle waves at 10 Hz (arrows). One typical cycle of these two combined rhythms is indicated by the dotted box; note the inhibitory postsynaptic potentials in the VL neuron leading to a postinhibitory rebound. (Right) Top and bottom traces represent field potential from the depth of association cortical area 5 and intracellular recording from thalamic reticular (RE) neuron. In neuronal circuits (far right), synaptic projections are indicated with small letters, corresponding to the arrows at left, which indicate the time sequence of the events. The depolarizing phase of the field slow oscillation (depth-negative, downward deflection) in the cortex (Cx) travels through the corticothalamic pathway (a) and triggers in the thalamic reticular nucleus (RE) a spindle sequence that is transferred to thalamocortical cells (TC) of the dorsal thalamus (b) and thereafter back to the cortex (c), where it shapes the tail of the slow oscillatory cycle (middle panel). Slow + gamma, fast activity (40 Hz) crowns the depolarizing phase of the slow oscillation. Three traces depict depth EEG waves from primary somatosensory cortex (S1), intracellular recording from S1 neuron, and filtered intracellular trace (between 10 and 100 Hz). Note the fast waves (40 Hz) during the depolarizing phase of the slow sleeplike oscillation and the absence of such fast waves during hyperpolarization.

rhythmic activity led to hypotheses postulating that linkages between spatially distributed oscillatory elements in the visual cortex may be the bases for pattern recognition function. However, beta and gamma activities are also present in the spontaneous activity of neurons and EEG, and these oscillations have been recorded under deep anesthesia when cognitive processes are suspended.

The best candidates for generation and synchronization of fast activities are fast rhythmic-bursting neurons. These neurons are both corticothalamic excitatory and local circuit inhibitory neurons, which may serve synchronization of fast activities within corticothalamic circuits and also be part of the role played by cortical inhibitory neurons in these oscillations. The thalamus and neocortex display coherent beta and gamma

rhythms. At variance with the long-range synchrony of the slow sleep oscillation, fast rhythms are synchronized over restricted cortical territories and within specific circuits between thalamocortical and neocortical areas.

Synaptic Plasticity Induced by Sleep Oscillations

Far from being epiphenomena of intrinsic properties and synaptic operations in cortical and thalamic neuronal networks, with little or no functional significance, sleep oscillations lead to synaptic plasticity and are implicated in memory consolidation. Earlier views that considered sleep to be associated with widespread inhibition throughout the cortex and subcortical structures, which would lead to abolition of cognitive and conscious events, have been challenged by intracellular recordings during natural slow-wave sleep demonstrating rich spontaneous firing of neocortical neurons. These data refute the assumption that cortical neurons are inactive in this state. Although external signals are blocked at the thalamic level during slow-wave sleep, mainly because thalamocortical neurons are inhibited during spindle oscillations, the intracortical dialog is maintained and the responsiveness of cortical neurons to cortical volleys is even increased during slow-wave sleep. In humans too, this cortically evoked response is stronger in slow-wave sleep than in waking. That the neocortex is active during slow-wave sleep suggests a reorganization/specification of neuronal circuits. This view is supported by studies using indicators of neuronal activities during slow-wave sleep in humans, revealing more marked changes in those neocortical areas that are implicated in memory tasks and decision making during wakefulness.

Then, spontaneously occurring brain rhythms may lead during sleep to increased responsiveness and plastic changes in the strength of connections among neurons, a mechanism through which information is stored. Next, the results of animal experiments and human studies on synaptic plasticity are briefly presented.

The experimental model of sleep spindles is the sequence of augmenting responses, defined as thalamically evoked cortical potentials that grow in size during the first stimuli at a frequency of approximately 10 Hz, which mimics the initially waxing pattern of spindle waves. In the intact brain, augmenting responses evoked by rhythmic thalamic stimulation are characterized in cortical neurons by an increase in the secondary depolarization, at the expense of the primary EPSP. Synaptic plasticity is not only seen by progressively enhanced amplitudes of responses during the pulse train but also by persistence of self-sustained potentials, with the same pattern and frequency as those of responses during the prior stimulation period (Figure 3(a)). Stimulation of the corticothalamic projection with pulse trains at 10 Hz results in evoked responses and also, after protracted stimulation, in 'spontaneously' occurring spike bursts whose form and rhythmicity are similar to those of evoked responses, as if the repetition of volleys was imprinted in the 'memory' of the corticothalamic network (Figure 3(c)). Short- and medium-term (5–30 min) neuronal plasticity can occur inside cortical circuitry, even in the absence of the thalamus (Figure 3(b)).

Thus, besides their role in cortical disconnection through inhibition of incoming messages in the thalamus, sleep spindles are also operational in important cerebral functions. During spindles, rhythmic and synchronized spike bursts of thalamic neurons depolarize the dendrites of neocortical neurons, which is associated with massive Ca^{2+} entry that may provide an effective signal to efficiently activate Ca^{2+}/calmodulin-dependent protein kinase II, implicated in synaptic plasticity of excitatory synapses.

Similar phenomena, with Ca^{2+} entry in dendrites and somata of cortical neurons, occur with rhythmic spike trains associated with oscillations in the slow (0.5–1 Hz) or delta (1–4 Hz) frequency bands, during later stages of slow-wave sleep. The hypothesis that the slow oscillation is responsible for the consolidation of memory traces acquired during the state of wakefulness is supported by data showing that slow and delta oscillations are implicated in the cortical plasticity of the developing cortex.

These experimental data are congruent with human studies demonstrating that the overnight improvement of discrimination tasks requires some steps, including those in early slow-wave sleep stages. Also, procedural memory formation may be associated with oscillations during early sleep stages. The early part of night sleep favors retention of declarative memories, whereas the late part of sleep favors retention of nondeclarative memories.

At variance with the commonly used notion of global brain processes in slow-wave sleep are two major findings reported in humans subjects: slow-wave sleep activity increases 2 h after a motor learning task, and the enhancement is expressed locally in parietal association areas that receive converging visual and proprioceptive inputs relevant to spatial attention and skilled actions.

The increased cortical activity that accounts for consolidation of memory traces during slow-wave sleep also explains the presence of dreaming mentation during this state. In slow-wave sleep, dreaming is rational and repetitive, in contrast with the vivid, illogical, and emotional perceptions during REM

Figure 3 Synaptic plasticity in thalamocortical and intracortical systems, and 'memory' of electrical responses in corticothalamic system, induced by low-frequency stimuli mimicking sleep spindles. (a) Dual simultaneous intracellular recordings from cortical and thalamocortical (TC) neurons in cat (top trace is depth EEG from area 4). (1) Pulse train (five stimuli at 10 Hz; arrowheads) applied to the thalamic ventrolateral (VL) nucleus produced augmenting responses in the cortical neuron, whereas simultaneously recorded VL neuron displayed hyperpolarization. (2) Expanded fifth response; the augmented response in cortical neuron followed the rebound spike burst of the VL neuron. Note the self-sustained oscillatory activity at 10 Hz in the cortical neuron after cessation of thalamic stimuli, despite persistent hyperpolarization in the VL neuron. (b) Intracellular responses of cat area 7 bursting cortical neuron to repetitive callosal stimulation (10 Hz). The thalamus ipsilateral to the recorded neuron was extensively lesioned using kainic acid. The intracortical augmenting responses to the first and eighth pulse trains are illustrated. Note the depolarization by approximately 7 mV and the increased number of action potentials within bursts after repetitive stimulation. (c) Extracellular recording of the VL neuron in brain stem-transected cat. Motor cortex stimulation with pulse trains at 10 Hz (stimuli are marked by dots). (1) The pattern of responses in the thalamic VL neuron in early stages of rhythmic pulse trains. (2 and 3) Responses at later stages of stimulation. Note the appearance of spontaneous spike bursts resembling the evoked ones as a form of 'memory' in the corticothalamic circuit.

sleep. The brain is never 'empty,' and mental activity is present during all stages of normal sleep.

Ponto-Geniculo-Occipital Waves

PGO waves are sharp field potentials that are generally recorded in the visual thalamic lateral geniculate (LG) nucleus and occipital cortex, where they appear in clusters of up to six waves, closely related to gaze direction in dream imagery. Although the term PGO indicates their presence in the visual pathway, these potentials appear in many thalamic nuclei and cortical areas, outside the visual system. This widespread occurrence is due to the generalized thalamic projections of PGO generators, which are cholinergic neurons located in the pedunculopontine tegmental (PPT) nucleus and an adjacent nucleus at the mesopontine junction. Five distinct neuronal types have been recorded within cholinergic nuclei, whose discharges are temporally related to PGO field potentials in the visual thalamic nucleus.

The major input sources of PPT neurons are in adjacent areas of the upper brain stem reticular formation,

hypothalamic areas, and cerebral cortex. Impulses in the PGO generators can be triggered by any of these inputs through direct excitation or postinhibitory rebound excitation. Then, PPT neurons can be regarded as the final link in the brain stem–thalamic path that generates PGO waves. Because PGO potentials are thought to represent 'the stuff dreams are made of' and in view of the emotional nature of dreaming mentation in REM sleep, hypothalamic and forebrain structures that store some of the emotionally charged information may be most effective in driving the PGO brain stem neuronal generators.

In naturally sleeping cats – the species of choice for experimental studies because they display sleep patterns similar to those of humans – PGO waves precede other signs of REM sleep by approximately 30–90 s, and they appear during the last period of slow-wave sleep. Thus, there is a transitional period between EEG-synchronized and EEG-activated (REM) sleep that is called the pre-REM period, during which PGO waves appear over the background of a fully synchronized EEG. Thalamic neurons are hyperpolarized during the pre-REM period, when the sleep EEG is still fully synchronized, whereas they are depolarized during REM sleep. These two states (pre-REM and fully developed REM sleep) generate different PGO-related responses of LG neurons to brain stem cholinergic inputs, which influence the signal-to-noise ratio in the visual channel – that is, the ratio between the neuronal activity related to the PGO signal and the background firing of the same neuron. During pre-REM, the activity of thalamic LG cells starts with a short spike burst coinciding with a high-amplitude PGO wave and continues with a train of single spikes. By contrast, during full-blown REM sleep, the rate of LG cells' spontaneous firing is much higher than in pre-REM; LG cells do not fire spike bursts but, rather, single action potentials; and the amplitudes of PGO waves are much lower than during the pre-REM state. The peri-PGO histograms of LG neuronal activities show that the signal-to-noise ratio reaches values of approximately 7 during the pre-REM epoch, whereas the ratio values during REM sleep are approximately 2.

Why all these details? Because PGO waves are commonly regarded as the physiological correlate of dreaming, the greater signal-to-noise ratio in the LG-cortical channel during the pre-REM epoch than during REM sleep suggests that the vivid imagery associated with dreaming sleep may appear before fully developed REM sleep, during a period of apparent slow-wave sleep. Discussing dreaming from experiments in cats is justified in view of the behavioral repertoire typical for dreaming mentation that can be elicited in cats after having prevented muscular atonia by lesions of certain brain stem reticular structures. The idea that PGO waves with greater amplitudes during the pre-REM stage may reflect more vivid imagery during that epoch than even during REM sleep corroborates earlier data showing that after interrupting sleep immediately after the occurrence of the first PGO wave (in the pre-REM stage) and eliminating approximately 30 s of the slow-wave sleep stage that precedes REM sleep, the increased time of the REM sleep rebound was due to phasic events (PGO waves) rather than the loss of REM sleep *per se*. This observation fits in well with data on dream reports from the last epoch of EEG-synchronized sleep, which are indistinguishable from those obtained from REM sleep awakenings.

PGO waves are thought to play a role in development and structural maturation of the brain. PGO waves also exert specific excitatory effects on complex neurons in the visual cortex, and their deprivation may modify the expression of long-term potentiation in immature animals.

Sleep Research and Sleep Medicine in Historical Perspective

R Pelayo and C Guilleminault, Stanford University Sleep Medicine Program, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

When the history of sleep research and sleep medicine began is a matter of debate, but modern sleep medicine may be related to development of sleep research tools. In 1929, J-H Berger recorded the electrical activity of the human brain and demonstrated differences in these rhythms during wakefulness and sleep. He called the signals that he recorded 'electroencephalogram' (EEG). At Harvard University, Loomis et al. studied sleep onset and overnight sleep, and they published the results of their investigation in several reports between 1937 and 1939, dividing sleep into five states (A–E). Blake et al. provided information on sleep subdivision. The description of specific EEG rhythms during sleep was the beginning of a new era in sleep research.

However, the overall development of neurosciences at the beginning of the twentieth century had other impacts on the clinical understanding of sleep. Constatin Von Economo probably provided the most insight on central nervous system structures involved in the control of sleep. While investigating the viral pandemic that began at the end of World War I and killed many people, he made important observations on patients affected by 'encephalitis lethargica.' He correlated the clinical symptoms of insomnia and continuous lethargy with the presence of two different sites of inflammatory lesions. Lesions in the preoptic area and anterior hypothalamus led to insomnia and hyperkinetic movements, whereas lesions of the posterior hypothalamus led to sleepiness, continuous lethargy, and eye movement abnormalities. The role of the ventrolateral preoptic nucleus in sleep induction has been demonstrated, as has the role of the hypocretin peptides along with the identification of the hypocretin-containing neurons in the posterolateral regions of the hypothalamus. However, in the early 1920s Von Economo had found that the anterior hypothalamic lesions were often extended to the diencephalon (basal ganglia), whereas the posterior hypothalamic lesions were associated with lesions in the periaqueductal gray matter with frequent extension to the oculomotor nuclei, which thus explained the oculomotor symptoms. This led Von Economo to speculate that the anterior hypothalamus contained a sleep-promoting area and that an area spanning from the posterior wall of the third ventricle to the third cranial nerve was involved in activity promoting wakefulness. He also speculated that the syndrome of narcolepsy involved this posterior hypothalamus area (a fact also mentioned by CP Symonds in 1926, based on Von Economo's findings), as reported again very recently.

In 1949, Moruzzi and Magoun made an important discovery that had a major impact on further electrophysiological research on sleep that began to attract increasingly more researchers. They showed that the brain stem netlike core of neurons, the reticular formation, had ascending pathways, leading to the discovery of the 'ascending reticular activating system.' Stimulation of this neuronal network induced long-lasting and widespread cortical activation, marked by replacement of cortical slow waves with fast activity. They also showed that lesions of the reticular formation, but not those of sensory pathways, produced a loss of cortical activation. The lesions with most marked effect were located in the oral pontine and midbrain reticular formation and the posterior hypothalamic–subthalamic regions where ascending pathways reach into the forebrain. Additional, smaller lesions in the midbrain tegmentum and caudal diencephalons showed that dissociation between cortical activation and behavioral arousal of wakefulness could be obtained.

Deficiency of cortical activation without prevention of behavioral responsiveness to sensory stimulation is obtained with lesions of central midbrain tegmentum, whereas lesions of the ventral tegmentum and hypothalamus lead to unresponsiveness without loss of cortical activation.

Following these initial studies, increasingly more lesions at different levels were performed, leading to a delimitation of structures responsible for activation of the cortex, more numerous than initially considered, including not only the reticular formation but also the posterior hypothalamus–subthalamus and basal forebrain systems (nucleus basalis of Meynert). Transection of the brain stem behind the oral pontine tegmentum by Batini and other collaborators of Moruzzi resulted in a complete insomnia.

The understanding of sleep was greatly changed by the discovery of what has been called rapid eye movement (REM) sleep, paradoxical sleep, or desynchronized sleep. It is related to the investigations by Nathaniel Kleitman on rest and activity cycles. Eugene Aserinsky, a graduate student of Kleitman, was collecting data on napping infants and designed a data sheet with 5 min periods with indication of 'periods of motility' or 'absence of motility.' Aserinsky and Kleitman obtained data suggesting the presence

of an 'eye motility rhythm' and decided to verify it in adults. In order to monitor the eye movements during the night, they decided to measure eye movements using electro-oculography (EOG). While monitoring these electro-oculograms, they noted for the first time the presence of two very different types of movements: movements with bursts different from slow eye movements seen at sleep onset. Initially thought to be artifacts, direct observations of the phenomenon indicated by the recordings confirmed the reality of the movement. The investigators also noted that simultaneously during these specific eye movements, irregular breathing and heart rate accelerations were seen. Based on their observations, they assumed that there was a 'lightening' of sleep with these movements and that they may represent dreaming. Aserinsky and Kleitman had no continuous EEG recording but woke up their subjects during periods of occurrence and absence of eye movements, obtaining very different findings as reported in 1953. It was with another student, William C Dement, that Kleitman monitored EEG continuously to further investigate the association of EOG and EEG. In 1957, Dement and Kleitman reported the cyclical variation of EEG during sleep and its relation to eye movements, body motility, and dreaming. They found that the cyclical variation from a period of eye movement to the successive one was between 90 and 100 min, and that there was a regular re-occurrence of rapid eye movements and dreaming. However, at that time, sleep was still considered as only one state. They called these periods with rapid eye movements 'emergent stage 1' sleep. After reading Dement's 1958 report on the occurrence of low-voltage, fast EEG patterns during behavioral sleep in cats, French researcher Michel Jouvet replicated the findings and indicated that the cat also presented a muscle atonia in association with the rapid eye movement and the characteristic EEG pattern. In 1962, Jouvet used the term 'paradoxical sleep,' with the 'paradox' being that although the studied cat had an EEG that resembled wakefulness, behaviorally the animal remained asleep and unresponsive. With Francois Michel, Jouvet also reported that this new 'state' was associated with the presence of large electrical potentials that were first seen in the pons but appeared a few milliseconds later and were able to be recorded most easily in the lateral geniculate nucleus and, with further but limited delay, in the occipital cortex, leading to the term ponto-geniculo-occipital spikes. Sleep was divided by the Lyon, France, team into two states: slow wave sleep and paradoxical (also called dysynchronized or REM) sleep.

Following these discoveries, under the initiative of WC Dement, a small group of researchers formed the Association of Psychophysiological Study of Sleep. This small group invited other North American, European, and Asian researchers to participate in its research and to built a 'common sleep scoring system.' By consensus, these researchers agreed on a final product that had a tremendous impact on human sleep research. An atlas was created that could be used as a reference to score sleep in a similar way throughout the world. This atlas also included recommendations on how to monitor sleep as well as how and what to tabulate. This atlas, edited by Alan Rechtschaffen and Anthony Kales, was published in 1968.

These different efforts opened the field for systematic investigation of pathology of sleep in humans. However, there had previously been publications on specific disorders during sleep. In 1685, Willis gave the best description of restless leg syndrome, long before the 1945 publication of Ekbom that gave the name to the syndrome. An associated syndrome was noted with small movements of the big toe that occurred at regular intervals during sleep. This motor manifestation was questioned, and called 'nocturnal myoclonus' and erroneously thought to be an epileptic equivalent by Charles P Symonds in 1953; it was renamed periodic limb movement syndrome after demonstration of its linkage to restless leg syndrome (RLS) by Lugaresi and colleagues. Jean Baptiste Gelineau described the narcolepsy syndrome in 1880. He named the syndrome that he considered as an independent entity. If the terminology 'narcolepsy' began in 1880, Caffe in 1862, as cited by Gelineau, had already described a 'sleeping sickness' that plagued a subject with short attacks of sleepiness. The patient also presented 'hallucinations' that had him hospitalized in a mental hospital. Also, Westphal in 1877 published a report on a patient with sleeping attacks associated with episodes of loss of motor and language abilities. He also indicated that the mother was also affected by the same problem. What would be called the 'Pickwickian syndrome' by William Oster was first reported in the nineteenth century by Robert Caton in England. He reported on 8 February 1861 to the Clinical Society of London about a 37-year-old poulterer with excessive sleepiness: "The moment he sat down on his chair sleep came on and even when standing and walking he would sink into sleep constantly while serving customers in shop, sleep would come as he stood by the counter, he would wake and find himself holding in his hand the duck or chicken which he had been selling to a customer a quarter of an hour before, the customer having in the meantime departed." Caton goes on to describe that "when in sound sleep a very peculiar state of the glottis is

observed, a spasmodic closure entirely suspending respiration (1889). The thorax and abdomen are seen to heave from fruitless contractions of the inspiratory and expiratory muscles; their efforts increase in violence for about a minute or a minute and a half, the skin mean time becoming more and more cyanosed, until at last, when the condition to an on-looker is most alarming, the glottic obstruction yields, a series of long inspirations and expirations follows and cyanosis disappears. This acute dyspneic attack does not awaken the patient. The night nurses stated that these attacks go on throughout the night." The usage of polygraphic recording during sleep led to a new understanding of syndromes during sleep.

The first 'polysomnogram' monitored during nocturnal sleep was probably by Bulow and Ingward, who studied breathing during sleep in normal subjects and in 1961 published a report stating that there was a clear change of breathing pattern during sleep onset, with the presence of a short respiratory pause and a change of carbon dioxide tension that occurred much earlier than the notion of the 'apnea threshold' and also a change in arterial CO2 set point when a transition from wakefulness to sleep was noted. Influenced by these researchers, Werner Gerardy in Heidelberg modified an EEG machine to monitor respiration and pulse rate. He performed the recording of an obese patient hospitalized for headaches and who presented episodes of 'periodic breathing' with intermittent absence of airflow and association with change of heart rate. Thereafter, Gerardy et al. monitored another 'Pickwickian' patient, noted a similar phenomenon, and reported their findings in 1960. They reported the first sleep recording of a Pickwikian patient and first demonstration of apnea during sleep. These different reports, followed by those of Gastaut et al. and others on Pickwickian subjects, were still the realm of neurologists and clinical neurophysiologists.

However, in 1970, Christian Guilleminault, who had benefited from the advances in understanding in sleep physiology, pharmacology, and biochemistry, believed that the existence of three different states of being – wakefulness, nonrapid eye movement (NREM) sleep, and REM sleep – with many important neuronal changes implied that the control of vital functions would be affected by passage from one state to another and that pathologies may be seen. For Guilleminault there was a different dimension: the states of sleep that led to different controls as those seen during wakefulness. The existence of these different controls during the two sleep states led to special clinical presentations, required treatment aimed at the dysfunction occurring during the sleep states, and justified the development of what he called 'sleep medicine.' He was given limited funding in 1970 by the Societe Medicale des Hopitaux de Paris for investigation of sleep medicine patients in La Salepétriere Hospital, Paris. The skepticism in France led him to accept the invitation from William C Dement and Stanford University to work there in 1972.

Also in 1972, Elio Lugaresi and Pierre Sadoul organized the first international meeting on 'hypersomnia with periodic breathing' focusing on the abnormalities of breathing during sleep in obese subjects. In 1973, Guilleminault et al. reported sleep apnea and insomnia, and in 1975 the definition of an 'obstructive sleep apnea syndrome' was given. It was followed by the publication of obstructive sleep apnea syndrome in children and a presentation of the state of the art on sleep apnea syndrome in a monograph titled *Sleep Apnea Syndromes* that included most researchers involved in the study of the syndrome. Colin Sullivan, in the pulmonary physiology laboratory in Sydney, designed equipment to apply continuous air pressure to avoid the collapse of the upper airway. Using an air compressor and an airtight mask, Sullivan and colleagues succeeded in eliminating the sleep-related obstruction in a severely affected patient. After observing the results obtained with their prototype, they not only began treating patients in the hospital but also made major advances with regard to the possibility of a permanent nonaggressive treatment of obstructive sleep apnea (OSA) with application of continuous positive airway pressure (CPAP) through nasal mask at home, as reported in 1981.

The search for new treatments for OSA was not limited to the creation of nasal CPAP. Dr. Ikematsu, an otolaryngologist in Japan, developed a surgical procedure performed on the soft palate. The procedure was aimed at eliminating loud chronic snoring that was disturbing to spouses. Fujita, an American-Japanese otolaryngologist from Detroit, extended the procedure under the name uvulopalatopharyngoplasty (UPPP) in 1981. Because the procedure was not completely successful in several cases, this led to a search for other anatomy-oriented treatment modalities. The development of what became known as the 'Stanford surgical protocol' based on work by Nelson Powell, Robert Riley, and Christian Guilleminault began in 1981 and initially involved only mandibular geniotubercle advancement, but later involved a 'phase I' and a 'phase II' surgical approach, with phase II consisting of bimaxillary advancement that could provide results similar to those noted with nasal CPAP treatment. To avoid performing orthognathic surgery, efforts were made to use dental-related

devices to protrude the tongue forward during sleep. Samelson and Cartright reported objective results obtained with the 'tongue retaining device.' Following these initial trials, different types of dental appliances were designed to help patients with the syndrome of mild to moderate severity or residual problems post-UPPP.

The understanding that OSA was, commonly, a familial syndrome, often with involvement of anatomical and particularly mild changes in craniofacial features, led to systematic investigation of nonsyndromic children not only in families of adult patients with OSA but also in children with chronic snoring. Orthodontic techniques were explored. Rapid maxillary distraction (RMD), a well-defined orthodontic procedure, was thus first used in adults by Cistulli et al. for mild OSA. It was applied thereafter to prepubertal children with residual OSA post-adenotonsillectomy and narrow hard palate by the Rome and Stanford teams. Also, mandibular distraction osteogenesis with or without RMD on the hard palate was introduced for treatment of teenagers. Finally, investigation of children and, later, adults with more sophisticated monitoring sensors allowed the description of an abnormal breathing pattern that may not be associated with the defined sleep apnea and hypopnea syndrome: the upper airway resistance syndrome.

The first international meeting on narcolepsy was held in 1975 at Montpellier, France, at which the modern definition of the syndrome was developed. In 1983, Fuji and Honda reported a dominant association between a specific group, HLA (DR2), and the presence of narcolepsy in Japanese people. A strong HLA association between a certain HLA typing and narcolepsy was quickly confirmed. Neely and colleagues investigated different ethnic groups, particularly African Americans, and did not find an association with DR2, and the Stanford group showed that the best and most common HLA association was with HLA DQB1–0602.

The discovery of a canine model for narcolepsy cataplexy led to many pharmacological studies and allowed the recognition that the narcoleptic Doberman had a genetic defect on a newly discovered brain system – the hypocretin/orexin system. This discovery was nearly simultaneously associated with the finding that mice with knockout hypocretin receptor presented cataplectic attacks. In 2000, Nishino et al. showed that human narcoleptics presented an absence of measurable hypocretin/orexine levels in cerebrospinal fluid, and it was found that genetic defect was very rare in human narcolepsy. Also in 2000, Peyron et al. and Thannickal et al. showed destruction of hypocretin cells in the posterolateral region of the hypothalamus (the same region as identified by Von Economo in the brains of human narcoleptics) was the most common cause of narcolepsy and identified the presence of primary and secondary narcolepsy. The cause of the primary narcolepsy, which is most common, is unknown.

After the association between RLS and periodic leg movement had been made by Lugaresi et al. in 1968, the presentation of periodic limb movement as an isolated syndrome was made by Guilleminault et al. in 1978 and extended in 1982 by Coleman et al. In 1982, Akpinar reported the beneficial effect of dopamine agonist in the treatment of RLS – a finding largely confirmed over time. However, the underlying defect associated with RLS is still elusive, despite the clear demonstration of a large group of familial cases and the identification in Quebec families of specific chromosomic loci associated with RLS occurrence.

Abnormal Behavior during Sleep

NREM Sleep Parasomnia

Broughton and Gastaut coined the term 'disorders of arousal' to qualify these clinical presentations and dissociate them from an epileptic disorder occurring during stages 3 and 4 of NREM sleep, usually during the first one-third of the night. Fisher et al. emphasized the presence of 'hypersynchronous' delta waves, which were later called 'delta bursts' or 'delta sequence' by others. The existence of a familial pattern of sleepwalking was noted by Kales et al., but data call into question whether the familial pattern is related directly to sleepwalking or it is related to an underlying cause of behavior. Analysis of sleep EEG patterns associated with NREM sleep parasomnia has used new approaches, particularly the investigation of the cyclic alternating pattern (CAP) initially described by Terzano et al. in adults. This analysis shows the presence of an abnormal CAP rate in patients, indicative of instability of NREM sleep. It is most often related to other underlying unrecognized and untreated sleep disorders, usually sleep-disordered breathing, particularly upper airway resistance syndrome or, rarely, RLS.

REM Behavior Disorder

Experimental lesions performed in cats on the brain stem induced an 'active' REM sleep: cats presented motor activity similar to dreaming (i.e., acting as if hunting or playing). They 'act out' their dreams due

to the absence of REM sleep motor atonia. In humans, Japanese teams observed similar findings with delirium. It was also observed in patients with a brain stem neurodegenerative disease, olivo-ponto-cerebellar degeneration, by Quera-Salva and Guilleminault. Finally, Schenck and Mahowald reported a series of 'idiopathic cases' and called the disorder 'REM behavior disorder' (RBD). Initially thought to be 'idiopathic,' it progressively appeared to be associated with other neurological disorders – not only narcolepsy, a syndrome of dissociated REM sleep, but also very prominently with Parkinson's disease, multiple system atrophy, and Lewy's dementia. The notion has emerged that RBD is more commonly associated with synucleopathy, raising the issue of idiopathic RBD being the first clinical indication of the presence of Lewy bodies located mostly in the lower brain stem before caudal extension of lesions.

Sleep investigations uncovered another neurodegenerative disorder: fatal familial insomnia (FFI). The genetic nature of the disorder, its direct linkage to a prion disease, and its inexorable evolution toward the complete disappearance of sleep and then death were identified by the continuous research led by Elio Lugaresi and involving both the Gambetti team in Cleveland and many researchers in Bologna. FFI is associated with the development of very severe dysautonomia, complete insomnia before death, severe dementia, and bilateral symmetrical degeneration of the thalamus.

Sleep–wake is part of chronobiology, and the history of sleep disorders is very much intertwined with the understanding of chronobiology and its defect leading to dyschronosis or chronobiologic disorders. Identification of genes such as CLOCK and PERIOD (or PER) led to research on circadian rhythms and sleep pathologies. Two syndromes, 'sleep phase delay' and 'sleep phase advance' syndromes, were described. The term sleep phase delay syndrome was introduced by Weitzman and colleagues and by Czeisler et al., who reported the first treatment attempt called 'chronotherapy.' The discovery of a very large family in Utah presenting phase advance syndrome led to the identification of a specific genetic marker for this syndrome. Advances in the treatment of dyschronosis have been based on the investigation of the role of light and dark cycles and placement of sleep in this cycle.

Conclusion

In 1994, the Center for Sleep Research of the National Heart, Lung, and Blood Institute of the National Institutes of Health was created after a major Congress-supported effort by a special committee chaired by WC Dement. The American Sleep Disorders Association and its successor, the American Academy of Sleep Medicine, have had their efforts recognized in accreditation of training centers in sleep medicine, and the accreditation process was handed over to the American Council on General Medical Education in 2005. The Sleep Medicine Board examination will be administered under the auspices of the American Board of Medical Specialties beginning in 2007. Sleep medicine is a living history.

Sleep: Development and Circadian Control

The states of arousal, wake, rapid eye movement (REM) sleep, and nonrapid eye movement (NREM) sleep, are physiologically and behaviorally well defined in adult mammals, and their temporal expression is clearly organized by the circadian system. The situation is not clear, however, in developing mammals. Comparing studies of the development of sleep/wake and circadian rhythms in different species of mammals is complicated because of the major differences in maturity at the time of birth. However, understanding the development of these systems can contribute to understanding their basic biology and their possible contributions to certain postnatal pathologies, such as sudden infant death syndrome.

Three Stages of Sleep Development

Altricial mammals are less fully developed at birth than are precocial mammals, and this difference is clearly reflected in the development of sleep/wake and circadian rhythmicity. Whereas precocial species have brain activity at birth that shows characteristic differences associated with adult arousal states, the electrical activity recorded from brains of altricial species is undifferentiated. This difference is not surprising given the fact that in altricial brains at the time of birth most axons have not yet reached their targets and much synaptogenesis has yet to occur. However, in both altricial and precocial species, the development of sleep/wake can be divided into three stages, some of which take place *in utero* in the precocial species. These stages are dissociation, concordance, and maturation.

Dissociation is the stage of development when the defining electroencephalography (EEG) characteristics of arousal states are absent but the other correlates of arousal states, such as changes in heart rate and respiratory rate and phasic or tonic motor activity, are present. However, these correlates are not coordinated with each other. In studies of premature human neonates, Hamburger applied the term 'presleep' to refer to the period prior to the emergence of the EEG components of sleep states. Similar situations have been observed *in utero* in studies of precocial species such as lambs and baboons. In altricial species such as the kitten, the absence of sleep EEG patterns and dissociation of the other hallmarks of sleep states are seen postnatally.

Concordance occurs with the emergence of differentiated EEG patterns characteristic of adult arousal states and the alignment of the other correlates of wake and sleep states with those EEG parameters. In precocial species, concordance occurs in late gestation and EEG definable arousal states are observable in the newborn. Concordance in humans begins between gestational weeks 28 and 32 and is completed sometime in the last month of fetal life in full-term infants. Throughout the period of concordance in precocial species, there is no evidence of transitional or precursor sleep states that are homologous with adult sleep states. Rather, the EEG characteristics of REM and NREM sleep emerge at approximately the same time and the other sleep parameters come into alignment with those EEG patterns.

Concordance in altricial species is not as clear and has generated some controversy. EEG patterns are undifferentiated in the newborn altricial animal, but motor patterns that appear similar to those associated with arousal states are evident. Specifically, these motor patterns are coordinated movements, jerky movements (twitches), or quiescence. Periods of tonic, coordinated motor activity are considered wake, and the rest of the time is considered to be sleep. Sleep is then divided into behavioral quiet sleep (BQS), characterized by quiescence, or behavioral active sleep (BAS), characterized by phasic twitches. Because the undifferentiated EEG pattern is relatively fast and low amplitude, it resembles the activated EEG that in adults is associated with wake and REM sleep. This association of an apparent activated EEG with phasic muscle activity (BAS) has been assumed to be a precursor of mature REM sleep, whereas quiescent periods (BQS) have been assumed to be the precursor of mature NREM sleep. However, the problem of equating an undifferentiated EEG with an activated EEG casts doubt on what appears to be an obvious continuity between these apparent precursor sleep states and adult sleep states defined by differentiated EEG patterns. We examine more critically the assumption that BAS is the precursor of REM sleep and that BQS is the precursor of NREM sleep later in this article. Note, however, that the terms 'active sleep' and 'quiet sleep' used to describe sleep states in premature and term human infants refer to different suites of variables than are described by these same terms in altricial species. The difference is that the EEG patterns of active and quiet sleep are clearly differentiated in human preterm and full-term infants. In contrast, BAS and BQS in altricial species are not distinguished by any differential EEG activity; rather, these states are distinguished primarily by the presence or absence of myoclonic twitches.

Following concordance of parameters into distinct sleep states, there are rapid and sometimes dramatic maturational changes in the amount and timing of those states and in some of the EEG characteristics that define them. Early in the maturation of sleep, the amount of REM sleep is much higher than adult levels and declines, whereas the amount of NREM sleep decreases to a lesser degree and wake increases. The characteristic brain activities that define the sleep states in the adult become increasingly well defined and in some cases altered. In altricial species, for example, the activated EEG of REM sleep precedes the development of the slower, highly regular theta rhythm, which has a frequency in the 4 or 5 Hz range early on and gradually increases to the characteristic adult frequency of 7 or 8 Hz. Pontine–geniculate–occipital waves do not appear until a week or more after the emergence of REM sleep, and the characteristic muscle atonia of REM sleep is even slower to develop. The two major EEG correlates of NREM sleep, slow waves (delta band, 0.5–4.5 Hz) and sleep spindles (7–14 Hz), develop at different rates. First to appear is slow wave activity, which in the rat steadily increases in amplitude from approximately postnatal day (P) 9 to P21, reaching higher levels than are seen in the adult. Sleep spindles appear in the third postnatal week. Relatively late to mature are the regulatory mechanisms governing the expression of sleep – the ultradian, circadian, and homeostatic controls.

BAS and BQS May Not Be Homologous with REM and NREM Sleep

In altricial species such as the rat, the undifferentiated EEG is the same in the behaviorally defined states of BAS and BQS. Since the undifferentiated EEG lacks high-amplitude wave patterns, it somewhat resembles the activated EEG of REM sleep. This resemblance, however, is superficial, as might be expected based on the fact that most axons traveling to the cortex have not yet reached their targets and most synaptogenesis has not yet occurred. Since REM sleep is a cholinergically mediated state, it is especially important to note that the cholinergic system is very immature at the time BAS is maximally expressed. There is an inverse relationship between BAS expression and (1) expression of muscarinic receptors and their signal transduction mechanisms, (2) the development of cholinergic nuclei and their efferents, and (3) neuronal responsiveness to cholinergic drugs. In fact, cholinergic blockade which eliminates adult REM sleep has no effect on BAS in the rat until late in the second postnatal week after differentiated EEG patterns have developed. Lesions of brain stem structures essential for mature REM sleep have no effect on BAS in neonatal rats or kittens. Even transection of the neonatal rat's spinal cord below the brain stem does not eliminate the phasic twitches that define BAS. In adult mammals, such transections eliminate all episodes of myoclonia that normally accompany REM sleep. These results pose the obvious question of what is the nature of the myoclonia of BAS. It is likely that the twitches of BAS are 'nonspecific fetal activity' that is associated with the development of spinal reflex circuits prior to the imposition of descending inhibitory control.

There is also no compelling evidence for assuming that BQS is a precursor state to NREM sleep. The comparison of different studies of BQS is complicated by the lack of a clear set of criteria that define BQS. If the definition of BQS is quiescent periods with regular respiration and no twitches, this amounts to only 2% of total recording time in 1-week-old rats. However, in other studies in which small movements or 'startles' are allowed in BQS, it can be more than 30% of total recording time. Similar variances in the designation of BQS in kittens exist, all depending on the behavioral criteria used by the investigators.

The first EEG hallmark of sleep states to appear in altricial species is slow waves, and when they appear, they are not restricted to episodes of BQS. In fact, when slow waves first appear in the neonatal rat, they are as likely, if not more likely, to occur during episodes of BAS than during episodes of BQS. By the third week of postnatal life, slow wave activity is mostly restricted to periods of motor quiescence and regular respiration, and the amplitude of the slow waves steadily grows until they reach maximum values at approximately the beginning of the fourth week. EEG theta activity, which marks REM sleep, appears in the neonatal rat at approximately the same time as slow waves, but it matures to adult levels more slowly than do slow waves.

In summary, the view most consistent with existing data is that both REM and NREM sleep emerge from an undifferentiated brain state, and they do so at approximately the same time even though NREM sleep patterns seem to mature more rapidly than REM sleep patterns. Thus, in both precocial and altricial species of mammals, there are not precursor sleep states that precede EEG differentiation. Rather, the development of the EEG hallmarks of sleep reflects the development of the underlying neuronal mechanisms, and presumably therefore the yet-to-be-discovered functions of the sleep states.

Sleep Regulation

There are three components of sleep regulation that develop after the concordance of EEG defined states: ultradian, circadian, and homeostatic. Ultradian refers

to the cyclicity of sleep states, or the sleep cycle. In most mammals, the distribution of total sleep time is approximately 80% NREM sleep and 20% REM sleep, but these sleep times are distributed into bouts that alternate with each other. The sleep cycle in the human adult is approximately 90 min and the sleep cycle in a rat is approximately 10 min. This cyclicity of sleep states is poorly developed at the time the states first emerge, and it develops gradually, with the cycles becoming more regular and longer.

Circadian refers to the daily cyclicity of sleep and wake which is dependent on the circadian pacemaker that resides in the suprachiasmatic nucleus (SCN) of the hypothalamus. Although the pacemaker is probably oscillating in the fetus and is probably entrained by the periodicity of the mother, its coupling to the systems controlling sleep states occurs considerably after the emergence of sleep states. In rats, the circadian organization of sleep begins to appear on approximately P15. In humans, circadian organization of sleep emerges in the second or third month after birth, but it takes longer to become entrained to the environmental cycle of light and dark.

Homeostatic regulation refers to the relationship between sleep and the duration of prior wake. In adult mammals, sleep homeostasis is robust. An increase in wake time results in an increase in sleep time, but most important, it results in an increase in the EEG slow wave activity in NREM sleep. Thus, whereas the effect of sleep deprivation on REM sleep is to increase its duration, the main effect of sleep deprivation on NREM sleep is to enhance the expression of slow wave activity, also called delta power. One striking developmental change is an increased tolerance of sleep pressure. The amount of wake is very low in neonatal humans and altricial species, and they are unable to sustain long episodes of wake. Short periods of sleep deprivation that would be insignificant in the adult result in clear sleep rebound in the neonate. However, the nature of the sleep rebound changes with age. Early on when there are robust rebounds in NREM sleep, there are none in REM sleep. In the rat, responses in REM sleep time to prior sleep deprivation first appear toward the end of the third postnatal week. Thus, as with the development of the EEG characteristics of sleep, the homeostatic characteristics of REM sleep seem to emerge later and develop more slowly than those of NREM sleep. A most striking change in the homeostatic regulation of NREM sleep occurs in the fourth postnatal week. Prior to this time, the response to sleep deprivation is increased NREM sleep time with no changes in NREM sleep slow wave activity. In the fourth postnatal week, the response of the rat pup to sleep deprivation is no longer an increase in NREM sleep time but, rather, an increase in slow wave activity or delta power. The significance of this sudden shift is not known, but it occurs after the time when normal delta power levels have reached their maximum and are declining and at the time when the ability of the animal to sustain longer episodes of wake is rapidly increasing. These observations indicate that the generation of EEG slow waves is a critical aspect of the restorative function of sleep.

Development of the Circadian System

The circadian system of mammals is practically synonymous with the SCN of the hypothalamus, but it also involves the pineal gland, which produces the hormone melatonin. In contrast to the complexity of the neural structures involved in sleep, the SCN and the pineal are discreet structures that can be studied anatomically, neurochemically, and functionally. Therefore, we can ask questions about the development of the circadian system at these levels.

The SCN is a compact but heterogeneous cluster of cells with a definite structure, yet the relationship between the organization of the SCN and its function as the circadian pacemaker is not understood. SCN cells arise from the germinal epithelium of the anterior, ventral diencephalon. In the rat, this begins on approximately embryonic day 14 (E14) and is complete by several days before birth. The fate determination of putative SCN cells is quite robust in that deafferentation of the area does not alter their differentiation, and even if they are excised and transplanted into the chamber of the eye, they still develop into SCN cells. Also, when SCN tissue is extracted in early postnatal life and placed in culture, the cells continue to express the properties of SCN cells, including circadian rhythmicity.

There are three major afferent pathways to the SCN, and their development has been described in the rodent. Information from photoreceptors reaches the SCN by a direct and an indirect route. The direct route is via the retinohypothalamic tract, in which the neurotransmitters are glutamate and pituitary adenylate cyclase-activating polypeptide (PCAP), and these connections develop between P1 and P10. The indirect pathway for photic information through the intergeniculate leaflet uses the neurotransmitter neuropeptide Y and develops between P4 and P11. The third set of projections are serotonergic from the midbrain raphe nuclei, and they develop between the day of birth and P10. These pathways are the major mechanisms of entrainment in the adult mammal, but as discussed later, entrainment of the fetal SCN occurs considerably before birth. Thus, additional mechanisms must be responsible for the initial entrainment of

the fetal SCN. Strong evidence shows that melatonin and dopamine may be two such factors that mediate the maternal entrainment of the circadian systems of her pups, and fetal SCN cells do express the receptors for these two neurochemicals.

Functional development of the circadian system involves: (1) pacemaker function, or the generation of rhythms; (2) entrainment of rhythms; and (3) the coupling of SCN rhythmicity to drive other variables, such as body temperature and sleep/wake. The first of these properties to develop, of course, is pacemaker function. Circadian cycles are observable in the SCN within days after the cells become postmitotic. The first evidence of rhythmicity in the fetal SCN was documented in rats by the differences in uptake of 2-deoxyglucose (2DG) by SCN cells when the 2DG was injected at two different times of day. The earliest these oscillations were observed in rats was approximately 3 days before birth. Of course, these changes in fetal SCN metabolism could have been solely imposed by a maternal influence. However, subsequent studies revealed daily changes in 2DG uptake and in electrical activity of the SCN in brain slices taken from fetuses. Such rhythms have also been observed in fetuses or in brain slices from fetuses after the dam received SCN lesions early in gestation and was herself arrhythmic. The evidence supports the view that pacemaking function develops in the SCN prior to birth.

The ability of the SCN oscillations to be entrained also develops before birth in rodents, but the entraining stimuli come from the mother. In normal circumstances, the newborn pups are in synchrony with each other and with the maternal circadian rhythm. If the dam has received an SCN lesion early in gestation and is therefore arrhythmic, the newborn pups express circadian rhythms, but they are not in synchrony with each other. Most telling are cross-fostering experiments in which the newborn pups are presented to mothers that are 180 degrees out of phase from their natural mothers. In these litters, when rhythmicity is expressed in the pups, it is in phase with the rhythm of their birth mothers and not their foster mothers. The fetal SCN seems to be highly sensitive to entraining signals, including melatonin, dopamine, and probably other compounds such as the cholinergic drug nicotine. Whether or not disruption of fetal rhythms by exposure to such compounds *in utero* has effects on postnatal health is not known. However, when pregnant ewes were kept in constant light, their circadian rhythms were disrupted, as evidenced by vasopressin levels in the cerebrospinal fluid, and their fetuses did not survive. When kept on a light/dark cycle, their circadian rhythms were normal and their fetuses survived. In the postnatal period, the sensitivity of the SCN to the entraining influence of light develops as the afferent pathways bringing photic information to the SCN develop.

The coupling of SCN oscillations to various physiological and behavioral properties of the newborn emerges at different postnatal ages. In the rat, a rhythm of pineal *N*-acetyltranferase (the rate-limiting enzyme for melatonin synthesis) activity develops in the first postnatal week, a rhythm of body temperature develops in the second postnatal week, and a rhythm of sleep/wake appears in the third postnatal week. In the human newborn, a clear day/night organization of sleep/wake develops by the third month of life.

Sleep and Circadian Development Continues throughout Life

Focusing on the human, it is known that many characteristics of sleep and circadian rhythmicity change from birth through childhood, adolescence, adult, middle age, and old age. Total sleep time (TST) is maximal in the neonate and may reach 17 or 18 h a day, with almost half of that being REM sleep. Circadian organization of sleep is absent in the neonate but gradually develops between the second and third months of life. When circadian organization appears, it is in phase with the environment, so entrainment of the pacemaker occurs before the coupling of the circadian system to sleep control. By age 5 years, TST declines to approximately 10–12 h per day, with only approximately 20% of that being REM sleep. Thus, the major change in sleep amounts over early childhood is the decrease in REM sleep.

Adolescence is a time of significant changes in characteristics of sleep and circadian rhythms. The spectral properties of the NREM sleep EEG show considerable change at this time. The power density in the slow wave band (delta power) is high during childhood and at a maximum at approximately 9 or 10 years. Delta power then declines significantly (approximately 25%) between ages 12 and 14 years. After that, delta power continues to fall slowly and steadily with age. Since delta power is the definitive characteristic of stages 3 and 4 NREM sleep, these stages decrease linearly with age and are practically nonexistent in the elderly. REM sleep amounts, in contrast, show no major change with adolescence and follow a modest, linear decline from an average of approximately 22% in childhood to approximately 18% in old age.

The major circadian changes that occur after infancy are a phase advance of the timing of sleep

onset at adolescence and a gradual dampening of the amplitude of circadian rhythms with advanced age. To a certain extent, this leveling of circadian organization of sleep/wake may be due to declining levels of physical activity during the day. Sleep during the day leads to a lessening of sleep pressure at night, and hence reduced quality of nocturnal sleep.

Sleep-Dependent Memory Processing

Introduction

An exciting renaissance is currently under way within the biological sciences, centered on the question of why we sleep, and focusing specifically on the dependence of memory and plasticity on sleep. Although this resurgence is relatively recent in the annals of sleep research, the topic has a surprisingly long history. In the early nineteenth century, the British psychologist David Hartley proposed that dreaming might alter the strength of associative memory links within the brain. Yet it was not until 1924 that Jenkins and Dallenbach performed the first systematic studies of sleep and memory to test Ebbinghaus' theory of memory decay. Their findings showed that memory retention was better following a night of sleep than after an equivalent amount of time awake. However, they concluded that the memory benefit following sleep was passive and resulted from a lack of sensory interference during sleep. They did not consider the possibility that the physiological state of sleep could actively orchestrate these memory modifications.

It is only in the past half century, following the discovery of rapid eye movement (REM) and nonREM (NREM) sleep, that research began testing the hypothesis that sleep, or even specific stages of sleep, actively participated in the process of memory development. In exploring what has become known as sleep-dependent memory processing – and its associated brain basis, sleep-dependent plasticity – we focus herein primarily on evidence in humans (for more extensive reviews covering animal data, see the publications listed in the section 'Further reading').

Delineations and Definitions

We begin our discussion of interactions between sleep and memory by clarifying the complexities that these terms encompass – specifically, sleep states, memory categories, and memory stages.

Sleep States

To begin, it is important to note that the brain does not remain in one single, physiological state across the 24-h day, but instead cycles through periods of differing neural and metabolic activity, associated with distinct biological states, most obviously divided into those of wake and sleep. Sleep has been broadly divided into REM and NREM sleep stages, which alternate across the night in humans in a 90-min cycle (Figure 1(a)). In primates and felines, NREM sleep has been further divided into substages 1–4, corresponding to increasingly deeper states of sleep (Figure 1(a)). The deepest NREM stages, stages 3 and 4, are collectively referred to as 'slow-wave sleep' (SWS), based on a prevalence of low-frequency cortical oscillations in the electroencephalogram (EEG). Dramatic changes in brain electrophysiology, neurochemistry, and functional anatomy accompany these sleep stages, making them biologically distinct from the waking brain, and dissociable from one another. Thus, sleep cannot be treated as a homogeneous state, which either does or does not affect memory. Instead, each sleep stage possesses a set of physiological and neurochemical mechanisms that may contribute uniquely to memory processing and plasticity.

Memory Categories

In the same way that sleep cannot be considered homogeneous, the spectrum of memory categories believed to exist in the human brain, and the processes that create and sustain memory appear equally diverse. Although often used as a unitary term, 'memory' is not a single entity. Human memory has been subject to several different classification schemes, the most popular based on the distinction between declarative and nondeclarative memory (Figure 1(b)). Declarative memory can be considered as the consciously accessible memories of fact-based information (i.e., knowing what). Several subcategories of the declarative system exist, including episodic memory (autobiographical memory for events of one's past) and semantic memory (memory for general knowledge, not tied to specific events). Current neural models of declarative memory formation emphasize the critical importance of structures in the medial temporal lobe, especially the hippocampus, a structure that is thought to form a temporally ordered retrieval code for neocortically stored information, and to bind together disparate perceptual elements of a single event. In contrast, nondeclarative memory is expressed through action and behavior, and includes procedural memory (i.e., knowing how), such as the learning of actions, habits, and skills, as well as implicit learning, and appears to depend on diverse neural anatomies.

Although these categories offer convenient and distinct separations, they rarely operate in isolation in real life. For example, language learning requires a combination of memory sources, ranging from

Figure 1 The sleep cycle, memory systems, and memory stages. (a) The human sleep cycle. Across the night, rapid eye movement (REM) and non-REM (NREM) sleep go through a cycle every 90 min in an ultradian manner, while the ratio of NREM to REM sleep shifts. During the first half of the night, NREM stages 3 and 4, slow wave sleep (SWS), dominate, whereas stage 2 NREM and REM sleep prevail in the latter half of the night. Electroencephalogram patterns also differ significantly between sleep stages, with electrical oscillations such as K-complexes and sleep spindles occurring during stage 2 NREM, slow (0.5–4 Hz) delta waves developing in SWS, and theta waves occurring during REM. (b) Memory systems. Human memory is most commonly divided into declarative forms, including episodic and semantic memory, and nondeclarative forms, including an array of different types (e.g., procedural skill memory). (c) Developing stages of memory. Following the initial encoding of a memory, several ensuing stages are proposed, beginning with consolidation and including integration of the memory representation and translocation of the representation, or erasure of the memory. Also, following later recall, the memory representation is believed to become unstable once again, requiring periods of reconsolidation.

nondeclarative memory for procedural motor programs to articulate speech, to memory of grammatical rules and structure, and to aspects of declarative memory for the source of word selection. This too must be kept in mind as we consider the role of sleep in learning and memory.

Memory Stages

Just as memory cannot be considered monolithic, there similarly does not appear to be one sole event that creates or sustains it. Instead, memory appears to develop in several unique stages over time (Figure 1(c)). For example, memories can be initially formed or encoded by engaging with an object or performing an action, leading to the formation of a representation of the object or action within the brain. Following encoding, the memory representation can undergo several subsequent stages of development, the most commonly recognized of which is consolidation. The term 'memory consolidation' classically refers to a process whereby a memory, through the simple passage of time, becomes increasingly resistant to interference from competing or disrupting factors in the absence of further practice . That is to say, the memory becomes more stable.

Recent findings have begun to extend the definition of consolidation. For example, consolidation can be

thought of as not only stabilizing memories, but also as enhancing them – two processes that may be mechanistically distinct. While the stabilization phase of consolidation appears to occur largely across time, the enhancement stage appears to occur primarily, if not exclusively, during sleep, either restoring previously lost memories or producing additional learning, both without the need for further practice. From this perspective, the enhancement phase of memory consolidation causes either the active restoration of a memory that had shown behavioral deterioration, or the enhancement of a memory over its simple maintenance. Thus, consolidation can be expanded to include more than one phase of postencoding memory processing, with each phase occurring in specific brain states such as wake or sleep, or even in specific stages of sleep. Finally, following its initial consolidation, a memory can be retained for days to years, during which time it can be recalled.

Although the focus here is primarily on the effects of sleep on encoding and consolidation, it is important to note that additional postencoding stages of memory processing should also be appreciated. These include the integration of recently acquired information with past experiences and knowledge (a process of memory association), the anatomical reorganization of memory representations (memory translocation), reactivation and reconsolidation of memory through recall, and even the active erasure of memory representations, all of which appear to occur outside of awareness and without additional training or exposure to the original stimuli. It is interesting to note that sleep has already been implicated in all of these steps.

Sleep and Memory Encoding

Some of the first studies to investigate the relationship between sleep and human memory examined the influence of sleep on posttraining consolidation (see later), rather than its influence on initial encoding. However, more recent data have described the detrimental consequence of inadequate pretraining sleep on successful memory encoding.

One of the earliest studies to report the effects of sleep deprivation on declarative memory encoding in humans found that 'temporal memory' (memory for when events occur) was significantly disrupted by a night of pretraining deprivation. These findings have been recently revisited in more rigorous studies, again using the temporal memory paradigm. The task comprised photographs of unknown faces, with the temporal memory component involving recency discrimination, together with a confidence judgment. Significant impairments of temporal memory were evident in a group deprived of sleep for 36 h, which scored significantly lower than did controls. Indeed, significant impairment was evident even in a subgroup that received caffeine to overcome nonspecific effects of lower arousal. Furthermore, the sleep-deprived participants displayed significantly worse insight into their memory-encoding performance.

Neuroimaging reports have begun to investigate the effects of similar periods of total sleep deprivation on verbal memory. As in previous studies, total sleep deprivation resulted in significantly worse acquisition of verbal learning. Surprisingly, however, individuals showed more prefrontal cortex activation during learning when sleep deprived than when not sleep deprived. In contrast, regions of the medial temporal lobe were significantly less activated during learning when sleep deprived. Perhaps most interesting, the parietal lobes, which were not activated during encoding following normal sleep, were significantly activated after sleep deprivation. These findings confirm that sleep deprivation induces a significant behavioral impairment in verbal memory learning, and suggest that these impairments are mediated by a dynamic set of bidirectional changes – overcompensation by prefrontal regions combined with a failure of the medial temporal lobe to engage normally, leading to compensatory activation in the parietal lobes.

We recently investigated the impact of sleep deprivation on declarative memory encoding of both emotional and nonemotional material. Individuals were either sleep deprived for 36 h or allowed to sleep normally prior to an incidental memory encoding session composed of sets of emotionally negative, positive, and neutral words. Following two subsequent nights of sleep, individuals returned for an unexpected recognition task. Overall, individuals in the sleep-deprived condition exhibited a 40% reduction in memory retention relative to individuals who had slept normally prior to encoding (**Figure 2(a)**), results that represent a striking impairment of declarative memory formation under conditions of sleep deprivation. When these data were separated into the three emotional categories (positive, negative, or neutral), the encoding deficit remained, although the magnitude of effect differed across the emotion categories (**Figure 2(b)**). Within the sleep control group, both positive and negative stimuli were associated with superior retention levels relative to the neutral condition, consonant with the notion that emotion facilitates memory encoding. However, there was severe disruption of encoding and hence later memory retention deficit for neutral and especially positive emotional memory in the sleep-deprived group, which exhibited a significant 59% retention deficit relative to the control condition for positive emotional words. Most interesting, however, was the resistance of negative emotional memory

Figure 2 Sleep deprivation and encoding of emotional and nonemotional declarative memory. Effects of 36 h of total sleep deprivation on encoding of human declarative memory (a) when combined across all emotional and nonemotional categories. (b) Effects when separated into emotional (positive and negative valence) and nonemotional (neutral valance) categories.

to sleep deprivation, showing a markedly smaller (19%) and nonsignificant impairment. These data indicate that sleep deprivation severely impairs the encoding of declarative memories, resulting in significantly worse retention 2 days later. Although the effects of sleep deprivation are directionally consistent across subcategories, the most profound impact is on the encoding of positive emotional stimuli and, to a lesser degree, emotionally neutral stimuli, while the encoding of negative stimuli appears more resistant to the effects of prior sleep deprivation.

In summary, sleep deprivation in humans, of varying durations, significantly impairs the ability to effectively form human episodic memories, the effects of which appear be most pronounced for stimuli of positive emotional valence. Furthermore, early evidence suggests that these deficits may be associated with a failure of normal memory encoding networks to respond normally to information acquisition.

Sleep and Memory Consolidation

In addition to the impact of prior sleep deprivation on memory encoding, a plethora of work also demonstrates the critical requirement for sleep after learning for later memory consolidation. Using a variety of behavioral paradigms, evidence of sleep-dependent memory consolidation has now been found in numerous species, including humans, nonhuman primates, cats, rats, mice, and zebra finch.

Declarative Memory

Much of the early work investigating sleep and memory in humans focused on declarative learning tasks. These studies offered mixed conclusions, some in favor of sleep-dependent memory processing and others against it. For example, significant increases in posttraining REM sleep have been observed after intensive foreign language learning, with the degree of successful learning correlating with the extent of REM sleep increase. Such findings suggest that REM sleep plays an active role in memory consolidation, and that posttraining increases reflect a homeostatic response to the increased demands for such consolidation. However, other studies have reported no alteration of posttraining sleep architecture following learning of a verbal memory task. Similar inconsistencies have been reported both for the degree to which training on declarative tasks alters subsequent sleep-stage properties and for the degree of learning impairment that follows selective sleep deprivation. Recently, several studies by Born and his colleagues have shown improvement on a word-pair associates task after SWS-rich early-night sleep, as well as modification of this posttraining sleep. These findings are striking in the face of earlier studies that showed no effect. However, the discrepancy may reflect the nature of the word pairs used. Whereas older studies used unrelated word pairs, such as dog–leaf, Born used related word pairs, such as dog–bone. The nature of the learning task thus shifts from forming and retaining completely novel associations (dog–leaf) to the strengthening or tagging of well-formed associations (dog–bone) for subsequent recall. Thus, sleep's role in declarative memory consolidation, rather than being absolute, might depend on more specific aspects of the consolidation task, such as the degree of semantic association.

A further example of this subtlety pertains to the emotional nature of the material being learned. For example, it has been shown that late-night sleep, rich in REM sleep, selectively favors retention of previously learned declarative emotional texts relative to neutral texts. We have also investigated the time course of emotional and neutral episodic declarative memory consolidation across the day and overnight. Individuals performed an initial study session containing standardized emotional and neutral pictures, either in the evening or morning. Twelve hours later, after sleep or wake, individuals performed a recognition test, discriminating between the original and novel pictures. When the wake and sleep time periods were combined, significantly better emotional memory recognition was observed, relative to neutral memory – consistent with the notion that emotion enhances consolidation (Figure 3(a)). However, when separated according to the wake and sleep periods, a remarkable dissociation was evident (Figures 3(b) and 3(c)). While memory recognition was consistently superior following sleep, consolidation effects were particularly strong for emotional rather than neutral stimuli, with recognition accuracy for emotional pictures improving by 42% overnight, relative to the 12-h waking period. Indeed, emotional memory performance following the wake period was no different from neutral memory in either the wake or sleep conditions. These data indicate the selective facilitation of emotional declarative memory consolidation across sleep, rather than simply across time *per se*, resulting in the enhancement of memory retrieval.

It is important to note that such findings have only begun to test sleep-related effects at the most basic of memory levels – recognition and recall. Several recent studies have now explored more varied measures of memory, demonstrating that the strengths of associative memories are altered in a state-dependent manner. For example, it has been demonstrated that REM sleep provides a brain state in which access to weak associations is selectively facilitated, and flexible, creative processing of new information is enhanced. It has also been demonstrated that, following initial practice on a numeric-sequence problem-solving task, a night of sleep can trigger insight into a hidden rule that can enhance performance strategy the following morning.

Taken as a whole, these studies suggest a rich and multifaceted role for sleep in the processing of human declarative memories. Although contradictory evidence is found for a role of REM sleep in the processing of simple, emotion-free declarative memories, such as the learning of unrelated word pairs, a substantial body of evidence indicates that both SWS and REM sleep contribute to the consolidation of complex, emotionally salient declarative memories, embedded in networks of previously existing associative memories.

Figure 3 Consolidation of emotional and neutral declarative memory across wake and sleep. Individuals ($n = 14$) entered a repeated-measures design, composed of a sleep phase and a wake phase, presented in counterbalanced cross-over design. During the sleep phase, individuals performed the study session in the evening and 12 h later underwent the recognition test session following a night of sleep. In the wake phase, individuals underwent the study session in the morning and 12 h later performed the recognition test session that evening, without intervening sleep. These two phases were counterbalanced; so that half of the individuals experienced the wake phase first, followed by the sleep phase, while the remaining half experienced the sleep phase first, followed by the wake phase, with the two always being separated by a 1-week interval.

Nondeclarative Procedural Memory

The reliance of procedural, nondeclarative memory on sleep is now a robust finding. These data span a wide variety of functional domains, including both perceptual and motor skills.

Motor learning Motor skills have been broadly classified into two forms – motor adaptation (e.g., learning to use a computer mouse) and motor sequence learning (e.g., learning a piano scale). Beginning with motor sequence learning, we have shown that a night of sleep can trigger significant improvements in speed and accuracy on a sequential finger-tapping task, while equivalent periods of wake provide no significant benefit. These sleep-dependent benefits appear to be specific to both the motor sequence learned and the hand used to perform the task. Furthermore, overnight learning gains correlate with the amount of stage 2 NREM sleep, particularly late in the night (Figures 4(a)–4(c)). This sleep window corresponds to a time when sleep spindles – a defining electrophysiological characteristic of stage 2 NREM – reach peak density. Spindles have been proposed to trigger intracellular mechanisms required for synaptic plasticity, and they increase following training on a motor task. Thus, sleep spindles produced in late-night sleep may trigger key cellular events that in turn initiate mechanisms for neural plasticity.

At the behavioral level, the motor sequence task has been dissected to determine where in the motor program this sleep-dependent improvement occurs. More specifically, differences in transition speeds between each of the separate key-press movements, before and after sleep, were analyzed. For example, in the sequence 4–1–3–2–4, there are four unique key-press transitions: (a) from 4 to 1, (b) from 1 to 3, (c) from 3 to 2, and (d) from 2 to 4 (Figure 5(a)). When individual transition-speed profiles of study participants were analyzed before sleep, the speed of individual key-press transitions within the sequence was unequal (Figure 5(b); open circles), with some transitions seemingly easy (fast) and others problematic (slow), as if the entire sequence was being parsed into smaller subsequences during initial learning (a phenomenon termed 'chunking'). Surprisingly, after a night of sleep, the problematic slow transitions (problem points) were preferentially improved, whereas transitions that had already been effectively mastered prior to sleep did not change (Figure 5(b), filled circles). Most remarkable, however, for participants who were trained and retested after an 8-h waking interval across the day, no such improvement in the profile of key-press transitions, at any location within the sequence, was seen (Figure 5(c)).

These findings suggest that the sleep-dependent consolidation process involves the unification of smaller motor memory units into one single memory element by selectively improving problem regions of the sequence. This overnight process would therefore offer a greater degree of performance automation, effectively optimizing speed across the motor program, and would explain the sleep-dependent improvements in speed and accuracy previously reported. But more importantly, it again suggests that the role of

Figure 4 Sleep-dependent motor skill learning. (a) Wake first: after morning training (10 a.m., clear bar), individuals showed no significant change in performance when tested after 12 h of wake time (10 p.m., clear bar). However, when tested again following a night of sleep (10 a.m., filled bar), performance had improved significantly. (b) Sleep first: after evening training (10 p.m., clear bar), individuals displayed significant performance improvements just 12 h after training following a night of sleep (10 a.m., filled bar), yet expressed no further significant change in performance following an additional 12 h of wake time (10 p.m., filled bar). (c) sleep stage correlation; the amount of overnight improvement on the motor skill task correlated with the percentage of stage 2 non-rapid eye movement (NREM) sleep in the last (fourth) quarter of the night (stage 2 $NREM_4$). Asterisks indicate significant improvement relative to training, and error bars indicate standard error of the mean.

Figure 5 Single-subject examples of changes in transition speeds. Within a five-element motor sequence (e.g., 4–1–3–2–4), there are four unique key-press transitions: (a) from 4 to 1, (b) from 1 to 3, (c) from 3 to 2, and (d) from 2 to 4. (Left) The transition profile at the end of training before sleep (open circles) demonstrated considerable variability, with certain transitions being particularly slow (most difficult; problem points), whereas other transitions appear to be relatively rapid (easy). Following a night of sleep (filled circles), there was a specific reduction (improvement) in the time required for the slowest problem-point transition. (Right) Similarly, at the end of training before a waking interval, transition profiles were uneven (open circles), with some particularly slow transitions (problem points) and other relatively fast transitions (easy). However, in contrast to postsleep changes, no change in transition profile was observed following 8 h of wake (filled circles).

sleep is more subtle and complex than simply increasing the strength of existing memory representations.

Moving from motor sequence learning to motor adaptation learning, it has been demonstrated that selective sleep deprivation impairs retention of a visuomotor adaptation task. All participants were trained and tested on the task and were retested 1 week later. However, some individuals were either completely or selectively deprived of different sleep stages across the first night following memory acquisition. At later retest, individuals deprived of stage 2 NREM sleep showed the most pronounced deficits in motor performance, which again suggests that stage 2 NREM is a crucial determinant of successful motor memory enhancement. Using high-density EEG, more recent studies have been able to show that daytime motor skill practice on a similar task is accompanied by a discrete increase in the subsequent amount of NREM slow-wave EEG activity over the parietal cortex at the start of the night, and that this increase in slow-wave activity is proportional to the amount of delayed learning that developed overnight; individuals showing the greatest increase in slow-wave activity in the parietal cortex that night produced the largest motor skill enhancement the next day.

Visual perceptual learning Learning of a visual texture discrimination task, which does not benefit from 4–12 h of wake following training, has similarly been shown to improve significantly following a night of sleep and appears to require both SWS and REM sleep. For example, overnight improvement has been shown to be specifically sleep dependent, not time dependent (Figure 6(a)), and to correlate positively with the amount of both early-night SWS and late-night REM sleep. Indeed, the product of these two sleep parameters explains more than 80% of interindividual variance (Figure 6(c)). Selective disruption of REM sleep, or of either early sleep (normally dominated by SWS) or late-night sleep (normally dominated by REM and stage 2 NREM), results in a loss of overnight improvement, suggesting that consolidation is initiated by SWS-related processes, but that subsequent REM sleep then promotes additional enhancement. In addition, these delayed performance benefits have been shown to dependent absolutely on the first night of sleep following acquisition (Figure 6(b)).

Taken together, these reports build a convincing argument in support of sleep-dependent learning across several forms of procedural motor and perceptual skill memory. All of these studies indicate that a night of sleep triggers delayed learning, without the need for further training. In addition, overnight skill improvements consistently display a strong relationship to specific sleep stages, and, in some cases, to specific sleep-stage windows at specific times in the night.

Procedural memory and daytime naps Although the majority of sleep-dependent studies have investigated learning across a night of sleep, several reports have begun to examine the benefits of daytime naps on perceptual and motor skill tasks. Based on evidence that motor learning continues to develop overnight,

Figure 6 Sleep-dependent visual skill learning. Individuals were trained (during which baseline performance was obtained) and then retested at a later time; the respective improvement in performance (in milliseconds) is illustrated across time. Each individual was retested only once, and each point represents a separate group of individuals. (a) Wake versus sleep: individuals who were trained and then retested on the same day after either 3, 6, 9, or 12 h of subsequent wake (clear squares) showed no significant improvement as a consequence of the passage of waking time across at any of the four time points. In contrast, individuals who were trained and then retested 8, 12, 15, or 23 h after one night of sleep (filled squares) showed a significant improvement occurring as a consequence of sleep. In total, $n = 57$, with $n = 7$–9 for individual points. (b) Sleep and sleep deprivation. Individuals ($n = 89$) who were trained and retested 1–7 days later (filled bars) continued to improve after the first night, without additional practice. Individuals ($n = 11$) sleep deprived the first night after training showed no improvement (crosshatched bar), even after two nights of recovery sleep. (c) Overnight improvement was correlated with the percent of slow-wave sleep (SWS) in the first quarter of the night (SWS_1) and rapid eye movement (REM) sleep in the last quarter of the night (REM_4); $^*p < 0.05$; error bars indicate standard error of the mean.

we have explored the influence of daytime naps on motor sequence learning. Two groups trained on the task in the morning. One group subsequently took a 60- to 90-min midday nap, while the other group remained awake. When retested later that same day, individuals who experienced a 60- to 90-min nap displayed a significant learning enhancement of nearly 16%, while individuals who did not nap failed to show any significant improvement in performance speed across the day (Figure 7). Interestingly, however, when individuals were retested a second time following a subsequent full night of sleep, those individuals in the nap group showed only an additional 7% overnight increase in speed, while individuals in the control group, who had not napped the previous day, displayed speed enhancements of nearly 24% following the night of sleep. These results demonstrate that as little as 60–90 min of midday sleep is sufficient to produce large significant improvements in motor skill performance, while equivalent periods of wake produce no such enhancement. In addition, these data suggest that there may be a limit to how much sleep-dependent motor skill improvement can occur over the course of 24 h, such that napping changes the time course of when learning occurs, but not how much total delayed learning ultimately accrues. Thus, while both groups improved by approximately the same total amount 24 h later (Figure 4), the

Figure 7 Daytime naps and motor skill learning. Individuals practiced the motor skill task in the morning and either took a 60- to 90-min midday nap or remained awake across the first day. When retested later that same day, individuals who experienced a 60- to 90-min nap (filled bar; across day) displayed significant performance speed improvements of 16%, whereas individuals who did not nap showed no significant enhancements (clear bar; across day). When retested a second time after a full night of sleep, individuals in the nap group showed only an additional 7% increase in speed overnight (filled bar; overnight), whereas individuals in the control group expressed a significant 24% overnight improvement following sleep (clear bar; overnight). Therefore, 24 h later, the groups averaged nearly the same total amount of delayed learning (filled and clear bars; total). Asterisks indicate significant improvement and error bars indicate standard error of the mean.

temporal evolution of this enhancement was modified by a daytime nap.

As with motor skill learning, daytime naps also appear to benefit visual skill learning, although the characteristics of these effects are subtly different. For example, if a visual skill task is repeatedly administered across the day, performance deteriorates rather than remaining stable or improving. This may reflect a selective fatigue of brain regions recruited during task performance, a characteristic not observed in the motor system. However, if a 30- to 60-min daytime nap is introduced among these repeated tests, the performance deterioration is ameliorated. If a longer nap period is introduced, ranging from 60 to 90 min and containing both SWS and REM sleep, performance not only returns to baseline, but is also enhanced. Furthermore, these benefits did not prevent additional significant improvements across the following night of sleep, in contrast to findings for motor skill task performance.

Together these studies build a cohesive argument that daytime naps confer a robust learning benefit to both visual and motor skills and, in the case of visual skill learning, are capable of restoring performance deterioration caused by repeated practice across the day.

Sleep and Brain Plasticity

Memory formation depends on brain plasticity – the brain's lasting structural and/or functional neural changes in response to stimuli (such as experiences). If sleep is to be considered a critical mediator of memory consolidation, then evidence of sleep-dependent plasticity would greatly strengthen this claim. In this section, we consider a mounting wealth of data describing sleep-dependent brain plasticity; our focus here is on neuroimaging studies in humans.

Modification of Posttraining Sleep and Brain Activation

Several studies have investigated whether daytime learning is capable of modifying functional brain activation during subsequent sleep. Based on animal studies, neuroimaging experiments have explored whether the signature pattern of brain activity elicited while practicing a memory task actually reemerges (i.e., is 'replayed') during subsequent sleep. Using positron emission tomography (PET), it has been shown that patterns of brain activity expressed during training on a motor sequence task reappear during subsequent REM sleep, whereas no such change in REM sleep brain activity occur in individuals who received no daytime training. Furthermore, the extent of learning during daytime practice exhibits a positive relationship to the amount of reactivation during REM sleep. As with previously described animal studies, these findings suggest that it is not simply experiencing the task that modifies subsequent sleep physiology, but rather it is the process of learning that does so. Similar findings have been reported using a virtual maze task. Daytime task learning was initially associated with hippocampal activity. Then, during posttraining sleep, there was a reemergence of hippocampal activation, this time specifically during SWS. The most compelling finding, however, was that the amount of SWS reactivation in the hippocampus was proportional to the amount of next-day task improvement, which suggests that this reactivation is functional, and leads to offline memory improvement. Such sleep-dependent replay may potentially modify synaptic connections established within specific brain networks during practice, strengthening some synaptic circuits while potentially weakening others in the endeavor of refining the memory.

Overnight Reorganization of Memory Representations

A second approach, which more directly examines sleep-dependent plasticity, compares patterns of brain activation before and after a night of sleep. In contrast to approaches that measure changes in functional activity during sleep, this technique aims to determine whether next-day improved performance results from an overnight, sleep-dependent restructuring of the neural representation of the memory. Using a sleep-dependent motor skill task, we have recently investigated differences between patterns of brain activation before and after sleep using functional magnetic resonance imaging (fMRI). Following a night of sleep, and relative to an equivalent intervening period of wake, increased activation was identified in motor control structures of the right primary motor cortex (**Figure 8(a)**) and left cerebellum (**Figure 8(b)**) – changes that allow more precise motor output and faster mapping of intention to key-press. There were also regions of increased activation in the medial prefrontal lobe and hippocampus (**Figures 8(c) and 8(d)**), structures recently identified as supporting improved sequencing of motor movements. In contrast, decreased activity postsleep was identified bilaterally in the parietal cortices (**Figure 8(e)**), possibly reflecting a reduced need for conscious spatial monitoring as a result of improved task automation, together with regions of signal decrease throughout the limbic system (**Figures 8(f)–8(h)**), indicating a decreased emotional task burden. In total, these findings suggest that sleep-dependent motor learning is associated with a large-scale plastic reorganization of memory throughout several brain regions, allowing skilled motor

Figure 8 Sleep-dependent motor memory reorganization in the human brain. Individuals were trained on a sleep-dependent motor skill task and then tested 12 h later, either following a night of sleep or following intervening wake, during a functional magnetic resonance imaging brain-scanning session. Scans after sleep and wake were compared (subtracted), resulting in regions showing increased functional magnetic resonance imaging activity postsleep (in red/yellow; a–d) or decreased signal activity (in blue; e–h) postsleep, relative to postwake. Activation patterns are displayed on three-dimensional rendered brains (top row of each graphic), together with corresponding coronal sections (bottom row of each graphic). Following sleep, regions of increased activation were identified in the right primary motor cortex (a), the left cerebellum (b), the right hippocampus (c), and the right medial prefrontal cortex (d). Regions of decreased activity postsleep were expressed bilaterally in the parietal lobes (e), together with the left insula cortex (f), left temporal pole (g), and left frontopolar area (h), all regions of the extended limbic system. All data are displayed at a corrected threshold of $p < 0.05$.

movements to be executed more quickly, more accurately, and more automatically following sleep.

We have also investigated whether overnight reorganization similarly occurs in sensory–perceptual systems using a sleep-dependent visual texture discrimination task, described earlier. Individuals were trained and then tested with or without intervening sleep. Relative to the condition without sleep, testing following sleep was associated with significantly greater activation in an area of primary visual cortex corresponding to the visual target location. However, there were also several other regions of increased postsleep activity throughout both the ventral object recognition (inferior parietal and occipital–temporal junction) and dorsal object location (superior parietal lobe) pathways, together with corresponding decreases in the right temporal pole, a region involved in emotional visual processing. Thus, a night of sleep appears to reorganize the representation not only of procedural motor but also of visual skill memories. Specifically, greater activation throughout the visual processing streams likely offers improved identification of both the stimulus form and its location in space, with signal decreases in the temporal pole reflecting a reduced emotional task burden resulting from the overnight learning benefits.

While the aforementioned studies examine the benefit of a night of sleep, reports have also investigated the detrimental effects of a lack of sleep on underlying brain activity, using a visuomotor adaptation task. Individuals were trained on the task and

tested 3 days later, with half of the individuals deprived of sleep the first night. Controls, who slept all three nights, showed both enhanced behavioral performance at testing and a selective increase in activation in the superior temporal sulcus (a region involved in the evaluation of complex motion patterns), relative to individuals deprived of sleep the first night. In contrast, no such enhancement of either performance or brain activity was observed in these individuals, indicating that sleep deprivation had interfered with a latent process of plasticity and consolidation. These findings indicate that sleep deprivation disrupts not only consolidation, but also the underlying neural mechanisms that support it.

In summary, learning and memory are dependent on processes of brain plasticity, and sleep-dependent learning and memory processing must be mediated by these processes. Many examples of such plasticity across sleep have now been reported over a range of descriptive levels – from whole brain to molecules. As reviewed in this discussion, neuroimaging studies have now identified changes in (1) the functional patterns of brain activity during posttraining sleep periods and (2) the reorganization of newly formed memories following a night of sleep. These plastic brain changes likely contribute to the consolidation of previously formed memory representations, resulting in improved next-day behavioral performance.

Summary

Over the past 25 years, the field of sleep and memory has grown exponentially, with the number of publications per year doubling every 9–10 years, faster than the growth for study of either sleep or memory alone. These reports, ranging from studies of cellular and molecular processes in animals to behavioral studies in humans, have provided converging evidence that pretraining sleep plays a critical role in preparing the brain for initial memory encoding, while posttraining sleep is important in triggering offline memory consolidation and associated neural plasticity. In the end, the question appears not to be whether sleep mediates memory processing, but instead, how it does so. The future of the field is truly exciting, and the challenge to neuroscience will be both to further uncover the mechanisms of brain plasticity that underlie sleep-dependent memory consolidation and to expand our understanding of sleep's role in memory processes beyond simple encoding and consolidation, into the constellation of additional processes which are critical for efficient memory development. Work across the neurosciences will be necessary to answer these questions, but with the current rate of growth of research in the field, we can expect important advances in our understanding of this critical function of sleep. By way of such a multidisciplinary approach, and with a measured appreciation that sleep plays a fundamental role in forming, consolidating, integrating, and reforming memories, we can look forward to new advances in treating disorders of memory, and perhaps even in improving the capacity of memory in healthy individuals.

Sleeping Sickness

M Bentivoglio, University of Verona, Verona, Italy

Introduction

Sleeping sickness or human African trypanosomiasis (HAT) is a re-emergent disease prevalent in sub-Saharan Africa. It is caused by the hemoflagellate protozoan *Trypanosoma brucei* (*T.b.*, also called African trypanosome), and it is transmitted by bites of flies of the genus *Glossina* (tsetse flies).

There are two clinically distinguishable forms of HAT caused by two different subspecies of African trypanosome and localized to separate geographical areas, although they overlap in many foci of central Africa. The Gambian or West African form of the disease occurs west to the Rift Valley and is caused by *T.b. gambiense*, with humans as primary host and main reservoir. The Rhodesian or East African form of sleeping sickness occurs east to the Rift Valley and is caused by *T.b. rhodesiense*. Rhodesian sleeping sickness is a zoonosis, for which cattle or wild game animals are primary hosts. Both forms are lethal if untreated, but their temporal profile differs. The infection caused by *T.b. gambiense* lasts for several months or even years, whereas that caused by *T.b. rhodesiense* can progress more rapidly in humans. This difference in temporal profile may reflect a relative inefficiency of the tsetse flies as vectors, which renders a long-term infection in the primary host necessary to increase the chances for transmission.

A third subspecies of the parasite, *T.b. brucei*, produces a relatively mild form of disease in native game animals but a severe condition in most domesticated animals. *T.b. brucei* is noninfective for humans, who have a serum protein that inhibits this parasite, but produces a lethal disease in rodents and is therefore used in experimental studies.

Although drugs for treatment of both forms of HAT early during the infection are relatively effective, treatment later during infection, when most of the patients may seek medical advice, still widely employs arsenical-based preparations, which have a high degree of toxicity. Better diagnostic tools for surveillance, early detection of HAT in the field, diagnostic tools for the distinction between early and late stages of the infection, as well as less toxic drugs for the cure of brain infection are therefore of high priority. Understanding the mechanisms by which the severe neurological disturbances develop during the disease is essential to prevent, diagnose, and cure neuroinvasion of the parasites. These disturbances are complex but hallmarked by alterations of the sleep pattern. Such alterations and experimental data on their pathogenesis are the focus of this article.

Historical Notes and Current Prevalence

Sizeable epidemics of sleeping sickness in humans were not identified until the turn of the twentieth century, although the disease had been recognized in West Africa for more than 600 years. A plausible explanation for these outbreaks of the disease is the migration of people caused by the European colonization of the continent. By this migration, individuals carrying the parasites were moved from areas with widely spread infections into novel areas. It has been estimated that half a million people died of sleeping sickness along the Congo River at the time of its exploration between 1896 and 1908. The most renowned outbreak of the disease occurred on the northern shore of Lake Victoria between 1898 and 1908. This epidemic may have killed two-thirds of the population in Uganda and the hunt for its causative agent was therefore intensified. In 1902, Robert M. Forde discovered in the blood of a patient with 'Gambian fever' the presence of parasites that were identified as trypanosomes by Joseph E. Dutton. Aldo Castellani found in 1903 the parasites in the cerebrospinal fluid (CSF) of cases of sleeping sickness in Uganda. This finally determined that the etiological agents of the disease were African trypanosomes. David Bruce and his wife Mary discovered in 1895 that tsetse flies were vectors for infections caused by these parasites in horses and cattle (*nagana*, from the Zulu language meaning 'feeble, useless').

In the following decades, the incidence of sleeping sickness gradually decreased and the disease had almost disappeared from several areas by the 1960s. This was due to surveillance and treatment of infected patients, as well as to tsetse fly control programs. Thus, the disease was almost forgotten during the first postcolonial period when other, and more urgent, problems came into focus. Because of the low level of awareness and due to political instability and civil unrest, a recrudescence of the disease occurred during the late twentieth century, most notably in Angola, R-D Congo, Uganda, and southern Sudan. In certain regions of these countries, the incidence of infection reached the level of the early decades of the century. This recrudescence reflects

shortcomings in surveillance and treatment, increased migration of human populations due to streams of refugees, as well as disruption of tsetse fly control programs.

Sleeping sickness is certainly the most dreadful of sleep diseases in terms of victims. HAT now occurs in approximately 250 foci in 36 sub-Saharan countries. Approximately 50–60 million people live in endemic areas and are therefore at risk, but only approximately 10% are under surveillance. The estimated number of 70 000 new cases detected and treated per year is therefore underscored. According to the World Health Organization (WHO), the actual annual number of cases may be in the range of 300 000–500 000. The disease was estimated to cause a loss of 2.1 million disability-adjusted life-years in 1999.

The Gambian form of the disease presents the major human health problem, whereas the Rhodesian form only occurs in a minority of patients. During the past few years, the situation has stabilized in areas with less political unrest and improved socioeconomic conditions, although the reemergence of sleeping sickness in many foci in Africa in the past few years is alarming. Cases of infections by *T.b. rhodesiense* and *T.b. gambiense* in travelers have been repeatedly reported in recent years, focusing attention on the increased risk of infection and on the need to consider this diagnostic possibility for imported cases.

With the recent awareness of the situation, eradication of the disease during the coming decades should become a realistic objective. To accomplish this, accurate and cost-effective diagnostic methods have to be developed and need to be implemented in remote and impoverished regions, in addition to re-institution of efficient programs for the vector control.

The Parasite and Human Infections

The Parasite

T.b. gambiense is transmitted mostly by the tsetse fly species *Glossina palpalis* and, as mentioned previously, humans are the major host, although domestic animals such as pigs may also be a reservoir. *T.b. rhodesiense* is transmitted mostly by *Glossina morsitans*, with wild game and domestic livestock as reservoir.

The single-celled *T.b.* parasites belong to the Salivarian group of the genus *Trypanosoma* and they complete their development in the proboscis/salivary glands of the tsetse flies. These flies attack and bite moving animals during the day and have a phototactic behavior, being attracted by blue and black surfaces. The blood-sucking female tsetse flies become infected when encountering a host animal with parasites circulating in the blood. In the tsetse fly, the parasites migrate from the hindgut to the salivary glands, in which they are transformed into metacyclic trypanosomes that are ready to be inoculated into a new mammalian host animal during a blood meal. Approximately 5000 metacyclic trypanosomes are inoculated into the dermal connective tissue of the host with the tsetse fly saliva during a feed. At the site of inoculation, an inflammatory reaction will ensue, sometimes forming a 'chancre' (a skin lesion with edema and also cell infiltration and proliferation). From the inoculation site, trypanosomes enter the lymphatics and bloodstream of the host, where the metacyclic forms are transformed into the slender bloodstream form. The slender parasites divide, resulting in high levels of parasitemia which fluctuate in the host in waves lasting in rodents for approximately 3 or 4 days. Troughs in the parasitemia are caused by the humoral immune response of the host.

The three strains of *T.b.* parasite are morphologically and mostly serologically indistinguishable. They are covered on their surface by a single species of variant surface glycoproteins (VSGs) and express a new species of VSG on their surface after each immune attack. By this mechanism, the parasites evade the humoral immune response and can avoid being eliminated in mammals. The VSG genes occupy 10% of the trypanosome genome and the mechanisms for the process of VSG switching well known. The sequence of the 26-megabase genome of *T.b.* was completed in 2005.

Stages of Sleeping Sickness, Treatment, and Neurological Signs

Sleeping sickness progresses through two clinical stages. The parasites first multiply in the lymph and blood to invade peripheral organs. This first (hemolymphatic) stage is followed by spread to the central nervous system. The second (meningoencephalitic) stage leads to the most severe, and ultimately fatal, consequences of the infection, and it requires treatment with drugs which pass the blood–brain barrier (BBB).

According to current WHO criteria, diagnosis of the second stage relies on the occurrence of trypanosomes, more than five white blood cells, and/or increased levels of protein in the CSF. However, these criteria are debated and need to be better validated considering the important therapeutic implications.

Early during infection, pentamidine is the drug of choice for clearance of *T.b. gambiense*, whereas suramin is used against *T.b. rhodesiense*. Both drugs are given parenterally, but formulas for oral drug delivery are currently being sought. Treatment of the second

stage with an arsenical derivative (melarsoprol, the trypanocide introduced in 1949), which crosses the BBB, kills the parasites but in 5–10% of cases causes a reactive arsenical encephalopathy which can be fatal in approximately half of the patients. Another problem is that melarsoprol resistance is increasingly reported, in certain areas in as many as 30% of patients. The relatively new drug difluoromethylornithine (DFMO) is used as an alternative against the West African form of HAT but requires long-term intravenous injections at high doses. Because of this, and also due to side effects and insufficient availability, the utility of DFMO in HAT treatment is limited.

The neurological symptoms and signs are most prominent in the Gambian form of the disease due to its more protracted course. There is considerable variation between afflicted individuals in the neurological picture of the disease, which involves a constellation of sensory, motor, and mental disturbances. Increase in muscle tone and abnormal movements, which include trembling of the hands and fingers, as well as choreiform and athetoid movements, are common. There are no objective sensory defects, but patients usually develop a peculiar pain syndrome in which a slight touch is sufficient to provoke an intense pain episode (Kerandel's sign).

States of mental confusion are common and patients may develop psychiatric disturbances, including emotional instability, indifference, aggression, asocial and stereotypic behavior, impulsive actions, fugue states, manic episodes, melancholia, and delirium. Dementia is common at the end stage, and patients will finally become comatose and die in a state of wasting. The most characteristic sign of sleeping sickness, however, is represented by sleep alterations.

Sleep and Circadian Rhythmicity Disturbances

Interestingly, sleeping sickness is not a hypersomnia, as its name may suggest. The name of the disease derives from the observation that patients develop frequent and sudden sleep episodes during the day. On the other hand, patients have wakefulness episodes during the night. Polysomnographic recordings in HAT patients have demonstrated that the total sleep time and total amount of each sleep stage during 24 h are not increased. Instead, the main alternations during sleeping sickness involve the sleep–wake cycle and the sleep pattern. The sleep–wake alteration tends to occur in short cycles, with sleeping and waking occurring equally during the day and night (Figure 1). The internal structure of sleep is altered, with frequent onset of rapid eye movement (REM) sleep periods and REM sleep episodes occurring soon after long wakefulness transitions with latency shorter than 15 min. Such sleep onset of REM sleep (SOREM) periods without any intermediary non-REM sleep, and with the occurrence of SOREM episodes during wakefulness, are considered characteristic of the disease. However, such alterations have also been documented in narcolepsy. In addition, abnormal electroencephalographic (EEG) events have been recorded in sleeping sickness patients, with slowing of EEG or periodic slow waves during wakefulness and sleep stages.

It has been reported that the sleep–wake disturbances in sleeping sickness are related to the severity of the disease, and that the occurrence of sleep alterations can be used as diagnostic criterion for the second stage. However, it has not been determined experimentally whether the onset of sleep changes corresponds to the brain parenchyma invasion by the parasites or stage I drug treatment failure.

The alterations in sleep and sleep–wake cycle generally ameliorate with arsenical drug treatment, but the recovery of these parameters in surviving patients is extremely slow and can occur months after the interruption of treatment. This indicates that sleep-regulatory structures are not destroyed by neurodegenerative phenomena during the disease, as also assessed experimentally, and that sleep changes are not directly related to the presence of the parasites in the brain parenchyma. Further potential long-term consequences have not been thoroughly investigated.

Loss in the circadian rhythmicity of cortisol and prolactin secretion, as well as loss of growth hormone release, has been recorded. The relationship between plasma hormone pulses and sleep–wake stages is preserved, however. Melatonin secretion maintains its circadian rhythmicity but exhibits a phase advance. Together, these findings, in the presence of a severe alteration of the sleep–wake cycle, point to the complexity of the interrelationships between different circadian rhythms.

Neuropathological Findings

The pathological changes in both forms of sleeping sickness are similar, and the Rhodesian form may be regarded as a compressed Gambian form. The neuropathological picture of the disease is relatively mild compared to its clinical severity. The alterations are mainly inflammatory, without marked neurodegenerative changes, and they are diffuse. The inflammatory changes are predominantly seen in the white matter of the cerebral hemispheres (leucoencephalitis), but areas of demyelination, when present, are confined to perivascular sites. Perivascular infiltration of monocytic inflammatory cells also occurs at several sites, including basal ganglia, brain stem, and cerebellar white matter. There is also an infiltration in the brain of peculiar cells, the so-called Mott cells,

Figure 1 Hypnograms showing the 24 h distribution of wakefulness (W), rapid eye movement (REM) sleep, and stages 1–4 of non-REM sleep in an African patient affected by sleeping sickness (top) and in a healthy African subject (bottom). Hypnograms were recorded in both subjects at bed rest and with an intravenous catheter (due to which the sleep of the healthy subject had many interruptions). Note the disruption of the circadian distribution of sleep and wakefulness in the patient, with frequent occurrence of sleep-onset REM sleep episodes. Reproduced from Buguet A, Bourdon L, Bouteille B, et al. (2001) The duality of sleeping sickness: Focusing on sleep. *Sleep Medicine Reviews* 5: 139–153, with permission.

which are morular shaped and contain IgM; they are most numerous in long-standing cases. Marked activation of microglial cells and widespread astrocytosis in the brain of human victims have been reported in early descriptions of sleeping sickness.

In most of these studies, trypanosomes were not detected in the brain parenchyma. This may reflect a high degree of sensitivity of the parasites to post-mortem autolysis, or it could be due to arsenical drug treatment that may kill the parasites in the brain before patients die.

Experimental Studies and Hypotheses on Pathogenesis of Sleep Disruption during the Disease

The pathogenesis of sleeping sickness is complex and poorly understood. Because the causative agent is an extracellular parasite, neuronal dysregulation causing neurological symptoms should be due to factors released by the parasite, its interactions with the immune system of the host, or both.

In view of laboratory safety conditions, as mentioned previously, most experimental studies have employed *T.b. brucei*.

Neuroinflammation in *Trypanosoma brucei*-Infected Rodents

Experimental studies have revealed a temporal profile of *T.b.* neuroinvasion, which seems to occur stepwise. Early after infection in experimental rat and mouse models, *T.b. brucei* localizes to the choroid plexus and circumventricular organs, which lack a BBB. Later during infection, the parasites can penetrate into the brain parenchyma across the BBB. However, the parasites can cross the BBB with preserved endothelial cell tight junction proteins. This finding supports the clinical observation that drugs that cannot penetrate the BBB are inefficient in the treatment of HAT late during infection. As described later, a major unsolved pathogenetic problem is the identification of factors which, in the parasite and/or the host or their interaction, determine *T.b.* passage through the BBB.

The pathological picture in experimental infections in rodents is neuroinflammatory, as in humans, with only minor signs of neurodegeneration, and the reaction is predominant in the white matter, into which the parasites penetrate. There is a marked activation of astrocytes and microglia, which shows a predilection for certain areas including the hypothalamus, as well as production of cytokines in the brain.

The protagonists of the immune response to the infection (in experimental animals, as well as in humans) are proinflammatory cytokines, including interleukin (IL)-1, tumor necrosis factor (TNF)-α, and interfron (IFN)-γ. TNF-α was isolated in 1985 from *T.b.*-infected rabbits in the search for the cause of cachexia in trypanosomiasis, and it was initially named 'cachectin.' In the brain, cytokines can have an endogenous origin, being released by activated glial cells. The action of proinflammatory molecules,

however, can be counteracted by the release of anti-inflammatory cytokines such as IL-6 and IL-10 and also other extra- and intracellular factors that control inflammation. Free radicals, including nitric oxide, and prostaglandins are also induced in the brain during the infection. In particular, high levels of prostaglandin D2 have been reported in late-stage patients. A prostaglandin released by *T.b.* has also been identified, but its eventual role in sleep changes during the disease has not been examined.

Alterations of Sleep and Endogenous Rhythms in Rodent Models

In rats infected with *T.b. brucei*, the sleep pattern has been found to be markedly fragmented, with major dysregulation of the REM/non-REM sequence of sleep episodes on EEG recordings. Frequent awakenings during slow-wave sleep (SWS) episodes, a reduction of the average length of SWS episodes, and a reduced REM sleep latency have been observed. The sleep structure is marked by abnormal transitions and especially the appearance of SOREM-like episodes. However, the duration of REM sleep episodes is unaffected.

The experimental infections in rodents do not reproduce the full spectrum of the human disease, which mostly develops over a long period of time, whereas the rodent infections allow only a limited survival of a few weeks. However, 24 h EEG recordings have revealed that, in addition to sleep fragmentation, disruption of the sleep–wake cycle can also occur in late stages of the experimental infection in rats.

It should be emphasized that, as in humans, despite the pronounced secretion of somnogenic and pyrogenic cytokines (i.e., IL-1 and TNF-α), neither hypersomnia nor fever are characteristic of the infection in experimental animals. The reason for this paradox is unknown.

Experimental data also point to a disturbance in the melatonin-generating system in the pathogenesis of the disease, with decreased amplitude of the nocturnal peak of melatonin secretion in the urine of *T.b.*-infected rats. The EEG alterations are also ameliorated by treating infected animals with melatonin. However, the locomotor activity and body core temperature rhythms are preserved in *T.b.*-infected rats, but the amplitude of locomotor activity is markedly reduced even early during infection, and a phase advance in the temperature cycles has been noted.

Involvement of Neural Centers That Regulate Circadian Rhythms and Sleep

The sleep disturbances during *T.b.* infection in rodents are in part reminiscent of those observed after lesions of the hypothalamic suprachiasmatic nucleus (SCN), which is the master circadian pacemaker in the mammalian brain. Therefore, functional parameters of this nucleus have been investigated during experimental infections.

The SCN is entrained by environmental light through the retinohypothalamic tract, which utilizes glutamate as a neurotransmitter. The circadian timing system can interact with diencephalic sleep-regulatory centers, whereby circadian information can be transmitted to arousal- and sleep-promoting centers. In the posterior hypothalamus, the histamine-containing tuberomammillary nucleus and the dorsolateral group of neurons containing the peptide orexin/hypocretin (**Figure 2**) have been identified as key relay centers in the regulation of wakefulness. The ventrolateral preoptic nucleus of the anterior hypothalamus (**Figure 2**) has been identified as a sleep-promoting center. These regions have been proposed to be involved in a bistable 'flip-flop' model by which sleep and wakefulness can be switched by reciprocal inhibitory circuits. A decreased resistance in this circuit would weaken the stability of the switch and could therefore result in disruption of the sleep–wakefulness pattern. In particular, the orexin/hypocretin-containing neurons have been suggested to stabilize the switch, causing arousal through an excitatory effect on tuberomammillary neurons directly and by disinhibition.

Experimental data in rodents suggest an involvement of sleep–wakefulness-regulating hypothalamic cell groups during trypanosome infections (**Figure 2**). Marked impairment of the SCN response to a photic stimulus, in the absence of structural changes of retinohypothalamic fibers, was documented in infected rats, and this was accompanied by altered expression of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) glutamate receptor subunits. The amplitude of spontaneous firing in the SCN was also found to be severely altered in *T.b.*-infected rats. Alterations in the synaptic machinery of SCN neurons, particularly disturbances in excitatory neurotransmission, were found in slice preparations of the SCN from infected rats, and these were also caused by treatment with IFN-γ in combination with the endotoxin lipopolysaccharide and TNF-α. Data also indicate a dysregulation of orexin/hypocretin-containing neurons in infected rodents. Furthermore, effects of trypanosome infections on the brain stem serotoninergic raphe nuclei (**Figure 2**), which is also a major sleep-modulatory center, have been suggested.

Together, the findings indicate that due to targeting of trypanosomes in the brain to circumventricular organs close to diencephalic centers and prolonged release of proinflammatory molecules during the infection, trypanosomes could interfere with the function

Figure 2 This drawing depicts on the medial surface of the human brain the localization of African trypanosomes at early stages of central nervous system infection, as derived from experimental studies on rodent models. Sitting in circumventricular organs and in the choroid plexus before penetration into the brain parenchyma, the parasites release factors and elicit response of the immune system of the host, with release of inflammatory molecules, including proinflammatory cytokines. Long-term exposure to these molecules could affect neural centers which regulate the sleep–wake alternation and organization. Over time, this could cause dysfunction of circadian timing and sleep-regulatory neuronal assemblies and/or their coupling. The solid circles indicate circumventricular organs; the stars indicate the choroid plexus in the lateral and fourth ventricles and also circadian timing and sleep-regulatory neural centers. AP, area postrema; cc, corpus callosum; fx, fornix; LC, locus coeruleus; ME, median eminence; oc, optic chiasm; Orx, orexin/hypocretin-containing cell groups; OVLT, vascular organ of lamina terminalis; POA, preoptic area; RN, raphe nuclei; SCN, suprachiasmatic nucleus; SFO, subfornical organ; THAL, thalamus; TMN, tuberomammillary nucleus.

of the master circadian pacemaker and sleep-regulatory centers and/or with the coupling between these structures. This neural functional derangement could be built up over time in the molecular interaction between the parasite and the host and/or reach a threshold revealed by the onset of sleep changes in the host.

The Blood–Brain Barrier and Implications for Treatment

As indicated previously, a major problem with regard to therapy of the encephalitis that evolves during sleeping sickness is that the only available drugs which penetrate the BBB are very toxic. Important questions to address are how the parasites cross the BBB, whether there are clinical correlates or markers for parasite penetration into the brain parenchyma, and whether the parasites can hide behind the BBB from the immune response or whether a continuous influx of parasites into the brain is needed to maintain the cerebral infection.

In experimental rodent models, trypanosomes do not move passively into the parenchyma through a disrupted BBB but, rather, follow processes similar to the infiltration of white blood cells (WBCs) into the brain during inflammation. Infiltration of WBCs into the brain can be modulated by cytokines, which also influence *T.b. brucei* neuroinvasion. Thus, the migration of trypanosomes from the lumen of cerebral blood vessels into the brain parenchyma is impeded in mutant mice deficient in IFN-γ, IFN-γ receptor, IL-12p40, and recombinant activating gene-1, despite higher levels of parasitemia in the mutant strains compared to wild-type mice. In the mutant mice, there is a striking accumulation of parasites in the perivascular compartment, confined between the endothelial and the parenchymal basement membranes. These data also indicate that a host immune response molecule, IFN-γ, paradoxically may facilitate penetration of trypanosomes across cerebral blood vessels.

That mechanisms for penetration of parasites into the brain parenchyma are related to those of WBCs is further supported by studies on the effect of the drug minocycline on parasite neuroinvasion. This tetracycline antibiotic impedes the penetration of WBCs into the brain in experimental allergic encephalomyelitis models and, similarly, it impedes neuroinvasion of trypanosomes in *T.b. brucei*-infected mice. Weight loss occurring during infection with *T.b. brucei* is not observed after minocycline treatment of the mice, which also survive longer than nontreated mice.

Due to the treatment hazards of the disease at a late stage, there is an urgent need for better

staging criteria of the infection. For instance, since experimental animals develop sleep pattern changes, a correlation between changes in sleep parameters and passage of trypanosomes across the BBB should be sought. Until there are novel drug discoveries for late-stage disease, early diagnosis and treatment are mandatory to control the infection.

Sleep–Wake State Regulation by Acetylcholine

B E Jones, McGill University, Montreal, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

Background

Since early histochemical and pharmacological studies in the 1960s, acetylcholine (ACh) has been known to comprise a key element of the activating systems in the brain. The catabolic enzyme acetylcholinesterase (AChE) was found to be contained in fibers which ascended from the brain stem reticular formation into the forebrain and from the basal forebrain into the cerebral cortex in what Shute and Lewis called the 'cholinergic reticular activating system.' This designation advanced the concept that the neurons which utilized ACh as a neurotransmitter formed the principal component of the 'ascending reticular activating system' previously delineated by Moruzzi and Magoun and colleagues in the 1940s and 1950s and shown to be critical for the cortical activation of waking. Enhancement of synaptic ACh through drugs such as physostigmine, which inhibits AChE, stimulated fast cortical activity on the electroencephalogram (EEG), which is indicative of cortical activation. The ACh receptor agonists, nicotine and muscarine, were long known as stimulants and also found to elicit cortical activation. Conversely, blocking nicotinic or muscarinic ACh receptors diminished fast cortical activity. Yet interestingly, atropine, which blocks muscarinic ACh receptors, produced slow wave activity on the cortex but did not prevent behavioral activity and arousal, and thus led to a disassociation of the normal EEG activity and behavior of waking. This dissociation revealed the selective role of ACh in stimulating cortical activation. Indeed, ACh was subsequently found to stimulate cortical activation during the behavioral quiescence and immobility that occurs during the state of rapid eye movement (REM) sleep (also called paradoxical sleep (PS); Figure 1). The cholinergic systems are thus well known to play an important role in cortical activation that occurs during both waking and REM sleep. Conditional upon the activity of other systems, they can also promote either waking or REM sleep states.

Cholinergic Systems in the Brain

The two major groups of cholinergic neurons with ascending projections are located in the pontomesencephalic tegmentum and the basal forebrain (Figure 1). They have been identified and localized definitively by employing immunohistochemical staining for choline acetyl transferase (ChAT), the synthetic enzyme for ACh. The enzyme is found in select neurons that synthesize ACh for use as a neurotransmitter and were thus presumed to be 'cholinergic.' As originally visualized by Shute and Lewis, AChE, the catabolic enzyme, is contained in many more neurons, including monoaminergic and glutamatergic reticular and thalamic neurons, which are likely target neurons of the cholinergic cells. Nonetheless, ChAT immunohistochemistry revealed the presence of cholinergic neurons within the brain stem reticular formation and basal forebrain as well as the presence of cholinergic fibers ascending through the brain and from the basal forebrain up to the cerebral cortex in parallel with other ascending systems to confirm the essential characterization of a cholinergic reticular activating system. The presence of the vesicular transporter protein for ACh (VAChT), which permits storage and synaptic release of ACh, in the brain stem and forebrain ChAT-immunostained cell bodies and terminals confirmed the use of ACh as a neurotransmitter by these accordingly established 'cholinergic' neurons.

The pontomesencephalic cholinergic neurons are located within the laterodorsal tegmental (LDTg) and pedunculopontine tegmental (PPTg) nuclei (Figure 1). Together with other neurons of the reticular formation (which predominantly utilize glutamate (Glu) as a neurotransmitter), these cholinergic cells send ascending projections dorsally up to the thalamus and ventrally to the hypothalamus and, to a lesser extent, the basal forebrain. In the thalamus, they innervate some of the specific thalamocortical relay nuclei (particularly the medial and lateral geniculate nuclei) but innervate most prominently and ubiquitously the neurons of the nonspecific thalamocortical projection system (the midline and intralaminar nuclei, which, like all thalamic projection neurons, utilize Glu), which in turn project in a widespread manner to the cerebral cortex to have the capacity to stimulate widespread cortical activation. Either through collaterals of the forebrain projecting cells or by unique projections, the pontomesencephalic cholinergic neurons also project into the brain stem reticular formation, where they can influence reticular neurons with ascending, local, or descending projections, which are important for REM sleep generation.

The basal forebrain cholinergic neurons are located within the medial septum and diagonal band of Broca (MS-DBB) rostrally and the magnocellular preoptic nucleus, substantia innominata, and globus pallidus (MCPO-SI-GP) more caudally (Figure 1). These two major collections of cells provide prominent innervation to the hippocampus and paleocortex (MS-DBB)

Figure 1 Cholinergic and other neurons involved in sleep–wake state control. Sagittal schematic view of the rat brain depicting neurons with their chemical neurotransmitters and pathways by which they influence cortical activity or behavior across the sleep–wake cycle. Wake (W) is characterized by fast gamma activity on the cortical electroencephalogram (EEG; top left) and high postural muscle tone on the neck electromyogram (EMG; bottom right), slow wave sleep (SWS) is characterized by slow delta EEG and low tone on the EMG, and paradoxical sleep (PS) is characterized by fast gamma EEG and atonia on the EMG. Neurons that are active during waking (red symbols) include cells with ascending projections toward the cortex which stimulate fast cortical activity and cells with descending projections toward the spinal cord which stimulate postural muscle tone and behavioral arousal. The cholinergic (ACh) neurons and other glutamatergic (Glu) neurons which have predominantly ascending projections discharge in association with fast EEG activity (gamma+) and cease firing with delta activity (delta-) to be active during W and PS (W-PS; solid red symbols). The serotonergic (Ser), noradrenergic (NA), orexinergic (Orx), and some putative glutamatergic (Glu) neurons which have more diffuse or descending projections discharge in association with behavioral arousal and EMG activity (EMG+) and cease firing with muscle atonia to be active during W and silent during PS (W; open red symbols). Neurons that are active during sleep (aqua symbols) include cells with descending projections into the brain stem and spinal cord which diminish behavioral arousal and muscle tone. Important among such cells are GABAergic (and glycinergic) neurons in the ventral medulla which project to the brain stem and spinal cord, where they can inhibit motor neurons during sleep. The cholinergic neurons have the capacity to stimulate cortical activation during waking and PS and also to promote PS with muscle atonia by acting in part upon such GABAergic neurons, when the monoaminergic and orexinergic neurons are silent. 7g, genu seventh nerve; ac, anterior commissure; ACh, acetylcholine; CPu, caudate putamen; Cx, cortex; DR, dorsal raphe nucleus; Gi, gigantocellular RF; GiA, gigantocellular, alpha part RF; GiV, gigantocellular, ventral part RF; Glu, glutamate; GP, globus pallidus; Hi, hippocampus; ic, internal capsule; LC, locus coeruleus nucleus; LDTg, laterodorsal tegmental nucleus; Mes RF, mesencephalic RF; MCPO, magnocellular preoptic nucleus; NA, noradrenaline; opt, optic tract; Orx, orexin; PH, posterior hypothalamus; PnC, pontine, caudal part RF; PnO, pontine, oral part RF; POA, preoptic area; PPTg, pedunculopontine tegmental nucleus; PS, paradoxical sleep (also called REM sleep); RF, reticular formation; Rt, reticularis nucleus of the thalamus; s, solitary tract; scp, superior cerebellar peduncle; Ser, serotonin; SI, substantia innominata; SN, substantia nigra; Sol, solitary tract nucleus; Th, thalamus; VTA, ventral tegmental area. and to the neocortex (MCPO-SI-GP). Projecting in a topographically organized, though widespread manner, the basal forebrain cholinergic neurons thus have the capacity to stimulate widespread cortical activation through both paleo- and neocortex.

Cholinergic Systems and Cortical Activation of Waking

The pontomesencephalic cholinergic neurons send their major projections into the thalamus by which they can excite thalamocortical neurons to in turn stimulate cortical activation. Release of ACh in the thalamus is maximal in association with fast cortical activity during waking and during REM sleep, indicating that the thalamic projecting cholinergic cells discharge during both waking and REM sleep. Acting on both nicotinic and muscarinic ACh receptors, ACh depolarizes and excites thalamocortical projection neurons. It thereby prevents their slow bursting discharge, which occurs during slow wave sleep (SWS), and stimulates their fast tonic discharge, which occurs during, while also stimulating, fast cortical activity of waking or REM sleep.

The basal forebrain cholinergic cells project directly to the hippocampus and neocortex, where they act on

cortical neurons to alter their discharge. Release of ACh from hippocampus and neocortex is high in association with fast cortical activity during both waking and REM sleep. ACh prevents the slow bursting discharge of cortical neurons, which occurs during SWS, and stimulates the fast tonic discharge that occurs during waking and REM sleep. ACh's action in the cortex occurs largely through muscarinic receptors of different types on pyramidal cells and interneurons. Some interneurons are hyperpolarized through muscarinic ACh receptors, whereas others, such as pyramidal cells, are depolarized and excited through muscarinic and nicotinic ACh receptors. Overall, however, ACh and the basal forebrain cholinergic neurons stimulate fast cortical activity particularly in the gamma frequency range (30–60 Hz), which is maximal during attentive or active waking and REM sleep. ACh also stimulates theta activity (4–10 Hz), which is similarly maximal during attentive or active waking and REM sleep. Indeed, it may stimulate these in parallel since the high-frequency gamma activity rides on the slow rhythmic theta waves. Local injections of glutamate or other agonists acting on the cholinergic cells in the basal forebrain evoke theta with enhanced gamma activity. The basal forebrain cholinergic neurons can modulate this rhythmic cortical activity by their discharge, which, as established for identified ChAT-immunostained cells, occurs in rhythmic bursts with theta along with high gamma activity during active waking and REM sleep (Figure 2(a)).

Figure 2 Discharge cholinergic and orexinergic units across sleep–wake states. Average discharge rate (spikes s^{-1}) across the sleep–wake states and transitions (t) of a cholinergic cell (a) in basal forebrain (BF; within MCPO-SI, identified by juxtacellular labeling with neurobiotin and immunohistochemical staining for ChAT) and an orexinergic neuron (b; in the posterior hypothalamus (PH) within the perifornical area, identified by juxtacellular labeling with neurobiotin and immunohistochemical staining for orexin). ACh neurons discharge in association with cortical activation (fast EEG active, gamma+/Delta−) during wake and paradoxical sleep (W-PS; solid red symbols in Figure 1), whereas orexinergic neurons discharge, like NA and Ser neurons, in association with behavioral activity and postural muscle tone (behavioral wake active, EMG+) during W (open red symbols in Figure 1). The discharge of cholinergic neurons when orexinergic and monoaminergic neurons are silent leads to PS. aW, active wake; qW, quiet wake; tSWS, transition to slow wave sleep; SWS, slow wave sleep; tPS, transition to paradoxical sleep; PS, paradoxical sleep (also called REM sleep). Data from Lee MG, Hassani OK, Alonso A, and Jones BE (2005) Cholinergic basal forebrain neurons burst with theta during waking and paradoxical sleep. *Journal of Neuroscience* 25: 4365–4369; and Lee MG, Hassani OK, and Jones BE (2005) Discharge of identified orexin/hypocretin neurons across the sleep–waking cycle. *Journal of Neuroscience* 25: 6716–6720.

Cholinergic Systems and REM Sleep

Following identification of the cholinergic neurons by ChAT immunohistochemistry, it became apparent that the major cell groups in the LDTg and PPTg were located in a region previously shown by Jouvet to be important in the generation of REM sleep, named by him 'paradoxical sleep.' Indeed, complete transections of the brain stem through the caudal midbrain which allowed the persistence of PS in the periphery (marked by postural muscle atonia on electromyogram) would have left intact the pontomesencephalic cholinergic cells innervating the brain stem (Figure 1). In later studies, neurotoxic lesions destroying the pontomesencephalic cholinergic neurons resulted in the loss of PS, including the phasic pontogeniculo-occipital (PGO) spikes accompanying REM sleep and tonic muscle atonia of that state. It had also been shown in both early and later studies that local injections of the cholinergic agonist carbachol into the pontine tegmentum could elicit PS, including PGO spikes with REM, theta activity, and muscle atonia.

On the other hand, the pharmacological elicitation of REM sleep through cholinergic agonists was not always automatic. AChE inhibitors such as physostigmine commonly stimulated cortical activation with wakefulness in otherwise untreated normal animals or humans. However, in early studies it was found that if physostigmine was administered following depletion of the monoamines (with reserpine), it elicited REM sleep. By these pharmacological studies, it was evident that the occurrence of REM sleep depends on

the activity of cholinergic neurons, but it also depends on the inactivity of monoaminergic neurons, a principle which was subsequently formalized in a model of reciprocal interaction by McCarley and Hobson.

Single unit recording studies indicated that whereas many neurons in the pontomesencephalic tegmentum discharged robustly during REM sleep, including those in the region of the cholinergic cells, the presumed serotonergic neurons in the raphe and presumed noradrenergic neurons in the locus coeruleus ceased firing during REM sleep (Figure 1). Although definite identification of recorded neurons awaits absolute confirmation of these principles, c-Fos expression, which reflects neural discharge, was found to be maximal in identified cholinergic pontomesencephalic neurons and minimal in serotonergic and noradrenergic neurons during REM sleep. Finally, ACh release is high during REM sleep in both the forebrain and the brain stem, whereas the release of the monoamines is minimal during REM sleep. Converging lines of evidence thus indicate that cholinergic neurons trigger REM sleep if monoaminergic neurons are silent. ACh can act in different ways on various brain stem and spinal neurons, including GABAergic (and glycinergic) neurons which can inhibit motor neurons, such as to provoke decreased activity and muscle tone. In contrast, serotonin and noradrenaline can stimulate behavioral arousal along with postural muscle tone through excitatory actions on brain stem and spinal neurons, including reticular glutamatergic and motor neurons.

It has also been revealed that hypothalamic neurons containing the peptide orexin (or hypocretin) normally stimulate behavioral arousal with postural muscle tone in a critical manner since in their absence narcolepsy with cataplexy results in humans and animals. Like the presumed monoaminergic neurons and in contrast to the cholinergic neurons, the orexin neurons fire selectively during waking and are silent during REM sleep (Figures 1 and 2(b)). Like monoaminergic neurons, orexin neurons would thus also oppose cholinergic neurons in the generation of REM sleep, although they can work together with cholinergic neurons to stimulate behavioral arousal together with cortical activation during waking.

Cholinergic Systems, Sleep, and Memory

The importance of ACh in memory processes has been known since early pharmacological studies showed serious decrements in memory consolidation following administration of the muscarinic ACh receptor antagonists atropine or scopolamine. Both short- and long-term memory processes have been shown to be enhanced by ACh. ACh enhances long-term potentiation (LTP) and stimulates theta, which in turn enhances LTP and plasticity. Stimulation of the basal forebrain has been shown to promote learning and plasticity. It thus follows that states with heightened ACh release and maximal cholinergic unit discharge would be associated with enhanced learning and memory. These states are active or attentive waking and REM sleep. Although it has long been known that learning is maximal during aroused or attentive waking, it has also been shown in multiple studies that memory consolidation for implicit and explicit or particularly procedural, emotional, and spatiotemporal elements is enhanced during REM sleep.

Sleep–Wake State Regulation by Noradrenaline and Serotonin

B E Jones, McGill University, Montreal, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

Background

The monoamines, noradrenaline (NA) and serotonin (5-HT), were found to have the capacity to influence sleep–wake states in the 1960s through early pharmacological and histochemical, combined with lesion, studies. Particularly through the work of Jouvet with his colleagues, evidence was presented for an important role of NA and the major NA-containing locus coeruleus (LC) nucleus in wakefulness and for a role of 5-HT and the 5-HT-containing raphe nuclei in sleep, particularly slow-wave sleep (SWS). Pharmacological depletion of NA (with inhibition of its synthesis by α-methyl-paratyrosine (AMPT)) and lesions of the ascending pathway from the LC led to decreased wakefulness. Conversely, depletion of 5-HT (with inhibition of its synthesis by para-chloro-phenylalanine (PCPA)) and lesions of the raphe, including the dorsal raphe (DR) nucleus, led to decreased SWS. These early studies and conclusions indicating opposite roles for the noradrenergic and serotonergic systems in sleep–wake state control have since been further scrutinized by finer techniques, including single-unit recording, and revised to reveal different – but not opposite – roles of these systems in the sleep–wake cycle.

Projections and Role of Noradrenergic Locus Coeruleus Neurons in Arousal

The LC is a collection of NA-containing neurons located in the periventricular region of the rostral pons, which can be likened to a sympathetic ganglion because from it emerge multiple major projection pathways of varicose and highly collateralized axons that reach out to innervate the entire central nervous system (Figure 1). Although the neurons are somewhat segregated according to their predominant projections (such that the most dorsal cluster projects primarily to the thalamus and lateral cortex; the more intermediate projects to the hypothalamus, basal forebrain, and medial cortex; and the most ventral cluster projects to the brain stem and spinal cord), a single neuron can project through multiple collaterals to all regions. This highly diffuse noradrenergic system is thus uniquely organized to simultaneously influence the entire central nervous system in a way that could alter its fundamental mode of operation, as occurs in a change of state from sleeping to waking. It was indeed thus proposed in early studies that the noradrenergic LC neurons formed the most important contingent of an ascending activating system of the brain stem. In support of this concept, one of the major stimulants, amphetamine, was found to act by release of NA and also dopamine (DA). The early lesion studies involving multiple systems did diminish wakefulness and cortical activation which were thus proposed to depend on the noradrenergic LC innervation of the cortex. However, subsequent more selective lesions or destruction by neurotoxins (6-hydroxydopamine (6-OHDA)) of the noradrenergic system did not result in the same loss of cortical activation and waking as did the earlier nonselective lesions. These results thus indicated that, although the noradrenergic neurons have the capacity to stimulate cortical activation and wakefulness, they are not essential for these functions. They represent, instead, one of multiple partially redundant, although differentiated, arousal systems in the brain, which include most notably the acetylcholine (ACh)-releasing cholinergic neurons of the brain stem and basal forebrain and the orexin (Orx, or hypocretin) neurons of the posterior hypothalamus (Figure 1).

The NA LC neurons discharge during active waking, gradually decrease their firing during SWS, and cease firing during rapid eye movement (REM) sleep, also called paradoxical sleep (PS) (Figure 2(a)). They accordingly discharge during active or attentive waking associated with behavioral arousal and the presence of postural muscle tone recorded on the electromyogram (EMG; Figure 1). They discharge during orientation and response to sensory stimuli. They also respond to physiological stimuli which activate the sympathetic nervous system and situations which are associated with stress. Given their diffuse projections and actions, the noradrenergic neurons can simultaneously stimulate fast cortical activity on the electroencephalogram (EEG) and motor activity with postural muscle tone on the EMG during waking in a tonic and phasic manner. Acting through α_1-adrenergic receptors (α_1-AR), NA can depolarize and excite many neurons through the central nervous system, including thalamo-cortical and basalo-cortical projection neurons, which respectively release glutamate (Glu) and ACh in the cortex, and excitatory (Glu) reticulo-spinal projection or motor neurons (Figure 1). These actions appear to be very important or at least potent for stimulating and maintaining an aroused and attentive state in that the condition of hypersomnia and narcolepsy is best treated by drugs which enhance NA release, including amphetamine-like compounds or

Figure 1 Noradrenergic (NA), locus coeruleus (LC), and serotonergic (5-HT) raphe nuclei along with other neurons involved in sleep–wake state control. Sagittal schematic view of the rat brain depicting neurons with their chemical neurotransmitters and pathways by which they influence cortical activity or behavior across the sleep–wake cycle. Wake (W) is characterized by fast gamma activity on the cortical EEG (upper left) and high postural muscle tone on the neck EMG (lower right); slow-wave sleep (SWS) is characterized by slow delta EEG and low tone on the EMG; and paradoxical sleep (PS) is characterized by fast gamma EEG and atonia on the EMG. Neurons that are active during waking (red symbols) include cells with ascending projections toward the cortex, which stimulate fast cortical activity, and cells with descending projections toward the spinal cord, which stimulate postural muscle tone and behavioral arousal. The NA LC neurons give rise to diffuse projections with highly collateralized and varicose axons that innervate multiple regions as way stations along their major pathways. One major projection pathway ascends dorsally through the reticular formation into the thalamus and beyond to the cortex. Another ascends ventrally through the ventral tegmentum into and through the hypothalamus via the medial forebrain bundle to reach the preoptic area and basal forebrain (MCPO and SI) and continue forward to the cortex, which is diffusely innervated. A third projection pathway passes ventrally into the pontine tegmentum to descend through the brain stem reticular formation and continues into the spinal cord, where multiple, including motor, neurons are innervated. 5-HT raphe nuclei also give rise to multiple and relatively diffuse projections, which, however, are segregated such that the dorsal raphe (DR) gives rise to prominent ascending projections and the medullary raphe (including the raphe magnus, RM) gives rise to prominent descending projections to the spinal cord. The NA and 5-HT neurons along with orexinergic (Orx) and some putative glutamatergic (Glu) neurons which commonly have relatively diffuse or descending projections discharge in association with behavioral arousal and EMG activity (EMG+) and cease firing with muscle atonia to be active during W and silent during PS (W, empty red symbols). The cholinergic (ACh) neurons and other Glu neurons which have predominantly ascending projections discharge in association with fast EEG activity (gamma+) and cease firing with delta activity (delta−) to be active during W and PS (W-PS, filled red symbols). Neurons that are active during sleep (aqua symbols) include cells with descending projections into the brain stem and spinal cord which diminish behavioral arousal and muscle tone. Important among such cells are GABAergic (and glycinergic) neurons in the ventral medulla which project to the brain stem and spinal cord, where they can inhibit motor neurons during sleep. The cholinergic neurons have the capacity to stimulate cortical activation during waking and PS and also to promote PS with muscle atonia by acting in part on such GABAergic neurons, when the monoaminergic and orexinergic neurons are silent and also inhibited by GABAergic neurons. 5-HT, serotonin; 7g, genu seventh nerve; ac, anterior commissure; ACh, acetylcholine; CPu, caudate putamen; Cx, cortex; DR, dorsal raphe nucleus; EEG, electroencephalogram; EMG, electromyogram; GABA, γ-aminobutyric acid; Glu, glutamate; Gi, gigantocellular RF; GiA, gigantocellular, alpha part RF; GiV, gigantocellular, ventral part RF; Glu, glutamate; GP, globus pallidus; Hi, hippocampus; ic, internal capsule; LC, locus coeruleus nucleus; LDTg, laterodorsal tegmental nucleus; Mes RF, mesencephalic RF; MCPO, magnocellular preoptic nucleus; NA, noradrenaline; opt, optic tract; Orx, orexin; PH, posterior hypothalamus; PnC, pontine, caudal part RF; PnO, pontine, oral part RF; POA, preoptic area; PPTg, pedunculopontine tegmental nucleus; PS, paradoxical sleep (also called REM sleep); RF, reticular formation; RM, raphe magnus; Rt, reticularis nucleus of the thalamus; s, solitary tract; scp, superior cerebellar peduncle; SI, substantia innominata; SN, substantia nigra; Sol, solitary tract nucleus; SWS, slow-wave sleep; Th, thalamus; VTA, ventral tegmental area; W, wake. catecholamine-uptake blockers. NA also excites and can thereby recruit Orx neurons, which in turn give rise, like the LC neurons, to highly diffuse projections and act by exciting multiple arousal systems together with cortical and spinal motor neurons. Orx, which also excites the LC neurons in return, is essential for the maintenance of waking because in its absence narcolepsy with cataplexy results.

Figure 2 Discharge of (a) locus coeruleus (LC) and (b) dorsal raphe (DR) units across sleep–wake states: (a) mean firing rate (in hertz) per percentage of stage or seconds across a full sleep–wake cycle for multiple LC neurons (normalized according to completion of the entire cycle); (b) mean firing rate (in spikes s^{-1}) per state or stage across a full sleep–wake cycle for multiple DR neurons. As shown in (a), there is a progressive decrease in discharge with transition from waking into SWS and a cessation of firing during PS prior to an increase with the return of muscle tone (EMG) that actually anticipates the EMG change (inset). The graph in (b) also shows a progressive decrease with transition from aroused waking to late SWS and a virtual cessation of firing during PS prior to an increase with awakening. AW, active waking; DRO, drowsy; EMG, electromyogram; P-AR, phasic arousal; P-post-REM, phasic post-REM; Pre-REM, 60 s before REM onset; PS, paradoxical sleep; QW, quiet waking; REM, rapid eye movement sleep; SWS, slow wave sleep; SWS-1 early slow-wave sleep; SWS-2, middle slow-wave sleep; SWS-3, late slow-wave sleep; T-AR, tonic arousal; T-post-REM, tonic post-REM; W, waking. NA also promotes waking by inhibiting sleep-promoting γ-aminobutyric acid (GABA)ergic neurons in the preoptic area (POA) and basal forebrain which bear α_2-AR (Figure 1). These GABAergic neurons discharge during SWS and PS in a reciprocal manner to the NA LC neurons and, accordingly, in negative correlation with muscle tone on the EMG. By descending projections, these sleep-promoting GABAergic neurons can inhibit Orx neurons in the posterior hypothalamus (PH) and also NA cells in the LC more caudally. The NA LC neurons thus promote arousal by synergistic activity with other arousal systems, including the Orx neurons, and prevent sleep by antagonistic activity with sleep-promoting systems, including GABAergic preoptic and basal forebrain neurons.

Specifically with regard to PS, the NA LC neurons were found long ago to have a reciprocal relationship in their discharge with respect to presumed cholinergic neurons of the brain stem, as formalized in a model by McCarley and Hobson. Whereas LC neurons cease firing during PS, presumed cholinergic pontomesencephalic neurons discharged at maximal rates during PS. From pharmacological and electrophysiological studies, it appeared that the monoaminergic, including, significantly, noradrenergic neurons, had to be off for the cholinergic neurons to stimulate the

constellation of events, including cortical activation with REMs and muscle atonia, of PS (Figure 1). Indeed, at least some cholinergic neurons are inhibited by NA through α_2-AR. On the other hand, ACh excites the NA LC neurons and thus must act to inhibit the NA cells through GABAergic interneurons in the region, which from c-Fos expression, as an indication of neural activity, are active together with the cholinergic neurons during PS (Figure 1). The NA LC neurons have thus been conceived as PS-permitting (by permitting PS to occur through their cessation of activity and resulting disinhibition of cholinergic cells along with disfacilitation of motor systems), whereas the cholinergic and local GABAergic neurons are PS-promoting (and act in part by inhibiting the NA LC neurons).

Projections and Role of Serotonergic Raphe Neurons in Waking and Sleeping

Following pharmacological and lesion studies which indicated that 5-HT and raphe neurons play a role in promoting sleep, single-unit recording studies were undertaken to determine when they discharged. These early studies by McGinty and Harper surprisingly revealed that presumed 5-HT neurons in the DR discharged during waking, decreased their firing during SWS, and ceased firing during PS, in a similar manner to the NA LC neurons (Figures 1 and 2). Subsequent studies examining the discharge of presumed 5-HT neurons in the other raphe nuclei through the brain stem similarly found the same profile of activity across the sleep–wake cycle, and studies examining release in the forebrain also indicated that 5-HT release was greatest during waking and minimal during sleep. So, it became clear through these results that 5-HT could not generate SWS, as was originally proposed.

However, many lines of pharmacological and physiological evidence indicated that 5-HT and raphe neurons did not act in the same way that the NA neurons did. First, as already stated, depletion of NA resulted in decreased waking, whereas depletion of 5-HT resulted in decreased sleep. Second, whereas NA LC neurons discharged during orientation to a novel sensory stimulus, presumed 5-HT DR neurons ceased firing. Moreover, whereas NA LC neurons discharged in response to physiological challenges which activated the sympathetic nervous system, 5-HT raphe neurons did not. So, perhaps 5-HT neurons promote a less attentive or responsive waking state from which sleep onset is facilitated.

The 5-HT DR neurons project along similar pathways as the NA LC neurons to reach the thalamus, hypothalamus, basal forebrain, and cortex while leaving collaterals along the way (Figure 1). Their ascending projections are complemented by those of the central superior nucleus. The major descending 5-HT projections originate from neurons in the medulla (raphe magnus, pallidus, and obscurus) and extend through the entire spinal cord. 5-HT acts on multiple, different receptors and thus has the capacity to excite or inhibit different cell populations through the central nervous system. Whereas, its actions on certain thalamo-cortical projection (i.e., Glu) neurons and basalo-cortical (i.e., ACh) neurons are often inhibitory through 5-HT1 receptors, they are excitatory on some cortical, including pyramidal, cells, through 5-HT2 or other receptors. In the brain stem and spinal cord, 5-HT depolarizes and excites, like NA, motor neurons and can thus enhance muscle tone and activity. It can inhibit sensory transmission.

With respect to PS, the presumed 5-HT neurons of the DR, like the NA LC neurons, cease firing in a reciprocal manner to the presumed cholinergic cells of the pontomesencephalic tegmentum. As for the NA LC neurons, the 5-HT DR neurons are inhibited by local GABAergic neurons during PS. 5-HT hyperpolarizes and inhibits cholinergic cells in both the brain stem and basal forebrain. It can thus prevent the occurrence of PS with muscle atonia promoted by brain stem cholinergic neurons and diminish cortical activation evoked by basal forebrain cholinergic neurons.

Given their discharge during waking behaviors involving rhythmic motor activities, such as locomotion or grooming, and their cessation of discharge during orientation to sensory stimuli, it has been proposed by Jacobs that 5-HT neurons are primarily involved in facilitating rhythmic motor patterns and attenuating responses to extraneous sensory stimuli during those activities. Their discharge thus facilitates muscle tone with motor activities, yet diminishes cortical activation in response to external sensory stimuli during those activities. In this way, they function in opposition to the cholinergic cells, which diminish muscle tone and motor activities and enhance cortical activation during attentive waking and PS. The discharge of the NA LC cells facilitates muscle tone and arousal, but also enhances cortical activation in response to external sensory stimuli during waking. NA, which excites and depolarizes the basal forebrain cholinergic cells and can act in synergy with certain cholinergic neurons during waking but operates in opposition to other pontomesencephalic cholinergic cells whose discharge occurs during PS. Collectively, both the NA and 5-HT systems prevent loss of muscle tone and the apparition of PS, and drugs which are used to treat narcolepsy include reuptake blockers, which act to enhance both 5-HT and NA transmission.

Slow Axonal Transport

A Brown, Ohio State University, Columbus, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

Overview

Axons can be 1 m or more in length in large animals, yet they are dependent on the cell body for the synthesis of most of their components. Materials destined for the axon are transported anterogradely, toward the axon tip, and materials destined to return are transported retrogradely, toward the cell body. This bidirectional transport process, known as axonal transport, is not fundamentally different from the pathways of macromolecular and membrane traffic found in other parts of the neuron, or indeed in any eukaryotic cell, but it is unique for the volume and scale of the traffic.

Kinetic studies on axonal transport *in vivo* using radioisotopic pulse labeling have defined two distinct patterns of movement, termed fast and slow. Fast axonal transport represents the movement of membranous organelles, including Golgi-derived vesicles, endocytic organelles, mitochondria, peroxisomes, lysosomes, and autophagosomes. For the most part, these organelles move rapidly and frequently at rates of up to several hundred millimeters per day, which corresponds to several micrometers per second. Some of these organelles move anterogradely, some retrogradely, and some (such as mitochondria) are capable of frequent reversals and move in both directions. Ribosomes and ribonucleoprotein particles, which are transported along developing and regenerating axons, probably also move by fast axonal transport.

In contrast to fast axonal transport, slow axonal transport represents the movement of proteins that make up the cytoskeleton and cytosol of axons. These proteins, which are not associated with membranous organelles, move in an intermittent manner at average rates of approximately millimeters or tenths of millimeters per day, which corresponds to several nanometers or tens of nanometers per second, much slower than fast axonal transport. The cargo structures of slow axonal transport are largely unknown, but they are believed to include cytoskeletal polymers and cytosolic macromolecular complexes. For many years, it was assumed that slow axonal transport is an exclusively anterograde movement, but it is now clear that at least some of the cargoes of slow axonal transport can move in both anterograde and retrograde directions, although the net direction of movement may still be anterograde.

The different rates of fast and slow axonal transport have long been assumed to reflect fundamentally distinct mechanisms of movement, but direct observations of membranous organelles and cytoskeletal polymers in living cells now suggest that all axonal cargoes are transported by fast motors. Thus, the principal difference between fast and slow transport is not thought to be the rate of movement *per se* but, rather, the frequency of movement and the nature of the cargo structures. The terms fast and slow refer to the average rate of movement on a timescale of days or weeks and do not reflect the actual velocity of the transport motors.

Methods for Studying Slow Axonal Transport

There are essentially three different kinds of experimental techniques for studying axonal transport: accumulation techniques, pulse-labeling techniques, and imaging techniques (Table 1). Although these approaches can all be applied to both fast and slow axonal transport, their use for studies on slow axonal transport is emphasized here. Each technique has strengths and limitations, and each reveals different aspects of the motility, so they should be regarded as complementary approaches, not as alternatives.

Accumulation Techniques

The oldest and simplest technique for studying axonal transport is to locally impede movement along an axon or nerve and then observe what cargo structures accumulate and the rate at which they do so. Retrogradely moving materials accumulate on the distal side of the blockade and become depleted on the proximal side, whereas anterogradely moving materials accumulate on the proximal side and become depleted on the distal side. The most commonly used approaches are to surgically ligate or crush a nerve *in vivo*. A variant on these approaches is the cold block, in which local cooling is applied to a nerve *in vivo*. This method is technically more challenging, but eliminates the tissue damage that is associated with the ligation and crush approaches. Another approach, which has been applied to isolated axons teased apart from peripheral nerves and to single axons of cultured neurons, is to locally compress axons with fine nylon or glass fibers (Figure 1).

Pulse-Labeling Techniques

The most widely used pulse-labeling technique is radioisotopic pulse labeling, which was first introduced

Table 1 Three experimental methods for studying slow axonal transport

	Accumulation techniques	*Pulse-labeling techniques*	*Imaging techniques*
Example	Ligate or constrict single axons or entire nerves and observe the accumulation of transported materials	Inject radioactive amino acids into the vicinity of nerve cell bodies *in vivo* and then sacrifice the animal and analyze the distribution of the radiolabeled proteins along the axons	Inject or transfect neurons with fluorescent proteins and observe the moving structures by fluorescence microscopy
Strengths	Simple; can be performed *in vivo* or in cell culture	Permits the kinetics and composition of axonal transport to be studied *in vivo*	High temporal resolution (seconds or milliseconds); high spatial resolution (micrometers); permits individual cargoes to be tracked
Limitations	Poor spatial resolution; poor temporal resolution	Poor spatial resolution (1 mm at best); poor temporal resolution (hours or days at best); each animal yields only one time point, so multiple animals are required for each analysis	Not well suited to long-timescale studies; cannot presently be performed *in vivo*

Figure 1 Constriction of an axon of a cultured neuron growing on a glass coverslip: (a) axon prior to constriction; (b) axon after 1 min constriction with a flexible glass fiber (~1 μm in diameter); (c) axon after 30 min; (d) axon after 120 min; (e) constricted axon after fixation and removal of the glass fiber; (f) distribution of neurofilament protein in the fixed axon, visualized by immunofluorescence microscopy. Note that the glass fiber compresses the axon without severing it. Anterogradely and retrogradely moving membranous organelles, which are cargoes of fast axonal transport, accumulate rapidly, causing the axon to swell on both sides of the constriction (proximal is left, distal is right). As shown in (f), the net anterograde movement of neurofilaments in these axons results in an accumulation of neurofilament protein proximal to the constriction, which is evident from the bright fluorescence in the proximal swelling. Scale bar = 5 μm. Reproduced from Koehnle TJ and Brown A (1999) Slow axonal transport of neurofilament proteins in cultured neurons. *Journal of Cell Biology* 144: 447–458.

in the late 1950s and 1960s. Most of what we know about the composition and kinetics of slow axonal transport has come from studies using this approach, and it remains to this day the preferred method for studying the composition and kinetics of slow axonal transport *in vivo*. Essentially, this technique involves the injection of radiolabeled precursors of macromolecules (amino acids, sugars, or nucleotides) into the vicinity of neuronal cell bodies in an animal. Most published studies have used radiolabeled amino acids, which permit the movement of proteins to be investigated. The radiolabeled amino acids are taken up by the cell bodies, creating a pulse of radiolabeled proteins. Those proteins destined for the axon move into and along the axon in association with distinct cargo structures. By injecting numerous animals and sacrificing them at various time intervals, the kinetics of transport can be analyzed (each animal yields a single time point). The most powerful approach is to dissect out the nerves containing the radiolabeled proteins and then cut them into contiguous segments, permitting biochemical analysis of the radiolabeled proteins by subcellular fractionation, immunoprecipitation, and/or electrophoresis (Figure 2).

Radioisotopic pulse-labeling studies of slow axonal transport can be performed on a variety of different nerve cell types. Those that are best suited are ones whose cell bodies are located in an anatomically discrete region, facilitating reproducible injection of the radioisotope, and ones whose axons extend in a nerve that can be dissected readily and that is long with minimal branching. Most radioisotopic pulse-labeling studies have been performed on rats or mice, and the most commonly used axons are the retinal ganglion cell axons of the optic nerve (radiolabeled precursor injected into the eye) and the motor

Figure 2 The radioisotopic pulse-labeling technique. (a) Radiolabeled amino acids are injected into the vicinity of nerve cell bodies (the dorsal root ganglion in this example), and the amino acids are incorporated into proteins in the nerve cell bodies. The proteins move out along the axons in association with distinct cargo structures (shown here as purple, blue, and red dots), which move at different rates. At early times the faster- and slower-moving cargo structures overlap considerably, whereas at later times they become spatially separated. At various time intervals, the animals are sacrificed and the nerves are cut into contiguous segments. (b) For each time interval (time 1–4), the proteins in each nerve segment are separated by gel electrophoresis and the amount of radioactivity associated with each protein is quantified. Labeled proteins associated with the purple, blue, and red cargo structures in (a) are shown as purple, blue, and red bands, respectively, in (b). Reproduced from Lodish H, Berk A, Zipursky SL, Matsudaira P, Baltimore D, and Darnell J (2000) *Molecular Cell Biology*, 4th edn. New York: W. H. Freeman.

and sensory axons of the sciatic nerve (radiolabeled precursor injected into the ventral horn of the lumbar spinal cord or into the lumbar dorsal root ganglia, respectively).

Imaging Techniques

A third approach for studying axonal transport is direct observation of the movement of the cargo structures in living cells using light microscopy. Membranous organelles can be detected by video-enhanced differential interference contrast microscopy, but fluorescence microscopy is required to detect the cargoes of slow axonal transport because of their small size. Because fluorescence microscopy *in vivo* is problematic, experiments using this technique are presently limited to embryos or cultured nerve cells. The most common approach is to express fluorescent proteins in neurons or microinject them into cell bodies and then to observe the fluorescently labeled cargo structures by time-lapse imaging. The expression approach necessitates construction of a recombinant protein fused to green fluorescent protein or one of its variants, whereas the microinjection approach necessitates purification of the protein of interest and covalent modification with a fluorescent dye. The first attempts to detect slow axonal transport using these approaches date back to the late 1980s, but it was not until 2000 that the movement was demonstrated convincingly. To date, the movement of neurofilament proteins, tubulin, α-synuclein, synapsin I and glyceraldehyde-3-phosphate dehydrogenase have been observed in cultured nerve cells, but these are just a few of the many hundreds of proteins that are conveyed by slow axonal transport. The movements are fast, so imaging must be performed at intervals of several seconds or less. Because the cargo structures of slow axonal transport may be distributed continuously along the axon and cannot always be resolved from one another, it can be difficult to detect those that are moving. One way to

Figure 3 Movement of a single fluorescent neurofilament through a photobleached region in an axon of a cultured neuron. Neurofilaments were visualized by transfection with a neurofilament protein fused to green fluorescent protein, and the bleached region was observed by time-lapse fluorescence microscopy. The large arrowheads mark the edges of the photobleached region, and the small arrowheads mark the leading and trailing ends of the neurofilament, which is fluorescent because it originated from outside of the bleached region. Neurofilaments move at peak velocities of up to 3 μm s^{-1}, but the movements are infrequent and bidirectional. Scale bar = 5 μm. Reproduced from Wang L and Brown A (2001) Rapid intermittent of axonal neurofilaments observed by fluorescence photobleaching. *Molecular Biology of the Cell* 12: 3257–3267.

overcome this problem is to bleach the fluorescence in a segment of axon and then observe fluorescent cargo structures that originate from the flanking unbleached regions and move into the bleached region (Figure 3).

Two Distinct Subcomponents of Slow Axonal Transport

Radioisotopic pulse-labeling studies in a variety of neuronal cell types have shown that the proteins conveyed by slow axonal transport tend to resolve into two kinetically distinct subcomponents, termed slow

Figure 4 Autoradiographs of radiolabeled proteins in mouse optic nerve separated by two-dimensional gel electrophoresis: (a) slow component a (SCa); (b) slow component b (SCb). SCa (a) includes neurofilament triplet proteins (nf), tubulin (T; α and β subunits), tau (m), spectrin (s), and a small amount of actin (ac) trailing behind the SCb wave. SCb (b) includes actin (ac), calmodulin (ca), clathrin (cl), creatine kinase (ck), hsp70 (70), and nerve specific enolase (e). Some SCb proteins, such as aldolase (al) and pyruvate kinase (p), are not visible because they focused outside of the pH range of the isoelectric focusing gel. Reproduced from Lasek RJ, Garner JA, and Brady ST (1984), Axonal transport of the cytoplasmic matrix, *Journal of Cell Biology* 99: 212s–221s.

components a and b. Although some proteins are found in both subcomponents, most are unique to one or the other (Figure 4). Slow component a is slower and simpler in composition, being composed primarily of neuronal intermediate filament proteins, tubulin, and certain microtubule-associated proteins. In contrast, slow component b comprises more than 200 distinct proteins, indicating a remarkable complexity. Some of these proteins have been identified, and they include actin as well as the full spectrum of housekeeping proteins that make up neuronal cytosol, including proteins of glycolysis and intermediary metabolism, structural proteins, regulatory proteins, and motor proteins (Table 2).

The proteins that move in slow components a and b have generally been described as moving in a highly cohesive manner, but a careful reading of the literature suggests a more complex picture. For example, tubulin and neurofilament protein, which both move in slow component a, do not always move exactly in unison, and this is also the case for some of the proteins that move in slow component b. Moreover, although tubulin is transported predominantly in slow component a in some neurons, it is found in both slow components a and b in others. The explanation for this complexity is most likely that each subcomponent actually represents the movement of multiple distinct species of cargo structure that move independently. For example, tubulin and neurofilament proteins appear to be transported in the form of

Table 2 The composition and cargo structures of slow axonal transport

Rate class	*Average rate*	*Moving structures*	*Identified proteins*
Slow component a	0.2–1 mm day^{-1} ($\approx$ 0.002–0.02 μm s^{-1})	Neurofilaments and microtubules	Neurofilament proteins L, M, and H; internexin, peripherin, tubulin, neuronal spectrin (fodrin), tau, calcium/calmodulin-dependent protein kinase IIβ
Slow component b	2–8 mm day^{-1} ($\approx$ 0.02–0.09 μm s^{-1})	Unknown (may include microfilaments and supramolecular cytosolic protein complexes)	Actin, tubulin (in some neurons), dynein, dynactin, myosin Va, calmodulin, clathrin, clathrin uncoating protein hsc70, heat shock protein hsp70, cytosolic chaperonin containing T-complex polypeptide 1 (CCT), molecular chaperone hsc73, calcium/calmodulin-dependent protein kinase IIα, aldolase, creatine phosphokinase, enolase, glyceraldehyde-3-phosphate dehydrogenase, phosphofructokinase, superoxide dismutase 1, cyclophilin A, cofilin, actin depolymerizing factor, profilin, synapsin I, annexin VI, ubiquitin, ubiquitin C-terminal hydrolase PGP 9.5

microtubule and neurofilament polymers, which are distinct structures. It is possible that neurofilaments and microtubules could move at similar average rates in some axons and at different average rates in others. Moreover, the transport kinetics of any given protein is determined not just by the average rate of movement of the cargo structure with which it associates but also by the proportion of the time that the protein spends bound to that structure. Thus, proteins that associate with the same cargo structure may move with different kinetics if they differ in their affinity for that structure. Additional complexity can also arise if a given protein is capable of diffusion when it is not bound to its cargo structure.

The Kinetics of Slow Axonal Transport

When considering the rate of slow axonal transport, it is important to make a distinction between measurements made on the fast and slow timescales. In the radioisotopic pulse-labeling experiments, which are performed on a timescale of days or weeks, each protein conveyed by slow axonal transport moves out along the axon in the form of a unimodal bell-shaped wave that spreads as it moves distally. The rate of slow axonal transport is generally quoted as the rate of movement of the peak of the wave, which represents the modal transport rate, although the width and spreading of the waves clearly indicate that the proteins actually move at a range of rates. The modal rate differs in different neuronal cell types and may also vary spatially (along axons) as well as temporally (during development, maturation, and aging), but it is generally around 0.2–1 mm day^{-1} (0.002–0.02 μm s^{-1}) for slow component a and 2–8 mm day^{-1} (0.02–0.09 μm s^{-1}) for slow component b.

In contrast to the radioisotopic pulse-labeling experiments, direct observations on the movement of neurofilaments and microtubules in cultured neurons using fluorescence microscopy on a timescale of seconds or minutes indicate that these structures actually move very rapidly, at rates of up to several micrometers per second, and that these movements are also intermittent and infrequent (Figure 5). Thus, the bell-shaped waves that characterize slow axonal transport in the radioisotopic pulse-labeling experiments can be considered to represent the distribution of hundreds or thousands of pulse-labeled cargoes whose individual movements and pauses are summed over the days, weeks, or months that they spend traveling down the axon. Whether the movement is considered to be fast or slow depends on the timescale of the observations.

A Brief History of Experimental Studies on Slow Axonal Transport

The existence of material transport along axons was inferred by biologists more than 100 years ago, but it was not demonstrated experimentally until the classic study of Weiss and Hiscoe, published in 1948. These authors severed peripheral nerves in laboratory animals and then allowed the proximal axonal stumps to regenerate through segments of transplanted arteries. As the regenerating axons matured, they increased in caliber and experienced a gradually increasing constriction by the arterial sheath through which they passed. Over a period of days or weeks, the axons swelled proximal to the constrictions due to the accumulation of anterogradely transported materials. When the constrictions were released, the axonal swellings propagated distally at a rate of approximately 1 mm day^{-1}. The enlargement of the axons

Figure 5 Kinetics of neurofilament transport on fast and slow timescales: (a) timescale of weeks to months as revealed by radioisotopic pulse labeling in rat spinal motor neurons *in vivo*; (b) timescale of seconds to minutes, as revealed by live cell fluorescence imaging in cultured nerve cells. In (a), the pulse of radiolabeled neurofilament proteins moves out along the sciatic nerve in the form of a bell-shaped wave that spreads as it moves distally. The graph in (b) represents a single neurofilament moving in an anterograde direction. The filament was tracked by time-lapse imaging (as described in **Figure 3**). Each point represents the position of the leading end of the neurofilament along the axon in one 5 s interval. Both anterogradely and retrogradely moving neurofilaments exhibit a similar behavior, characterized by bouts of rapid movement interrupted by pauses of varying durations. (a) Data from Hoffman PN, Griffin JW, Gold BG, and Price DL (1985) Slowing of neurofilament transport and the radial growth of developing nerve fibers. *Journal of Neuroscience* 5: 2920–2929, courtesy of Paul Hoffman. (b) Data from Wang L and Brown A (2001) Rapid intermittent of axonal neurofilaments observed by fluorescence photobleaching. *Molecular Biology of the Cell* 12: 3257–3267.

proximal to the constrictions was referred to as damming, and it was considered to be due to an 'axomotile' mechanism. The authors termed this movement axonal flow, but we know it today as axonal transport. The axoplasm was considered to move in a slow anterograde direction as a semirigid column propelled by peristaltic contractions of the axolemma. The fact that this model turned out to be incorrect should not detract from the importance of this paper, which was published long before the era of modern cell biology. In fact, the authors' appreciation of the significance of axonal transport for the growth and maintenance of axons was remarkably prescient, and this study remains a landmark in the field of axonal transport.

With the introduction of radioisotopic tracer techniques in the late 1950s, it became apparent that axonal transport was bidirectional, with distinct anterograde and retrograde components, and that many of the components moved at very fast rates. Based on these findings, the concept of axonal transport as a bulk anterograde cytoplasmic flow evolved into one of bidirectional movement of discrete cytological structures at a broad range of rates. In the 1970s and early 1980s,

two competing theories emerged. In the structural hypothesis of Lasek and colleagues, axonal transport was considered to be comprised of multiple discrete rate components, each corresponding to the cohesive movement of a distinct subset of cytological structures. Lasek and colleagues postulated that all axonal proteins move by association with, or as integral parts of, cytologically identifiable subcellular carrier structures. The strength of this perspective was the recognition that the fast and slow components of transport have a distinct polypeptide composition and that this distinct composition reflects the movement of distinct organelles and macromolecular structures. In fact, one of the original predictions of the structural hypothesis was that cytoskeletal polymers are among the cargoes of slow axonal transport, which is now known to be true. However, the emphasis of this hypothesis on the cohesive nature of the movement within each subcomponent of axonal transport gave rise to the widely held perception that cytoskeletal and cytosolic proteins move along the axon *en masse* (i.e., in a slow and synchronous manner), which is no longer thought to be the case. In a competing theory termed the unitary hypothesis, Sydney Ochs and colleagues questioned the existence of slow axonal transport and proposed that there is a single fast transport mechanism that explains all movement in axons. Ochs and colleagues proposed that proteins conveyed by fast axonal transport could become deposited along the axon by dropping off the transport mechanism, with turnover of these deposited proteins giving rise to the appearance of slowly moving waves. The strength of this hypothesis was the recognition that both fast and slow transport could be generated by fast movements. However, this hypothesis failed to recognize that slow axonal transport represents a genuine movement of cargoes that are structurally distinct from those of fast axonal transport.

During the 1980s, the notion that slow axonal transport is a slow and synchronous movement became widely accepted and had a profound influence on the design of experiments to observe this movement in living cells. For example, in the late 1980s and 1990s, there were numerous attempts to observe slow axonal transport directly in cultured neurons using fluorescence microscopy. All these experiments focused on the cytoskeletal subunit proteins, and most used fluorescence photobleaching or photoactivation to mark these proteins in a short segment of axon and time-lapse imaging to observe their movement. Because the movement was thought to be slow and synchronous, these studies were designed to detect a slow translocation of the marked zone toward the axon tip. When they failed to detect such a movement, this failure was widely interpreted as evidence that cytoskeletal polymers in axons do not move and that cytoskeletal subunit proteins must be transported in some other unassembled form. This perspective became known as the subunit transport hypothesis, and it attracted considerable controversy. However, the failure of the photobleaching and photoactivation studies to detect any movement, either of subunits or polymers, was perplexing.

The controversy surrounding the subunit transport hypothesis was resolved in 2000 with the direct observation of the movement of neurofilaments, and shortly thereafter microtubules, in cultured nerve cells. The solution to the controversy was disarmingly simple – cytoskeletal polymers do move in axons, but their movements are not slow after all. The key to detecting these movements was the development of direct imaging strategies capable of detecting the rapid movement of single cytoskeletal polymers (e.g., Figure 3). Experiments using this approach have shown that neurofilaments and microtubules move at fast rates, approaching the rate of movement of membranous organelles, but that the average rate of movement is slow because the movements are infrequent, bidirectional, and highly asynchronous. Thus, the slow rate of slow axonal transport is actually the result of rapid movements interrupted by prolonged pauses. For example, it has been estimated using computational modeling that neurofilaments in motor axons of the mouse ventral root and sciatic nerve spend approximately 97% of their time pausing during their journey along the axon, and similar extents of pausing have been observed experimentally in cultured neurons. It seems likely that the many other proteins conveyed by slow axonal transport exhibit a similar motile behavior, but this has not been shown.

The Mechanism of Slow Axonal Transport

Current research on slow axonal transport is focused on addressing four central questions: (1) What are the cargo structures of slow components a and b, (2) what are the tracks along which they move, (3) what are the motors that move them, and (4) how is their movement regulated? The observation of the rapid intermittent movement of neurofilament and microtubule polymers in axons indicates that these cytoskeletal polymers are among the cargo structures of slow axonal transport, although this does not preclude the possibility that cytoskeletal subunit proteins may also move in an unassembled form. The form in which the many other proteins in slow axonal transport move remains unclear. One hypothesis is that they are transported by binding to (and effectively riding piggyback on) moving cytoskeletal polymers. The relatively simple protein composition of slow

component a suggests that neurofilaments and microtubules could be the sole carrier structures for this rate component; all the proteins that move in slow component a are either integral parts of these cytoskeletal polymers or are known to associate with these polymers *in vivo*. The presence of actin in slow component b suggests that microfilaments could function as a carrier structure for this rate component, although it seems unlikely that the several hundred different proteins that move in slow component b all bind to microfilaments. More probably, many of these proteins form supramolecular complexes that, in turn, associate with the moving filaments or that associate with motor proteins independently of the moving filaments. However, this hypothesis is speculative because the movement of microfilaments and most other cytosolic proteins in axons has not yet been demonstrated.

The rapid rate of movement of neurofilaments and microtubules in axons indicates that they are transported by fast motors, perhaps similar to or even the same as the motors that move membranous organelles, but the identity of these motors and the tracks along which they move are not known. By analogy with the movement of membranous organelles, it seems likely that neurofilaments and microtubules and other cargoes of slow axonal transport move along either microtubule or microfilament tracks. For example, there is evidence that dynein may transport axonal microtubules anterogradely along microfilaments and that dynein and kinesin may transport axonal neurofilaments bidirectionally along microtubules. The frequency of neurofilament movement may be regulated by phosphorylation of the neurofilament proteins. Axonal neurofilaments can also interact with myosin Va, but the role of this interaction in neurofilament movement is presently unclear. Although much remains to be learned about the mechanism of movement, it seems likely that the cargo structures of slow axonal transport each interacts with a number of different motor proteins and that these motors act cooperatively to translocate and organize these polymers in both the longitudinal and radial dimensions of the axon.

A Unified Perspective for Fast and Slow Axonal Transport

The rapid intermittent movement of cytoskeletal and cytosolic proteins in axons when observed on a time scale of seconds or minutes suggests a unified perspective for fast and slow axonal transport which combines elements of the structural hypothesis of Lasek and colleagues and the unitary hypothesis of Ochs and colleagues. According to this perspective, multiple distinct classes of membranous and nonmembranous cargoes are all transported along axons by the same underlying mechanism, but they move at different rates due to differences in their duty ratio (the proportion of the time that they spend moving). Each molecule moves by virtue of its association, directly or indirectly, with a particular class of cargo structure. The transport rate of individual proteins is determined by the proportion of the time that they spend in association with their cargo structure as well as the velocity and duty ratio of that structure. The difference in the rate of fast and slow axonal transport is therefore due to differential regulation of the direction, duration, and frequency of movement of the cargo structures. Membranous organelles on the secretory and endocytic pathways move rapidly and continuously in a unidirectional manner, either anterograde or retrograde, pausing for only brief periods. Many of these cargoes function to deliver membrane and protein components to a particular site along the axon or at its tip, and the high duty ratio of these organelles ensures that these components are delivered rapidly. In contrast, the cargo structures of slow axonal transport move very infrequently, with a low duty ratio, pausing most of the time and sometimes reversing during their journey along the axon. Although we refer to these structures as cargoes, they are not simply the luggage of intracellular transport; these cytoskeletal polymers and cytosolic protein complexes are probably preassembled functional units that fulfill their architectural, physiological, and/or metabolic roles in the axon during their transit. For these cargoes, the journey is perhaps more important than the ultimate destination, and this may explain why they move so slowly.

SNAREs

Introduction

Chemical synaptic transmission is mediated by neurotransmitters that are released by Ca^{2+}-triggered synaptic vesicle exocytosis. The exquisite spatial and temporal regulation of this process depends on a highly complex protein machinery that is formed in part by components with homologs in most types of intracellular membrane traffic, including *N*-ethylmaleimide sensitive factor (NSF), soluble NSF attachment proteins (SNAPs), SNAP receptors (SNAREs), Sec1/Munc18 (SM) proteins, and Rab guanosine triphosphatases (GTPases). Among these components, the SNAREs are believed to be at the heart of a conserved mechanism of membrane fusion by virtue of their ability to form tight SNARE complexes that bring two opposing membranes together. The neuronal SNAREs involved in neurotransmitter release are the synaptic vesicle protein synaptobrevin 2 (also known as vesicle associated protein 2 (VAMP2)) and the plasma membrane proteins syntaxin 1 (which in mammals includes two closely related isoforms, syntaxin 1A and 1B) and SNAP-25 (for synaptosomal associated protein of 25 kDa; no relation to SNAPs).

Neurotransmitter release depends also on proteins such as synaptotagmin 1 and complexins that play specialized roles in the tight regulation of this process and are not generally involved in other types of intracellular membrane traffic. Several of these proteins bind to the neuronal SNAREs and probably function in the regulation of SNARE complex assembly and/or in conjunction with the SNARE complex. Hence, synaptobrevin 2, syntaxin 1, and SNAP-25 have unique properties that have been adapted to the regulatory requirements of synaptic exocytosis, in addition to conserved features that are shared with SNAREs from other membrane compartments. This article focuses on the structural, biochemical, and functional properties of the neuronal SNAREs, but it also describes key findings on other SNAREs that have helped us to understand which of these properties are general and which are specialized.

SNARE Structure

SNAREs constitute a family of proteins characterized by sequences called SNARE motifs that comprise ~60–70 residues and have a high propensity to form coiled coils. Most SNAREs contain only one SNARE motif that is adjacent to a single C-terminal transmembrane (TM) region (e.g., synaptobrevin 2 and syntaxin 1). Some SNAREs contain two SNARE motifs connected by a long linker and do not have a TM sequence (e.g., SNAP-25) (Figure 1), but are attached to membranes through a posttranslational modification such as palmitoylation.

Circular dichroism (CD) and nuclear magnetic resonance (NMR) studies showed that isolated SNARE motifs are generally unstructured and adopt α-helical conformations when they bind to other SNARE motifs to form SNARE complexes. A SNARE complex contains four SNARE motifs that assemble into a parallel four-helix bundle, as first demonstrated for the neuronal SNAREs by electron paramagnetic resonance (EPR) spectroscopy and X-ray crystallography (Figure 2(a)). The neuronal SNARE complex is very stable (it is resistant to sodium dodecyl sulfate (SDS) and requires high temperatures for denaturation). This stability is conferred in large part by contacts between many hydrophobic residues that are arranged in layers, with each SNARE motif contributing one hydrophobic side chain to each layer. However, a polar, or zero layer, in the middle of the bundle is formed by one arginine (from synaptobrevin 2) and three glutamine side chains (one from syntaxin 1 and two from SNAP-25) (Figure 2(b)). These features are highly conserved in four different subfamilies of SNAREs and have led to their classification into Qa, Qb, Qc, and R SNAREs, depending on their homology with the SNARE motifs of syntaxin 1 (Qa), SNAP-25 (Qb and Qc for its N- and C-terminal SNARE motifs, respectively), or synaptobrevin (R). This classification is less ambiguous for SNAREs involved in homotypic membrane fusion than the original classification into v- and t-SNAREs (for vesicular and target membrane SNAREs, respectively). The assembly of the SNARE four-helix bundle is most likely at the center of the mechanism of membrane fusion. The functional importance of the polar layer is currently unclear, but it has been suggested to play a role in aiding SNARE complex disassembly or in dictating the proper register for SNARE complex formation.

In addition to a SNARE motif and a TM sequence, many SNAREs have an N-terminal region that spans more than half of its sequence. NMR studies have shown that the N-terminal regions of all SNAREs from the syntaxin subfamily, including syntaxin 1, contain an autonomously folded domain that adopts an antiparallel three-helix bundle structure, known as the H_{abc} domain (Figure 2(a)). This domain is connected to the SNARE motif through a linker region and is preceded by a short N-terminal

sequence (NTS) (Figure 1). The N-terminal regions of SNAREs from other subfamilies may also contain H_{abc} domains or autonomously folded domains with completely unrelated structures, such as longin domains or PX domains.

In the assembled SNARE complex, the H_{abc} domain of syntaxin 1 is flexibly linked to the four-helix bundle formed by the SNARE motifs. However, the H_{abc} domain binds intramolecularly to the SNARE motif in isolated syntaxin 1, forming a closed conformation that is incompatible with the SNARE complex. These findings suggested that the H_{abc} domain regulates SNARE complex formation and that syntaxin 1 must undergo a large conformational transition from a closed to an open conformation during exocytosis (Figure 3). However, only a few SNAREs from the syntaxin subfamily adopt a closed conformation, which thus appears to represent a specialization arising from unique regulatory requirements of neurotransmitter release and a few other membrane traffic processes. Conversely, some SNAREs outside the syntaxin family adopt closed conformations involving different types of autonomously folded N-terminal domains, indicating that intramolecular regulation of SNARE complex assembly is not restricted to syntaxins.

Figure 1 Domain structures of the neuronal SNAREs. The SNARE motifs, TM regions, and the helices of the H_{abc} domain are represented by cylinders; other sequences are represented by black lines. NTS, N-terminal sequence; SNAP-25, synaptosomal associated protein of 25 kDa; SNARE, soluble *N*-ethylmaleimide-sensitive factor attached protein receptor; TM, transmembrane.

The closed conformation of syntaxin 1 binds tightly to the neuronal SM protein Munc18–1 and its structure at atomic resolution (Figure 2(c)) was revealed by X-ray analysis of a syntaxin 1–Munc18–1 complex. This mode of interaction is not generally conserved

Figure 2 Three-dimensional structures of the neuronal SNAREs: (a) illustration of the three-dimensional structures of the syntaxin 1 H_{abc} domain determined by NMR spectroscopy (Fernandez et al.) (left) and the neuronal SNARE complex formed by the SNARE motifs of synaptobrevin 2, syntaxin 1, and SNAP-25 determined by X-ray crystallography (Sutton et al.) (right); (b) stick models of selected layers forming the neuronal SNARE complex; (c) illustration of the structure of the closed conformation of syntaxin 1 bound to Munc18–1 determined by X-ray crystallography. In (a), the dashed curved represents the flexible linker between the H_{abc} domain and SNARE motif of syntaxin 1. The color coding is the same as in Figure 1. In (b). the stick models include the polar layer formed by R56 of synaptobrevin 2, Q226 of syntaxin 1, and Q53 and Q174 of SNAP-25, as well as the preceding and ensuing layers, which are formed exclusively by hydrophobic residues. The backbone atoms are in the same color code as in Figure 1. Side chain atoms are in cyan for carbon, red for oxygen, and blue for nitrogen. In (c), the H_{abc} domain of syntaxin 1, its SNARE motif, and the linker region connecting them are in orange, yellow, and black, respectively. Munc18–1 is in violet (Misura et al.). C, C-terminus; N, N-terminus; NMR, nuclear magnetic resonance; SNAP-25, synaptosomal associated protein of 25 kDa; SNARE, soluble *N*-ethylmaleimide-sensitive factor attached protein receptor.

Figure 3 Diagram illustrating that syntaxin 1 must undergo a large conformational change during synaptic vesicle exocytosis. In the SNARE complex (right), the H_{abc} domain of syntaxin 1 is flexibly linked to the four-helix bundle formed by the SNARE motifs of syntaxin 1, SNAP-25, and synaptobrevin 2. In isolated syntaxin 1 (left), the H_{abc} domain binds intramolecularly to part of the SNARE motif, forming a closed conformation that is incompatible with SNARE complex formation. The color coding is the same as in **Figure 1**. N, N-terminus; SNAP-25, synaptosomal associated protein of 25 kDa; SNARE, soluble *N*-ethylmaleimide-sensitive factor attached protein receptor.

in other syntaxins and SM proteins, but many SM protein/syntaxin interactions depend on the syntaxin N-terminal region, particularly the NTS. Hence, it is likely that the general function of the syntaxin N-terminal region is related to coupling with SM protein function.

Evolution of Ideas on SNARE Function

SNARE proteins have been investigated by a wide variety of techniques, providing a vivid example of the power of interdisciplinary research and a fascinating history with twists and turns that may continue for years to come. The first SNAREs were found in genetic screens for membrane traffic defects in yeast and in molecular cloning analyses of components from synaptic vesicle and synaptosomal membranes that identified syntaxin 1, synaptobrevin 2, and SNAP-25. The first evidence of the functional importance of these proteins for synaptic exocytosis was provided by the discovery in the early 1990s that they are the targets of clostridial neurotoxins, agents that potently inhibit neurotransmitter release. Around the same time, sequence analyses revealed a homology between these neuronal proteins and some of the proteins identified in the studies of membrane traffic defects in yeast. Moreover, NSF/Sec18p and SNAPs/Sec17p were identified as crucial factors for vesicle-mediated transport in yeast and mammalian cells. Homologies were also observed between yeast and neuronal Rab proteins, as well as between SM proteins involved in traffic at different membrane compartments. All these findings led to the now widely held notion that a conserved machinery mediates most types of intracellular membrane traffic.

Crucial discoveries in the understanding of SNARE function were also the observations in 1993 that synaptobrevin 2, syntaxin 1, and SNAP-25 form a tight 7S complex (the SNARE complex) that binds to SNAPs and NSF to form a larger, 20S complex, and that adenosine triphosphate (ATP) hydrolysis by NSF leads to SNARE complex disassembly. These findings, and the belief that NSF was directly involved in membrane fusion, led to the proposal that synaptobrevin 2, syntaxin 1, and SNAP-25 act as receptors for the membrane fusion apparatus and hence to their designation as SNAREs (for SNAP receptors). These results led also to a model of intracellular membrane traffic whereby binding of SNAREs in transport vesicles (v-SNAREs) to SNAREs on target membranes (t-SNAREs) mediates vesicle docking and target specificity (known as the SNARE hypothesis). In this model, the SNAREs were envisaged as binding in an antiparallel fashion and the disassembly of the SNARE complex by NSF/SNAPs was proposed to initiate fusion.

The finding that clostridial neurotoxins inhibit release by cleaving SNAREs from the synaptic vesicle and plasma membrane was consistent with the notion that SNAREs are required on opposing membranes for fusion, which was further supported by subsequent studies of yeast vacuolar fusion. However, it was noted that the SNAREs could not play a role in vesicle docking because docking is not affected on SNARE cleavage by the neurotoxins or by genetic ablation of syntaxin 1 in *Drosophila* (note that very recent data have suggested that syntaxin 1 may actually function in docking; these contradictory conclusions that still need to be resolved probably arise because redundant docking mechanisms may exist and/or because of differences in the methodology used to prepare samples for electron microscopy (EM)). The genetic studies in *Drosophila* also revealed that syntaxin 1 is critical for release and, together with the neurotoxin data, led to the proposal that SNAREs function downstream of docking. Moreover, studies of exocytosis in PC12 cells and of homotypic vacuolar fusion in yeast showed in 1996 that NSF functions at a prefusion step rather than fusion itself, and the SNARE motifs of synaptobrevin 2 and syntaxin 1 were shown in 1997 to interact in an antiparallel fashion by EM and fluorescence resonance energy transfer (FRET). Because the SNARE motifs are

adjacent to the TM regions of synaptobrevin 2 and syntaxin 1, which are anchored on the synaptic vesicle and plasma membrane, respectively, this key discovery led to the proposal that the energy of formation of the SNARE complex could be used to bring the membranes together and initiate membrane fusion (known as the zippering model; Figure 4(a)). In this model, disassembly of the SNARE complex by NSF/SNAPs after membrane fusion recycles the SNAREs for another round of fusion.

The zippering model is attractive because of its similarity to the mechanism of viral fusion and has gained wide acceptance. A similar model that in addition postulates that the SNAREs constitute a minimal membrane-fusion machinery was proposed based on reconstitution experiments, but this minimal model has been strongly challenged by subsequent reconstitutions. Further debate about the central role of the SNAREs in membrane fusion predicted by both models emerged from analyses of mice lacking synaptobrevin 2 or SNAP-25. The synaptobrevin knockout revealed a strong impairment of evoked release and a less marked decrease in spontaneous or hypertonic sucrose-induced release; evoked release was also impaired strongly in SNAP-25-knockout mice, but spontaneous release was increased. Although these results reinforced the notion that the SNAREs function downstream of vesicle docking, the persistence of release in these mice contrasts with the total abrogation of any form of release in Munc18–1-knockout mice. It seems likely that the release remaining in the absence of synaptobrevin 2 and SNAP-25 may arise from functional redundancy with other isoforms of these proteins, but this hypothesis remains to be validated experimentally. Despite these ongoing debates, there is currently a general consensus that SNARE function is related to their ability to bring two membranes together and that synaptobrevin 2, syntaxin 1, and SNAP-25 play a critical role in neurotransmitter release. In addition to resolving these debates, recent and ongoing research on SNAREs is focusing on investigating the mechanism of SNARE complex assembly and studying how the roles of other key proteins are coupled to SNARE function.

Figure 4 Models of SNARE function in membrane fusion: (a) original zippering model of SNARE-mediated membrane fusion based on EM data, showing that the SNARE motifs of syntaxin 1 and synaptobrevin 2 bind in a parallel fashion; (b) model showing how isolated assembling SNARE complexes might diffuse to the center of the space between the membranes, which requires much less energy than inducing membrane fusion; (c) same model as (b) with the diffusion prevented because the assembling SNARE complexes are bound to a bulky protein (in violet); (d) model illustrating the notion that complexin (in pink) may favor full or almost full SNARE complex formation and at the same time inhibit fusion to yield a metastable state. In (a), the model assumes that the SNARE motifs and TM regions of both proteins form continuous helices and that membrane fusion is forced as these continuous helices zipper from the N- to the C-terminus. In (b) and (c), the model assumes that the SNARE motifs and TM regions of synaptobrevin 2 and syntaxin 1 are connected by short flexible linkers. In (d), the metastable state (left) is predicted to be the substrate for synaptotagmin 1 to trigger neurotransmitter release by binding simultaneously to both membranes and to the SNARE complex, displacing complexin, on Ca^{2+} influx (right). Synaptotagmin 1 is in light blue, except for the C_2B domain, which is in dark blue. The – and + signs illustrate overall features of the surface electrostatic potential of the synaptotagmin 1 C_2 domains that may prevent phospholipid binding in the absence of Ca^{2+} or activate phospholipid binding and membrane fusion upon Ca^{2+} influx. Positive charges at the C-terminus of the SNARE complex that may also help to bend the membranes to induce membrane fusion are not shown. The N-terminal region of syntaxin 1 is not shown in any of the models. EM, electron microscopy; SNARE, soluble *N*-ethylmaleimide-sensitive factor attached protein receptor; TM, transmembrane.

SNAREs and Membrane Fusion

The minimal model of SNARE-mediated membrane fusion was based on reconstitution experiments that demonstrated lipid mixing between proteoliposome populations containing synaptobrevin 2 or syntaxin 1/SNAP-25. This model has been accepted by many researchers, but has also been strongly challenged by others for diverse reasons. On one hand, there were multiple technical problems with the initial reconstitution experiments and mixing of the proteoliposome contents without leakiness, a key feature expected for physiological membrane fusion, has never been

demonstrated; on the other hand, a fundamental problem from a biological perspective is that the minimal model does not account for the strict requirement of SM proteins for all types of SNARE-dependent membrane traffic, including the essential nature of Munc18–1 for neurotransmitter release. Moreover, from a biophysical point of view, the structural-energetic basis of the minimal model is unclear. A key aspect of the original zippering model was the prediction that the SNARE motifs and TM regions of synaptobrevin 2 and syntaxin 1 could form continuous α-helices, which would therefore exert mechanical force on both membranes to induce fusion (Figure 4(a)). However, the available structural data suggest that the SNARE motifs and TM regions are connected by short flexible linkers, which is expected to hamper transduction of the energy of SNARE complex formation into the energy required to bend the membranes and initiate fusion. Hence, as they assemble, the SNARE complexes could diffuse into the space between the membranes and hinder (rather than facilitate) fusion (Figure 4(b)). In addition, introduction of helix-breaking residues or the insertion of long flexible linkers in the sequences between the SNARE motifs and TM regions had little or only moderate effects on the lipid mixing observed in the initial reconstitution experiments. Because the long linkers should have strongly uncoupled SNARE complex formation from its action on the membranes, the observed lipid mixing probably arose in part from factors beyond SNARE complex formation (e.g., instability of the vesicles).

Some of these factors became clear in subsequent reconstitution experiments. Thus, the proteoliposomes used in the initial reconstitutions may indeed have been unstable because they contained extremely high protein-to-lipid ratios (1:20 for synaptobrevin 2, which translates into a protein surface concentration comparable to a 12 mM concentration in bulk solution). Moreover, the proteoliposomes were prepared with a reconstitution method that relies on co-solubilization of proteins and lipids with detergent and yields heterogeneous vesicles (both in terms of size and protein density). Reconstitutions with this method using lower protein densities (e.g., 1:200) yielded less efficient lipid mixing, even though these densities are still comparable to a 1.2 mM protein concentration in bulk solution, and the observed lipid mixing could arise from populations of small vesicles with higher than average protein densities (note that the resulting high curvature destabilizes the vesicles because of membrane stress). Indeed, no significant lipid mixing was generally observed at these proteins densities when vesicles were prepared by a reconstitution method that involves the incorporation of detergent-solubilized SNAREs into preformed liposomes and yields more homogeneous proteoliposomes. Significantly, efficient SNARE complex formation without lipid mixing was observed using proteoliposomes prepared by this method, as predicted from the structural arguments described in Figure 4(b).

From the available reconstitution data, it seems clear that SNARE complex formation is not sufficient for membrane fusion, and lipid mixing can only be induced under conditions in which membranes are destabilized and a large number of SNARE complex force the two membranes to collapse. However, an important notion that emerged from some of the reconstitution experiments is that the TM regions of the SNAREs can destabilize the bilayer, which may contribute to the function of SNAREs in membrane fusion. Moreover, recent reconstitution data obtained with SNAREs, synaptotagmin, and complexin appear to reproduce events that may occur during neurotransmitter release. Hence, the reconstitution approach is providing insights into important features of the release machinery and, with the appropriate methodology, this approach promises to provide a critical tool to understand the mechanism of neurotransmitter release. Note also that, even though the minimal model now appears to be incorrect, the original idea arising from the zippering model that SNARE complex formation causes membrane fusion could still be valid without the requirement that the SNARE motifs and TM regions form continuous helices. Thus, a modified model predicts that the energy of SNARE complex assembly could be used to induce fusion if the SNAREs are kept apart by virtue of interactions with a bulky protein or proteins (Figure 4(c)), which would prevent the undesired diffusion of the SNARE four-helix bundle into the center of the intermembrane space (Figure 4(b)). This model remains to be tested but emphasizes the necessity of understanding the functions of additional factors that are crucial for release in order to fully understand the function of the SNAREs themselves.

SNARE Interactions with Other Conserved Components of the Fusion Machinery

A wide variety of proteins have been shown to play a role in synaptic vesicle exocytosis. Elucidating how the functions of these proteins are coupled to SNARE function is thus critical to understanding the mechanism of release. A difficulty in this endeavor has arisen because of the stickiness of the SNAREs, which has led to the identification of many interactions that are probably irrelevant (for instance, more than 40 proteins have been described that bind to syntaxin 1). Nevertheless, the complementary information provided by genetic and electrophysiological experiments, together with structural studies, have helped to unravel

the nature of some of these interactions and to support their physiological significance.

Among the interactions of the SNAREs with other conserved components of the intracellular membrane fusion machinery, those with SNAPs/NSF have a clear functional role, namely the disassembly of the SNARE complex after fusion to recycle the SNAREs for another round of fusion. Rab proteins, which have been implicated in vesicle docking or tethering, do not appear to interact directly with the SNAREs but have been shown to be functionally coupled to the SNAREs in diverse systems and may indirectly regulate the SNARE complex assembly. The most fascinating and at the same time enigmatic SNARE interactions with the conserved components of the fusion machinery are those with SM proteins. The strict requirement for SM proteins in all types of SNARE-dependent membrane fusion, their localization at sites of fusion, and their diverse interactions with SNAREs suggest that SM proteins may have a direct function in fusion. However, this function has remained elusive, in part because of the diversity of these interactions. Neuronal Munc18–1 was shown to bind tightly to the closed conformation of syntaxin-1, but this interaction hinders SNARE complex formation and hence does not explain the essential nature of Munc18–1 for neurotransmitter release. Conversely, the yeast plasma membrane SM protein Sec1p was found to bind to SNARE complexes instead of to the cognate syntaxin. Moreover, syntaxins from diverse intracellular compartments in yeast and mammals bind to SM proteins through their NTS, in an interaction that is compatible with SNARE complex assembly. Finally, the yeast vacuolar SM protein Vps33p appears to bind to SNARE complexes at least in part through the N-terminal PX domain of the SNAP-25 homolog Vam7p.

This diversity of SM protein–SNARE interaction modes has probably emerged from distinct regulatory requirements of traffic in different membrane compartments, but it seems likely that a common binding mechanism between these two conserved protein families must exist. In this context, increasing evidence has suggested that all SM proteins bind to SNARE complexes, and a direct interaction between Munc18–1 and neuronal SNARE complexes was recently identified. Hence, Munc18–1 exhibits at least two different modes of interactions with the SNAREs: one with the syntaxin 1 closed conformation, which probably represents a specialization that evolved for the tight regulatory requirements of neurotransmitter release, and another with the SNARE complex, which may be conserved in all types of intracellular membrane traffic. The former interaction may play a role in stabilizing syntaxin 1 or preventing this promiscuous protein from binding to other proteins. In addition, syntaxin 1 has been shown to form two different types of four-helix bundles with SNAP-25, containing two copies of syntaxin 1; these complexes represent kinetic traps that hinder SNARE complex formation, and binding of Munc18–1 to the syntaxin 1 closed conformation may prevent the formation of these traps. Because the closed conformation contains a four-helix bundle and Munc18–1 also binds to the SNARE complex, it has been proposed that Munc18–1 may provide a template for assembling the four-helix bundle formed by the SNARE motifs of syntaxin 1, SNAP-25, and synaptobrevin 2 in the same site. In this context, Munc18–1 could play the role of the bulky protein depicted in the model in **Figure 4(c)**, but this model remains to be tested and the precise nature of the Munc18–1–SNARE complex interaction still needs to be defined. Moreover, alternative models can be envisaged for the active role of Munc18–1 in release. For instance, the SNARE motifs of synaptobrevin 2 and syntaxin can bind in an antiparallel fashion, which hinders fusion; Munc18–1 may ensure assembly of the SNARE complex in the proper, parallel orientation.

The transition from the Munc18–1–syntaxin 1 complex to the Munc18–1–SNARE complex may be a central event in the priming reaction that makes docked synaptic vesicles readily releasable, but the mechanism of this transition is also unclear. Functional experiments in *Caenorhabditis elegans* have suggested that this transition may be mediated by Unc13/Munc13s and Unc10/Rab3 interacting molecules (RIMs), which are large proteins from presynaptic active zones with critical roles in release. Unc13/Munc13s were initially thought to bind to syntaxin 1, but recent evidence indicates that they do not form binary complexes with syntaxin 1. Hence, gaining insight into the biochemistry of these proteins, the interactions underlying the conformational transition of syntaxin 1, and the role of the Munc18–1–SNARE complex interaction will be crucial to the understanding of the mechanism of neurotransmitter release. It will also be critical to better understanding which aspects of the coupling mechanism between Munc18–1 and the neuronal SNAREs are conserved in other systems and may reflect the general function of SM proteins in membrane fusion, although it is becoming increasingly clear that this function is somehow coupled to SNARE complex assembly.

SNARE Interactions with Specific Components of the Release Machinery

Interactions of the SNAREs with components of the exocytotic machinery that have specialized roles in

release also appear to be associated with the regulation of SNARE complex assembly, but may also attract factors that facilitate and/or inhibit membrane fusion to confer the exquisite Ca^{2+} sensitivity of neurotransmitter release (the fast, synchronous components of release is triggered in less than 100 μs after Ca^{2+} influx in some synapses). An example of the former category is the interaction of syntaxin 1 and SNAP-25 with tomosyn, a large protein with a SNARE motif homologous to that of synaptobrevin 2. Indeed, the crystal structure of tomosyn bound to syntaxin 1 and SNAP-25 revealed a four-helix bundle analogous to the SNARE complex but with synaptobrevin replaced by the tomosyn SNARE motif (Figure 5(a)). Therefore, formation of this complex is expected to inhibit release by preventing the assembly of functional SNARE complexes containing synaptobrevin 2. This prediction has been confirmed by genetic experiments in *C. elegans*, although tomosyn may play additional functions through the long sequences preceding the SNARE motif. These experiments revealed at the same time a functional interplay between tomosyn and Unc13/Munc13s that may control the balance between unproductive tomosyn–syntaxin 2–SNAP-25 complexes and productive SNARE complexes containing synaptobrevin 2.

Diverse functional data have suggested that the SNAREs are directly or indirectly coupled to Ca^{2+} sensing during neurotransmitter release, including the alteration of the Ca^{2+} sensitivity of secretion in chromaffin cells caused by some point mutations in SNAP-25 and the finding that elevated Ca^{2+} can compensate the inhibition of release caused by botulinum neurotoxin A, which cleaves SNAP-25 close to its C-terminus. Whereas NMR studies showed that the SNARE complex does not contain specific Ca^{2+}-binding sites that could be directly involved in Ca^{2+} sensing during release, it has become increasingly clear that interactions of the SNAREs with synaptotagmin 1 and complexins are key for the Ca^{2+}-triggered step of neurotransmitter release.

Figure 5 Structural basis for SNARE interactions: (a) with tomosyn; (b) with complexin. Crystal structures of the complex formed by the tomosyn, syntaxin 1, and SNAP-25 SNARE motifs (Pobbati et al.) (a) and the complexin–SNARE complex (Chen et al.) (b). Tomosyn is in salmon, complexin is in pink, and the remaining color coding is as in Figure 1. Note the similarity between the structures of the tomosyn–syntaxin 1–SNAP-25 complex (a) and the SNARE complex (Figure 2(a)), with the tomosyn and synaptobrevin 2 SNARE motifs occupying the same positions in the complexes. Note also that complexin forms an α-helix that binds to a groove between the syntaxin 1 and synaptobrevin 2 SNARE motifs in the SNARE complex (b). C, C-terminus; N, N-terminus; SNAP-25, synaptosomal associated protein of 25 kDa; SNARE, soluble *N*-ethylmaleimide-sensitive factor attached protein receptor.

Synaptotagmin 1 is a synaptic vesicle protein that acts selectively as a Ca^{2+} sensor in synchronous release. This function depends on Ca^{2+}-dependent phospholipid binding to the two C_2 domains that form most of the synaptotagmin 1 cytoplasmic region (the C_2A and C_2B domain), with the C_2B domain playing a preponderant role. Many studies described interactions of the SNAREs with synaptotagmin 1, but it was unclear which of these interactions might be functionally relevant. Recent data may have yielded key insights into this issue. Thus, Ca^{2+}-bound synaptotagmin 1 was shown to bind simultaneously to the C-terminus of the SNARE complex and to phospholipids through the C_2B domain, and the C_2B domain was also found to interact simultaneously with two membranes on Ca^{2+} binding. Moreover, both the Ca^{2+}-bound C_2B domain and the C-terminus of the SNARE complex are highly positively charged. These observations suggest that the SNARE complex and the C_2B domain may cooperate in bringing the membranes together and in bending them to accelerate fusion (Figure 4(d), right). Although these ideas provide an attractive mechanism for coupling synaptotagmin 1 and SNARE function that explains the preponderant role of the C_2B domain, their validity remains to be demonstrated and alternative models can be envisaged. For instance, it is also possible that the highly positive electrostatic potential generated by the SNARE C-terminus and synaptotagmin 1 may help to open the fusion pore if the synaptic vesicle and plasma membranes are already partially merged (forming a hemifusion state) before Ca^{2+} influx.

Complexins are small soluble proteins that bind tightly to the neuronal SNARE complex in a Ca^{2+} independent manner. Knockout of the two major complexin isoforms in mice revealed a selective impairment of the Ca^{2+}-triggered step of synchronous release, but an excess of complexin can also inhibit release. X-ray crystallography and NMR spectroscopy showed that complexin binds in an antiparallel α-helical conformation to a groove between the SNARE motifs of synaptobrevin 2 and syntaxin 1 (Figure 5(b)), stabilizing the SNARE complex.

Because SNARE complexes are generally believed to assemble from the membrane-distal N-terminus and zippering toward the C-terminus is expected to be hindered by membrane repulsion, these findings led to a model whereby complexin helps to complete SNARE complex assembly, yielding a metastable state that is critical for the fast speed of synchronous release (Figure 4(d), left). Interestingly, recent reconstitution experiments showed that complexin inhibits SNARE-induced liposome fusion at a hemifusion state and that Ca^{2+} plus synaptotagmin 1 release the inhibition, resulting in a fast burst of fusion that cannot be observed with the SNAREs alone. In addition, simultaneous binding of the synaptotagmin 1 C_2B domain to phospholpids and SNARE complexes was shown to displace a complexin fragment bound to these complexes. Altogether, these data suggest that complexin may indeed play an active role in release by promoting SNARE zippering toward the C-terminus and thus bringing the system closer to fusion (perhaps to hemifusion), but at the same time plays an inhibitory role to prevent full fusion before Ca^{2+} influx; such inhibition is then released by simultaneous binding of synaptotagmin 1 to Ca^{2+}, to both membranes, and to the SNARE complex to active release (Figure 4(d)). Clearly, there are alternative models to explain the available data, including the active function of complexin for release, but these data show that there is a fascinating interplay among the SNAREs, complexin, synaptotagmin 1, Ca^{2+}, and phospholipids that is probably crucial for the exquisite regulation of neurotransmitter release. The relation between Munc18–1, complexin, and synaptotagmin 1 binding to the SNARE complex remains to be studied.

SNARE Specificity

The contribution of SNAREs to the specificity of membrane traffic has been another area of strong debate about SNARE function. This issue is important for interpreting the phenotypes of synaptobrevin 2 and SNAP-25 mice because, given the observation that neurotransmitter release can still be observed in these mice, an absolute specificity in SNARE pairing implies that the SNAREs are not essential for membrane fusion. Biochemical assays showed that some SNAREs have a tendency to bind to both cognate and noncognate SNAREs, and hence can be quite promiscuous. Conversely, reconstitution studies suggested a high specificity in SNARE-induced lipid mixing, but the noncognate SNARE pairings identified biochemically were not analyzed. A recent study showed that early endosome fusion is specifically mediated by a set of SNAREs in living cells, whereas the same set of SNAREs promiscuously induce liposome fusion with SNAREs from the plasma membrane or late endosomes.

These results can be interpreted in the framework of sequence analyses and the known structures of SNARE complexes. Because SNARE complex assembly involves protein–protein interactions, assembly must involve some degree of specificity. Moreover, the SNAREs are one of the most diverse among the protein families generally involved in intracellular membrane traffic (25 members in yeast and 36 in humans; only Rab proteins are more diverse). However, because coiled-coil interactions can be considerably promiscuous and the hydrophobic residues involved in SNARE complex formation are highly conserved in each subfamily, it is not surprising that some degree of nonspecificity exists in SNARE pairing. Hence, the picture that emerges is that SNAREs contribute to the specificity of traffic in distinct membrane compartments but that this specificity also involves other proteins. In particular, there is little doubt that an important contribution to specificity arises also from Rab protein interactions. Note also that the contribution of the neuronal SNAREs to specificity in neurotransmitter release most likely also involves interactions with factors specialized for release, such as synaptotagmin 1 and complexins.

Outlook

Research on SNARE proteins has provided an emphatic example of the power of interdisciplinary approaches to studying protein function and of the difficulties of exactly pinpointing the specific roles of proteins that act as part of complex macromolecular assemblies. Hence, the divide-and-conquer approach has provided crucial clues to the understanding of the functions of the SNAREs and other components of the release machinery, but increasing evidence illustrates the complexity and cooperativity of this system. Clearly, a true understanding of the mechanism of release requires further studies in which more and more of these components are examined together in the presence of membranes. A critical foundation for these studies has been provided by the astonishing advances in this field made during the past 20 years.

Social Brain: Evolution

R I M Dunbar, University of Oxford, Oxford, UK

Explaining Brain Evolution

Although neuroscientists do not often consider the evolutionary history of the brain, understanding how and why brains have evolved may help explain why they have come to have the structure they do. Vertebrate species, for example, vary enormously in both absolute brain size and brain size relative to body size, but some species (notably primates) have disproportionately large brains. Why should that be? Why do all mammals not have primate-like brains? A second issue is that brain researchers have conventionally assumed that the brain's main function is to acquire and process information about the environment, usually information directly relevant to the business of survival (i.e., finding food and avoiding predators). While obviously broadly correct, this view contains an implicit assumption that may be less defendable: the assumption that 'environment' here means the physical environment. Of course, a great deal of brain activity is about the physical environment, and, in the final analysis, it is the physical properties of the environment that constitute all perceptual inputs.

However, for more advanced vertebrates (birds and mammals), and in particular the more intensely social of these species, the environmental behavior that needs to be processed by the brain is that of the 'social' world. In the limiting case, the social world is a virtual world of behavior, the nature of which is understood and manipulated only in the animal's mind. Because the dynamic complexities of this virtual social world vastly exceed the complexities of the physical world, it is inevitably much harder to understand. Hence, intensely social species (such as primates) have brains that are specialized for dealing with this aspect of their world.

The emphasis on primates in the early literature on comparative brain evolution led to a natural focus on neocortex volume. The scaling relationships among mammalian brain units are such that neocortex volume increases much faster than that of all other parts of the brain, and especially among the primates. Although the neocortex accounts for as little as 10% of total brain volume in some of the more primitive insectivores and at most ~40% in nonprimate mammals, it accounts for a minimum of 50% in primates and rises to as high as 80% in humans. Thus, while the neocortex may be viewed as a mammalian invention, large neocortices are clearly a primate speciality – so much so, in fact, that when one asks why primates have big brains, one is really in effect asking why they have big neocortices.

In the following sections, the selective advantages of large brains are first discussed, in order to identify why large brains have evolved in various animal lineages. Then the role that cognition plays in these processes is considered. Finally, the question of whether these forms of social cognition relate to specific brain structures is briefly explored.

Theories for the Evolution of Large Brains

We might expect large-bodied species to have large brains simply because they have larger muscle masses to coordinate if they are to survive effectively. However, it has long been recognized that some groups of species (e.g., primates) have unusually large brains for their body size compared to all other groups of vertebrates. Why this should remain so is unclear, although it has been generally assumed that it probably has something to do with the ecology of these species.

Initial Explanations

Initial attention was drawn to the fact that, within many mammalian taxa, species with larger brains have larger territories, or have diets that are more difficult to locate or process (e.g., diets of ephemeral fruits as opposed to more widely available leaves, or of invertebrates that have to be extracted from hiding places). Others have pointed to correlations with altriciality (giving birth to babies that are not mature enough at birth to move and forage for themselves) and the scaling of maternal energy demands, and have argued that it was spare maternal energy capacity that made large brains possible. By the late 1980s, however, this assumption began to be questioned: it eventually became clear that the kinds of ecological tasks faced by primates do not differ much from those faced by other species. This realization begged the question as to why primates should need a substantially larger brain (in effect, more computing power) to solve the same foraging problems as, say, cows. The social brain hypothesis was proposed as an explanation.

The initial proposal, known as the 'Machiavellian intelligence hypothesis,' was intended to explain why primates had larger brains for body size than all other species. It was suggested that this might have something to do with the fact that primates live in unusually complex social systems. Primate sociality is characterized by kinds of behaviors (for example,

tactical deception, the formation of coalitions and alliances long before they are actually needed) that are rare or entirely absent in nonprimate species. This proposal was later renamed the 'social brain hypothesis' (or 'social intelligence hypothesis') in order to avoid unnecessary and unintended implications of sociopolitical scheming and to focus attention more closely on the positive socially integrating aspects that really underpin primate sociality.

Asking the Right Questions

An important consideration at the outset is to appreciate that there is an important distinction between functional hypotheses (those that provide a reason why large brains might be selected for) and explanations that are essentially about constraints. Most developmental hypotheses fall into the latter category: they identify trajectories along which brain evolution is forced to run, or system limitations that have to be overcome. Examples of the first include the fact that the way brain tissue is laid down necessarily results in unavoidable scaling of all brain parts: if such scaling is very tight, then it may result in all parts of the brain enlarging proportionately when evolution imposes selection on just one component. This might mean that in order to evolve more capacity in some key brain component, it is necessary to evolve everything on a larger scale. Examples of the second kind of limitation would be energetic constraints that limit brain growth: some diets may not provide sufficient surplus energy that can be channeled into brain growth. Consequently, species that need to evolve a larger brain may only be able to do so if they first change diet in order to bypass the energetic constraint.

While these kinds of developmental hypotheses are perfectly legitimate and tell us something about how large brains are evolved, they do not specify why they should evolve. Given that brain tissue is among the most 'expensive' in the body (the so-called expensive tissue hypothesis), to merely show that evolutionary change in a particular direction is possible is not enough. The costs of evolving (and indeed growing) a large brain are such that they provide an extremely steep gradient, up which selection has to push the organism. In the absence of any selective benefit (or advantage), the costs impose strong negative selection that will constantly favor a reduction in size (or, at best, a stable state). Some real advantage of having a large brain is needed to counteract that natural stabilizing effect.

Hypotheses for Brain Evolution

In considering likely selective factors that have been responsible for driving increases in brain size, we are left with two main contenders that can broadly be defined as ecological theories and social theories. Ecological hypotheses argue for a focus on foraging decisions (how to extract nutrients from the environment, how to find one's way about, etc.). In contrast, the social hypotheses argue that the computational load is created by the demands of tracking social relationships and calculating the pros and cons of alternative social actions.

In both cases, of course, the fundamental issue is the brain's problem-solving capabilities, but the focus of the problem and the mode of solution are different in each case. However, it is worth emphasizing that, either way, the root issue is essentially ecological: all animals have to overcome problems of day-to-day survival if they are to contribute offspring to the next generation (the root of all evolutionary processes). The difference lies in how this is done, and which particular computational demand imposes the highest cognitive load. Ecological hypotheses assume that the basis of an animal's decision-making in this respect is explicitly trial-and-error learning on an individual basis; the social hypotheses assume that the ecological problems are solved cooperatively (and that the limiting cognitive demand is created by the need to coordinate one's behavior with that of others in some way).

One way to test between these competing hypotheses is to correlate some measure of relative brain size with one or more behavioral indices that represent the hypothesis of interest. Relevant indices that have been used include the amount of fruit in the diet (representing the claim that the cognitive constraint lies in finding and monitoring high-quality food sources such as fruiting trees), the style of extractive foraging (whether or not food items are extracted from some physical matrix, such as a pod, or dug out of the ground, i.e., an index of complex food-processing decisions), day journey length and territory size (indices of mental mapping capacities), and social group size (a simple index of social complexity). When these indices have been correlated with indices of relative brain size, only group size is correlated with brain size (and specifically with neocortex size) (see **Figure 1**).

More recently, a number of new analyses have been undertaken that use new and more powerful statistical methods that allow the multivariate influences of a wider range of variables to be taken into account simultaneously. These have been able to show that, while other strictly ecological variables (notably, diet, diurnality, and foraging strata) play a role in brain evolution, sociality and/or social group size remain the strongest predictors of brain/neocortex volume in primates. In addition, the scope of the social brain

Figure 1 $\log_{10}$ Mean social group size for different primate species plotted against relative neocortex volume (indexed as neocortex volume divided by the rest of the brain, so as to remove scaling effects due to body and brain size). Solid symbols are New World monkeys; open circles are Old World monkeys; squares are apes. Note that the apes lie on a separate grade to the monkeys: they seem to require more computing power to handle groups of a particular size than monkeys do, suggesting that their social life is cognitively more complex.

hypothesis has now been convincingly extended to other mammalian orders, including carnivores, ungulates, whales, and bats, and even to birds. In all these cases, brain size is larger relative to body size in more social species than in relatively asocial species. However, there appears to be an important distinction between the primates and all other species in the way this process works. While the main effect of this relationship in primates is a quantitative effect with group size, in all other species the effect shows up most clearly as either a contrast between social and asocial species (those that live alone, except during the mating season) or a strong effect of monogamy (monogamous species have larger brains than do those living in other mating systems). The same tendency for monogamous (i.e., pairbonded) species to have disproportionately large brains is still present in primates, but it is much overshadowed by the strong quantitative group size effect. The implications of this are explored in the following sections.

In summary, the social brain hypothesis has proved to be an extremely robust explanation for the evolution of brain (but especially neocortex) size in primates, and more generally for the evolution of brain size in mammals as a whole. It has proved to be more successful in explaining the pattern of brain size evolution than have any of the alternative ecological hypotheses.

Social Complexity

Although the social brain hypothesis has been successfully tested using simple demographic indices like social group size or differences in mating system, its real focus lies in the subtleties of behavior. The argument is that group size is ultimately limited by the animals' abilities to maintain coherent social relationships with other individuals. Group size is thus an emergent property of animals' abilities to manage their social relationships.

This has been borne out by evidence that a number of indices of behavioral complexity also correlate with relative brain size in primates. These have included the use of coalitions, the size of alliances (indexed as grooming cliques), the frequency of tactical deception (behavior that misleads another individual), and the use of subtle social tactics that allow low-ranking males to undermine the dominant males' monopolization of matings. The fact that monogamous pairbonding (and especially lifelong pairbonding) is particularly strongly associated with large brain size across three major mammalian orders (primates, carnivores, and ungulates) likewise emphasizes the importance of social complexity, since pairbonded social systems are only possible if mates have the sociocognitive skills to negotiate a relationship in which each individual's needs are properly integrated into an effective partnership. This is most obvious, perhaps, in birds, where the pair has to coordinate and schedule two major activities: sitting on the nest (to keep eggs or fledglings warm and protected) and foraging.

The significance of social complexity as opposed merely to sociality, at least in primates, is given further emphasis by the fact that development can be shown to play an important role. While it has long been known that total brain size correlates with the level of parental investment (as indexed, for example, by the duration of pregnancy and lactation), neocortex volume correlates best with the period between weaning and puberty (i.e., the main period of socialization before the animal finally joins the adult world). This suggests that growing a big brain depends on how long the mother can afford to invest in direct parental care, but having a socially complex brain (and this really means neocortex) depends on the time you can afford to invest in socialization (in effect, the equivalent of the software programming). Further evidence is provided by the fact that, in primates, neocortex size also correlates with the proportion of all play that

is social (as opposed to instrumental or solitary): most social play takes place during this main period of socialization between weaning and puberty.

Thus, although brain size is the central issue in the social brain hypothesis, it is important to appreciate that the situation is rather different from that in the case of more conventional brain systems. A distinction needs to be drawn between what we might think of as first-order processing systems (those in which sensory inputs are analyzed for their intrinsic patterns) and those which involve secondary or even tertiary analyses of these inputs (e.g., those in which meaning is attached to the sensory patterns). While sensory processing mechanisms function more or less efficiently from the moment the animal engages with the world, the upstream neural systems responsible for adding the layers of social meaning (and which thus constitute the heart of the social brain) seem to require extensive tuning before they can operate at full capacity. That tuning presumably occurs in the social environment provided during development.

The Nature of Social Cognition

We do not have a clear idea of how cognition interfaces between the neural systems of the brain and the observable behavior of the animals in the social domain. However, there is general agreement that, at least in primates, it involves specialized processes that are collectively but loosely termed 'social cognition.' In humans, these are identified with the cognitive mechanism known as 'theory of mind' or 'mentalizing' (the ability to understand the minds of other individuals). Although the exact nature of this phenomenon is still a subject of debate, it provides at least a useful way of thinking about the general cognitive demands of sociality.

Theory of mind refers to the capacity to mentally represent another individual's mind state: "I *believe* that you *suppose*. . . ." This is generally understood to be equivalent to what philosophers of mind refer to as second-order intentionality, where intentionality refers to the capacity to use words that involve the 'intentional stance' (in other words, the ability to reflect on one's intentions, or more generally one's beliefs about the world). In principle, intentionality forms a reflexive hierarchy that is infinite: "I *believe* that you *suppose* that I *intend* that you *want* me to *understand*. . . ." Theory of mind is generally held to be acquired by children at around age 4 years. Prior to that, children, in common with all nonhuman animals, have only first-order intentionality: in effect, they understand their own minds, but not those of other individuals. The only exception to this is the chimpanzee (and possibly other great apes), for whom there is some (albeit weak) evidence for second-order intentionality. In contrast, normal adult humans are able to cope with fifth-order intentionality. These additional levels of intentionality appear to be acquired sequentially by the early teenage years.

Although we know quite a lot about theory of mind (but rather less about the higher levels of intentionality), in fact we do not really know what it actually is. There are two views on this: one views theory of mind as a specialized cognitive module; the other views it as simply a product of more conventional executive functions (memory, causal reasoning, etc.). An alternative view is that theory of mind is an emergent property of a number of other higher order cognitive abilities, including causal reasoning, analogical reasoning, the time frame over which consequences of actions can be forecast, the ability to compare two behavioral trajectories through time, etc. These might be viewed as 'middle-range' cognitive modules that intervene between the more conventional Fodorian modules (those associated with basic percept processing) and the higher order inferential processes associated with social cognition.

In effect, theory of mind is what 'pops' out when an individual can do all of these on a large-enough scale and focus them sufficiently onto a single problem. In other words, it is an emergent property of cognitive mechanisms that are both general and essential for everyday life. This being so, on a simple information-processing model, we might expect the ability to engage these middle-range processing capacities to be a function of brain size. Presumably, the capacity to engage in higher levels of intentionality beyond theory of mind (level 2) is simply a reflection of a correspondingly greater computational capacity.

Cognition and the Brain

This brings us to the last issue we need to consider, namely exactly how these higher order aspects of social cognition relate to the brain. There appear to be two possible positions on this. One is that several decades of research in neuroscience is enough to make it clear that the interconnectedness of the brain is of such an order that it does not make sense to consider the brain as modularized in any naïve sense: it functions as an integrated whole, in which processing capacities of different kinds are called up from different cortical and subcortical regions. The alternative view is that the specialized cognitive functions identified with theory of mind and social cognition can be equated with particular brain regions (specifically in the neocortex).

While it may be true that brain function does commonly involve activity in many parts of the brain that

are physically distant from each other, nonetheless there is convincing evidence that these higher-level skills are associated with specific neocortical regions, and specifically with the frontal lobe (an area of the brain that has proved to be singularly resistant to attempts to partition it into functional subunits). There is considerable clinical evidence, from the famous case of Phineas Gage in the 1890s onwards, that stroke or physical injury to the frontal lobes is particularly likely to disrupt social skills (and only social skills). However, several other sources of data also suggest that the frontal lobe of the neocortex plays a critical role in social cognition.

First, a detailed analysis of data for primates shows that when all other brain components are held constant, only neocortex size correlates with social group size; no other brain unit has any association with group size. Indeed, the correlation between neocortex volume and social group size improves measurably if the primary visual cortex is removed, and improves still further if only the frontal lobe volume is considered. In other words, the more one focuses on the frontal lobe, the better the relationship seems to be. Second, such differences as there are in mentalizing capacity between primate species (essentially first-order intentionality in monkeys, second order in apes, and fifth order in adult humans) are linearly related to frontal lobe volume, but not to any other part of the brain. Finally, neuroimaging studies have emphasized a particularly important role for frontal lobe units in social cognitive tasks (even though units elsewhere in the parietal and temporal lobes may also be involved).

One reason why the more occipital areas of the brain may not play a central role is that, as the principal visual areas, they are mainly concerned with primary and secondary visual processing, and the computational demands for this are largely dependent on the sensory input from the retina. Indeed, there is a near linear relationship in primates between orbit volume (and hence retinal area) and volumes of the successive segments of the visual pathway (optic nerve, lateral geniculate nucleus, and primary visual cortex in the occipital lobe). This is, in part at least, a consequence of the fact that the size of the retina is the rate-limiting factor in visual acuity, and there is little point in having a cortical visual processing capacity that is more powerful computationally than its input. Indeed, this seems to be a general principle in brain system organization. Hence, with orbit size relatively constant across primate species, any increases in brain volume are mainly associated with more frontal brain units.

Indeed, the brain (and neocortex in particular) is known to both evolve and develop from back (occipital lobe) to front, so that increases in brain volume are largely associated with increases in frontal lobe volume. Plotting 'spare' neural volume over and above that predicted by primary visual area (Figure 2) suggests that the volume of spare capacity (most of which is in the frontal lobe and thus supports executive function) starts to increase disproportionately at the brain size of great apes (i.e., just at the point where we have the first evidence for second-order intentionality) and is massive in modern humans (with their fifth-order capacities).

Figure 2 Neocortex volume excluding the primary visual area plotted against the primary visual area for different monkey and ape species. Solid symbols, monkeys; open symbols, apes. The maximum achievable level of mentalizing (intentionality order) is indicated beside each major group, and suggests that brains of the size seen in the great ape mark a critical juncture at which spare neural capacity in the more frontal units of the brain suddenly becomes available, thus allowing higher orders of mentalizing to develop.

Introduction

In everyday life we constantly interact with the people around us, whether it is to cooperate, compete, or simply to go about our day-to-day business. For such interactions to be successful we must be able to understand and predict the actions of these other people. We typically understand actions in terms of minds: beliefs, desires, and intentions. This is termed having an 'intentional stance' or having a 'theory of mind,' while our ability to 'read' mental states has been called 'mentalizing.' A range of functional imaging studies have attempted to identify the neural correlates of mentalizing when participants make 'off-line' inferences about the mental states of interacting characters in stories, cartoons, and animations. A number of brain regions have been consistently activated by these tasks, including the medial prefrontal cortex (MPFC), temporal poles, and temporoparietal junction.

Yet, like most psychological and neuroimaging studies, these studies were investigations of people in isolation. Even imaging studies of social cognition do not typically involve true interactions. Brain activity is measured in various social contexts or when an individual thinks about her own mental states or those of another person. In all of these paradigms the flow of information is one way. The participant simply responds to a facial expression or to a social scenario. In a true interaction the information flows both ways. We do not simply read the signals of others. We send back signals for them to read. We do not simply respond passively to other persons, we respond actively in order to change them: to make them trust us or fear us. For such interactions, it is not sufficient to represent our own mental state or the mental state of the other. We need also to represent the other's representation of our mental state. In a successful interaction our mental states are effectively shared. Perhaps the simplest example of such an interaction is joint attention, in which each participant knows that there is mutual attention to the same object. However, it is only recently that studies have started to investigate how brain systems are engaged when we directly interact with another person in order to perform 'on-line' mentalizing.

The most basic form of social interaction is joint action in which two people cooperate in order to achieve some common goal. In order to successfully achieve their shared goal, participants must understand how they and their partner view each other's roles within the partnership. This process involves at least four levels of mentalizing: (1) our belief about our partner's role, (2) our belief about how our partner views his role, (3) our belief about how our partner believes we view our role, and finally (4) our belief about how our partner believes we view him. If we are able to represent all levels of this mentalizing structure, we should be able to understand the intentions of our partner and predict his actions.

This section summarizes findings from recent studies in which two participants socially interact in a variety of tasks. We start by noting some important behavioral studies and then discuss neuroimaging findings that suggest an important role for the medial frontal cortex, including the anterior cingulate cortex (ACC), in on-line social interaction. Next, we highlight the new breed of 'hyperscanning' studies that go beyond analysis of a single brain to look at systems of interacting brains.

What Can Behavioral Studies Tell Us?

A variety of experiments have been used to explore cooperative behavior between humans and nonhuman animals. Tasks have included attainment of a reward that is not accessible to the individual, successful completion of a joint action task, and exchange of information in a communicative partnership. Such cooperation is highly prevalent in human society. Children as young as 18–24 months old are able to interact with an adult human in a cooperative activity, unlike their chimpanzee counterparts.

Even though language plays a vital role in most cooperative endeavors, it is not necessary for successful cooperation. As long as we can monitor the actions of others we can identify their goals and intentions and modify our own behavior accordingly. Indeed, the mere presence of another person performing a task with us can modify our own response. Sebanz and colleagues used a spatial compatibility task wherein participants made one of two spatially distinct actions in response to a color cue and in the presence of an irrelevant spatial cue. When participants worked alone and assigned one hand to each of two response alternatives, reaction times were slowed when there was an incompatibility between the desired response and the irrelevant spatial cue. This effect disappeared when the participant responded to only one of the two alternatives. However, the

incompatibility effect returned when a second participant was assigned to respond to the other alternative. This result suggests that we automatically represent the actions of the person sharing the task with us even though this impairs our own performance.

In the task used by Sebanz and colleagues the performance of one participant had no direct effect on the performance of the other. Reed and colleagues used a simple task in which a crank handle was used to align a cursor with a target. In the joint action condition both participants effectively held the same handle, but had no communication except via the force the other was applying. Participants perceived the contribution of the other as a hindrance, but, in practice, when they worked together, their performance became more efficient than when they worked alone. The force profiles of the participants' actions dramatically changed in the joint response as they developed strategies to work together. Most often one participant contributed more to acceleration and the other to deceleration of the movement of the crank, thereby achieving more efficient and faster movement.

Although cooperative behavior between nonrelated participants are uncommon in the animal kingdom, Mendres and DeWaal have shown that pairs of capuchin monkeys can work together to pull a tray forward in order to receive a reward. The monkeys made more communicational glances to their partner in the joint action task than when they acted alone, in an attempt to motivate their partner. Joint action performance became poorer when the partners were unable to see each other, and the authors suggest this was because the capuchins required visual contact to coordinate the timings of their responses.

The more complex tasks typical of human cooperative interactions are greatly helped by direct communication. Communication is not only a way to express our intentions to others, it also enables the exchange of information relevant to the task in hand. This bilateral process requires both participants to input their own information, monitor their partner, and update their action. Communicators must constantly evaluate and amend their actions to take account of the reactions of listeners, and listeners must inform communicators of any changes in their current understanding to make sure that both have common knowledge. Common knowledge acts to set a mutual base, where all participants are aware of the information and know that all the other participants are also informed. Much of this common knowledge emerges as a by-product of the interaction.

Communication does not rely solely on the monitoring of speech, but also on many other communicative signals, such as facial expressions, posture, and body movements, and what is happening in each participant's workspace and in the surrounding environment. When any part of this information is blocked, communication becomes less effective and less efficient. Understanding is further worsened if communication becomes a noninteractive process, as with written instructions. For example, Clark and Krych studied a task in which one participant gave directions while the other participant followed these directions in order to build a structure. Task efficiency was greatly reduced when a barrier obscured the view of each other's workspace. Furthermore, noninteractive communication using prerecorded directions produced the greatest number of errors.

Cooperative behavior is usually mutually beneficial to both participants, but often it requires at least one participant to invest their trust in the other with some degree of risk. To prevent betrayal of trust and loss of investment we must wisely choose our partners and invest the minimal amount to reap maximal reward. We must continually monitor our partner for trustworthiness and at the same time give out signals indicating that we are worthy of trust (reputation management). Trust and reciprocity have been studied in economic games such as the Prisoners' Dilemma. An optimal strategy in such games is 'tit-for-tat,' in which trust is repaid by trust and betrayal is repaid by betrayal. Players in economic games have a strong sense of the 'fairness' of interactions. Given the opportunity, they will punish those who make unfair offers, even at some cost to themselves (altruistic punishment). The occurrence of altruistic punishment increases group cooperation.

Neural Activity Associated with Social Interactions

To date the majority of imaging studies of on-line social interactions have involved various kinds of trust and reciprocity games in which the brain activity of each participant is recorded while each interacts with partners outside the scanner.

Some of these experiments have manipulated participants' 'intentional stance' by making them believe that they are interacting with a human or computer partner. In these studies, which have used both competitive and cooperative games, greater activity is seen in the MPFC and adjacent ACC when participants believe they are interacting with a human rather than a computer. This activity is located in the anterior rostral region of the MPFC (using the terminology of Amodio and Frith), where most of the MPFC activity associated with off-line mentalizing tasks has also been observed. A recent study in monkeys has shown that lesions in the ACC cause a loss of interest in social stimuli.

Brain regions concerned with emotion are strongly implicated in these trust and reciprocity games. For example, the ventral striatum and other regions concerned with reward are activated after episodes of mutual cooperation. Unfair offers, on the other hand, decrease activity in reward areas while activating the anterior insula. Insula activity also occurs in response to negative emotions such as disgust and pain. Given these effects, is not surprising that the faces of game partners who persistently cooperate or defect rapidly come to elicit positive and negative emotions, respectively. These effects are largely eliminated if the other player is believed to be a computer or a person who is not a free agent, but merely follows instructions.

When persistent defectors are seen to be punished, activity also increases in brain regions associated with reward. This involvement of reward systems suggests a mechanism whereby cooperation and altruistic punishment can be maintained during social interactions.

Two Brains, Two Scanners

Investigating the brain activations of one player only gives half the story, because another person (and their brain) is involved in a dyadic social interaction. To address this problem a new type of neuroimaging has been developed by Read Montague and his colleagues. This system, known as 'hyperscanning,' allows the simultaneous brain scanning of two socially interacting people by using an Internet link to temporally align two functional magnetic resonance imaging (fMRI) scanners and their presentation systems. Timing and presentation information, such as scanner onset or type and onset of stimuli and rewards, can be transmitted between different scanning laboratories. The Internet connection allows participants to interact with other participants in fMRI scanners located around the world and opens the opportunity to investigate the correlation between the activities of socially interacting participants.

The two hyperscanning studies published so far have both involved trust and reciprocity games. Participants played against the same human partner and were free to make their own choices to allow models of trust and reputation to be built. One participant, the investor, was given money and then decided how much money to share with the other participant, the trustee. Any shared money was tripled and then the trustee decided how much money to repay the investor.

As in previous studies, brain areas associated with reward (dorsal striatum) were activated when trust was reciprocated. However, in the course of the game this signal increasingly anticipated the time at which the investor knew that her trust had been reciprocated. The authors suggest this anticipatory signal is analogous to reward prediction in simple conditioning experiments. As trust builds during the course of the game, the investor becomes increasingly confident that her benevolent behavior will be rewarded by benevolent reciprocity.

However, the importance of the hyperscanning paradigm lies in the possibility of direct investigation of interactions between brains. For example, a cross-brain correlation analysis indicates whether activity in a region in one brain can predict activity in a region of the other brain. In the trust and reciprocity game a strong correlation was found between the investor's middle cingulate cortex and the trustee's ACC. These different locations in cingulate cortex could be related to representations of the 'self' (middle cingulate cortex active during submission of the participants' own responses) or the 'other' (ACC active during the revelation of their partners' responses). These representations were independent of the role of each participant or the type of reciprocity produced. The authors concluded that the cingulate cortex has a spatial map of response agency along the anteroposterior axis. Given this account of the representations in cingulate cortex, the cross-brain analysis indicates that the linked brain regions represent the same thing. Thus, the investor's representation of himself/herself (participant A) is linked to the trustee's representation of the other (participant A). This could be evidence, at the neural level, of the alignment between representations that is necessary for successful social interactions.

Conclusions

Investigations of the neural basis of interacting minds have only just begun. The possibilities are very exciting. As we have seen, there are many behavioral paradigms, in addition to economic games, that have yet to be adapted for brain imaging experiments. Hyperscanning is a particularly important development since interacting minds depend upon interacting brains. When we analyze activity in interacting brains, we need to treat the two (or more) brains as a single system, which has emergent properties that cannot be seen in the single brain. fMRI is perhaps not the ideal modality for such analysis, since we can only look at rather slow hemodynamic changes. Electroencephalography and magnetoencephalography, with their high temporal resolution and direct reflection of neural activity, will provide powerful

ways for looking at links between brains during social interactions. Analytic techniques already developed for looking at functional connectivity within brains, such as structural equation modeling and casual modeling, can be applied without modification to analysis of connectivity between brains.

Social Communication in Whales and Dolphins

P L Tyack, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Whales and dolphins are part of the mammalian order Cetacea. The primary division in the cetaceans is between the baleen whales (mysticetes) and the toothed whales (odontocetes), which includes dolphins and larger toothed whales, such as killer and sperm whales. As the ancestors of whales and dolphins entered the sea about 50 Ma, they encountered a sensory environment very different from life in air. Olfaction is a sense primarily for airborne chemicals, and the olfactory system is reduced in baleen whales and absent in toothed whales. By contrast, the sense of touch is well developed in marine mammals, which rely on tactile communication for close-range interactions in ways that are similar to terrestrial mammals. Vision is the optimal distance sense in air, but objects underwater can seldom be seen at ranges of more than tens of meters. Some low-frequency sounds, by contrast, can be heard at ranges of thousands of kilometers in the ocean. These differences between air and water as media for communication created new selection pressures for sensory systems in marine mammals. Toothed whales evolved high-frequency hearing and sound production mechanisms for communication at low frequencies specialized for echolocation. Baleen whales evolved hearing and sound production mechanisms for communication at low frequencies that propagate over hundreds of kilometers. Because of the critical importance of sound as a communication medium for marine mammals, this article will focus on acoustic communication.

All marine mammals produce sound by moving air past phonic lips. For terrestrial animals, this kind of pneumatic mechanism produces stable voice cues that can be used for individual identification. As a marine animal dives, however, air-filled cavities in the vocal tract change shape, leading to changes in voice cues. This suggests that the motor commands required to generate a vocalization with a specific acoustic structure may vary with the animal's depth. One solution to this problem involves learning mechanisms that can match vocal output to an auditory template. This problem with maintaining stable vocalizations may help explain how common vocal learning is among marine mammals.

Vocal Learning

There is only weak evidence for vocal learning among nonhuman primates, and it is rare among other terrestrial mammals, but three major marine mammal taxa, seals, toothed whales, and baleen whales, all show evidence of sophisticated vocal learning skills. Hoover, a harbor seal (*Phoca vitulina*) at the New England Aquarium, imitated human speech with a clear Maine accent. His mother had died soon after giving birth, and he was raised by a family in Maine for the first few months of life. Captive bottlenose dolphins (*Tursiops truncatus*) have repeatedly been shown to be capable of precise imitation of frequency-modulated tonal signals. The songs of humpback whales (*Megaptera novaeangliae*) are similar within a population at any one time, but they change continuously so that each sound is replaced within a few years. This 'hit parade' can be explained only by vocal learning in which whales copy the most popular songs at any one time.

The songs of humpback whales are made up of a series of 'themes' that are produced in such a well-defined order that each theme is given a number such that theme 3 always follows theme 2 and precedes theme 4. Each theme is made up of a variable number of repetitions of a 'phrase,' which is a sequence of about six to eight individual sound units. Humpback whales do not emit bubbles as they vocalize, and it is thought that at the end of each phrase, the whale recycles air from above the sound production organ back to the lungs. The sequences of sounds produced by a humpback singer cannot be replicated by Markov processes but rather are generated by a hierarchical mechanism with strong syntactic constraints. None of the changes in the song appear to correlate with changes in the meaning, so this sophisticated syntactic structure appears to be divorced from the semantic elements that are so well correlated with syntax in human language.

There is limited evidence for convergence of vocalizations in groups of terrestrial nonhuman mammals, but nothing like the evidence of imitative skills demonstrated for marine mammals. Most terrestrial mammals have a fixed vocal repertoire of communication signals, and the structure of these signals is inherited, developing normally even in the absence of exposure to auditory models. By contrast, many species of birds, humans, and a few mammals maintain an ability to learn new vocalizations throughout the lifetime. Several costs are associated with vocal learning. It may take longer for animals that require

auditory input to develop appropriate signals, and development can be derailed if an animal is not exposed to the appropriate auditory environment.

Animals that can learn their vocal signals have an open communication system that requires modes of understanding that are different from those of closed communication systems. Animals that produce vocalizations with no auditory feedback can be said to have a fixed vocal repertoire, each sound of which may evolve to meet specific communicative functions. Dolphin and avian vocal repertoires can be open and can differ significantly between individuals. In some species, different elements of the learned repertoire appear to be equivalent, suggesting that it is inappropriate to assume that each signal has a different function and raising questions about the significance of precise imitation versus copying errors.

Two communicative functions have been associated with vocal learning in marine mammals. These involve the development of songs for reproductive advertisement and of signature signals for individual or group recognition. Some species of seal and baleen whale use vocal learning to produce their reproductive advertisement displays. The best evidence among marine mammals for the uses of vocal learning in reproductive advertisement stems from humpback song because of the continuous change in so many features of this complex signal. Geographical dialects have been reported for songs of other whale species and for seals. Dialects are often cited as evidence for vocal learning, but vocal dialects in elephant seals from different islands are thought to result from founder effects. Regional dialects in animals such as blue whales are more likely a result of vocal learning, as dialect areas are not as isolated as breeding islands for seals. The songs of blue and fin whales are less complex and more repetitive than those of humpback whales, apparently as an adaptation for long-range communication. Humpback whales congregate to breed on traditional breeding grounds, while blue and fin whales are thought to disperse into tropical seas during the winter breeding season. The songs of blue and fin whales are simple low-frequency sounds that are regularly repeated. They can be detected at ranges from hundreds to more than 1000 km. Since these whales routinely swim more than 100 km day^{-1}, it is possible that the functional range of advertisement extends to these ranges. One of the adaptations required for such long-range communication involves specializations for production and reception of low-frequency signals, including an unusually wide, thin, and floppy apical end of the basilar membrane in the inner ear.

Many toothed whales use acoustic signature signals to maintain social cohesion between individuals that share strong social bonds. Bottlenose dolphins have societies characterized by strong bonds between individuals within fluid social groups. Even though calves are precocious in terms of ability to swim away from the mother, there is a prolonged period of dependency in which calves suckle and are sighted near the mother for years. As male dolphins mature, they tend to form alliances with one or two other males, and allied males tend to be sighted together 90% of the time. While groups of dolphins often change membership on timescales of minutes, social bonds between individuals often last a decade or longer. Even dolphins with strong social bonds separate out of sight of one another many times each day. After bonded dolphins separate, they use frequency-modulated whistle vocalizations to mediate reunions.

Infant dolphins produce simple unstereotyped whistles as soon as they are born. They develop an individually distinctive signature whistle during the first 1–2 years of life. As in some songbirds, the young tend to develop a whistle that differs from that of close associates but that resembles the whistle of a member of the population sharing low levels of association with the calf. Dolphins born in captivity tend to have whistles with less frequency modulation than those of wild dolphins, apparently because they incorporate acoustic features of the nonmodulated whistles used by trainers. Females retain a stable signature whistle for the rest of their life, but as males form an alliance, their whistles converge with those of their partners, becoming more similar while retaining distinctive elements.

A striking element of the communication system of dolphins involves one animal producing precise imitations of the signature whistle of another. Research with captive dolphins demonstrates that they are capable of learning to imitate artificial sounds and to produce these sounds when they are exposed to a manmade object. It is not known whether imitation of signature whistles represents naming other dolphins in the same way they can vocally label objects. The issue of defining how referential dolphin communication is remains a hot topic.

In contrast to the fluidity of dolphin social groups, sperm (*Physeter macrocephalus*) and killer whales (*Orcinus orca*) live in stable groups and produce group-specific repertoires of calls. Social structure in both sperm and killer whales is based on stable matrilineal groups. The best-studied killer whale population lives in inshore waters of the northeastern Pacific Ocean and feeds primarily on fish. One of the remarkable features of this resident population is that neither sons nor daughters have been seen to emigrate from their natal group. The basic social unit is a matriline consisting of one to four generations of

matrilineally related animals. The most commonly sighted group is a 'pod' composed of one or more related matrilines.

Killer whales produce a variety of sounds: echolocation clicks, frequency-modulated tonal whistles, and stereotyped pulsed calls called discrete calls. Each pod produces an average of ten types of discrete call, and the more closely related pods are, the more overlap there is in their discrete call repertoires. Pods do not use different discrete calls in different behavioral contexts, but rather the group-specific repertoire appears to function as an acoustic 'badge' to maintain pod cohesion. Animals within a pod often disperse beyond visual range, to forage separated by hundreds of meters, and different pods may form aggregations with animals from other pods. Discrete calls are most commonly produced when whales are separated while foraging or when different pods meet, settings when these animals need to reassociate to form their pods again.

There may be slight but predictable differences in calls shared by different matrilines within a pod. The acoustic features of some calls change over time, with different calls having different rates of change. This pattern of vocal change is thought to represent a form of cultural drift, leading over time to the observed pattern of repertoire differences between pods. However, while there are limited observations of vocal matching in captivity and the wild, there is no definitive evidence for vocal production learning in killer whales.

Sperm whales form matrilineal groups like those of killer whales, but in contrast to killer whales, maturing male sperm whales leave their natal groups. Female and immature sperm whales are usually found in groups of ten to 40 whales. These groups contain clusters of individuals that are closely related genetically, along with unrelated individuals. Individuals that associate over long periods of time (years) are called a unit, and most groups sighted at sea represent temporary combinations of several units that may stay together for a few days. One of the primary benefits of group living for sperm whales is thought to be social care of the young. The lability of size and composition of groups may allow units to balance optimal size of groups for local foraging conditions versus social defense against predators.

When sperm whales forage at depth, they produce regular clicks for echolocation. At other times, they produce rhythmic patterns of clicks, called 'codas,' that are thought to be used for communication. Each sperm whale unit produces a repertoire of codas. Analysis of coda repertoires from sperm whales throughout the South Pacific Ocean suggests that there are five sympatric 'clans' of sperm whales units that tend to share coda repertoires. These are similar to the vocal clans seen in resident killer whales but span on the order of 10 000 km, compared with 1000 km for killer whales, and involve many more individuals, perhaps 10 000 sperm whales, compared with about 100 killer whales in the entire resident population. Even though clans are sympatric, units appear preferentially to associate with other members of the same vocal clan. It is thought that these coda dialects allow units to identify units from the same clan, perhaps mediating communal defense and allomaternal care. While these coda dialects have been described as learned aspects of animal culture, there is no direct evidence that they are learned.

The directionality of signals of dolphins and toothed whales has led to a new appreciation of how directional signals can cue a receiver as to the orientation of a calling animal. The higher the frequency of a signal compared with the aperture of the sound production organ, the more directional the signal can be. This leads to a pattern in communication signals that parallels directional echolocation clicks. When the signaling animal is pointing directly toward a receiver, the ratio of high- to low-frequency energy is higher than when the signaler is pointing away. This means that when a dolphin whistles or a killer whale produces a discrete call, other animals nearby can detect whether the signaler is pointing toward or away from them. This information is particularly useful for cohesion signals used to coordinate movements between animals sharing a bond.

While most research on animal models of vocal learning in the past have focused on reproductive advertisement, there is growing evidence for the importance of vocal learning in the development of signature signals, including vocal convergence in the formation of group-distinctive calls. Sexual selection leads to the evolution of extreme displays, and the songs of birds and whales stand out as some of the most dramatic examples of learned displays. There are some similarities between language learning in humans and song learning in birds – normal vocal development in both songbirds and humans requires hearing species-specific vocalizations during a sensitive period early in life. But there are also significant differences. Vocal learning in many songbirds is largely limited to males and mainly to one type of vocalization – song.

Neurobiologists interested in comparative models of vocal learning with a prime focus on humans should consider vocal convergence among animals within a group in addition to sexual selection for vocal learning of advertisements. While there are no nonhuman primate models of vocal learning similar to songbirds, vocal convergence has been

shown in several nonhuman primates. Similar vocal convergence has been demonstrated for a wide variety of other mammals, including bats, toothed whales, baleen whales, seals, and elephants. Neurobiologists with broader comparative interests in the evolution of vocal learning should strive to embrace a broad taxonomic scope including groups whose phylogenetic relationships are distant enough to guarantee independent evolution of the traits of interest. Comparison of the ecological and social settings of a diverse array of animals will help provide a fuller understanding of the selection pressures for this important skill. For example, dolphins with stable bonds within fission–fusion societies use vocal learning to develop individually distinctive signatures, whereas killer whales with stable groups learn to develop group-distinctive repertoires of discrete calls.

There has been a growing appreciation of mechanisms that animals can employ to maintain effective communication in a noisy channel. One simple strategy is to increase the level of a signal in increased noise to improve the ratio of signal to noise. This can be achieved with relatively simple effects of auditory feedback. However, in situations where different conspecific signalers are competing for the attention of a receiver, such as when multiple males advertise to a female, more-complex strategies may come into play. Similarly, the diversity and increasing pace of introduction of novel sources of anthropogenic sounds may select for vocal plasticity that can help a signaler adapt to a changing acoustic environment. Birds and whales exposed to anthropogenic noise have been reported to shift the level, frequency, or repetitiveness of their calls to reduce interference. As humans alter the acoustic environment of animals that use sound for critical functions, vocal plasticity may become more important than during the preindustrial era, when the auditory environment was likely more stable. To the extent that successful use of vocal communication is required for growth, survival, and reproduction, it will be important for humans to understand the impact of disrupting the use of sound by animals.

Social Emotion: Neuroimaging

T F Heatherton and A C Krendl, Dartmouth College, Hanover, NH, USA

Humans are social beings who live in groups. Dependency on group living is not unique to humans, but the nature of relations among and between in-group and out-group members is especially complex in human societies. Decades of research in psychology has established the central role of emotional processes in facilitating social relationships and guiding group behavior. 'Social emotions,' which are complex subjective experiences (e.g., pride, admiration, jealousy, envy, irritation, and flirtatiousness), serve many important social functions that promote long-term relationships and group stability. From a functional perspective, social emotions enable people to be good group members, thereby avoiding rejection and enhancing their survival and reproduction. Thus, social emotions are essential to human social life.

Social emotions facilitate successful social relationships through two primary pathways: they provide incentives to engage in social interactions (e.g., affection, love, feelings of pride, or admiration for those with whom we interact), and they increase the likelihood that people will adhere to societal norms that are necessary for group living. When such norms are violated, people experience negative social emotions (e.g., feelings of guilt, embarrassment, or shame) that subsequently encourage them to act within the bounds of socially acceptable conduct, thereby reducing the risk of social exclusion and promoting positive social interactions. Moreover, long-lasting social emotions (such as remembering an embarrassing moment from adolescence) reduce the likelihood of repeat violations.

Although it is possible that nonhuman animals experience emotional states that modulate behavior, it is apparent to most researchers that complex social emotions are particularly characteristic of humans and some are possibly uniquely human. An open question, however, is whether social emotions are innate or learned behaviors. From an evolutionary perspective, social emotions serve the adaptive function of fostering social relationships within groups. Thus, it is possible that people have evolved dedicated neural circuits for social emotions, much as has been argued for the more basic emotions, such as fear. At the same time, some evidence suggests that many social emotions are influenced more by socialization than by genes, indicating that important aspects of social emotions develop within a social context. Indeed, research suggests that the influence of the shared environment on feelings of guilt increases over time, whereas the influence of genes disappears. Nonetheless, for most people, social emotions play a powerful and prominent role in their interactions with other people. Extensive evidence from patient research, as well as recent efforts using the methods of neuroscience to study human social emotions (i.e., neuroimaging), have started to provide important insights into the factors that produce and maintain social emotions.

Neuropsychological Evidence for Discrete Neural Networks in Social Emotions

Extensive evidence from patient research suggests that there are two primary neural regions involved in perceiving social emotions. The first (the amygdala) contributes to the identification of the social emotion, whereas the second (discrete regions of the prefrontal cortex) translates those emotions into information that can be used to facilitate social interactions. The process of garnering socially relevant information from social emotions involves three critical components. First, social emotions require people to be aware of their behavior, so as to gauge it against societal or group norms. Second, people need to understand how others are reacting to their behavior so as to predict how others will respond to them. To do so requires them to be able to make attributions about the mental states of others, a capacity often called 'theory of mind' (ToM). Finally, there need to be mechanisms for detecting discrepancies between self-knowledge and social expectations of norms, thereby motivating behavior to resolve any conflict that exists.

The first evidence that regions of the prefrontal cortex plays a critical role in social emotions came from the case of Phineas Gage, who suffered profound frontal lobe damage when a railroad tamping rod misfired into his head. Formerly described by friends as dependable, polite, and hardworking, Gage became capricious, volatile, and lewd after the accident, showing no evidence of embarrassment or remorse at his socially inappropriate behavior. Gage's radical personality change after his injury provided convincing evidence that the prefrontal cortex plays a crucial role in the social emotions that regulate behavior (e.g., guilt, embarrassment, and remorse). Since Gage's accident, abundant evidence from patient research, and more recently neuroimaging studies, has further identified discrete neural

networks involved in both identifying and using social emotions.

Neuroimaging and Patient Research on Self-Awareness

Social emotions require that people be aware of the effects of their behavior on others, which necessitates self-awareness. That is, when people commit a *faux pas*, they must be able to recognize that the behavior they performed is inappropriate and that the feelings they are experiencing are embarrassment at having committed the *faux pas*. Self-awareness occurs when people themselves are the objects of their attention, such as when they think about themselves or process other information in a personal manner. Many years of research in psychology has revealed that information processed with reference to self seems to be treated 'specially.' For instance, people show a robust enhancement in memory for material that has personal meaning. This self-reference memory enhancement effect has been observed in many contexts, such as when people remember information processed with reference to self better than information processed with reference to other people (i.e., friends and politicians). The use of functional neuroimaging has provided key insights into the brain regions that support self-awareness.

A series of functional magnetic resonance imaging (fMRI) studies conducted over the past 10 years have indicated that the medial region of the prefrontal cortex (MPFC) plays a vital role in self-awareness. This region is more active, for example, when people report on their personality traits, make self-relevant judgments about pictures, or retrieve autobiographical memories of past events. Recent research indicates that regions of the ventral anterior cingulate cortex (ACC) may work in conjunction with MPFC to reflect the valence of self-relevant information. Interestingly, the MPFC has also been identified as part of a 'default network,' which also includes the posterior cingulate gyrus and precuneus. This network is active when the brain is at rest (i.e., not engaged in an overt cognitive task). An abundance of positron emission tomography (PET) and fMRI data suggest that the default network plays a dominant role in self-awareness. As such, the default network supports important components of social emotions.

It is interesting to note that converging evidence from patient research indicates that frontal lobe lesions, particularly to the MPFC and adjacent structures, have a deleterious effect on personality, mood, motivation, and self-awareness. Patients with frontal lobe lesions show dramatic deficits in recognizing their own limbs, engaging in self-reflection and introspection, identifying a *faux pas* as being socially inappropriate, and even reflecting on personal knowledge. Indeed, frontal lobe patients are particularly impaired in social emotions, such as feeling embarrassed in appropriate contexts. The convergence of patient and imaging data support the conclusion that MPFC plays a prominent role in self-awareness, a necessary and critical contributor to the experience of social emotions.

ToM and the MPFC

In addition to recognizing our own mental states, social emotions require that we are able to accurately interpret the emotional states of others. For instance, to feel guilty about hurting a loved one, people need to understand that other people have feelings. Indeed, all social emotions related to empathy require the capacity to attribute specific mental states to others. Similarly, at the core of many social emotions is the belief that one is being evaluated by others (thereby giving rise to emotions such as embarrassment and social anxiety), which means recognizing that other people make evaluative judgments. The ability to infer the mental states of others is commonly referred to as mentalizing, or having the capacity for ToM. ToM enables the ability to empathize and cooperate with others, accurately interpret other people's behavior, and even deceive others when necessary. The rapidly emerging neuroimaging literature on ToM has consistently implicated MPFC as a central component of the neural systems that support mentalizing. Patient research in this area primarily focuses on people who have syndromes that involve impaired ToM (i.e., Asperger's or autism). This line of research indicates that such people have decreased neural activity and cerebral blood flow to the MPFC during ToM tasks. Such findings suggest that the MPFC plays a vital role in mentalizing tasks.

It is interesting to note that the ability to mentalize relies heavily on similar neural networks engaged in processing self-relevant information, notably MPFC. However, this region of MPFC tends to be more dorsal in ToM studies than in self-reference studies, although overlap in activity has been observed. In a typical neuroimaging study of ToM, participants are required to make judgments about other people's mental states after reading scripted scenarios or observing pictures of people with differing facial expressions. For instance, early investigations compared neural activity observed during trials in which participants were asked to judge the motivations of an actor's behavior (e.g., "he turned himself into the police because they knew he had committed a crime") with that observed during nonmentalizing tasks, such

as judging a person's physical actions, and revealed MPFC activation in the mentalizing task only. MPFC activation can also be observed when participants are asked to determine the underlying motivation of an actor as depicted by pictures that convey specific social behavior (i.e., stealing, sharing). This region is also engaged when perceivers are asked to infer the mental states of targets that are most similar to them. This latter finding suggests that self-reflection is possibly engaged in mentalizing tasks, illustrating perhaps a common role that MPFC is playing for both self-awareness and ToM. Indeed, deficits in this brain region are associated with a reduction in ToM, reinforcing the importance of MPFC in ToM tasks. Although activity in other brain regions has been observed during ToM tasks, notably the superior temporal sulcus (STS), the temporoparietal junction, and less often the amygdala, MPFC appears to play a central role in the ability to make mental state attributions about other people. This ability is critical for social emotions because it enables us to modify our behavior in order to promote smooth social interactions.

Social Emotions and the Amygdala

In addition to MPFC, a distributed network of brain regions has been implicated in selecting and processing social emotions. One such region is the amygdala. For decades, the amygdala was considered most often in the context of fear learning and attention tasks. More recently, however, amygdala activation has been observed in making social judgments, such as evaluating stigmatized individuals. Not surprisingly, then, evidence has emerged from patient and neuroimaging research to implicate the amygdala in perceiving social emotions. For instance, patients with unilateral or bilateral amygdala damage have been shown to be impaired at recognizing specific social emotions from facial expressions (e.g., arrogance, guilt, admiration, and flirtatiousness). Interestingly, this deficit appears to be limited to social emotions, and does not extend to other emotions, suggesting that the amygdala plays a central role in recognizing social emotions.

Neuroimaging studies have also demonstrated an important role for the amygdala in processing a variety of social emotions. For instance, when participants are asked to choose the appropriate reaction (from varying perspectives) to sentences that represented different social emotions (e.g., embarrassment, pride, shame, guilt, admiration, irritated, and impressed), as compared to sentences conveying nonsocial emotions, heightened amygdala activation is observed, regardless of perspective taken during the task. Interestingly, when participants are asked to examine intentional violations of social norms through stories (e.g., "You are invited for dinner at your friend's house") that have one of three endings: one that was descriptive of normal social behavior (e.g., "You have a bite of the first course and like it, congratulate your friend for her good cooking"); one that described an embarrassing conclusion (e.g., "You have a bite of the first course, you choke and spit out the food while you are coughing"); or one in which the protagonist violated a social norm (e.g., "You have a bite of the first course, but do not like it and spit the food back onto your plate"), a similar pattern of activation is observed. When taking their own perspective, participants showed greater amygdala activation in response to intentional violations of social norms. These results suggest that the amygdala is indeed involved in processing social emotions.

Based on the extant literature on the amygdala, it is not surprising that this area may be involved in processing social emotions. It has long been argued that the primary role of the amygdala is to automatically respond to arousing emotional stimuli, particularly fear-inducing or aversive items. From this perspective, the role of the amygdala in processing social emotions may simply be to respond to the highly arousing nature of the unique conditions that produce social emotions. More recently, however, this region also has been implicated in drawing attention to novel stimuli that have biological relevance. Under this argument, it is plausible that the amygdala plays a role in processing social emotions because they have direct relevance in maintaining long-term social relations, which is a fundamental biological need. Regardless, the role of the amygdala in processing social emotions suggests that an automatic response network exists in the brain for distilling social emotions.

Social Emotions and the ACC

In addition to the MPFC and amygdala, patient research and neuroimaging have also implicated the ACC in processing social emotions. Although the ACC is anatomically part of the prefrontal cortex, a wealth of evidence from patient and neuroimaging research illustrates that ACC activity is functionally distinct from MPFC regions involved in self-awareness and ToM. Evidence from patient studies suggests that the ACC is involved in integrating cognitive and affective information to guide behavior appropriately. For instance, imaging research has implicated the ACC in resolving cognitive conflicts. With respect to social emotions, the anterior cingulate appears to be engaged in social interactions that provide conflicting social feedback, thereby eliciting conflicting emotions.

Although emerging evidence from neuroimaging research has yielded disparate results as to the roles of discrete regions of the ACC in processing social feedback, it has provided a working framework for understanding the ACC. Rejection, for instance, is a social emotion that results from a violation of the expectancy that people believe they are valued. Some neuroimaging research has found that a region of the dorsal ACC (dACC) is responsive during tasks designed to elicit social rejection, such as when virtual interaction partners suddenly and surprisingly stop cooperating with research participants. It is possible, however, that the dACC activity observed in these types of tasks indicates cognitive conflict more than social pain resulting from rejection, *per se*. Indeed, being rejected may violate the fundamental expectancy of social inclusion. Other research has indicated that a more ventral region of the ACC (vACC) is important for the social emotion of feeling rejected. Interestingly, interpersonal distress, such as feeling unloved, is often involved in depression, and abnormalities in vACC activity have been observed in unipolar depression. For instance, imaging research has found differential patterns of vACC activity to emotional facial expressions between depressed and non-depressed subjects. Thus, one possible role for vACC reflects its involvement in general affective state, thereby affecting social emotions indirectly.

Another possible role for ACC in social emotions is its involvement in detecting and attempting to resolve cognitive conflict. Thus, information that conflicts with pre-established knowledge signals errors that must be resolved, a situation that produces ACC activity. From this perspective, then, the ACC may be involved in processing social emotions by detecting conflict between actions and outcomes. For instance, when a social norm is violated, the ACC may play a role in identifying this error because it detects differences between the expectation (social norm) and action (violation). The detection of errors in social behavior may produce social emotions that guide future appropriate behaviors.

Self-Conscious Emotions

An important distinction that emerges in the psychological literature is the subcategory of 'self-conscious emotions' from the more general social emotions. Self-conscious emotions, including embarrassment, guilt, and shame, occur when the emotional experience reflects an evaluation of the self. People feel embarrassed when they believe that others are evaluating them negatively, and ashamed when they do it to themselves. Either way, the self is implicated in a way that is more specific than emotions such as jealousy, admiration, or flirtatiousness. The primary adaptive value of self-conscious emotions is that they provide a clear disincentive for people to act in a socially inappropriate manner. Although, neuroimaging research on self-conscious emotions is still in its infancy, patient studies and a handful of imaging studies shed light on the neural networks involved in this specific category of social emotions.

Patient research has provided compelling evidence that damage to the orbitofrontal cortex, a region adjacent to the medial prefrontal cortex, severely impairs self-conscious emotions. Patients with lesions to this area exhibit extremely socially inappropriate behavior (e.g., making inappropriate jokes, kissing or hugging strangers, disclosing intimate information about themselves to strangers). Imaging studies of self-conscious emotions such as guilt and embarrassment implicate additional brain regions, including anterior cingulate gyrus, MPFC, STS, and insula. For example, asking people to recall the most guilt they ever experienced produces greater activity in these regions than does recalling events when they did not feel guilty. In research comparing guilt and embarrassment, both self-conscious emotions elicited MPFC activation, but guilt apparently does so more than embarrassment. Robust MPFC activity in self-conscious emotions may reflect the unique circumstances under which people mentalize about how others are evaluating them.

Imaging Moral Emotions

Another category of social emotions, namely, moral emotions, dictate what is ethically 'right' or 'wrong' in a given situation. As might be expected by the foregoing discussion, when participants are asked to resolve various moral dilemmas during imaging, MPFC activation is observed. Specifically, comparisons between making moral-personal (e.g., the footbridge dilemma), moral-impersonal (e.g., the trolley dilemma), and neutral (or nonmoral) decisions revealed that MPFC and posterior cingulate gyrus are significantly more active in the moral-personal condition than in the moral-impersonal and the nonmoral conditions. MPFC activation also emerges when morality is measured by eliciting disgust or indignation from the observer. For instance, participants who read a series of disgust-inducing (e.g., "A friend told you about a newspaper headline. A man had died after he ate a living rat") or indignation-causing (e.g., "As you arrived home, you saw that the nurse has put a spider on the baby's face") statements showed heightened MPFC and

orbitofrontal activation to both the disgust- and indignation-inducing statements. Disgust also elicited greater amygdala and anterior cingulate response as compared to indignation, whereas the latter elicited greater insula and right inferior frontal gyrus.

Substantial evidence has also been found in the patient literature that lends support to these findings. Patients who have experienced damage to regions of the prefrontal cortex, including MPFC and orbitofrontal cortex, early in life (i.e., before 2 years) show extensive deficits in their ability to engage in moral reasoning tasks. Together, the findings from emerging neuroscience and patient research suggest that the prefrontal cortex, particularly the MPFC, has a critical role in moral reasoning.

Conclusions

Although neuroimaging research on social emotions is in its early days, it has already revealed a strong overlap with the neural networks that give rise to social cognition and processing emotions. Imaging studies have indicated a prominent role of the MPFC for social emotions (especially self-conscious emotions) that require inferences to be made about the mental states for self or others. The extant literature also implicates the amygdala in social emotions, although it remains an open question as to whether the amygdala is selectively responsive to specific social emotions or whether it plays a more general role in emotional responding (i.e., arousal or vigilance). Moreover, initial imaging studies also indicate an important role for the anterior cingulate in detecting conflicting social information, such as detecting social rejection, and perhaps in getting behavior back on track. Indeed, burgeoning research on the neural correlates of social emotions include studies on the neural networks underlying attachment, love, and perceiving stereotypes. Considered as a whole, patient and neuroimaging research are producing important insights into social emotions. In order to successfully guide social interactions, social emotions require self-awareness, the ability to understand the mental states of others, and mechanisms to detect conflicts between personal behavior and appropriate social rules. It is likely that neuroimaging research will continue to provide insights into this important aspect of emotion.

Decision Making and Social Interactions

The study of decision making has as its goal the understanding of our fundamental ability to process multiple alternatives and choose an optimal course of action. A good decision is one that chooses the best available course of action in the face of characteristic uncertainty about the consequences. Although some decisions are straightforward, many are more difficult, either because the stakes are high (e.g., the choice of a mate or deciding between potentially life-saving medical treatments) or because there are difficult trade-offs to make between competing options (e.g., the respective benefits and side effects of a drug). To complicate matters, often our decisions are, in addition, dependent on the possible responses of others, for example when we are deciding whether to ask someone on a date or when entering a business negotiation.

Traditional economic models of decision making, such as the Utility family of theories, propose several aspects of a decision that must be integrated in order to choose the best option. Broadly speaking, these are the subjective values of the potential outcomes that may occur and the likelihood of these outcomes actually occurring. These factors are then weighed to produce a utility for each option, with the alternative with the highest utility chosen. In social decisions, this computation is complicated by the fact that we must also attempt to infer the values and probabilities of our partner or opponent in attempting to reach the optimal decision.

Given that humans live in highly complex social environments, many of our most important decisions are made in the context of these social interactions. This article focuses on research investigating social decision making in two-person interactions, although social decision making often involves considerably more than this. Nevertheless, even in the course of dyadic social interactions, humans are regularly confronted with a wide range of decisions that have far-reaching consequences for the welfare of both the people involved and others. Should I affiliate with or trust this person? Should I compete with or be deferential toward this person? How should I respond to a breach of trust by this person? What is the socially appropriate thing to do in this situation?

An additional reason to focus on the neural basis of decisions in the context of social interactions stems from evolutionary considerations. Primate social behavior is more complex than that of most other mammals because primates form alliances and coalitions that compete with one another. On average, primates also have larger brains for their body size than other mammals. Moreover, relative neocortex size is positively correlated with social group size, a presumed proxy for social complexity, across anthropoid primates. These facts suggest that large primate brains may have evolved in response to social complexity in order to support greater social intelligence that would, in turn, allow an individual primate to successfully negotiate these complexities. If humans represent an extension of this primate trend, then a reasonable claim is that the human brain was designed in some measure to deal with complex social interactions and that our brain's decision-making circuitry probably evolved in part to support these types of decisions.

Finally, a number of psychiatric disorders involve deficits in social decision making. For example, depressed patients often withdraw from social interactions, choosing instead to be alone. Psychopathic individuals often manipulate and objectify others, making it difficult for them to establish stable, long-term bonds. Mania is often accompanied by impulsive and frequently damaging decisions about sexual behavior, shopping, travel, and driving. In addition, several axis II personality disorders involve poor choices within interpersonal relationships. Endeavoring to understand the neural bases of these disorders therefore rests in part on an understanding of the neural bases of social decision making.

Tasks

In a similar fashion to the framework provided by Utility Theory for studying individual decisions, Game Theory offers well-specified models for the investigation of social exchange. However, much of the decision behavior actually observed in these tasks deviates, often quite substantially, from the predictions of the standard game theoretic model, suggesting that psychological and neuroscientific approaches may help our understanding of these decisions and judgments. Recent research has combined these tasks with neuroimaging in an effort to gain a more detailed picture of social decision making. This research probes the neural basis of decision making in the context of social interactions and combines behavioral paradigms from

behavioral economics with a variety of methods from neuroscience.

A class of decisions has been investigated by experimental economics tasks, which, although beguilingly simple, require complex reasoning about the motivations and strategies employed by other players and thus offer a useful window into more complex forms of decision making – decisions that may better approximate many of the choices we make in real life.

One specific focus of these games is reciprocal exchange, exemplified by trust games and closely related Prisoner's Dilemma (PD) games. In the Trust Game (TG), a player (the Investor) must decide how much of an endowment to invest with a partner (the Trustee) in the game. Once transferred, this money is multiplied by some factor (usually tripled or quadrupled), and then the Trustee has the opportunity to return some or all of the amount to the Investor but, significantly, need not return any money if he or she decides against it. If the Trustee honors trust and returns money to the Investor, both players end up with a higher monetary payoff than was originally obtained. However, if the Trustee abuses trust and keeps the entire amount, the Investor ends up with a loss. Because the Investor and Trustee interact only once during the game, Game Theory predicts that a rational and selfish Trustee will never honor the trust given by the Investor. The Investor, realizing this, should never place trust in the first place and so will invest zero in the transaction. Despite these grim theoretical predictions, in most studies of the TG a majority of investors do send some amount of their money to the Trustee.

The well-studied PD game is similar to the trust game, except that both players simultaneously choose whether to trust one another without knowledge of their partner's choice (Figure 1). In the PD game, two players choose to either cooperate with one another or not (i.e., defection) and receive a payoff that depends on the interaction of their two choices. The largest payoff occurs when the player defects and the partner cooperates (DC = \$3). The second largest payoff is for mutual cooperation (CC = \$2), followed by mutual defection (DD = \$1), and finally player cooperation combined with partner defection (CD = \$0). Each outcome corresponds to a different outcome of a social interaction and typically elicits a different set of social emotions. Again, game theoretic predictions are that players will immediately default to mutual defection, but in most iterations of the game, players exhibit much more trust than expected, with mutual cooperation a common finding, at least in early rounds of the game. Mutual cooperation is often associated with friendship, love, trust, or obligation; mutual defection is often associated with feelings of rejection and hatred. Cooperation by one person and defection by the other typically results in the cooperator's feeling anger or indignation and in the defector's feeling anxiety, guilt, or elation from successfully exploiting his or her partner to advantage.

		You	
		Cooperate	Defect
Partner	Cooperate	\$2 (\$2)	\$3 (\$0)
	Defect	\$0 (\$3)	\$1 (\$1)

Figure 1 Payoff matrix used in PD game. The scanned player's choices are the column labels and nonscanned partner's choices are the row labels. Payoff to the scanned player is in black; payoff to the nonscanned partner is in red.

These games are good models for the reciprocal exchange of favors. Given that favors are rarely exchanged simultaneously in real life, the TG at first seems a better model for real-life behavior than the PD; however, the PD choices in round n can also be viewed as a response to the partner's choice in round $n - 1$. Both PD and TG can be played as either single-shot or iterated interactions. In the single-shot versions, cooperative moves by the trustee in the TG, or by either partner in the PD, are unambiguously altruistic insofar as individuals are sacrificing personal gain so that their partner can receive more. In the iterated versions of the games, in which several consecutive rounds are played with the same partner, cooperative choices are not necessarily selfless because consistent cooperation with a reciprocating partner generally yields the player higher cumulative earnings over the long term than does a noncooperative strategy that often settles into the equilibrium outcome of mutual selfishness. Whereas economists have emphasized the importance of these interactions being anonymous in order to eliminate reputation effects that could bias choices, others argue that humans are evolutionarily unprepared for such nonnaturalistic social interactions and that subjects should meet and know the identity of their playing partners. Both anonymous and nonanonymous versions of these games have been studied with neuroimaging.

Bargaining games are another common focus of experimental economics, with the family of Dictator and Ultimatum games often used to examine responses to equality and inequality. In the Dictator Game (DG), one player (the Proposer) decides how much of an endowment to award to the second player (the Responder). Allocations in this game measure pure altruism, in that the Proposer sacrifices personal

gain to share the endowment with his or her partner. The Ultimatum Game (UG) is a variant which examines more strategic thinking in the context of two-player bargaining. In the UG, the Proposer and Repsonder are also asked to divide a sum of money, with the Proposer specifying how this sum should be divided between the two. However, in this case the Responder has the option of accepting or rejecting the offer. If the offer is accepted, the sum is divided as proposed. However, if it is rejected, neither player receives anything. In either event, the game is over; that is, there are no subsequent rounds in which to reach agreement. The decision to reject an unfair offer is considered a form of altruistic punishment because the Responder chooses to receive no money rather than the amount offered by the Proposer, presumably to punish the Proposer for making a miserly offer. If people are motivated purely by self-interest, the Responder should accept any offer and, knowing this, the Proposer should offer the smallest nonzero amount. However, again Game Theory predictions are at odds with observed behavior, and in most industrialized cultures, low offers of less than 20% of the total amount are rejected about half the time. There are some interesting differences in more traditional cultures, but in general the probability of rejection increases substantially as offers decrease from 50% to 0%. Thus, people's choices in the UG do not conform to a model in which decisions are driven by immediate self-interest.

Methods

The neural correlates of decision making in these games have been investigated using a variety of methods. One approach uses functional neuroimaging, namely functional magnetic resonance imaging (fMRI) or positron emission tomography (PET), to image changes in blood flow while subjects are playing interactive games in the MRI or PET scanner. Subjects can view computer-projected visual stimuli from inside the scanner, either via goggles that display the visual stimuli or via a mirror that allows the subject to view a projection screen outside the scanner. Because verbal responses can create motion artifacts, subjects generally indicate choices by pressing specific buttons on a response box. With these imaging methods, it is possible to examine regional blood flow during the decision-making epochs of the task and to link these to specific choices.

Imaging studies of social interactions have emerged relatively recently within cognitive neuroscience. Many early fMRI studies presented subjects with stimuli of other human faces, given the obvious importance of faces in human social interactions. Typically, these stimuli were static, two-dimensional pictures of faces that subjects were instructed to either passively view or judge on some attribute (gender, age, etc.). Using similar types of stimuli, other studies examined face-processing deficits in patients with damage to specific brain regions such as the amygdala or the fusiform gyrus. Still others have attempted to probe social cognition by asking subjects to read stories or view cartoons and then make judgments about these hypothetical scenarios. For example, the neural correlates of both mentalizing and moral reasoning have been probed with this methodology. These studies have yielded valuable insights with respect to the neural underpinnings of human social cognition. However, for each, we can raise questions about the ecological validity of the stimuli. Does the pattern of brain activation in response to static two-dimensional face stimuli accurately reflect the brain's response to the dynamic embodied faces that we encounter in everyday life? Is the pattern of brain activation in response to reasoning about hypothetical fictitious scenarios the same as when grappling with significant real-life social problems? Is mentalizing about the actions of another person the same as making a consequential decision based on these actions?

One approach to improving the ecological validity of experiments in social cognitive neuroscience is to image brain function as subjects actually interact with other people in real social interactions. Recent innovative studies have imaged human subjects while playing both TG and bargaining games with partners communicating from outside the scanner. Potentially even more exciting, hyperscanning technology has been developed that makes it possible to image brain function in two or more interacting partners simultaneously, by using network connections between two separate scanners. Hyperscanning has obvious advantages in terms of data-collection efficiency (i.e., collecting twice as much data in the same amount of time), but will also open new vistas in social cognitive neuroscience. For example, it will allow the imaging of coordinated patterns of brain activity in people who are effectively working together toward a common goal. It could also be used to evaluate simulation theories of empathy, according to which we understand others by reproducing their neural states. Further applications for this method will undoubtedly emerge in the future.

Another approach to investigating the neural correlates of social decision making involves manipulating specific neurotransmitter systems and examining the effect on game-playing behavior. For example, dietary tryptophan depletion can be used to decrease brain serotonin levels, and central oxytocin (OT) levels can be elevated by intranasal self-administration of OT. Still another approach involves the use of transcranial magnetic stimulation (TMS) to temporarily activate

or deactivate a brain region and then examine the effect on a decision-making task. Finally, patients with circumscribed brain damage to particular regions can be tested in these games to see if the damaged brain area has an impact on social decision making.

Findings

Although the methods and tasks outlined here seem to offer exciting prospects for research on social decision making in years to come, the very recent development of this field has meant that the definitive findings revealed thus far are understandably limited. However, studies have outlined a number of tantalizing findings with respect to both brain regions and neurotransmitter systems that appear to be involved in decision making in the context of social interactions.

The Caudate Nucleus

There is good reason to suspect that mesencephalic dopamine projections to the caudate nucleus are involved in decision making in the context of reciprocal exchange (Figure 2(a)). Single-cell recording studies in monkeys demonstrated that midbrain dopamine neurons track reward prediction errors. Unexpected rewards increase the firing rate of midbrain dopamine cells, whereas the omission of expected rewards decreases their firing rate. These reward prediction error signals are hypothesized to play a critical role in learning stimulus–response associations, thereby shaping decision making. Midbrain dopamine cells project to both the ventral and dorsal striatum, including the caudate nucleus, and the activation in the human caudate nucleus is modulated as a function of trial-and-error learning with feedback, suggesting that the caudate nucleus may allow an organism to learn contingencies between its own responses and either rewarding or punishing outcomes. Several neuroimaging studies have demonstrated that the human caudate tracks a social partner's decision to reciprocate or not reciprocate cooperation in the TG or PD. This caudate response is also related to future game decisions. Specifically, reciprocated cooperation activates the caudate nucleus and unreciprocated cooperation deactivates this area, in line with the reward prediction error already described (Figure 3). In addition, caudate activation is associated with increased cooperation in subsequent rounds. These findings suggest that the caudate registers social prediction errors that guide decisions about reciprocity. Interestingly, these prediction error signals from partner feedback

can be blunted or even absent when people instead base their decisions on the prior moral reputations of social partners. That is, moral reputations lead to a discounting of feedback information from social partners, demonstrating both top-down and bottom-up influences on the neural basis of social cooperation. Finally, activation in caudate nucleus is also related to satisfaction with punishing nonreciprocators for their norm violations, even when this punishment involves a financial loss to the subject.

Anterior Insula

Activation within the anterior insula has been observed in response to a variety of negative social interactions, from social exclusion in a virtual ball-tossing task to unreciprocated cooperation in an iterated PD game to receiving an unfair offer in the UG to watching a loved one receive a painful stimulus (Figure 2(b)). The anterior insula is also responsive to physically painful stimuli, and its activity is correlated with skin conductance responses. These results, and others, suggest that the anterior insula is involved in mapping physiological states of the body, including pain, touch, and visceral sensations of autonomic arousal. The right anterior insula, in particular, is thought to be a site of interoceptive awareness that gives rise to subjective feeling states that may play a role in decision making. Finally, recent fMRI data implicate the right anterior insula in aversive conditioning. In the UG, unfair offers that are subsequently rejected have a stronger average anterior insula response than unfair offers that are subsequently accepted (Figure 4), and activation in the anterior insula is related to the degree of unfairness of the offer. In the iterated PD game, individuals with a stronger anterior insula response to unreciprocated cooperation have a higher frequency of defection, suggesting that the anterior insula marks the social interaction as aversive and discourages trusting the nonreciprocating partner in the future. Thus, activation within the anterior insula may be involved in marking negative social interactions as aversive and biasing subsequent social decision making.

Although both the anterior insula and the caudate nucleus are involved in social decision making, both are also involved in nonsocial decision making such avoiding physically noxious stimuli and adaptive foraging, respectively. These neural systems probably initially evolved to support these more fundamental aspects of behavior. When social skills became more crucial with the evolution of primates, these systems may have been exapted for new functions, such as detecting harmful social stimuli and learning when, and to whom, altruism should be dispensed. However, in the process of adapting these old systems to novel demands, they may well have been modified and social pressures may have left their imprint. Indeed, this is the manner in which the evolutionary process typically unfolds. For example, some land mammals such as otters have evolved to fill aquatic niches. But rather than evolving completely novel structures to propel them through water, they modified their feet, the primary function of which is locomotion on land, to make them better suited to also travel through water. The end result is limbs designed for terrestrial locomotion combined with webbed feet designed for aquatic locomotion. That is, the otter limb is adapted to both forms of locomotion. Analogously, human brain systems may be designed for a combination of social and nonsocial functions.

Dorsolateral Prefrontal Cortex

The dorsolateral prefrontal cortex (dlPFC) has long been recognized as critically involved in cognitive control, including cognitive control over emotions (Figure 2(c)). Recent studies suggest its specific involvement in overriding prepotent emotional biases, such as when delaying gratification or making utilitarian decisions in the context of moral dilemmas. The dlPFC is also activated by unfair offers in the UG, which subjects are more likely to accept when dlPFC activation exceeds anterior insula activation (Figure 4(b)). This has led to the hypothesis that UG decisions, and difficult social decisions more generally, often involve competition between emotional processing and higher-level controlled or deliberative processing that bias decision making in opposite ways. Emotional processes are driven by the subcortical, limbic, and paralimbic structures, whereas the deliberative processes rely on the anterior and dorsolateral regions of prefrontal cortex, as well as areas of posterior parietal cortex. Further evidence in support of the a role for the dlPFC in social decision making is provided by studies showing that application of repetitive transcranial magnetic stimulation (rTMS) to the dlPFC influences decision making in the UG. Finally, dlPFC activation is also associated with the choice to defect in the PD game, suggesting that most people may in fact have a prepotent emotional bias to cooperate in the game.

Ventromedial Prefrontal Cortex

Studies of patients who have suffered damage to the ventromedial prefrontal cortex indicate that this brain region is critical for appropriate social decision making. Previously well-adapted individuals who sustain damage to this region become unable to observe social conventions and unable to decide advantageously on matters pertaining to their own lives. Because these patients have generally well-preserved intellectual abilities and knowledge of appropriate social behavior, it has been hypothesized that their deficit lies in an inability to use emotions and feelings to guide social decision making. The result is that they often opt for behaviors that, although yielding immediate rewards, often have larger future negative consequences associated with them. This leads to the obvious but so far untested hypothesis that these patients should be less likely to endure the short-term cost associated with reciprocating altruism and should consequently have trouble sustaining long-term, mutually beneficial social relationships. This hypothesis could be formally evaluated by testing patients in an iterated PD game.

The Oxytocin System

In rodents, the neuropeptides oxytocin (OT) and vasopressin (AVP) facilitate social affiliation, making them attractive candidates for the neural modulation of human social relationships. Accordingly, in a TG, intranasal OT infusion was shown to increase initial monetary transfers by Investors. Recent research suggested that neuropeptides cross the blood–brain barrier after intranasal administration, bypassing the bloodstream, implying that these effects are due to OT's action in the brain. Intranasal OT administration has recently been combined with fMRI to assess the impact of OT on the neural response to fearful/threatening faces and scenes. Compared with

Figure 5 Intranasal oxytocin administration decreases amygdala response to threatening faces and scenes. Reproduced from Kirsch P, Esslinger C, Chen Q, et al. (2005) Oxytocin modulates neural circuitry for social cognition and fear in humans. *Journal of Neuroscience* 25: 11489–11493.

a placebo, OT decreased the activation in the amygdala for both types of fearful stimuli (Figure 5). These results are consistent with evidence that OT reduces stress and anxiety and are also consistent with the abundance of OT receptors in the rodent amygdala, although OT receptors have not yet been found in the human amygdala. This study suggests one potential mechanism by which OT could increase trust – by reducing anxiety about potential nonreciprocation. Another possibility suggested by animal experiments is that OT release in the nucleus accumbens renders social interactions more rewarding.

The Serotonin System

Serotonin plays a significant role in modulating prosocial behavior. Peripheral and central indices of serotonin function show negative associations with violent and aggressive behavior, but positive associations with socially affiliative behavior (such as grooming and approach) in primate models. Pharmacological interventions that increase serotonergic activity also facilitate affiliative behavior. These results suggest the possibility that serotonin levels could influence decision making in the context of social interactions. Indeed, depleting subjects of tryptophan, the amino acid precursor of serotonin, is associated with reduced rates of cooperation in the PD game. Given that serotonin is known to modulate dopamine reward pathways, these effects could be mediated by serotonin withdrawal's attenuating the rewarding and reinforcing effects of cooperation.

Conclusion

In summary, the neuroeconomics approach to social decision making has already yielded some interesting findings and hypotheses, and the combination of neuroscientific, economic, and psychological methods and tasks seems sure to uncover much more about the social brain in the coming years.

Social Interaction Effects on Reward and Cognitive Abilities in Monkeys

Introduction

When given a choice between receiving $100 in 30 days and $110 in 31 days, most people wait for the larger, more delayed reward. However, when the choice is between $100 today and $110 tomorrow, many people shift their preferences to the smaller, immediate reward despite the same difference of $10 and 1 day. Reward properties – such as time to receipt – play a crucial role in our processing of rewards. However, reward processing does not only occur for individual decisions but also for social interactions; we must decide whether to cooperate or compete with others for rewards. Humans stand out in the animal kingdom as exceptional cooperators, both in terms of the form that cooperation assumes as well as the nature of rewards attained. Regarding form, we are unique in the stability of our reciprocal interactions and in the scale of our cooperative coalitions, entailing multiple nation states in times of war. In terms of rewards, we are of course motivated, like all other animals, by the central survival payoffs such as food and water but also by abstract entities such as money, the promise of future support, and positions of power such as a king, president, or head of an academic department. To maintain these complicated interactions and evaluate the nature of reward, we must possess a number of prerequisite cognitive abilities. Here, we view this problem through the lens of evolutionary biology, asking which aspects of our cognitive machinery, and the social interactions it supports, are uniquely human and which are shared with other primates. Though we focus on lemurs, monkeys, and apes, we acknowledge that many of the processes we document are unlikely to be restricted to the primates, and, in many cases, there is already comparable evidence from other mammals and birds. We begin by reviewing a suite of cognitive mechanisms that are involved in both human and nonhuman primate reward processing. This article is particularly focused on the subset of situations with quantifiable rewards. We then describe the kinds of social interactions that are part and parcel of primate life, especially the highly social monkeys and apes. Finally, we merge these two sections and consider how constraints on primate cognition may limit the complexity of primate social interactions.

Primate Cognition

To set up the problem of reward processing in animals, we can distinguish between asocial, individually based processes and social ones. The primary difference is whether access to rewards entails competitive or cooperative social interactions or instead can be achieved by an individual on its own. Some processes operate across asocial and social contexts. For example, an individual seeking food as a reward must discriminate between food and nonfood objects, quantify the amount of food available and its relative value, recall where food is located in the environment as well as the timing of its seasonal availability, and inhibit the temptation to take a small, immediately available reward over a larger, more valuable but delayed reward. Social interactions add a layer of complexity to these processes, raising questions about the extent to which individuals can generate expectations about what others want and intend, their competitive abilities, and the value of a coalitionary partner.

Primates are an ideal group in which to study the comparative cognition of reward processing because they are phylogenetically closely related to humans and because primate species vary in their life histories, mating systems, and foraging ecologies. Thus, we can not only explore how these different socioecological parameters uniquely shape each species' capacity for reward processing but also explore the extent to which there are more general, derived mechanisms, having evolved before humans diverged from their phylogenetic ancestors.

Properties of Rewards

For folivorous, frugivorous, and omnivorous primates, individuals must distinguish between edible and inedible items, especially given the possibility of ingesting potentially toxic items. For many animals, recognition of edible foods entails using chemical cues, color patterns, textures, and shapes. And in some cases, these cues or features are detected in the context of social interactions. For example, in a study of rhesus macaques (*Macaca mulatta*), an experimenter ate one of two novel food items while a subject watched. The experimenter then placed new copies of each these food items on the ground and

allowed the subject to approach and select one. Consistently, subjects picked the food item eaten by the experimenter. To assess which features mediated response selection, a set of follow-up conditions put different features into competition, using artificially created foods. For example, in one condition, the experimenter ate an orange sphere while holding a blue cube and then presented a blue sphere and an orange cube. Subjects consistently picked the orange cube, showing that in the context of a social foraging problem, rhesus macaques use color over shape to identify valuable food.

Number

To reliably process rewards, animals must be able to quantify reward amounts, either using number or some continuous dimension of amount such as volume. There are at least two naturally occurring situations in which number would appear to matter for primates: aggressive competition between groups and foraging for food. In black howler monkeys (*Alouatta pigra*) and chimpanzees (*Pan troglodytes*), individuals attend to the number of competitors. Playback experiments demonstrate that a group of males is more likely to approach foreign males if the numerical odds are in their favor. Additionally, in many primate species, two or three individuals will form coalitions to defeat either a single dominant individual or a smaller coalition. Although these coalitions involve small numbers, they nonetheless require some capacity to quantify the number of competitors to acquire rewards such as mates or foraging areas.

Studies of foraging in animals show that individuals often maximize the rate of energetic returns, choosing patches with more over less food. Since estimates of rates of return depend on quantifying amount of food consumed over time, researchers have asked whether animals count the pieces, estimate the volume, or time the foraging periods in a patch. For instance, when given the choice between two different amounts of apple slices, rhesus macaques consistently picked two apples over one, three apples over two, and four apples over three. But when presented with five versus four apple pieces, some animals picked four and some five. Without training, rhesus monkeys can quantify the number of pieces of food up to about four but thereafter appear to rely on a general estimate of amount.

Based on an overwhelming number of carefully controlled experiments, it is now fair to say that animals have a number sense that likely consists of two naturally available systems. One system allows animals to quantify individuals up to about four with precision; the second allows them to approximate number but without any limits on magnitude. In the precise system, as evidenced by the rhesus macaque example, primates are limited to representing four items simultaneously in short-term memory. Human infants and adults demonstrate a similar limit in a variety of tasks, suggesting continuity across development and across species. In the approximate system, primates can discriminate between approximate quantities using analog magnitudes, in which performance is limited by the ratio between the quantities and is independent of absolute value. Other work on operantly trained rhesus macaques demonstrates that ratio determines numerical discrimination between quantities ranging from 1 to 30 items. Ratio is important because it suggests that primate numerical competence conforms to Weber's law, a psychophysical process in which the accuracy of discriminating different quantities scales with the magnitude of the quantities. Again, human infants and adults also represent large approximate numbers and show similar signature ratio limits.

Timing

Predicting the timing of reward availability is a critical capacity for primates. In many species, crucial elements of the diet are only seasonally available, requiring both timing and planning. For example, when chimpanzees discover a source of ripe palm nuts, they not only invest in the processing of these nuts with stone hammers and anvils, but often leave behind particularly good hammers, retrieving them on future visits. Studies conducted with captive apes reveal that they can recall the kinds of tools needed for certain tasks, and retrieve them in the service of planning for future tasks. Based on their patterns of movement, it is also clear that many primates store information about fruiting cycles, enabling them to time the optimum period of visitation and harvesting.

Like number, the capacity to time events is based on a mechanism that, both behaviorally and neurobiologically, shows the signature of the analog magnitude system that underlies number. Importantly, timing exhibits the scalar property of Weber's law: the variance of timing accuracy scales with interval magnitude and is therefore a function of the ratio between magnitudes. For instance, rhesus macaques showed similar accuracy levels between timing events with a 1:1.5 ratio, regardless of whether the discrimination was 4 versus 6 s, 6 versus 9 s, 8 versus 12 s, or 10 versus 15 s. Unfortunately, little work has explored primate timing abilities beyond a few seconds, with the exception of periodic timing of circadian cycles. Moreover, the work is largely restricted to studies involving operant training, with no work on the relationship between timing and the role of social or ecological contexts.

Impulsivity

Animals must often combine quantity and temporal information to choose between rewards available over different time intervals (intertemporal choice). For example, imagine a monkey encounters a tree full of unripe fruit but with only a few ripe fruit available: should it spend the time and energy to consume the few ripe fruit now or wait for the rest to ripen? Waiting would yield a higher reward amount, but the future is uncertain – another monkey may eat the fruit in the meantime, winds may knock them into a stream below, or a fungus may infest and spoil the perfectly good fruit. This uncertainty may have provided a strong adaptive benefit for impulsivity.

Decision makers can make intertemporal choices by means of at least two mechanisms. The first mechanism simply assumes that the forager maximizes its food intake rate over repeated foraging bouts. This rate maximization account predicts that foragers should maximize the total energy gained from rewards over the total time spent acquiring and processing the rewards. Evidence from operant experiments suggests that cotton-top tamarins (*Saguinus oedipus*) and common marmosets (*Callithrix jacchus*) may use rate maximization strategies when trading off future benefits. Temporal discounting represents the second mechanism and involves the subjective devaluation of future rewards. If animals discount the future (as the example in the introduction implied), delayed rewards are less valuable than immediate rewards, potentially resulting in impulsive choice. In experiments that estimate discounting levels, subjects are presented with two stimuli: one associated with a small, immediate reward and the other with a large, delayed reward. The discounting level is 'titrated' by incrementally increasing the delay-to-large until subjects are indifferent between choosing the large, delayed reward and the small, immediate reward. Therefore, researchers can find indifference points between immediate and delayed rewards over a range of small and large reward amounts. Psychologists have extensively studied discounting in rats and pigeons, but fewer studies have investigated primate discounting. Surprisingly, the handful of primate discounting studies that have been conducted demonstrate that cotton-top tamarins, common marmosets, brown capuchin monkeys (*Cebus apella*), and rhesus macaques show similar impulsivity levels to rats and pigeons.

The high levels of discounting observed for most nonhuman animals suggests that when rewards are distributed over time, individuals place a premium on immediacy, forgoing delayed rewards. This not only puts severe constraints on the foraging strategies of monkeys and apes, but constrains other behaviors such as cooperation, territory defense, and mate selection.

Inhibitory Control

Inhibiting prepotent responses to reward is a difficult task for nonhuman animals. Clearly, natural selection has favored a strong drive to obtain the largest reward available. This is evidenced by the performance of a number of primate species on the reversed-contingency task in which subjects must reach toward the smaller of two visible rewards to receive the larger reward. Brown and black lemurs (*Eulemur fulvus* and *Eulemur macaco*), tamarins, squirrel monkeys (*Saimiri sciureus*), rhesus macaques, orangutans (*Pongo pygmaeus*), gorillas (*Gorilla gorilla*), bonobos, and chimpanzees all invariably choose the large reward, only to receive the small reward – they seem incapable of controlling their desire to reach for the larger reward amount.

The reversed-contingency task has proven difficult for primates to solve but not impossible. A number of techniques can circumvent the inhibitory control problem. First, sheer repetition can allow subjects to choose the smaller and receive the larger food reward. Most subjects do not solve the task after 200 trials, though some are at chance rather than repeatedly choosing the smaller amount. After 400–2500 trials, however, six rhesus macaques received the larger reward in over 90% of trials. Thus, massive exposure to the reversed contingencies can eventually trump the inhibitory problems. Second, imposing costs for 'incorrect' choice can facilitate receiving the larger reward. By withholding all food when subjects pick the larger quantity, macaques and squirrel monkeys eventually learn to pick the smaller quantity; tamarins stick with the losing strategy, picking the larger and getting nothing at all. This suggests that part of the failure to point to the smaller quantity is due to the lack of costs associated with pointing to the larger quantity. Finally, including a mediator between seeing the food and receiving the food can curb the impulse to choose the larger reward amount. This has been most noticeably documented by an experiment testing chimpanzees trained on the Arabic number symbols from 1 to 6. Instead of choosing between one food treat versus four treats, the chimpanzees chose between a card with the numeral 1 written on its face and a card with the numeral 4; each card covered up the corresponding number of food treats. The chimpanzees quickly learned to pick the number 1 card and received four treats, indicating chimpanzees can learn a rule like "Point to the one you don't want to get the one you want." Surprisingly, once they learned

this rule with symbols, they were incapable of generalizing to the same problem with food presented on its own. Therefore, it seems as though the difficulty of this task results from the chimpanzees' strong motivation to reach for food rather than an inability to learn the reverse-contingency rule.

Memory

Memory is a multifaceted cognitive ability with clear evolutionary importance. Researchers have delineated several different types of memory that are applied to different types of information. Here we will focus on three types of memory – short-term, spatial, and episodic memory. One of the simplest tasks used to test short-term memory is the delayed-response task. In this task, a reward is placed under one of two (or more) identical but spatially separated stimuli. After a retention interval, subjects are allowed to chose one of the stimuli and receive the rewards if correct. Comparative data show that rhesus macaques are fairly good at remembering the location of the food item. They begin with about 80% accuracy after only a few seconds and drop to about 68% accuracy after a 15 s retention interval. Marmosets, however, though also starting at 80% accuracy, drop to 58% accuracy at 15 s, only slightly better than chance. Though some evidence suggests that the Old World monkeys may retain information better than the New World monkeys, this is by no means a universal, with capuchin monkeys being a notable exception to the rule.

Spatial memory plays an important role in primate reward acquisition. Recalling when and where food rewards are distributed is critical in foraging situations. In fact, some have suggested that foraging problems have posed strong evolutionary pressures on primate cognition, with species that feed on spatially and temporally variable foods showing higher levels of brain encephalization than species that feed on more stable food sources. Numerous studies have demonstrated strong spatial skills in primates, particularly in analogs to the radial arm maze. In this task, feeder stations placed throughout an enclosure are baited before subjects enter. After a subject finds all of the stations, researchers bait only some of the stations and, following a retention interval, record whether the subjects first attempt to feed at the previously baited stations. Most of the experiments on primates show high accuracy over retention intervals as long as 24 h. As predicted by the adaptive specialization hypothesis, species that search over longer distances for food in the wild tend to be more accurate at longer retention intervals (e.g., frugivorous golden lion tamarins (*Leontopithecus rosalia*) are more accurate than gummivorous Wied's marmosets (*Callithrix kulhi*)). Additionally, the contingency between space and reward plays an important role. Common marmosets, for instance, are more accurate in a win-stay paradigm in which previous food locations predict current locations than in a win-shift paradigm in which subjects are not rewarded for visiting previously visited food stations.

Probably one of the most interesting and controversial areas of primate memory is episodic memory. There is a feisty debate in the literature about whether nonhuman animals have the ability to mentally travel in time to recall previous experiences. The benchmark requirements for demonstrating episodic memory include showing that animals know 'what,' 'where,' and 'when' an experience occurred. Though this is difficult to study in nonlinguistic creatures, recent research provides suggestive evidence of episodic-like memory in corvids and primates. For example, up to 24 h after receiving a particular food item from an experimenter, a gorilla correctly identified the food type received and the experimenter from whom it was received.

Theory of Mind

Another highly contentious area of primate cognition is theory of mind. As mentioned earlier, this aspect of primate cognition is not strictly about reward. Yet, the capacity to make inferences about what others know, desire, believe, and intend often leads directly to cooperative and competitive rewards, and most of the experimental studies use food as a motivator to explore these mental states.

Early studies failed to find evidence of theory of mind in primates. One explanation for these failures was that the studies relied on animals making inferences about human mental states in contexts involving cooperation, as opposed to asking animals to make inferences about each other in the context of competition. Though several primate species do cooperate (see below), competition is far more common and may represent the most basic form of social interaction among animals. To test this hypothesis, recent studies of monkeys and apes have used both competitive and cooperative tasks, contrasting conspecific pairings as well as conspecific–heterospecific pairings. There is increasing evidence that monkeys and apes make inferences from seeing to knowing. Chimpanzees, for instance, can take the visual perspective of other individuals to understand whether they can see occluded food rewards: subordinate chimpanzees preferentially approach rewards that are obscured from the view of dominant individuals. Rhesus monkeys show similar abilities, stealing food primarily

from experimenters without visual access to the food rather than from those that do have access. Though visual perspective taking is only one component of having a theory of mind, it plays a significant role in the competitive and cooperative interactions of primates. What remains to be explored is whether primates go beyond this elemental capacity, attributing intentions, desires, and beliefs to others.

Primate Social Interactions

In socially living animals, such as some of the lemurs and most monkeys and apes, obtaining rewards is often coupled with socially competitive or cooperative interactions. In some instances, helping another individual yields payoffs for the helper, while in other cases, helping is costly for the helper. The existence of the latter poses a puzzle given the generally accepted Darwinian assumption that behavior evolves via natural selection to provide fitness benefits to the individual. Specifically, what selective pressure has favored individuals who provide benefits to other individuals?

Here, we address the evolution of cooperation by describing four different models (mutualism, kin selection, reciprocity, and punishment), focusing on evidence from monkeys and apes. We operationally define cooperation as social interactions resulting in a net benefit for all participants; here, benefit is measured in terms of increasing reproductive success.

Mutualism

The simplest type of cooperative behavior provides direct benefits to the cooperator, in addition to other individuals. Therefore, benefits to others are by-products of benefits to self. This model of cooperative behavior is termed by-product mutualism. Any individual that defects (does not cooperate) in mutualistic situations will, by definition, do worse than a cooperator; therefore, in the absence of a temptation to defect, cooperation provides the best option. Importantly, mutualism does not depend on the identity of one's partner and thus can occur between any members of the same species and even members of different species.

Mutualism is a common form of cooperation, with cooperative hunting providing a prime example. When multiple individuals cooperate to hunt the same prey, they can both increase the probability of successful prey capture and reduce the individual costs associated with hunting. Cooperative hunting provides mutualistic benefits only when the per capita intake rate increases with group size. Therefore, a pair of hunters would have to capture more than twice as many prey items as a solitary hunter. This typically requires the success rate of solitary hunters to be fairly low, making cooperation particularly successful. Increased success combined with lower hunting costs can lead to direct, immediate, and simultaneous fitness benefits for cooperative hunters, particularly when hunting small or difficult prey. For example, wild chimpanzees often cooperatively hunt arboreal monkeys. Although different populations vary, there is evidence that in some populations the per capita intake rate increases with group size, suggesting that the hunting is cooperative. Cheaters that do not hunt are discouraged by receiving only small amounts of meat in food-sharing bouts following a kill. Thus, it is in an individual's best interest to participate in a hunt to acquire the much-sought-after meat.

In the laboratory, mutualism has been documented in a variety of primates, including marmosets, capuchin monkeys, and chimpanzees. Typically, when joint action is required to receive separate benefits for each player, subjects succeed in cooperating. However, when food is monopolizable instead of divided between players, cooperation breaks down. That is, when immediate rewards are available, primates cooperate. But once competition reduces the probability of reward, there is no guarantee of immediate benefit and no apparent mechanism capable of maintaining cooperation. In a recent study of captive chimpanzees, individuals confronted an opportunity to manipulate an apparatus for a food reward; on some trials, the focal subject had to recruit the help of another individual in order to manipulate the apparatus and on other trials, the focal could operate the apparatus alone. Subjects only recruited help when two individuals were required to obtain the food reward. Moreover, in a second experiment, subjects selectively recruited effective helpers over ineffective helpers, demonstrating a keen knowledge of the role of others in the mutualistic acquisition of rewards.

Kin Selection

Whereas mutualism poses no problem for classic Darwinian theory, altruistic cooperation does as the actor incurs a cost while benefiting another. Kin selection provided the first clear theoretical solution to the paradox of altruism. Individuals may bias cooperation toward their genetic relatives because it helps propagate their own genes shared by common descent. What looks altruistic from an individual's perspective actually serves self-interest from the gene's view. Individuals have a certain probability of sharing a gene (r, the coefficient of relatedness) with

relatives due to common descent. If the benefits to kin discounted by this coefficient of relatedness outweigh the costs of helping, altruism toward kin can evolve.

Kin selection may be particularly powerful in primates because of the close-knit family groups found in many species. With a few notable exceptions, including chimpanzees, nonhuman primates follow the general mammalian pattern of philopatry in which males leave their natal groups upon reaching reproductive maturity whereas females stay in their natal groups for life; consequently, most primate groups consist of closely related female kin and genetically unrelated males. Kin selection theory predicts that individuals should preferentially help relatives and should help in proportion to their coefficient of relatedness. These types of quantitative predictions have proven difficult to test in primates, but there are data showing kin-directed helping, particularly in coalition formation and food sharing.

Primates frequently form coalitions in which multiple individuals form an alliance in agonistic interactions with other group members. This is particularly prevalent in primate species with matrilineal dominance hierarchies, such as macaques and baboons. In these species, females often assist relatives in aggressive encounters with other group members. Notably, the probability of coalitionary support tapers off with increasingly distantly related kin – mothers almost always aid offspring but are less likely to aid nieces and nephews. Therefore, as relatedness increases, these primates are more likely to pay costs associated with helping kin. Additionally, individuals are more likely to form coalitions with kin than nonkin against higher-ranking opponents, suggesting that they will pay a higher cost of helping related individuals. Male primates can also form coalitions, often to guard or acquire sexually receptive females. In situations in which few mating opportunities exist for males, these kin-based coalitions are especially relevant because aiding kin helps ensure the propagation of one's genes, even in the absence of direct mating opportunities. This is the case in red howler monkeys (*Alouatta seniculus*), where coalitions of related individuals have longer tenure in a troop (and therefore more mating opportunities) than unrelated individuals. Though many instances of coalitionary support are directed to kin, some are directed to nonkin and may be attributable to other benefits such as mutualism and reciprocity.

One of the most often-reported examples of apparent altruism is food sharing – voluntarily allowing another to consume food that one individual possesses. Food sharing is, of course, very common between mother and offspring for numerous primate species. However, it also occurs between grandparents and grandoffspring, siblings, and even adult relatives, often scaling with relatedness. In captive macaques, for instance, mother–daughter pairs ($r = 0.5$) frequently fed from the same food bin. Both grandmother–granddaughter pairs and sister–sister pairs ($r = 0.25$) co-fed at intermediate rates, and aunt–niece pairs ($r = 0.125$) co-fed at low levels indistinguishable from unrelated pairs. Though it is unclear what proportion of food transfers occurs between relatives, kin-based sharing likely explains the bulk of sharing in numerous species.

Reciprocity

Reciprocity occurs when an individual pays a short-term cost of cooperation for the future benefit of a social partner's reciprocated cooperation. As a form of altruistic cooperation, reciprocity aims to explain cooperative behavior among genetically unrelated individuals (thereby eliminating kin selection as an explanation) often using a unique type of social interaction termed the prisoner's dilemma. The keys aspects of the prisoner's dilemma are (1) cooperation maximizes the total payoff to everyone involved in the interaction (mutual cooperation provides more benefits than mutual defection); however, (2) any individual will receive a higher personal payoff by defecting, so a sizable temptation to cheat exists. Pursuing unilateral cooperation in this game is not a stable strategy.

Theoreticians suggested that reversing roles as donor and recipient of altruism may reduce the temptation to defect because it largely commits individuals to invest in future cooperation. When the fitness payoffs sum over a series of interactions with the same partner, reciprocal strategists can reap the benefits of mutual cooperation. The reciprocal strategy tit-for-tat, in which a player starts out cooperating and copies its opponent's behavior in previous interactions, can successfully dominate simulated populations of social partners engaging in prisoner's dilemma games, winning out over many alternative behavioral strategies. If the probability of interacting again exceeds a critical level, a reciprocal strategy can maintain cooperation.

Many authors have reported examples of reciprocity in animals, including primates, spanning such contexts as food sharing, grooming, and coalitions associated with mating opportunities. Unfortunately, in most cases these purported examples of reciprocity have either never been replicated or have been challenged by alternative explanations for the patterns of interaction, including especially kin selection and mutualism. Another alternative explanation, symmetry-based reciprocity, occurs when the reciprocal pattern can be explained by the symmetrical relationship between individuals. For instance, if individuals A and B interact frequently and cooperate, their behavior will appear to be reciprocal even though it is based on symmetrical interactions rather than contingent

cooperation. This contrasts with calculated reciprocity (such as tit-for-tat) in which individuals track debts owed and favors given when deciding whether to cooperate.

A field study of olive baboons (*Papio anubis*) provided one of the first reports of reciprocity. Males formed coalitions in order to drive off rival males and gain access to reproductively active females. Data suggested that males took turns reaping the benefits, implying evidence of reciprocity. The robustness of this finding, however, is unclear, given that a subsequent study of a different population of baboons did not find the same reciprocal patterns, and a study of a closely related species proposed an alternative, mutualistic explanation.

Another example comes from experimental tests of food sharing in captive capuchin monkeys. When pairs of capuchins were placed in adjacent chambers separated by a mesh partition, if individual A allowed individual B to consume dropped scraps of food in one particular trial, then B tended to allow A to gather scraps in the next trial. Because the food transfer is primarily passive and costs may be minimal, these results can be explained by a mutual tolerance between individuals. Therefore, the capuchins do not appear to be assessing the costs and benefits of their actions, making calculated reciprocity an unlikely explanation of capuchin food transfers.

Finally, in a series of experiments with captive cotton-top tamarins, subjects could pull a tool to give food to an unrelated recipient without getting any food for self. Tamarins pulled the tool most often for partners that always pulled and infrequently for partners that never pulled. The frequency of cooperation was, however, less than 50%, and as each game progressed, the amount of food given dropped. Tamarins, therefore, maintained moderate levels of cooperation with other cooperators, but the degradation of cooperation over time suggests an unstable system; in fact, game theoretic modeling of the data suggest that reciprocity crashes if an opponent fails to cooperate on two consecutive opportunities.

In summary, there are few examples of true, calculated reciprocity among monkeys and apes. Most putative examples can be explained by symmetry-based reciprocity, mutualism, or kin selection. Given the simplicity of the preconditions for reciprocity and the apparent ubiquity of reciprocity in humans, its rarity in primates (and other animals) is surprising. We take up this issue in the section on cognitive constraints on reward processing.

Punishment

Punishing individuals that defect can potentially impose enough costs to offset the temptation to cheat, and, like reciprocity, can elicit future cooperation. Punishment involves energetic costs, and, when accomplished by means of aggression, also involves the costs of risked injury. Consequently, as an adaptive behavior, punishment is a selfish strategy, favoring actions that ultimately benefit the punisher by eliciting cooperative behavior from the recipient of punishment. As defined, punishment resembles reciprocity, which should occur when it elicits cooperative behavior directed strictly at the reciprocator. Despite the theoretical interest, punishment is not well documented in animals; in fact, though animals act aggressively toward others in the context of resource defense (e.g., territoriality, dominance interactions), there are few examples in the context of cooperation.

Whereas punishment penalizes past behavior with the hope of future reward, a similar behavior called harassment penalizes present behavior to elicit immediate reward. Harassment occurs when an individual imposes costs such as aggression on another to induce immediate cooperation, thereby providing instant benefits to the harasser. Harassment may also influence future as well as current cooperation, suggesting that it can lead to punishment strategies. For instance, if a defector is in the process of consuming an entire food resource, a harasser could impose costs on the defector aimed at obtaining some portion of the food resource immediately. Whereas punishment appears relatively rare among animals, harassment may be more common. For instance, after capturing prey, chimpanzees frequently allow other individuals to consume part of the meat. Observational work has demonstrated that harassment best accounts for the pattern of food sharing, taking the form of individuals incessantly begging for food with hand gestures, grabbing at the food, and placing their hands over the mouths of the food possessors. In this context, harassment was costly for the food owner (food intake rate decreased as the number of beggars increased), owners shared more often when beggars harassed frequently and intensely, and when sharing occurred harassment levels decreased. Controlled experiments corroborated these findings with captive chimpanzees, as well as squirrel monkeys (*Saimiri boliviensis*), a species that rarely cooperates.

Harassment may, of course, influence future as well as current cooperation, suggesting that it may lead to punishment strategies. One example comes from rhesus macaques. When individuals find food, they often give food calls, an altruistic act that recruits others to the food source, thereby potentially benefiting kin. However, individuals sometimes find food and suppress their calls. If no one detects these silent discoverers, they reap more food rewards than those who announce their discoveries. If, in contrast, they are detected, then they are aggressively attacked, leading to an even larger loss of food to the attacker. Thus,

aggression yields an immediate benefit of accessing food for the attacker, clearly qualifying it as a case of harassment. In addition, the aggression may have a punishing effect on silence by eliciting future food calls. That is, aggressive behavior influences both immediate and future benefits.

The Cognitive Psychology of a Cooperator

Many researchers have argued that the frequency of complex social interactions in primates underlies the evolution of their cognitive abilities. Negotiating a complicated network of allies and enemies, dominants and subordinates, and mates and competitors has created selective pressure for cognitive abilities such as transitive inference, theory of mind, and deception. Though this connection between sociality and cognition has been well recognized, the cognitive constraints on social interaction have often been ignored. Put simply, much of the work on primate cognition has focused on how large brains enable rich social interactions instead of how limited cognitive abilities may constrain the range of social interactions. Here, we take up this 'cognitive constraints' perspective.

Mutualism and kin selection are both theoretically well-understood and empirically well-documented models of cooperation. By contrast, reciprocity and punishment, while theoretically feasible, are rare among primates (although harassment may be more widespread). Therefore, despite models purporting the evolutionary stability of all of these types of cooperation, some types occur much more frequently than others. Unfortunately, a strictly adaptive perspective has limited power to explain the frequency of mutualism and kin-biased cooperation and the rarity of reciprocity and punishment. A proximate perspective that links with the ultimate problem can, however, reveal how cognitive constraints limit or facilitate particular forms of cooperation.

The proximate approach emphasizes critical aspects of reciprocity and punishment that differ markedly from mutualism and kin-biased cooperation. In both reciprocity and punishment, the fitness benefits associated with cooperation depend on the partner's behavior: cooperation should only occur when the partner responds by reciprocating or punishing. When this contingent response occurs in the future, the temporal delay introduces cognitive challenges that may constrain the emergence and stability of cooperation. Animals can easily implement strategies that yield immediate benefits, such as mutualism and harassment, because individuals do not have to track benefits over time. With a time delay between cooperating and receiving return benefits, however, individuals must invest in an uncertain future. Delayed benefits impede learning the consequences of cooperation, place greater demands on the capacity to recall previous interactions, and trade off short-term fitness gains for long-term gains. Here we highlight how several key cognitive constraints play a role in mutualism, kin-biased cooperation, reciprocity, and punishment, thereby uniting the two sections of this essay.

Cognitive Constraints on Mutualism and Kin-Biased Cooperation

Because no temptation to cheat exists in mutualistic interactions, individuals should always cooperate. As a result, mutualism requires no special cognitive abilities above and beyond the challenges inherent in the cooperative behavior itself. Kin-biased cooperation does, however, require additional cognitive capacities. At a minimum, it requires the capacity to direct cooperative actions to related individuals.

Mechanisms of kin recognition include recognition alleles, phenotype matching, and spatial and familiarity cues. The recognition allele hypothesis predicts that individuals can compare a particular phenotypic cue (auditory, olfactory, visual, etc.) to an innately specified template. Such a model requires few cognitive skills other than discriminating the cue associated with relatedness. The closely related phenomenon of phenotypic matching occurs when an individual compares a conspecific's phenotypic cues to a learned template. This requires specialized perceptual and computational systems that detect cues at an early stage to form a template, then test cues against the template to discriminate kin. Though recognition alleles and phenotypic matching provide the most direct forms of kin recognition and have been observed in some animal species, they do not appear to be common mechanisms of primate kin recognition. Instead, primates seem to use a simple set of rules such as spatial and familiarity cues to discriminate kin. Often primates may use rules such as 'be nice to individuals near your home' or 'help those that you grew up with' to direct the benefits of cooperation toward kin. These familiarity mechanisms require little in the way of cognitive abilities, building on general laws of learning by association, and seem to be widespread throughout the primates.

Cognitive Constraints on Reciprocity and Punishment

The original formulation of reciprocity had three requirements for evolutionary stability: (1) the reciprocated benefit must outweigh the immediate cost, (2) individuals must interact repeatedly, and (3) individuals must recognize each other. These requirements, however, most likely underestimate what is cognitively necessary for both developing

and maintaining a system of stable reciprocity. In particular, the delay between the cost of a cooperative act and the benefit of reciprocated cooperation introduces a number of cognitive challenges. Like reciprocity, punishment can involve a delay between a costly act and a beneficial payoff, and in these cases it faces similar constraints. For this reason, we consider the constraints on reciprocity and punishment together, pointing to differences where appropriate.

Individual recognition Like kin selection, reciprocity and punishment require directing cooperation to others. Unlike kin selection, however, where altruistic acts are disseminated simply as a function of coefficients of genetic relatedness, reciprocity and punishment require targeting specific individuals. Therefore, the delayed, contingent response required for both reciprocity and punishment necessitates that individuals can distinguish different partners. Mechanisms for individual recognition appear to be the norm among animals, including lemurs, monkeys, and apes. Consequently, the paucity of evidence for reciprocity and punishment across primates cannot appeal to individual recognition as a constraint.

Number, amount, and time Numerical abilities can play a key role in reciprocity when individuals must precisely quantify the reward amounts being reciprocated. When primates engage in a bout of reciprocity, they will either be limited to small numbers of objects in cases where the exchange must be precise (a banana for a banana), or they will be freed from this constraint where approximate exchanges are tolerated. The same prediction holds for cases where the currency is time, such as the duration of a grooming bout. If one monkey grooms another for 10 min, the groomer will most likely accept as fair exchange a reciprocated grooming bout of 8–12 min. As reward quantity and time magnitudes increase, quantification accuracy decreases, making equitable exchange more difficult and leaving opportunities for cheaters to exploit the judgment errors. This constraint only applies when variance exists in the quantity and time magnitudes. If the exchange is always a banana for a banana, these quantification abilities are superfluous.

Inhibitory control and impulsivity Reciprocity is itself an inhibitory and impulsivity problem: can an individual inhibit the choice of the immediate large benefit to gain the delayed larger benefit? Like the reversed-contingency task, the chooser must first reach for the undesirable over the desirable reward. The first move can be likened to giving away food. By avoiding the temptation of the larger immediate reward, the first move is costly to self. As data on the reversed-contingency task in primates show, the cost often appears too great and the inhibitory system too weak.

The second move, waiting for the reciprocated benefit, is analogous to the intertemporal choices described earlier. Individuals must choose between the immediate reward of defecting and the long-term reward of cooperating. Indeed, a number of researchers have predicted that impulsivity can reduce the value of reciprocated benefits. Experimental data on variation in human impulsivity and cooperation validate the view that a preference for immediate rewards may inhibit reciprocity. Impulsivity correlates with cooperation such that individuals who prefer immediate gains also cooperate less frequently. In parallel, blue jays (*Cyanocitta cristata*) show stable cooperation in a prisoner's dilemma, only following an experimental reduction in their preference for immediacy. Although primates have not been tested in both impulsivity and cooperation tasks, it seems highly probable that a significant constraint on their capacity for reciprocity emerges from their steep discounting functions. Similar abilities are required for punishment: punishers must pay an immediate cost of punishing to achieve a future, discounted reward.

Memory Episodic memory may very well be required to implement reciprocity. Because individuals must track the actions ('what') of previous partners ('who') the last time that they interacted ('when'), fairly sophisticated memory systems may be required for reciprocity. Even if episodic memory itself is not required, limitations in memory decay, interference, and capacity can also constrain the frequency of reciprocity and punishment. Memory decay proceeds rapidly over time; therefore, longer time intervals between cooperative acts may make reciprocity and punishment more difficult. Even with short time delays between cooperative interactions and few distractions, every potential new partner increases the computational load of tracking debts owed, favors given, and costs imposed. Keeping score of reciprocal obligations and punishment with the extensive social network found in many primate species may place a computationally intensive burden on memory systems. Although few studies examine learning and memory constraints in primate cooperation, studies of human cooperation suggest that these constraints can pose challenges for maintaining stable cooperative relationships.

Theory of mind Understanding the knowledge of others is critical to strategic reasoning. 'I know that you know that I know that you know…' is a central assumption of economic decision making required

for rational agents in economic games. If, however, natural selection acts as the 'rational agent' by selecting for individuals that make good decisions, this capacity may not be required for individuals if they use simple rules that approximate the outcome of fully rational choice. Therefore, it is possible for primates to implement reciprocity without full theory of mind capacities. At present, only a few studies have attempted to integrate issues concerning mental state attribution with those involved in cooperation. For example, recent demonstrations of visual perspective-taking abilities in primates suggests that they might be able to attend to rewards that others seek, possibly aiding their ability to recognize cooperative situations. However, despite this evidence, recent work shows that chimpanzees do not demonstrate other-regarding preferences; that is, they do not preferentially acquire food rewards in such a way as to give food to others. Instead, they appear to be completely indifferent to how their own reward-based actions can benefit other individuals. In contrast, in the study of tamarins mentioned above, individuals were more likely to cooperate with individuals who intentionally gave food as an altruistic act as opposed to individuals who gave the same amount of food as an accidental by-product of an otherwise selfish act. Further study of what monkeys and apes understand of the goals, beliefs, and intentions of others will elucidate whether limitations in these areas constrain other-regarding preferences.

Conclusions

With increasingly sophisticated and ecologically relevant tasks, we are closing in on those aspects of reward processing and social cognition that have uniquely evolved in humans and those that evolved by common descent with other primates and, possibly, other nonprimate animals. We suggest that reward processing and social cognition are intimately linked, setting up cognitive constraints on the evolution of cooperative behavior. We do not propose that these reward-processing constraints are immutable. If the evolutionary benefit of cooperation is great, selection pressure may circumvent these constraints. This, however, is likely to occur in a domain-specific manner rather than a domain-general manner. For instance, food-caching species such as squirrels may suspend inhibitory and impulsivity problems when hiding nuts away for winter. Yet, this ability has evolved to solve a very specific problem and likely does not apply generally to the species' decision-making strategies. Therefore, domain-general cognitive systems must evolve to allow many of the more complex forms of cooperation. The possibly unique presence of reciprocal cooperation and punishment in humans may be directly attributable to a combination of our keen number sense, patience, inhibitory control, memory capacity, and theory of mind.

Social Stress in Adult Primates

Introduction

We westernized humans and our health are peculiar by the standards of most other species. With the exception of AIDS and tuberculosis, we are plagued by relatively few infectious diseases – we are no longer haunted by the specter of smallpox, malaria, or a minor cut gone septic. Moreover, we are mostly spared the diseases of poor hygiene and inadequate food. Instead, we have the remarkable luxury of living well enough and long enough to succumb to diseases of slow accumulation of damage. These include cardiovascular disease, cerebrovascular disease, diabetes, and metabolic syndrome.

A critical point is the recognition that many of the most prevalent diseases of westernized life can be significantly worsened by stress. A stressor can be considered to be any perturbation of physiological or psychological homeostasis, and such challenges trigger an array of endocrine adaptations. This 'stress response' is vital for surviving a short-term physical stressor, in that it mobilizes energy from storage sites to exercising muscle, increases cardiovascular tone, enhances immunity, suppresses inessentials such as growth and reproduction, and enhances aspects of cognition. However, if the stress response is mobilized chronically for reasons of psychosocial stress, these same adaptations can become deleterious, increasing the likelihood and severity of an array of maladies typical of westernized life.

Virtually any organism would activate the stress response following, say, breaking a limb. Yet, in the face of similar psychosocial circumstances, only a subset of individuals activates the stress response. As such, differences in personality and temperament are important for understanding individual differences in vulnerability to stress-related disease. Consider, for example, three disorders which can be framed as individuals perceiving stressors that others typically do not, namely general anxiety disorders, major depression, and Type A personality (now thought of as a style of responding to social interactions with a globalized hostility). Critically, all three carry an increased risk of cardiovascular disease.

As such, stress-related disease cannot be understood outside the context of the individual experiencing the disease. But an understanding of the role of stress in health requires expanding this view even further – disease also cannot be understood outside of the context of the society in which an individual dwells. This article focuses on the fact that the frequency and severity of stressors are not equally distributed among all the members of a society, and that this is pertinent to understanding patterns of health and disease.

The Socioeconomic Health Gradient in Humans

A clear demonstration of this pertinence in humans is the 'socioeconomic gradient' of health, where, throughout westernized societies, lower socioeconomic status (SES) is associated with a higher incidence of cardiovascular, respiratory, rheumatoid, and psychiatric diseases, lower birth weight, and higher infant mortality and mortality from all causes. Extensive research has revealed some of the key features of this SES/health relationship:

1. The vast majority of the SES/health relationship reflects the influence of SES on health, rather than the other way around.
2. This relationship is not a step function where health is roughly equal until reaching the poverty level; instead, it is a gradient where, with every step down the SES ladder from its highest stratum, health declines.
3. Differential health care access cannot explain the gradient, as it occurs in countries with universal health care, in instances where the poor, in fact, make more, rather than less, use of the health care system, and in diseases whose prevalencies are independent of health care access (such as juvenile diabetes).
4. SES differences in health risk factors account for only a minority of the variance in this relationship. Instead, a complex and subtle literature demonstrates that the bulk of the SES/health gradient arises from the psychosocial correlates of SES. As one example of these findings, while objective SES is a good predictor of many realms of health, subjective SES is at least as good; this makes the point that the SES/health relationship is not so much about being poor as it is about feeling poor.

Gleaning these insights has represented a triumph of public health, health psychology, and behavioral medicine research, as these are extraordinarily difficult issues to study in humans. As a result, many researchers have utilized nonhuman subjects to study

health/social status relationships. While SES is a human invention, hierarchical systems of status differences are common among many social species.

Work stretching back half a century has demonstrated a clear relationship between health and social status among rodents, namely that it is socially subordinate individuals who have the most elevated basal levels of stress hormones (such as glucocorticoids), the highest resting blood pressure, and the highest incidences of stress-related diseases. This seems quite logical, in that the cornerstones of psychological stress are lack of control and predictability, lack of outlets for the frustration caused by external challenges, and lack of social affiliation. These factors are all attributes of social subordination in a rodent (e.g., lack of control and predictability, in the form of being subject to random acts of displacement aggression at the teeth of more dominant individuals; lack of outlets, in the form of being unable to subsequently displace aggression onto another animal; lack of social affiliation, in the form of less access to social contact and grooming).

Prompted by these clear findings in rodents, investigators began to consider health/social status relations in nonhuman primates, with the obvious recognition that other social primates are far better models for understanding humans than are rodents. And here, the picture has been anything but clear, with vastly contradictory answers to the most basic question, namely whether it is dominant or subordinate individuals who show the greatest incidences of stress-related disease.

The resolution to this confusion rests on two key points:

1. There is enormous variability in the social systems of primates. Across the more than 150 different primate species, dominance systems vary dramatically as to how high rank is attained, maintained, and manifested, and as to how social subordination is experienced.
2. As a result of this, there is tremendous variation among different primate species as to whether it is high- or low-ranking individuals who experience the most psychological stress.

Sources of Variability in Health/Social Status Relations in Primates

What factors determine whether it is high or low rank that is most associated with psychological stress? A number have been identified:

- *Resource inequities*. Some primate dominance systems are marked by resources (e.g., food) being divided very unequally as a function of rank. In such cases, it is subordinate individuals who show the greatest pathophysiologic indices of stress. In contrast, this is not seen in more egalitarian dominance systems.
- *Maintenance of dominance*. While social rank is inherited and unchanging in some primate social systems (e.g., female rhesus monkeys), it changes over time in other primate systems. In some species (e.g., females of ring-tailed lemurs), dominance must be reasserted frequently, with high-ranking individuals having the highest rates of fighting and injury. In such cases, it is dominant individuals with the most pronounced pathophysiologic indices of stress. In contrast, the opposite is seen in species (such as the males among baboons, rhesus, and squirrel monkeys) where dominance in mostly maintained through intimidation, and where dominant individuals have among the lowest rates of fighting and injury.
- *Mating system*. Among some Old World primates, high-ranking females monopolize breeding access by way of harassing the mating efforts of subordinates. In such cases, social subordinate is associated with stress-related pathophysiology (including higher rates of reproductive impairments, a phenomenon called 'social contraception'). In contrast, in many New World primates (such as marmosets), while the alpha female is the only one to breed, subordinates are typically younger sisters, who help with child rearing and are not subject to harassment. In such cases, social subordination is not preferentially linked to stress pathophysiology.
- *Stability of social rank*. In a social system involving resource inequity, when the hierarchy is stable (i.e., where the bulk of dominance interactions reaffirm the status quo, rather than challenge it), it is social subordination which is most linked to stress-related disease. When hierarchies are unstable, the instability is most manifest in the upper echelon of ranks (where there are the highest rates of dominance interactions, including aggressive ones, the greatest fluctuations in outcome, and the most disruption of socially affiliative behaviors such as grooming), as are the stress-related pathologies. In feral populations, such instability is a rare event (secondary, perhaps, to the death of a key individual). In captive populations, it is characteristic of the first months after group formation, when dominance relationships are still being established.
- *Subordinate coping strategies*. Independent of the extent to which resources are distributed unequally, or of the frequency with which low-ranking individuals are subject to subordinating interactions with high-ranking animals, social systems differ as to what sorts of coping outlets are available to

subordinates (e.g., grooming with another individual, mating, displacing aggression onto a third party). The more such outlets exist for low-ranking individuals, the less subordination is associated with stress-related pathology.

- *Subordinate avoidance of dominant individuals.* The frequency with which a low-ranking individual is subject to subordinating interactions with a high-ranking one will increase, in part, with increased proximity between the two. This helps explain rank/health differences within the same species, depending on whether subjects are studied in captivity or in the wild. In the former, subordinate animals are less capable of avoiding dominant ones, and show greater indices of stress-related disease.
- *Alternative strategies to overt dominance competition.* It is coming to be recognized that among some primates, low-ranking individuals can pursue alternatives to overt (and unsuccessful) competition within the hierarchy. This can take the form, for example, of low-ranking animals foraging in a more solitary manner (e.g., female chimps). Fewer indices of stress-related disease are observed among subordinate male baboons who forgo overt male–male competition and, instead, increase reproductive success through covert social affiliation with females. The same is seen among subordinate male orangutans who forgo overt competition and, instead, increase reproductive success through forced mating with peripheral females.

Thus, a variety of factors help predict whether it will be dominant or subordinate individuals who show the most pathophysiological indices of stress in a particular primate species. These relationships can potentially be blunted or exacerbated by personality. For example, among male baboons, high-ranking individuals who react to nonthreatening interactions with rivals as if they are overt challenges have higher risks of stress-related disease than the high-ranking cohort in general. In contrast, low-ranking male baboons who are particularly adept at taking advantage of social support have a lower risk than their low-ranking cohort in general.

As emphasized, there is tremendous variability in social systems among different primate species. In addition, there is considerable variability within species. Different populations and social groups of the same species will differ in rates and intensities of dominance interactions, of aggression, of affiliative behaviors, of sexual behavior, and so on. Such variability can reflect factors external to the group, such as features of the ecosystem (e.g., extent of rainfall), density of predators, or frequency of flow of individuals to and from neighboring groups, as well as factors internal to the group, such as adult sex ratios or the temperament of the alpha individual.

The Adverse Health Consequences of a Stressful Social Rank in a Primate

The previous section reviews the factors that help predict whether it is high- or low-ranking individuals who show the most stress-related pathologies in a particular primate species and social group. What are those pathologies? A number have been identified.

Hypersecretion of Glucocorticoids

Glucocorticoid hormones (such as cortisol and corticosterone) are secreted in response to stress, and are essential for short-term adaptation to physical stressors. In contrast, excessive exposure to glucocorticoids in response to prolonged psychosocial stressors can have a number of adverse consequences for health, including insulin resistance, hypertension, and impaired growth, tissue repair, reproduction, and immunity. Numerous studies have shown there to be elevated glucocorticoid levels (basally, or during the recovery period from a stressor) in animals of the more stressed rank in various primate species. This includes dominant female ring-tailed lemurs (where dominance must be constantly reasserted) and dominant male baboons (during periods of rank instability), subordinate male baboons, squirrel and rhesus monkeys (in stable hierarchies), and male rhesus and female talapoins (in small captive enclosures).

Cardiovascular Pathologies

Studies have shown the social rank associated with more social stress to also be associated with a greater risk of cardiovascular pathologies, including basal hypertension, a sluggish activation of heart rate and blood pressure with challenge and a sluggish recovery thereafter, elevated low-density lipoprotein (LDL) and decreased high-density lipoprotein (HDL) cholesterol, and increased vulnerability to atherogenesis. These pathologies are more prevalent among subordinate macaques and baboons (in stable hierarchies) and dominant individuals of the same species (in unstable hierarchies).

Reproductive Impairments

Prolonged stress suppresses various facets of reproductive physiology in females, and a more stressful social rank in primates is associated with lower gonadal hormone levels and a greater likelihood of anovulation. This is observed among subordinate cynomolgus macaque monkeys (in stable hierarchies). Among males, there is (to some) a surprising lack of

relationship between the stressfulness associated with particular social ranks and basal testosterone levels.

Immune Function

While transient stress is immunostimulatory, prolonged stress is immunosuppressive, and the more stressful rank position is associated with suppressed circulating lymphocyte counts and a sluggish immune response to challenge. This can be dominant individuals (male captive chimpanzees in an unstable hierarchy) or subordinate ones (male baboons in a stable hierarchy).

Neurobiological Endpoints

Sustained stress can cause a variety of adverse consequences in the realm of neurobiological endpoints. Those associated with the more stressful social rank in primates include atrophy of dendritic processes in hippocampal neurons and inhibition of hippocampal neurogenesis. This has been observed in subordinate tree shrews (in stable, captive populations).

Conclusions

Studies such as these generate a number of broad conclusions. The first reflects the astonishing variety and flexibility of primate sociality. There is no such thing as 'a' typical primate or primate social group, a pleasing finding for primatologists and a cautionary one for those who might too readily overemphasize human universals. Intrinsic in that is a cautionary note for behavioral neurobiologists who would study a nonhuman species as 'the' model for some aspect of human behavior. This variety brings home a truism, namely that ethology, or, in this case, neuroethology, is the process of interviewing an animal, but in its own language.

Next, you cannot understand disease outside the context of the individual suffering from that disease, and relevant variables include the individual's social status, personality, and patterns of sociality. Finally, those same variables also must be understood in the larger context of the society in which they occur – that is, what such social status, personality, and patterns of sociality mean in that society.

Sodium Channels

W A Catterall, University of Washington, Seattle, WA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Voltage-gated sodium channels initiate action potentials in neurons and other excitable cells, and they are responsible for propagation of action potentials along nerve and muscle fibers. They are complexes of a large pore-forming α subunit and smaller β subunits. Multiple genes encode sodium channel subunits, and the distinct sodium channel subtypes have subtle differences in functional properties, differential expression in excitable cells, and differential distribution in subcellular compartments. These differences in function and localization contribute to the specialized functional roles of sodium channels in neuronal physiology and pharmacology.

Sodium Channel Subunit Structure

Na^+ channel proteins in mammalian brain are complexes of a 260 kDa α subunit in association with one or two auxiliary β subunits (β_1–β_4) of 33–36 kDa. The primary sequence predicts that the sodium channel α subunit folds into four internally repeated domains (I–IV), each of which contains six α-helical transmembrane segments (S1–S6) (Figure 1). In each domain, the S1 through S4 segments serve as the voltage-sensing module, and the S5 and S6 segments and the reentrant P loop that folds into the transmembrane region of the channel between them serve as the pore-forming module. A large extracellular loop connects the S5 or S6 transmembrane segments to the P loop in each domain, whereas the other extracellular loops are small. Large intracellular loops link the four homologous domains, and the large N-terminal and C-terminal domains also contribute substantially to the mass of the internal face of sodium channels. This view of sodium channel architecture originally derived from hydrophobicity analysis has been largely confirmed by biochemical, electrophysiological, and structural experiments.

Sodium Channel Genes

Sodium channels are the founding members of the ion channel superfamily that includes voltage-gated Ca^{2+} channels; TRP channels; voltage-gated, inward rectifying, and two-pore domain K^+ channels; and cyclic nucleotide-regulated CNG and HCN channels. In evolution, the four-domain sodium channel was last among the voltage-gated ion channels to appear, and it is only found in multicellular organisms. It is thought that sodium channels evolved by two rounds of gene duplication from ancestral single-domain bacterial sodium channels such as NaChBac found in *Baccillus halodurans,* which may also be the ancestral single-domain channel from which Ca^{2+} channels arose. Voltage-gated sodium channel genes are present in a variety of metazoan species, including fly, leech, squid, and jellyfish. The biophysical properties, pharmacology, gene organization, and even intron splice sites of these invertebrate sodium channels are largely similar to those of the mammalian sodium channels, adding further support for the idea that the primordial sodium channel was established before the evolution of vertebrates.

The human, mouse, and rat sodium channel genes and proteins are the best characterized. Ten related sodium channel genes are found in these species (Figure 2), which map to four paralogous chromosome segments within a HOX gene cluster. More than 20 exons comprise each of the nine sodium channel α subunit genes in vertebrates. Genes encoding sodium channels $Na_v1.1$, $Na_v1.2$, $Na_v1.3$, and $Na_v1.7$ are localized on chromosome 2 in human and mouse, and these channels share similarities in sequence, biophysical characteristics, block by nanomolar concentrations of tetrodotoxin, and broad expression in neurons. A second cluster of genes encoding $Na_v1.5$, $Na_v1.8$, and $Na_v1.9$ channels is localized to human chromosome 3p21–24 (and to the orthologous region of chromosome 3 in mouse). Although they are more than 75% identical in sequence to the group of channels on chromosome 2, these sodium channels all contain amino acid substitutions that confer varying degrees of resistance to the pore blocker tetrodotoxin. In $Na_v1.5$, the principal cardiac isoform, a single amino acid change from phenylalanine to cysteine in the pore region of domain I is responsible for a 200-fold reduction in TTX sensitivity compared to those channels on chromosome 2. At the identical position in $Na_v1.8$ and $Na_v1.9$, the amino acid residue is serine, and this change results in even greater resistance to TTX. These two channels are preferentially expressed in peripheral sensory neurons. In comparison to the sodium channels on chromosomes 2 and 3, $Na_v1.4$, which is expressed in skeletal muscle, and $Na_v1.6$, which is highly abundant in the central nervous system (CNS), have greater than 85% sequence identity and similar functional properties, including TTX sensitivity in the nanomolar concentration range. Despite

Figure 1 Transmembrane organization of sodium channel subunits. The primary structures of the subunits of the voltage-gated ion channels are illustrated as transmembrane folding diagrams. Cylinders represent probable α-helical segments. Bold lines represent the polypeptide chains of each subunit with length approximately proportional to the number of amino acid residues in the brain sodium channel subtypes. The extracellular domains of the β_1 and β_2 subunits are shown as immunoglobulin-like folds. ψ, sites of probable N-linked glycosylation; P, sites of demonstrated protein phosphorylation by PKA (circles) and PKC (diamonds); shaded, pore-lining S5–P–S6 segments; white circles, the outer (EEDD) and inner (DEKA) rings of amino residues that form the ion selectivity filter and the tetrodotoxin binding site; ++, S4 voltage sensors; h, inactivation particle in the inactivation gate loop; open shaded circles, sites implicated in forming the inactivation gate receptor. Sites of binding of α- and β-scorpion toxins and a site of interaction between α and β_1 subunits are also shown.

these similarities, phylogenetic analysis by parsimony comparisons suggests a more distant evolutionary relationship, consistent with their distinct chromosomal localizations (Figure 2). $Na_v1.4$ and $Na_v1.6$ are located on human chromosome 11 (mouse chromosome 17) and human chromosome 15 (mouse chromosome 12), respectively.

A tenth sodium channel, Na_x, whose gene is located near the sodium channels on chromosome 2, is evolutionarily more distant (Figure 2). Key differences in functionally important regions of the voltage sensor and inactivation gate and lack of functional expression of voltage-gated sodium currents in heterologous cells suggest that Na_x may not function as a voltage-dependent sodium channel. Consistent with this conclusion, targeted deletion of the Na_x gene in mice causes functional deficits in sensing plasma salt levels.

The $Na_v\beta$ subunits are encoded by four distinct genes in mammals. The gene encoding β_1 maps to chromosome 19q13, whereas β_2 and β_4 are located on chromosome 11q22–23 and β_3 is located nearby on chromosome 11q24. The β_1 and β_3 subunits associate noncovalently with the α subunits, whereas β_2 and β_4 are covalently linked by a disulfide bond. All four β subunits have a single transmembrane segment, a large N-terminal extracellular domain, and a small intracellular C-terminal domain (Figure 1). The $Na_v\beta$ subunits are dual-function proteins. Coexpression of $Na_v\beta$ subunits alters the kinetics and voltage dependence of activation and inactivation of sodium channel complexes. Moreover, their extracellular domain forms an immunoglobulin-like fold, similar to many cell adhesion molecules, and the β subunits are involved in interactions of sodium channels with proteins in the extracellular matrix, with other cell adhesion molecules, and with intracellular regulatory proteins such as protein kinases and phosphoprotein phosphatases. The importance of the functions of the $Na_v\beta$ subunits is underscored by the strong effects of deletion of the genes in mice encoding $Na_v\beta_1$ and $Na_v\beta_2$, which include impairments of myelination and axonal conduction, epileptic seizures, and premature death.

Expression and Localization of Sodium Channel Subtypes

The sodium channel subtypes are differentially expressed in tissues and differentially localized within

Figure 2 Amino acid sequence similarity and phylogenetic relationships of voltage-gated sodium channel α subunits. Phylogenetic relationships by maximum parsimony analysis of rat sodium channel sequences Na$_v$1.1–Na$_v$1.9 and Na$_x$. To perform the analysis, the amino acid sequences for all of the isoforms were aligned using ClustalW. The amino acid sequences in the alignments were then replaced with the published nucleotide sequences, and the nucleotide sequence alignments were subjected to analysis using the program PAUP*. Divergent portions of the terminal regions and the cytoplasmic loops between domains I–II and II–III were excluded from the PAUP* analysis. The tree was rooted by including the invertebrate sodium channel sequences during the generation of the tree, although these sequences are not shown in the figure.

individual cells. Na$_v$1.3 is highly expressed in fetal nervous tissues in rodents, whereas Na$_v$1.1, Na$_v$1.2, and Na$_v$1.6 are abundant in juvenile and adult CNS. Generally, Na$_v$1.1 and Na$_v$1.3 are primarily localized in neuronal cell bodies, where they may control neuronal excitability through integration of synaptic impulses to set the threshold for action potential generation and propagation to the dendritic and axonal compartments. Na$_v$1.2 is primarily localized in unmyelinated axons. During development, Na$_v$1.6 replaces Na$_v$1.2 in maturing nodes of Ranvier in myelinated axons. Na$_v$1.1, Na$_v$1.2, and Na$_v$1.6 are also expressed in the peripheral nervous system. However, the three isoforms that have been cloned from sympathetic and dorsal root ganglion neurons – Na$_v$1.7, Na$_v$1.8, and Na$_v$1.9 – are more abundant and are the principal sodium channels in the peripheral nervous system. The Na$_v$1.7 channel is localized in axons, where it functions in initiating and conducting the action potential. More restricted expression patterns are observed for Na$_v$1.8 and Na$_v$1.9; these channels are highly expressed in small sensory neurons of dorsal root ganglia and trigeminal ganglia, where they have a key role in nociception. Na$_v$1.4 and Na$_v$1.5 are the primary muscle sodium channels that control the excitability of the skeletal and cardiac myocytes, respectively. Na$_v$1.5 is transiently expressed in developing skeletal muscle but is replaced by Na$_v$1.4 in the adult.

Molecular Basis of Sodium Channel Function

Classical work by Hodgkin and Huxley defined the three key features of sodium channels: voltage-dependent activation, rapid inactivation, and selective ion conductance. Building on this foundation, structure–function studies employing molecular, biochemical, structural, and electrophysiological techniques have provided clear understanding of the molecular basis of sodium channel function. The narrow outer pore is formed by the reentrant P loops between transmembrane segments S5 and S6 of each domain (Figure 1). Mutation of a set of four residues in analogous positions in each domain (aspartate in domain I, glutamate in domain II, lysine in domain III, and alanine in domain IV; DEKA) to glutamates confers calcium selectivity, indicating that the side chains of these amino acid residues are likely to interact with sodium ions as they are conducted through the ion selectivity filter of the pore.

Similar to other voltage-gated ion channels, the voltage dependence of activation of sodium channels derives from outward movement of gating charges as a consequence of depolarization of the membrane and consequent reduction of membrane electric field. The S4 segments of each homologous domain serve as the primary voltage sensors for activation. They contain repeated motifs of a positively charged amino acid residue followed by two hydrophobic residues creating a transmembrane spiral of positive charges. Upon depolarization, outward movement and rotation of S4 is thought to initiate a conformational change that opens the sodium channel pore. This 'sliding helix' or 'helical screw' model is supported by strong evidence. For example, neutralization of the positively charged residues in S4 reduces the voltage dependence of gating. The outward and rotational gating movement of the S4 segment has been detected directly by reaction of substituted cysteine residues in S4 segments with extracellular sulfhydryl reagents following channel activation and by analysis of the movement of fluorescent probes incorporated into these substituted cysteine residues. A structural model of the voltage-sensing and pore-forming modules of sodium channels in the resting and activated states is illustrated in Figure 3.

Fast inactivation of the sodium channel is a critical process that occurs within milliseconds of channel opening. The generally accepted model of this process involves a conserved inactivation gate formed by the

Figure 3 Three-dimensional structure of sodium channels and a related potassium channel. (a) The three-dimensional structure of the Na_v channel α subunit at 20 Å resolution, compiled from electron micrograph reconstructions. (b) (Top) The hinged-lid mechanism. The intracellular loop connecting domains III and IV of the sodium channel is depicted as forming a hinged lid with the critical phenylalanine (Phe1489) within the (IFM) motif shown occluding the mouth of the pore during the inactivation process. The circles represent the transmembrane helices. (Bottom) Three-dimensional structure of the central segment of the inactivation gate as determined by multidimensional NMR. Isoleucine 1488, Phe1489, and methionine 1490 IFM are illustrated in yellow. Threonine 1491, which is important for inactivation, and serine 1506, which is a site of phosphorylation and modulation by protein kinase C, are also indicated. (c) $K_v1.2$ models of the closed and open states shown in cylinder representation. Only a single voltage-sensing module is shown attached to the tetramer of the pore-forming module for clarity. Transmembrane segments S1–S6 and P loop are colored by rainbow scheme from blue to red. The S4–S5 linker is shown in purple. Approximate positions of the α carbon atoms of the first and fourth gating charge carrying arginines in the S4 segment (labeled R1 and R4 and colored blue) and E226 in the S2 segment (labeled E1 and colored red) are shown in sphere representation. All intracellular and extracellular loops, except for the S4–S5 linker, are represented by curved lines for simplicity. Vertical translation of R4 between the closed and open states along the membrane normal vector and relative to the plane of the membrane is indicated by arrows. S3 is represented by ribbon to clearly show the positions of the gating charge-carrying arginines in the S4 segment. (a) Adapted from Sato C, Ueno Y, Asai K, et al. (2001) The voltage-sensitive sodium channel is a bell-shaped molecule with several cavities. *Nature* 409: 1047–1051. (b) Adapted from Catterall WA (2000) From ionic currents to molecular mechanisms: The structure and function of voltage-gated sodium channels. *Neuron* 26: 13–25.

intracellular loop connecting domains III and IV, which serves as a hinged lid that binds to the intracellular end of the pore and blocks it (Figure 1). Intracellular perfusion of proteases or intracellular application of antibodies directed to this loop prevents fast inactivation. The latch of this fast inactivation gate is formed by three key hydrophobic residues, methionine 1490 (IFM), and an adjacent threonine (T). Mutations of these amino acid residues destabilize the inactivated state, and peptides harboring the IFM motif can restore inactivation to sodium channels having mutated inactivation gates. The closed inactivation gate is thought to make multiple interactions with hydrophobic amino acid residues near the intracellular mouth of the pore that may constitute the inactivation gate receptor. Scanning mutagenesis experiments implicate hydrophobic residues in intracellular S4–S5 loops of domains III and IV, as well as the intracellular end of the S6 transmembrane segment in domain IV, in forming the inactivation gate receptor.

Three-Dimensional Structure of Sodium Channels

The three-dimensional structure of the sodium channel is not completely known, but some limited structural information has emerged. Structural determination at 19 Å resolution by cryo-electron microscopy and image reconstruction techniques shows sodium channels as having a bell shape from a side view, a fourfold symmetry of transmembrane masses as viewed from above the membrane, and large intracellular and extracellular masses through which several inlets and outlets allow aqueous access (Figure 3(a)). Unexpectedly, this image of sodium channels reveals a central pore that does not directly connect the intracellular and extracellular spaces, instead splitting into four branches near the membrane surface. Moreover, it suggests the presence of four peripherally located narrow transmembrane pores, which may function as gating pores for voltage sensor movement as described later.

The only high-resolution structure of sodium channels is the solution structure of the inactivation gate in the intracellular loop connecting domains III and IV, as determined by nuclear magnetic resonance (NMR) analysis of this intracellular loop expressed in bacteria (Figure 3(b)). This structural analysis reveals a rigid α-helical structure, preceded by two turns that position the key hydrophobic sequence motif IFMT such that it can interact with and block the inner mouth of the pore.

The global fold of the sodium channel is predicted to be similar to that of voltage-gated potassium channels (Figure 3(c)). The structure of the open state of this channel has been determined by X-ray crystallography, and the structure of the closed state has been determined by structural modeling using the Rosetta method. This structural view shows the S5 and S6 region of the sodium channel arrayed in fourfold symmetry around the aqueous ion conduction pathway (Figure 3(c), red, tan, and yellow). The selectivity filter of the pore at its narrow extracellular end is formed by the P loops (Figure 3(c), tan), whereas the wider vestibule in the center of the pore is formed mostly by the S6 segments (Figure 3(c), red). A single voltage sensor module is illustrated for simplicity (Figure 3(c), blue and green). In the resting (closed) state of the channel, the S4 segment is in an inward position. In this sliding helix model, activation of the voltage sensor by depolarization causes outward and rotational movement of the S4 segment and complementary movement of the S1–S3 segments around it. These coupled molecular movements translocate the gating charges in the S4 segment from exposure to the intracellular milieu to exposure to the extracellular milieu, as required for voltage-dependent gating.

Comparison of the primary structures of the auxiliary β subunits to those of other proteins reveals a close structural relationship to the family of proteins that contain immunoglobulin-like folds, which include many cell adhesion molecules. The extracellular domains of these type I single membrane-spanning proteins are predicted to fold in a similar manner as myelin protein P0, whose immunoglobin-like fold is known to be formed by a sandwich of two β sheets held together by hydrophobic interactions (Figure 1). Myelin P0 protein is a cell adhesion molecule involved in tight wrapping of myelin sheets, and many related cell adhesion molecules with extracellular Ig folds and a single membrane-spanning segment are involved in cell–cell interactions among neurons and glia. As expected from their structure, $Na_v\beta$ subunits interact with extracellular matrix molecules, other cell adhesion molecules, and intracellular cytoskeletal proteins and signaling proteins. These interactions are thought to localize and stabilize sodium channels in specific subcellular compartments such as axon hillocks and nodes of Ranvier where they are present in high density and also to bring crucial signaling molecules to the sodium channel to regulate it.

Sodium Channel Pharmacology

Sodium channels are the molecular targets for drugs used in prevention of acute pain and in treatment of cardiac arrhythmias, epilepsy, and bipolar disorder. Sodium channel-blocking drugs are also in development for treatment of chronic pain. Local anesthetics bind to a specific receptor within the pore of sodium channels, formed by the S6 segments in domains I, III, and IV (Figure 4). Their binding blocks ion movement

Figure 4 Model of etidocaine binding to the local anesthetic receptor site formed by transmembrane segments IS6, IIIS6, and IVS6 of the $Na_v1.2$ channel. Three-dimensional model of proposed orientation of amino acid residues within the Na^+ channel pore with respect to the local anesthetic etidocaine. Only transmembrane segments IS6 (red), IIIS6 (green), and IVS6 (blue) are shown. Residues important for etidocaine binding are shown in space-filling representation.

Table 1 Receptor sites on sodium channels

Receptor site	*Toxin or drug*	*Location (domain/segment)*
Neurotoxin receptor site 1	Tetrodotoxin	IP, IIP, IIIP, IVP
	Saxitoxin	IP, IIP, IIIP, IVP
	μ-Conotoxin	
Neurotoxin receptor site 2	Veratridine	IS6, IVS6
	Batrachotoxin	
	Grayanotoxin	
Neurotoxin receptor site 3	α-Scorpion toxins	IS5–IS6, IVS3–S4
	Sea anemone toxins	IVS3–S4
Neurotoxin receptor site 4	β-Scorpion toxins	IIS1–S2, IIS3–S4
Neurotoxin receptor site 5	Brevetoxins	IS6, IVS5
	Ciguatoxins	
Neurotoxin receptor site 6	δ-Conotoxins	IVS3–S4
Local anesthetic receptor site	Local anesthetic drugs	IS6, IIIS6, IVS6
Antiarrhythmic drugs		
Antiepileptic drugs		

through the pore and stabilizes the inactivated state of sodium channels. Antiarrhythmic drugs and antiepileptic drugs share similar, overlapping receptor sites. Complete block of sodium channels would be lethal. However, these drugs selectively block sodium channels in depolarized and/or rapidly firing cells, such as axons carrying high-intensity pain information and rapidly firing nerve and cardiac muscle cells that drive epileptic seizures or cardiac arrhythmias. This selective block arises because the drugs can reach their binding site in the pore of the sodium channel more rapidly when the pore is repetitively opened and they bind with high affinity to inactivated sodium channels that are generated in rapidly firing or depolarized cells. This use-dependent action of the sodium channel-blocking drugs is essential for their therapeutic efficacy.

In addition to these important pharmaceutical agents, sodium channels are the molecular targets for a large number of neurotoxins that paralyze prey by preventing neuromuscular function (Table 1). These toxins act at five or more distinct receptor sites and either block the pore of the channel or alter the kinetics or voltage dependence of gating. The pore blockers tetrodotoxin and saxitoxin bind to neurotoxin receptor site 1, which is formed by the P loops in the four domains. Alkaloids and other organic toxins from plants, frogs, and other species bind at neurotoxin receptor site 2 and cause persistent activation of sodium channels, which depolarizes nerves and muscles and causes repetitive firing and paralysis. Polypeptide toxins from scorpions and spiders bind at neurotoxin receptor sites 3 and 4 and either slow inactivation or enhance activation of sodium channels, which also causes repetitive firing and paralysis. Brevetoxins and ciguatoxins, which are large polyether compounds made by marine dinoflagellates, bind to neurotoxin receptor site 5 and cause persistent activation of sodium channels. The diversity of organisms that have developed toxins that target sodium channels is remarkable, highlighting the physiological importance of these channels in electrical signaling and neuromuscular function.

Sodium Channelopathies

Mutations that alter sodium channel function lead to human diseases of hyperexcitability (Table 2). Multiple mutations of $Na_v1.4$ that yield hyperactive skeletal sodium channels have been shown to cause hyperkalemic periodic paralysis and paramyotonia congenita. In contrast, mutations in S4 gating charges that cause reduced function of these channels and induce a sodium leak through their voltage sensor domains (termed 'gating pore current') cause hypokalemic periodic paralysis. Mutations of $Na_v1.5$ that impair inactivation or alter activation lead to

Table 2 Major inherited diseases of sodium channels

Disease	*Gene*	*Channel*
Generalized epilepsy with febrile seizures plus	SCN1A	$Na_v1.1$
Severe myoclonic epilepsy in infancy	SCN1A	$Na_v1.1$
Benign neonatal convulsions	SCN1A	$Na_v1.1$
Familial hemiplegic migraine type III	SCN1A	$Na_v1.1$
Hypokalemic periodic paralysis type II	SCN4A	$Na_v1.4$
K^+-sensitive normokalemic periodic paralysis	SCN4A	$Na_v1.4$
Hyperkalemic periodic paralysis	SCN4A	$Na_v1.4$
Paramyotonia congenita	SCN4A	$Na_v1.4$
Long QT syndrome type III	SCN5A	$Na_v1.5$
Brugada syndrome	SCN5A	$Na_v1.5$
Erythermalgia	SCN9A	$Na_v1.7$
Paroxysmal extreme pain disorder	SCN9A	$Na_v1.7$
Congenital indifference to pain	SCN9A	$Na_v1.7$

inherited long QT syndrome type 3 and Brugada syndrome, in which the risk of fatal cardiac arrhythmias is greatly increased. Generalized epilepsy with febrile seizure plus ($GEFS^+$) type II results from gain-of-function mutations of $Na_v1.1$ channels that enhance persistent inward sodium current, as well as from a mutation of the β_1 subunit. Gain-of-function mutations in $Na_V1.1$ channels also cause familial hemiplegic migraine type II. Severe myoclonic epilepsy in infancy is caused by inactivation of one allele of the gene encoding $Na_V1.1$ channels, and benign neonatal convulsions are caused by mutations in $Na_V1.2$ channels.

The requirement for intact sodium channel function in physiology is further highlighted by mouse knockout models, in which specific ablation of $Na_v1.1$, $Na_v1.2$, $Na_v1.5$, and $Na_v1.6$ led to premature lethality. In contrast, mutant mice lacking $Na_v1.8$ are viable and reveal defects in nociceptive response. These and other mouse models that target specific sodium channel genes should prove to be effective in delineating the significance of sodium channel function and its regulation in physiological contexts.

Somatosensory Cortex in Mammals with Little Neocortex

The organization of somatosensory cortex found in rats (Figure 1), is typical of that found in a wide range of mammalian species with relatively little phylogenetic expansion of neocortex. Much of somatosensory cortex in these mammals consists of two distinct systematic representations of the contralateral body surface, named in order of their discovery in cats, the first (primary) representation, or S-I, and the second representation, or S-II. Almost all neurons throughout both representations respond to gentle stimulation of the skin and body hairs. Thus, S-I and S-II appear to be related largely to cutaneous receptors. Neurons across the thickness of cortex at any location are all activated by stimulating the same region on the body surface. However, adjoining groups of neurons across the surface of the cortex are activated by different and typically nearby body regions so that all parts of the body eventually are represented in a pattern relative to the cortical surface. The larger S-I represents the body from tail to mouth in a mediolateral cortical sequence, while the smaller S-II has a head-to-tail mediolateral (or dorsoventral) cortical sequence. The two fields join along matched representations of the dorsal midline of the head. Thalamic input to both S-I and S-II is from a single representation of skin receptors in the ventroposterior nucleus. Axon pathways interconnect matched body parts of S-I and S-II of the same cerebral hemisphere and parts of S-I and S-II of the opposite cerebral hemisphere. S-I and S-II also have connections with other regions of cortex, including motor cortex.

Major features of organization of S-I in rats are common in S-I of other mammals:

1. A large proportion of S-I is devoted to the head. The representation of the head occupies half or more of S-I in rats, tree shrews, squirrels, opossums, rabbits, and several carnivores. Within this head representation, tree shrews and opossums emphasize the glabrous nose, rats emphasize the mystacial vibrissae, and squirrels and rabbits emphasize the lips. Raccoons and monkeys have enlarged representations of the hand. The disproportionate representation of body parts follows the general rule that those skin surfaces with the most receptors and the important tactile functions have the largest representations (cortical magnification).

2. The representation is largely continuous (somatotopic) so that skin surfaces that are adjacent are usually represented next to each other in cortex.

3. There are often partial disruptions, however, and the locations of these disruptions in the representation vary somewhat across species. For instance, a split representation of the dorsal and ventral trunk is an unusual feature found so far only in tree shrews. In primates, the representations of the anterior and posterior leg are commonly split in S-I to locations lateral and medial to the representation of the foot. Despite these disruptions, the representations of important sensory skin surfaces are typically continuous. The partial discontinuities seem forced by the requirements of disproportionately representing some skin surfaces, and by the need for representing the three-dimensional body surface within a two-dimensional cortical sheet.

4. Many somatotopic details of S-I in rats are widely found in S-I of other mammals. As in most other mammals, the head is represented with the dorsal surface posterior and the ventral surface anterior in cortex. The hand and foot are represented with the proximal surfaces posterior and the distal digit tips anterior. Digits 1–5 relate to lateromedial cortical sequences. The dorsal trunk is near the posterior border of S-I.

5. S-I is associated with cortex characterized by dense packing of small neurons in cortical layer IV (somatic koniocortex). In some mammals, discontinuities in the somatotopic map are associated with discontinuities in the dense packing layer IV cells. As a particularly striking anatomical specialization in mice and rats, the layer IV cells form ringlike aggregations (barrels) in the part of S-I representing vibrissae, with a barrel for each whisker.

The second somatosensory area, S-II, of rats also has an organization that is typical of that found in other mammals. S-II is oriented so that the top of the head joins the representation of the top of the head in S-I (a congruent border), and the distal limbs point ventrally away from S-I. The somatotopic organization of S-II is cruder than that of S-I in that receptive fields are considerably larger. However, the proportion of S-II devoted to different body parts roughly matches that of S-I. S-II is typically one-tenth to one-half the size of S-I. Rats also have a third representation of the body surface, the parietal ventral area,

Figure 1 The locations of sensory and motor areas on a dorsolateral view of the brain of a rat. The traditional somatosensory areas are S-I, the primary area, and S-II, the secondary area. Each contains a detailed representation of cutaneous receptors, but only the representations of major body parts are shown here. The parietal ventral area, PV, contains a third systematic representation. The dysgranular cortex, Dys., invaginating rostral S-I and parietal-medial, PM, and parietal-rostral, PR, regions appear to be additional somatosensory fields. In addition, primary, M-I, and secondary, M-II, motor fields have connections with somatosensory fields. Auditory and primary and secondary visual fields are indicated for reference.

PV, first discovered in squirrels but now identified in a number of mammalian species. PV receives some inputs from S-I and some from S-II, thus having components of both parallel and serial processing.

Some regions of additional cortex in rats can be considered somatosensory. A narrow fringe of cortex between S-I and motor cortex responds to more intense stimulation of the body, and it is possible that this cortex relates to noncutaneous (deep) body receptors, such as those in muscles, but this is uncertain. A narrow zone of cortex posterior to S-I responds to stronger stimulation, while cortex posterior to this less responsive somatosensory zone is visual or auditory. Cortex just ventral to PV, a parietal rostral area or PR, has inputs from PV. PR may be a final processing station before outputs to limbic centers associated with the formation of long-term memories. Finally, rats have a primary motor area, M-I, and a premotor or supplementary motor area, M-II, which have mainly motor but also somatosensory functions. Thus rats have six or more cortical fields that are involved in processing somatosensory information. Cortical organization is similar in a number of other mammals, including cats, squirrels, tree shrews, and rabbits.

Prosimian Primates

The prosimian primates have less-developed brains than monkeys and other advanced primates, apes, and humans. Of prosimian primates, the organization of somatosensory cortex has been studied most extensively in galagos. Much of somatosensory cortex in galagos consists of S-I and S-II. S-I is organized much like S-I (area 3b) in monkeys (Figure 2), although the representation of the hand is smaller. As for other mammals, S-I in galagos responds to cutaneous stimuli throughout its extent, receives input from the ventroposterior nucleus, and is coextensive with somatic koniocortex. S-I is adjoined lateroventrally by a smaller S-II, which extends into the lateral fissure. As for nonprimate mammals, S-II forms a congruent border with S-I along matched representations of the dorsal midline of the head. The distal limbs in S-II point away from S-I, and the hand is represented in cortex anterior to that devoted to the foot. PV probably exists rostral to S-II, but this area has not yet been identified in prosimians. A narrow strip of cortex on the anterior border of S-I appears to be the homolog of area 3a of monkeys because of its structural similarity and its activation by deep body receptors, possibly muscle spindle receptors. A strip of cortex posterior to S-I responds to more intense stimuli, and this strip may be related to deep body receptors in joints and muscles. Thalamic input to this strip is from neurons dorsal to the ventroposterior nucleus. As in most nonprimates, somatosensory cortex in galagos does not appear to be extensive or to consist of many subdivisions.

Monkeys, Apes, and Humans

Somatosensory cortex in higher primates contains more subdivisions than somatosensory cortex in generalized nonprimates. Most of what is known about somatosensory cortex in higher primates stems from

Figure 2 Somatosensory areas in owl monkeys, New World primates with small, relatively smooth brains. These monkeys lack a central fissure, so several sensory and motor areas can be indicated on a dorsolateral view of the brain (upper left). These exposed fields include areas 3a, 3b, 1, and 2 of anterior parietal cortex, posterior parietal cortex, PP, and primary motor cortex, M-I. Other somatosensory fields are hidden in cortex of the upper bank of the lateral fissure. Four of these hidden areas are shown in the expanded diagram of lateral and anterior parietal areas on the right. Little is known about the parietal rostral area, PR, but the other areas all contain systematic representations of body receptors. Detailed somatotopic features are indicated only for area 3b, where digit representations are numbered. Locations of major body part representations are noted for other fields. These areas appear to exist in monkeys, apes, and humans. Glut, gluteal region; N, nose; LL, lower lip; UL, upper lip; Tr, trunk; hatching, dorsal hand or foot.

experiments in monkeys, but it seems reasonable to conclude that somatosensory cortex contains at least as many subdivisions in apes and humans as in monkeys. Early experiments on the organization of anterior parietal cortex in macaque monkeys defined S-I as a broad region including architectonic areas 3 (3a and 3b), 1, and 2 of Brodmann. The locations of these four architectonic strips are shown for an owl monkey in Figure 2. It is now recognized from detailed microelectrode experiments on owl and other monkeys that each of the four architectonic fields 3a, 3b, 1, and 2 contains a separate representation of the body. Since these cortical areas roughly match each other in mediolateral representational sequence, early experiments using larger surface electrodes failed to distinguish them.

Because of the historical definition of S-I in monkeys, it is common to include areas 3a, 3b, 1, and 2 in S-I. However, only area 3b appears to be the homolog of S-I as generally defined in nonprimates and prosimians. Like S-I, area 3b is coextensive with cortex distinguished by densely packed small cells in layer IV, has dense input from the ventroposterior nucleus of the thalamus, is responsive throughout to light tactile stimuli, and has digit tips of the hand and foot represented along the rostral border. Area 3b forms a complete representation of the body surface. Major cortical projections of area 3b are to S-II, PV, area 1, and area 2.

Area 1 also contains a complete representation of the body surface. The somatotopic organization of area 1 is roughly a mirror reversal of that in area 3b (Figure 2). Thus, the digit tips of the hand and foot are represented posteriorly in area 1, and the somatotopic pattern is the reverse of that found in S-I of galagos and nonprimates. In comparison to area 3b, layer IV is less densely packed with small cells and the input from the ventroposterior nucleus is less dense. Area 1 also differs from area 3b by having fewer neurons with slowly adapting responses to maintained stimuli, neurons with larger and more complex receptive fields, and some neurons that appear to be activated by the rapidly adapting Pacinian receptor class. Major cortical projections are to areas 2, S-II, and PV. While area 1 is architectonically apparent in the cortex of monkeys, apes, and humans, there is no compelling evidence for this field in prosimians and nonprimates. Thus, it appears that the area 1 representation exists, or at least it is well developed, only in higher primates.

Area 3a is characterized by less dense packing of small layer IV cells and more layer V pyramidal cells than area 3b. Area 3a is activated predominantly by muscle spindle receptors and receives input from an anterodorsal division of the ventroposterior thalamic complex. The details of the somatotopic organization of area 3a have not been fully determined, but the field represents deep receptors in parallel with the adjoining representation of cutaneous receptors in area 3b. Major connections are with motor cortex. Similarities in responsiveness, histological structure, and even connections of area 3a in monkeys to the field termed 3a in cats are striking. Since a comparable 3a field has not been identified in a range of mammalian species, many of these similarities may be the result of parallel evolution. However, the reported presence of a somatosensory fringe along the anterior border of S-I of a number of mammals suggests that a less developed 3a field exists in many or most mammals.

Area 2 occupies a strip of cortex immediately caudal to area 1. Layers IV and VI are more densely

packed with cells than area 1. The posterior boundary of area 2 is less apparent, and there is disagreement on the location of this border. The somatotopic organization of area 2 is incompletely understood, but much or all of area 2 contains a body representation that is parallel to that in area 1, and at least partly mirrors that in area 1. Area 2 is activated by both cutaneous receptors and receptors in deep body tissues (muscles, joints, and tendons). The information from deep receptors appears to be relayed from dorsal divisions of the ventroposterior thalamic complex, and perhaps the anterior pulvinar, while information from cutaneous receptors appears to be relayed from areas 3b and 1 and, to a lesser extent, from the ventroposterior nucleus. Many neurons in area 2 are activated by both skin and deep receptors, and many respond best to complex stimuli involving shapes or direction of movement. Thus, area 2 seems to be a somewhat higher-order processing station. Major projections are to area 3a, S-II, PV, and posterior parietal cortex. There is no clear evidence for a homolog of area 2 in prosimians or nonprimates. However, in a number of mammals, cortex posterior to S-I receives input from part of the thalamus that is dorsal to the ventroposterior nucleus, and input from this location is suggestive of the input to area 2 from the dorsal parts of ventroposterior complex in monkeys.

Somatosensory cortex in monkeys also includes a large region of cortex on the upper bank and insular surface of the lateral fissure and the large posterior parietal region of cortex. The lateral fissure contains several somatosensory areas including an S-II proper that appears to be homologous to S-II in nonprimates. As in other mammals, S-II in monkeys responds to cutaneous stimuli and forms a systematic representation of the contralateral body surface. Cortical inputs are from areas 3b, 1, and 2 and thalamic inputs appear to be largely from the ventroposterior inferior nucleus and perhaps somewhat less from the ventroposterior nucleus. Pacinian receptors may relay to part of S-II or a subdivision of cortex outside of S-II.

One recent concept of S-II function in monkeys, and thereby in other mammals, is that S-II provides a hierarchical link in a relay of somatosensory information to limbic cortex that is critical in the permanent learning of tactile discriminations. This hierarchy also includes a PV and a ventral somatosensory area, VS. Both of these fields receive inputs from S-II and can be considered higher-order fields. Cortex rostral to PV, the PR region, receives inputs from PV and S-II. The organization of other regions of cortex in the lateral fissure of monkeys is not completely understood. Some of this cortex in the lateral fissure responds to somatosensory stimuli and contains subdivisions with different architectonic characteristics, types of neurons, and connection patterns with other fields and thalamic nuclei.

Posterior parietal cortex has been subdivided in various ways, but most investigators refer to subdivisions of area 5 and area 7 of Brodmann. These subdivisions are not completely satisfactory because there is no general agreement as to the exact locations and boundaries of cytoarchitectonic fields or on the criteria that defines them. In addition, and very importantly, these fields do not seem to be functionally homogeneous. Thus, the concepts of areas 5 and 7 have limited usefulness, and ultimately they may be redefined or replaced by more precisely defined subdivisions. Nevertheless, some general conclusions are possible. The more anterior part of posterior parietal cortex (area 5) receives cortical inputs from areas 1 and 2, and area 5 sends to more posterior parietal cortex (area 7). Area 7 also receives inputs from the lateral posterior nucleus of the thalamus and subdivisions of extrastriate visual cortex. The area 7 region appears to have higher-order functions since the response properties of neurons are complex and include types related to vision, eye movements, and visually guided movements. Lesions of area 7 produce visuospatial disorientation, defects in eye movements, misreaching, and a reluctance to use contralateral limbs.

Finally, as for other mammals, motor cortex has somatosensory inputs and thus somatosensory functions in monkeys. Cortical fields involved in sensorimotor functions include primary motor (M-I), supplementary motor (SMA), and dorsal (DPM) and ventral (VPM) premotor areas have been defined in monkeys.

Modular Organization

In early landmark studies of somatosensory cortex, Mountcastle proposed that cortical areas are not uniform in function, but are divided into small, functionally distinct processing modules, each containing a limited group of cells in a column extending from the surface of the cortex to fibers below. This concept has been widely accepted, but there have been only limited efforts to reveal the nature of processing units in any region of somatosensory cortex. The general validity of the concept is strongly supported by anatomical studies of connections, especially corticocortical connections, that cells in one location in the somatosensory system often project to a number of closely spaced separate foci in another area, thus suggesting a spacing of neurons involved in a particular function.

Recent electrophysiological evidence for one type of modular organization came from experiments where the local distributions of slowly adapting and

rapidly adapting cortical neurons were determined within area 3b of monkeys by recording from successive neurons across the depth of cortex in many closely spaced microelectrode penetrations. In the representation of the glabrous hand in area 3b of monkeys, most or all neurons respond to slight indentation of the skin with a probe. Some neurons respond only to the onset and offset of the indentation (rapidly adapting) while others continue to respond during a maintained indentation (slowly adapting). The slowly adapting neurons appear to be largely confined to the middle layers of cortex where they are clustered in extended foci that appear to form closely spaced bands coursing parallel to the surface. Cells in superficial and deep layers over and under these slowly adapting bands are rapidly adapting, and cells between the slowly adapting bands in layer IV form rapidly adapting bands. The reasons for this distribution are not clear. One possibility is that inputs relayed from slowly adapting and rapidly adapting receptor classes in the skin distribute in alternating bands in layer IV of cortex, and that slowly adapting responses are inhibited in cells outside the receiving layers. However, the observations demonstrate that processing modules in somatosensory cortex may be more band-like than column-like in form, and may be related to specific cortical layers, as are orientation-selective bands and ocular dominance bands in visual cortex.

The Reorganization of Cortical Maps after Injury

The somatotopic organizations of areas of somatosensory cortex do not reflect the full potential of the anatomical connections. Local features of organization in these maps can be altered by small lesions in the representations or by removal of the source of an input to part of a representation. Thus, cutting a sensory nerve to part of the hand or removing a finger does not permanently silence the cortex corresponding to the former representation of part of the hand or a finger. Rather, over a short period of hours to weeks, neurons throughout the deprived cortex become responsive to stimuli on the normally innervated parts of the hand. Likewise, following a small lesion of cortex that removes the representation of a given finger, neurons in cortex representing adjacent fingers come to be activated by inputs from the finger with the removed representation. These experiments indicate that somatotopic representations in adult mammals are subject to small degrees of change and reorganization, and that many local features of representations are dynamically maintained. Because some of the changes can be quite rapid, the anatomical connections mediating the rapid reorganization appear to be at least roughly in place, and the rapid reorganization appears to be one of changing the effectiveness of previously existing anatomical pathways. Other slowly emerging changes may involve the growth of new connections. The ability of these representations to change in internal organization may relate to recoveries after brain damage or sensory loss.

Somatosensory Cortex: Functional Architecture

R J Nelson and and Y Liu, University of Tennessee Health Science Center, Memphis, TN, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The phrase 'functional architecture' provides an interesting juxtaposition which, like 'mammalian somatosensory cortex,' must be explained in more detail. On one hand, dynamicism is implied by the use of the word 'functional,' suggesting something that is constantly changing in or being changed by the environment. On the other hand, architecture leads us to think about a fixed structure. It is safe to say that the somatosensory cortex has intrinsic scaffolding on which dynamic sensory processes act and that these processes are sculpted by inputs from the external sensory environment processed through the body surface (the exteroceptive system). Moreover, the somatosensory cortex plays double duty because it also receives sensory inputs from receptors deep within the body itself that signal the state of joints, muscles, and tendons (the proprioceptive system). The sculpting of processes may be accompanied by some changes in the architecture that can consist of changes in the way cortical neurons are connected or the strength of those connections. However, just as connections may contribute to functional plasticity, the extent of the plasticity may be limited by the architecture itself.

Vertical Architecture

The mammalian neocortex consists of six cellular layers stacked up on one another from the cortical surface (layer I) to the place where the deepest layer (layer VI) abuts the connectional fibers, called the cortical white matter (Figure 1). Each of these six layers contains neurons (some more than others) that are arranged vertically, that is, from the white matter border to the cortical surface. Neurons are arranged in units called minicolumn. Mountcastle describes a minicolumn as "... a narrow chain of neurons that extends vertically across the cellular layers II–VI, normal to the pial [cortical] surface" (1998, p. 165). By most accounts, in somatosensory cortex, these units consist of 80–100 neurons and form the building blocks from which larger, functionally specific cortical columns are made. As with all cortical sensory areas, the somatosensory cortex contains topographic representations of sensory inputs that project there and are thus made available to other cortical areas for processing.

The larger cortical columns that make up the somatosensory cortex consist of groups of minicolumns sharing a common feature, such as body surface location, but minicolumns within a cortical column may receive input predominantly from one type of peripheral sensory receptor type. As noted by Mountcastle, this is a way that several kinds of sensory signals can be represented in one cortical location. His pioneering work in the somatosensory cortex demonstrated that neurons in columns that are around 500 μm in size share similar functional properties and that properties change abruptly when examination moves from one column to the next. These property changes result because each column is driven by a small set of afferent fibers and afferents of several different types, or modalities, may be located at the same spot on the body. In somatosensory cortex, place is the primary representation and small zones on the body called receptive fields are best at activating neurons at a given cortical location.

Several features of the vertical architecture are unique and deserve additional mention. Although place is primarily represented in somatosensory cortex, afferents with different sensitivities and different ways of representing the same stimulus at the same peripheral location are often near each other in the cortex. Thus, contained within segments of a cortical place representation are several smaller islands in which inputs from one modality at that place are represented. The vertical organization of some parts of rodent somatosensory cortex stands out both visually and as a model for studying the relationships between peripheral receptors and their cortical representations. Cortical barrels can be seen in stained cortical cross sections and, in most instances, receive input from one peripheral hair, especially for those associated with whiskers. (This, as well as other model systems, is discussed later in this article.) Finally, some neurons in vertical units in the cortex are not so much limited to a columnar domain as they are relegated to spanning several columns. Neurons of this type may be either excitatory or inhibitory, but their function appears to be to shape the inputs and outputs of columns that may be near or at some distance from their location. Often times, inhibitory neurons are difficult to detect because, unlike neurons that are excited by stimuli, their influences are often seen in the activity of other cells whose activity patterns they influence.

Horizontal Architecture

Somatosensory cortex, like other regions of the brain, can be divided into areas based on a number of factors. Classically, Brodmann (*c.* 1909) divided the human neocortex into 52 areas based on the appearance or cytoarchitectonics of their cortical layers. Some functional regions consist of several areas. For example, the primary somatosensory cortex is thought to consist of areas 3, 1, and 2 of Brodmann. Area 3 was later subdivided into areas 3a and 3b based on different connections and functional properties of the cells located in these areas. Although many other systems for cortical classification have been offered, this one is the most commonly used.

Attempts to link cytoarchitectonics with specific functions have been, at times, instructive. Considering the primary somatosensory cortex, functions have been attributed to each of the four areas based on what functions seem impaired when one area is damaged while the others remain intact. Functions have also been inferred by recording the activity of single cells in response to control stimuli and based on connections with other brain structures having known functions. In general, areas 3b and 1 seem to process predominantly exteroceptive information, whereas areas 3a and 2 may be devoted more toward processing proprioceptive information (Figure 2). However, as with most attempts to link structure and function, this is a gross oversimplification. Certainly, each area has a different proportional distribution of submodality inputs to regions that represent a particular body part. What is now appreciated is that the activity induced in cortical neurons by stimuli cannot unequivocally be linked to select functions. This is because sensory processing of a given stimulus is itself dynamically altered by changes in attention, intention, and expectation in ways that are just now being appreciated. That appreciation has come because model systems have been used to study functional architecture.

Figure 1 Cross sections through the cortex of a rhesus monkey: (a) cross-section through the left sensorimotor cortex with boxes indicating the regions enlarged in (b) and (c); (b) an enlarged section through area 3b and the approximate boundaries of the six cortical layers (I–VI) that make up the cortex; (c) an enlarged section through area 1 and the approximate boundaries of the six cortical layers. Panels (b) and (c) depict the differences and similarities in the vertical organization of somatosensory cortex. WM, white matter.

Figure 2 The somatosensory cortex and representations of the body in the cortex: (a) lateral view of the left cortical hemisphere of a rhesus monkey, with the approximate location of somatosensory cortex visible on the surface of the postcentral gyrus shown as a blue region superimposed on the picture of the cortical surface; (b) simianuculi, distorted drawings of the body in portions approximately equal to how they are represented in cortex; (c) two parts of the representations of the body within somatosensory cortex. In (b), lighter shades indicate body regions represented more medially and darker shades indicate regions represented more laterally in the cortex. In (c) (as schematized in (b)), representations in adjacent cortical areas are essentially mirror images of one another.

Model Systems of Functional Architecture

The somatosensory cortex of some mammals is so specialized that it serves as a unique model system to study structure and function together. Functional segregation may even be seen at the macroscopic level on the surface of the brain itself. One example is the hand representation of the raccoon in which each of the lobules located in the lateral part of the cortex contains the representation of a single digit of the hand. Raccoons have great dexterity and are surprisingly agile when using their hand to manipulate objects. Perhaps this should not be a surprise because their brains are specialized to not only accommodate the myriad sensory inputs that arise from their relentless exploration of their sensory environment but also to control the movements that guide their hands. Thus, their motor cortex is highly specialized too. In some instances, animals find out about the world around them more by tactile cues than by visual ones. An example of this is the star-nose mole, which makes up for its poor eyesight with a specialized nose containing 22 fleshy appendages (Figure 3). The number of receptors per unit area in these appendages and the way in which these receptors are arranged make this mole's nose several times more sensitive than the human hand. These creatures have elaborate specialization of their brain maps which allows them to identify objects as edible in less than 10 ms.

In other animals, the segregation of functional units is no less specialized, but it is best seen with special staining. An example of this is the rodent barrel system that represents mystacial vibrissae. The rodent barrel cortex, as a model system, provides unique opportunities and challenges for studying the linkage between structure and function in the somatosensory cortex. Cortex barrels are seen best when selective tissue stains are applied to horizontal section of cortical tissue cut from flattened brains. From above, the distorted profile of much of the animal's body surface representation can be seen in sections cut through layer IV, particularly in areas representing the whiskers, where barrels are easier to spot than in other areas. This is especially true in the posteromedial barrel subfield in which there seems to be one barrel for each peripheral whisker. These barrels have cell-rich walls and cell-poor hollows or centers that are filled with fibers that synapse with cells in the wall. In layer IV, each barrel

Scale bar = 1 mm (c), 0.5 mm (d). Reproduced from Catania KC and Henry EC (2006) Touching on somatosensory specializations in mammals. *Current Opinion in Neurobiology* 16: 467–473, with permission from author.

represents predominantly one whisker, although above and below this layer inputs from adjacent whiskers can be found that shape the responses of the neurons of that barrel. Rodents explore their environment by whisking between 8 and 10 times per second. Thus, contact with objects sets up waves of afferent input that have unique spatial and temporal patterns. These can be demonstrated by recording the activity of many cortical cells simultaneously and displaying the activity patterns that arise in plots that describe what is happening spatially in the cortical representation over time. It has been shown that the waves of activation are not symmetrical but, rather, have directional biases that match well with the direction that rodents sweep their whiskers when exploring. Moreover, in time, one region of the somatosensory cortex may be highly active only to be suppressed in the next instant by sensory inputs that change the location of the focal points of activation in the cortex. In addition, when we carefully examine the activity of many neurons in different layers of the cortex, it is possible to see how information initially coming in from the thalamus is propagated through supra- and infra-granular layers of the cortex. Finally, alterations to the whiskers have been shown to result in the alteration of the sensory representations of those whiskers throughout the ascending somatosensory system. Because of the ease with which the structure of sensory representation can be demonstrated in rodent somatosensory cortex, it has been possible, using this model system, to show how excessive use or lack thereof changes the structure of the representations themselves. The ability to do this has led to theories about functional cortical plasticity that can be tested relatively easily in this model system, in which the demonstration of results is also somewhat easy to do.

Although many theories involving behavior can be tested with rodent models, those studying complex behaviors to unravel the functions that play out on the structure of the somatosensory cortex often turn to nonhuman primate models. Nonhuman primates have characteristics that make them uniquely suited for exploring the relationship between structure and function in the somatosensory cortex. Old World and New World primates have several somatosensory cortical areas that receive inputs from peripheral receptors but in different proportions. Because of this, it is possible to sample input from predominately cutaneous receptors in one region and proprioceptors in a regions just adjacent to the first. Thus, in a single experiment submodiality-specific responses to identical stimuli can be compared and contrasted. Nonhuman primates are the model choice for experiments involving complex sensory stimuli and behaviors in response to them.

Imaging the Functioning Somatosensory Cortex

The somatosensory cortex has not been imaged as much as other cortices such as the visual cortex or the frontal cortices. Those imaging studies that have involved the somatosensory cortex have provided us with a new appreciation of its complexity of function and the plasticity inherent in the system. As discussed by Mountcastle, imaging techniques in humans and animals are relatively good at answering questions about where within the somatosensory cortex functional processing is occurring and, to some extent, whether the region(s) involved stays relatively constant in size or expands and contracts as conditions change. For example, the central representations activated by peripheral stimulation have been imaged in experimental animals by 2-deoxyglucose. Often times, glucose use appears to reveal areas of activity that are many times larger than would be predicted or appreciated by conventional mapping experiments. With the use of positron emissions tomography (PET) and functional magnetic resonance imaging (fMRI) techniques has also come increasing resolution in describing regional specializations in cortical somatosensory representations. Increases in resolution have been accompanied by increases in understanding about the distributed nature of somatosensory processing and the fluidity of cortical activity. To a certain extent, these methods have shown that attention, intention to move, and expectation of reward can and do alter somatosensory cortical activity. Recent combinations of imaging techniques with electrophysiological recording within the sites of activation in experimental animals have yielded an appreciation for the potential of somatosensory cortical areas to simultaneously represent and process different types of information at the same cortical site.

Although cortical areas of activation seem to change based on stimulus conditions, there may be spatial limits to the expansion of the representation of sensory inputs imposed by the intrinsic structure of the cortex itself. Extreme examples of this are seen when sensory representations in monkeys were mapped after deafferentation. The somatosensory cortex can reorganize to represent what remains intact in the sensory periphery. But if the spatial extent of the deafferentation is too large, rather than filling in the gaps in the cortical representation, there are gaps. These gaps may belie the underlying distribution of cortical inputs to columns in the cortex. New inputs that seem to arise may actually have been there all along but have become unmasked. Spatial limitations and limits on the spread of inputs to the cortex may go hand in hand.

Plasticity in the cortex and limits on type of reorganization may themselves be different for different cortical layers. Recent evidence suggests that not all layers at a given cortical locus change in the same way in the face of stimulus conditions known to alter sensory responsiveness. Repetitive fictive whisking in rats causes facilitation of sensory responses in the cortical input layers (layers 4 and 5a) and suppression of responses in the superficial layers (layer 2/3). Moreover, repetitive touch stimulation results in stronger activation of layers 2/3 and 4 but not layer 5a. Facilitations were specific to protracting the whisker, whereas retraction was associated with depression of activity rates. This example illustrates that alterations in sensory input during active cortical processing may themselves alter the way in which the cortex responds. Moreover, this reorganization seems to be restricted by the intrinsic network dynamics which are superimposed on cortical structure.

Cortical Function during Movement

Although responses to sensory stimuli are sculpted during active use, certain similarities remain to what is seen in the quiescent condition. It is well known that the way neuronal responses under anesthesia often differ from those that can be observed during active behavior. As already noted, active areas of the somatosensory cortex depend on how and when the cortex receives input. To a certain extent, so does the extent of the region activated by a given stimulus. There are limits, however. When a portion of somatosensory cortex is deprived of functional innervation from the periphery for an extended period of time, that deprived region often can be shown to respond to inputs that were not originally there. Whether this is due to functional unmasking of inputs that were previously suppressed or the establishment of new connections to take the place of older ones is a subject of debate. What is true is that the somatosensory cortex rarely if ever reorganizes whereby new representations spring up in deprived areas that used to represent other major body parts. It seems that the line between body parts is not often crossed and may be a reflection of the intrinsic cortical connections underlying functional sensory representations.

When the activity of somatosensory cortical neurons is observed during purposeful movements, several things begin to become clear. Active movement is accompanied by the enhancement of some neurons and the suppression of others. These enhancements and suppressions vary over short time scales, of the order of tens of milliseconds, and are consistent from movement to movement if conditions remain the same. Many factors seem to influence whether somatosensory cortical neurons respond to sensory inputs. These include whether the inputs are useful in determining which type of movements should be made, whether the inputs may distract and thus compete for valuable cognitive resources needed to initiate desired behaviors, and whether inputs may get in the way of monitoring the execution of behaviors that have been initiated. As a result, for example, neurons activated by an input during the decision phase of a behavior may no longer respond as well, if at all, during the initial part of that behavior even though the activating stimulus is still present. Many have suggested that the parts of the brain that generate behaviors also send a copy of the generation signal (efference copy) to other brain regions. The purpose of this signal may be to inform the other regions that what is to come is self-generated, to cancel inputs that result from the behaviors themselves, or to establish a template against which feedback from behaviors can be compared to see if things are going according to plan. These centrally generated signals appear to alter somatosensory cortical neuronal responses to both central and peripheral inputs. The existence of these signals has been postulated, but proving unequivocally that they exist has been somewhat difficult. Theories behind them provide intriguing insights into the way the nervous system works when it is working.

Attention, Distractions, and Goals

Abrupt changes in attention, instruction and reward expectation, movement intention, and difficulty of making movements affect the activity of somatosensory cortical neurons in both profound and subtle ways. As already noted, responses in the somatosensory cortex are conditional. Attention directed toward or away from peripheral somatosensory inputs alters these responses in ways that suggest that, when the central nervous system is engaged fully in one task, things that are not important for that task have less chance of capturing the attentional spotlight. However, distracting or competing stimuli, if successful, may modify not only the response amplitudes of previously engaged cortical neurons, but may also alter the fidelity with which they represent the existence and characteristics of the stimuli to which they previously responded.

Goals instill value to inputs and allow those evaluating them to talk about the behavioral importance of both inputs to and outputs from the cortex. Most agree that representations of reward history exist in higher brain centers that are involved in decision making and strategy planning. These specialized regions of the brain ultimately connect with the somatosensory cortex, giving it access to plans and influencing the

responses to stimuli that are behaviorally important. When an individual receives positive reinforcement for a goal-oriented behavior, future behaviors often take on the same structure as those that were previously rewarded. Thus, enhanced responses to important stimuli and suppression of activity associated with inputs that are not important are maintained. However, as was recently pointed out, sometimes there is a failure to properly distinguish between previous and future goals. This situation may be associated with compulsive behavior whereby the nervous system constantly checks for behavioral completion or thinks that completed actions have not been. If higher-order brain regions involved in this sort of maladaptive behavior control the responsiveness of somatosensory cortical representations of peripheral inputs, an obvious but tragic mismatch between the actual and perceived may arise. Much remains to be known about how other brain regions influence the somatosensory cortex and how the intrinsic architecture of this cortex mediates these influences.

Changes in function of the somatosensory cortex may be momentary, as in the examples already presented, or prolonged, as in those thought to accompany aberrant motor outputs such as those associated with dystonia. Prolonged use results in prolonged sensory input which is virtually identical over time. In this worst-case scenario, local enhancements and suppressions of sensory information processing may spiral out of control until exuberant responses swamp the nervous system's ability to adjust to changing sensory and motor conditions. Forced alterations in behavior are at times effective in breaking the cycle which perpetuates inappropriate movements that may be the result of inappropriate sensory feedback about them. Although the dynamic regulations of somatosensory processing may be optimized normally and superimposed in the intrinsic structure of the cortex, things at times go drastically awry. Thus, the very processes that allow conditional adaptation may lock somatosensory processing into a cycle that must be actively broken.

Summary

Although much of the architectural framework of the somatosensory cortex is relatively fixed, dynamic changes in function occur. Even the primary somatosensory cortex does not always represent the sensory periphery in the same way. If changes in function are relatively short term, the dynamic modulations are probably accomplished without too much alteration in the structural framework. If, on the other hand, changes are profound and/or long term, structural changes may result as well. Proving that this is the case, however, has been extremely difficult because it is hard to mark what structures initially looked like to see how they have changed. In a very real sense, in the somatosensory cortex, structure and function are inextricably linked.

Somatosensory Pathways (Ascending): Functional Architecture

L Villanueva, INSERM U 677, Paris, France
L Monconduit and R Noseda, Université d'Auvergne, Clermont-Ferrand, France

© 2009 Elsevier Ltd. All rights reserved.

A number of animal and clinical studies indicate important differences in the functional architecture of ascending pathways that convey tactile and noxious inputs. Moreover, recent data demonstrate that the interactions between bottom-up and central, top-down mechanisms are probably crucial for the discrimination of innocuous and noxious information.

The Anterolateral Quadrant of the Cord

Experimental Findings in Animals

There are important differences in the anatomical and functional organization of the superficial and deep dorsal horn regions that contain the populations of spinal nociceptive neurons. These differences suggest that these areas probably play different roles in the processing of nociceptive information.

The vast majority of nociceptive primary afferent fibers terminate in the superficial dorsal horn (laminae I and IIo), some Aδ fibers terminate in lamina V, and C fibers of visceral origin terminate in laminae V–VII and X, sometimes bilaterally. Although there is no strict segregation of these two populations, it has been shown in several species that neurons activated specifically by noxious inputs are found mainly in the superficial dorsal horn (laminae I and II), whereas neurons activated by noxious and innocuous inputs are located mainly in deep laminae (V and VI). Moreover, there is also another population of neurons in the ventral horn (laminae VII and VIII) that respond to noxious inputs from widespread areas of the body.

Transections of the anterolateral quadrant (ALQ) that abolish pain arising from pathological conditions are associated with loss of thermal sensations at approximately the same levels where analgesia occurs. In this regard, ascending spinothalamic axons labeled following injections in dorsal horn lamina I neurons in monkeys cross at or just rostral to the segment of origin and ascend contralaterally in the middle of the lateral funiculus. There is in fact some variability between species and spinal cord levels with respect to the location of ascending axons from dorsal horn neurons, but most of their axons ascend within the ALQ. In the rat, these axons have a large dorsoventral dispersion within the lateral funiculus, and some are located quite dorsally. Some studies have suggested the possibility that thermoreceptive ALQ axons are located more dorsally than nociceptive axons originating from various dermatomes. Thus, it seems that thermal and pain sensations are close from both an anatomical and a functional standpoint, which could be related to the fact that both sensations are useful for homeostasis.

Although some controversy exists concerning the functional organization of nociceptive pathways in animals, the existence of an area within the ALQ that contains the main pathways giving rise to pain has been demonstrated in different species. The probability of misinterpreting the evidence obtained from experiments on species other than humans is always present since, obviously, animals cannot explain what they are feeling. Whether normal pain is always distinguished from other aversive sensations in experiments on animals is impossible to determine because the physiologist judges the presence of pain by obvious aversive reactions by the animal.

Clinical Findings
