Table 1 Classification of diabetic neuropathy based on the symmetry of the neuropathy and the type of nerves involved

Classification	*Clinical manifestations*
Symmetric	Sensory or sensorimotor polyneuropathy Autonomic neuropathy Proximal lower limb motor neuropathy
Focal or multifocal	Cranial neuropathy Trunk and limb mononeuropathy Asymmetric lower limb neuropathy Mixed

From Llewelyn JG, Tomlinson DR, and Thomas PK (2005) Diabetic neuropathies. In: Dyck PJ and Thomas PK (eds.) *Peripheral Neuropathy*, pp. 1951–1991. Philadelphia: Saunders.

painless and may represent inflammatory neuropathy concurrent with diabetes.

Focal or multifocal neuropathic manifestations Focal and multifocal peripheral nerve lesions appear to occur with increased frequency in the diabetic population. With respect to cranial nerves, painful lesions of the oculomotor nerve are the most frequent. Truncal mononeuropathies that result from lesions of the spinal or thoracic nerves may present as girdle pain or abdominal wall cutaneous hyperesthesia. At sites of entrapment, isolated limb lesions may occur. Asymmetric lower limb neuropathy is a multifocal neuropathy that, unlike proximal lower limb neuropathy, is not usually associated with a distal sensory neuropathy. Although the onset can be rapid and accompanied by proximal pain, most patients recover.

A form of proximal diabetic neuropathy linked to painful myopathy has been referred to as Bruns–Garland syndrome, diabetic amyotrophy, or diabetic lumbosacral radiculoplexus neuropathy. The clinical presentation includes acute onset of asymmetric weakness or paralysis of a lower limb. Symptoms are predominantly motor, but sensory disturbances, including altered nociception, may occur. Pain, usually worse at night, is a key symptom and often the presenting abnormality. The typical syndrome may affect the legs, perineum, and back, but radiculoplexus neuropathy has also been linked to other regions including cervical roots. The inflammatory process appears to be local rather than part of a systemic vasculitis, and in this respect, radiculoplexus neuropathies appear to be specific complications of diabetes. They occur mainly in males with type 2 diabetes mellitus. The mechanism responsible for the inflammatory process has not been identified.

Central nervous system complications The term 'diabetic encephalopathy' has been introduced to describe a syndrome of mild to moderate cognitive deficits, neurophysiological changes, and morphological abnormalities afflicting diabetics, especially elderly patients. Increased risk of stroke and poorer outcomes from cerebrovascular accidents represent additional complications resulting from diabetic angiopathy. Endocrine dysfunction manifesting as either hyper- or hypoglycemia constitutes an additional mechanism for neurological impairment. Radiological imaging studies provide evidence for brain atrophy, which is viewed as part of the phenomenon of accelerated aging in diabetic encephalopathy.

Pathophysiology

Analysis of human nerves and animal models has revealed two distinct phases of diabetic neuropathy. In the early metabolic phase, neuropathy is characterized by biochemical abnormalities and electrophysiological and blood flow deficits without significant morphologic changes. During the later phase, morphologic changes are apparent and chronic neuropathy is associated with degenerative changes of nerve fibers as well as microvascular disease.

Physiological Disturbances

Electrophysiological disturbances are extremely common in diabetic patients and are almost universal in animal models of diabetes mellitus. The earliest changes involve sensory nerve conduction and include a reduction in velocity and a decrease in amplitude as well as an increase in the temporal dispersion of compound action potentials. Motor nerve conduction is similarly affected. Nerve conduction abnormalities are often present in patients lacking symptoms of neuropathy; however, there is a greater reduction in conduction velocity in those with neuropathy. The severity of nerve conduction abnormalities increases with the duration of diabetes and is greater in newly diagnosed patients with poor control than in those with well-controlled disease. Improvement of conduction abnormalities in newly diagnosed patients has been observed following glycemic control. Improvements have also been reported following treatment with aldose reductase inhibitors (ARIs).

Diabetic nerve from patients or experimental animals possesses an ability to function during ischemia. Thus, diabetic nerve retains motor nerve conduction velocity, vibration, and tactile senses, and appreciation of pain for longer than normal nerve. Resistance to ischemic conduction failure reduces the readiness with which the person's limbs 'go to sleep' when kneeling or crossing the legs and appears to be independent of the presence of clinical neuropathy or subclinical electrophysiological changes. Resistance to ischemic conduction failure is not specific to

diabetes mellitus but is also observed in a number of other disorders, including uremia, motor neuron diseases, and chronic liver disease.

Paradoxically, although diabetic nerves are resistant to ischemic conduction failure, experimental studies have established susceptibility to nerve blood flow deficits and endoneurial hypoxia. Endoneurial hypoxia has also been reported in the sural nerves of diabetic patients and, interestingly, the hypoxia was greater in the nerves of those patients with evidence of clinical neuropathy.

Morphological Changes

The structural basis for diabetic neuropathy in humans and in animal models involves injury to all cellular elements of the nerve.

Myelinated fibers With respect to myelinated nerve fibers, the earliest structural change manifests as a diminution of the caliber of axons (axonal dwindling) that is associated with the early metabolic phase of diabetic neuropathy and occurs without other signs of fiber degeneration or loss. Axonal dwindling is thought by some to be the result of maturational arrest induced by the diabetic state. However, others have demonstrated that dwindling occurs in diabetic animals in which skeletal growth is similar to that of controls, and that it is associated with the loss of neurofilaments, the main cytoskeletal determinant of axonal caliber.

With chronic diabetic neuropathy, dystrophic and degenerative changes of axons occur (Figure 1). Dystrophic changes involve massive swelling due to accumulation of swollen organelles, microtubules, neurofilaments, dense bodies, and vesicles. Glycogen accumulation in the outer compartment of axonal mitochondria causes these organelles to swell and ultimately disintegrate. Degenerative material in axons is sometimes seen engulfed by adaxonal processes of the Schwann cell. These dystrophic changes are associated with overall loss of myelinated and unmyelinated fibers in the peripheral nerve trunks that is usually more marked distally but can involve the spinal roots. Axonal loss has been documented in symmetric, autonomic, and focal and multifocal diabetic neuropathies. Regenerative clusters of axonal sprouts provide evidence of regeneration that occurs coincident with axonal degeneration. Increased regeneration has been reported following treatment with an ARI in at least one clinical trial.

Schwann cell injury, including accumulation of lipid droplets, Pi granules of Reich (lysosomal inclusions), intermediate filament accumulation, and enlarged mitochondria, is also evident and can progress to complete dissolution of the Schwann cell with consequent demyelination. Proliferative Schwann cell changes, such as 'onion bulb' formation, are a feature of diabetic neuropathy and are indicative of repeated episodes of demyelination and remyelination (Figure 2). Interestingly, increases in the incidence of remyelination in sural nerve biopsies from diabetic patients with neuropathy have been claimed in a clinical trial following ARI treatment.

Morphologists have not resolved whether segmental demyelination or axonal degeneration is the primary lesion in diabetic neuropathy. Demyelination

Figure 1 Chronic human diabetic neuropathy: Axonopathy. Electron micrograph of nerve shows axonal dystrophy. The swollen axon is filled with cytoplasmic debris, electron-dense bodies, organelles, and filaments. Although surrounded by Schwann cell cytoplasm (arrows), the fiber is completely demyelinated.

Figure 2 Chronic human diabetic neuropathy: Schwann cell injury. Electron micrograph shows a myelinated nerve fiber surrounded by supernumerary Schwann cell processes ('onion bulb' formations). The abnormal proliferative changes emphasize the response of the Schwann cell to a chronic metabolic insult. Sprouting axons (stars) appear within some of the proliferating Schwann cells.

may be primary (i.e., resulting from a direct effect of diabetes on myelin or Schwann cell function) or secondary to axonal degeneration. Moreover, studies of other metabolic and toxic neuropathies have shown that either condition, when long established, can induce the other as a secondary change. Nevertheless, evidence is accumulating that both primary demyelination and primary axonopathy can occur independently in this complex neuropathy.

Unmyelinated fibers Early electron microscopic studies noted a distinct loss of unmyelinated fibers. Characteristic degenerative changes of these fibers include shrinkage of axons, accumulation of enlarged vesicular elements, and deterioration of tubular and filamentous elements of the cytoskeleton. Edematous Schwann cell cytoplasm has also been observed as well as hyperplasia of surrounding basal lamina. Complete degeneration results in empty or denervated Schwann cell subunits surrounded by a basal lamina. Loss of distal unmyelinated axons of the epidermal innervation has been documented using immunostaining techniques. Using similar techniques, comparable loss of intraepidermal unmyelinated fibers has also been documented in streptozotocin diabetic rats and mice. These methods are attractive not only because the biopsy is minimally invasive but also because they permit quantitative assessment of neuropathic changes and the regenerative response that may ensue.

Blood vessels A distinctive morphological change in human diabetic neuropathy is microangiopathy of the intrinsic vasa nervorum, the endoneurial blood supply of peripheral nerves. The severity of microangiopathy increases with the duration of diabetes, and reductions in endoneurial capillary density parallel reductions in nerve fiber density. Electron microscopic studies of human biopsies reveal that the marked thickening and hyalinization of capillary walls evident by light microscopy are the result of endothelial cell and pericyte basal lamina reduplication in conjunction with endothelial cell proliferation (Figure 3). Vessel wall thickening is associated with a reduction in the luminal area of endoneurial capillaries and, in one study, an increase in the number of 'closed' capillaries.

Inflammatory changes of the extrinsic vasa nervorum, ranging from epineurial vasculitis to microvasculitis, have been described in diabetic lumbosacral radiculoplexus neuropathy. Epineurial vasculitis occurs less frequently and involves larger arteries, arterioles, veins, and venules, which may have fibrinoid necrosis of their walls. More frequently, inflammatory changes manifest as microvasculitis, which involves mild perivascular and intramural infiltrates in the smaller epineurial vasculature.

Figure 3 Chronic human diabetic neuropathy: Microangiopathy. Electron micrograph of nerve shows an endoneurial capillary with mural thickening due to supernumerary basal laminae (arrows) and endothelial proliferation. A macrophage (star) filled with lamellar and crystalline debris is also visible.

Structural changes of cerebral blood vessels are part of the normal aging process, with loss of mural flexibility as the vessel walls acquire more collagen and basal laminae also thicken. Diabetic vessels appear less reactive to physiological stimuli since endothelial responses to nitric oxide-mediated dilation of cerebral vessels in streptozotocin diabetic rats is reportedly impaired.

Other changes With respect to morphological changes in other components of the nerve fascicle, thickening of the perineurial basal laminae, as well as calcification localized predominately to the outer lamellae of the perineurium, has been reported. Increases in endoneurial area have been documented in nerve biopsies from patients with diabetic neuropathy. Fibrosis is extensive, with collagen being found in the interstitium as well as within the original Schwann cell–basal lamina tube of degenerated nerve fibers. The persistence of Schwann cell basal lamina in circular profiles may reflect increased rigidity induced by nonenzymatic glycation.

Evidence for endoneurial edema had been found only in biopsy specimens until the use of magnetic resonance spectroscopy to examine the water content of the sural nerves of diabetic patients. Increased amounts of water were found in the sural nerves of patients with symptoms of diabetic neuropathy who had not received treatment but not in those treated with one of two structurally diverse ARIs. Mast cell proliferation and degranulation have been reported in animal models of diabetes as well as in diabetic patients. Mast cell granules, which contain biogenic amines capable of increasing vascular permeability and degranulation, could be either a cause or a consequence of endoneurial edema in diabetes.

Brain and spinal cord In the central nervous system, both radiological and morphological studies emphasize degenerative changes characterized by atrophy. Loss of cerebral cortical tissue accompanied by enlargement of lateral ventricles in aging diabetic patients support the idea of accelerated aging in type II diabetes. White matter changes also appear and may be related to vascular disease. Macrovascular disease involving atherosclerosis, hypertension, and impaired recovery from stroke are accompanied by microangiopathic changes in the brain and spinal cord.

Pathogenesis

It is unlikely that a single pathogenic mechanism will serve to explain the diverse clinical manifestations of diabetic neuropathy because multiple factors probably interact to produce this complex neuropathy. Current therapeutic approaches rarely normalize carbohydrate homeostasis, and both insulin-dependent and noninsulin-dependent diabetics develop neuropathy. Therefore, attention has focused on the metabolic and vascular consequences of hyperglycemia as a potential instigator of neuropathy.

Metabolic Consequences of Hyperglycemia

In diabetic complications, mechanisms of hyperglycemia-induced damage include polyol pathway flux, advanced glycation end product (AGE) formation, activation of protein kinase C (PKC), and hexosamine pathway activity. During hyperglycemia, reduction of intracellular glucose by aldose reductase results in the formation of sorbitol and concomitant oxidation of nicotinamide adenine dinucleotide phosphate (NADPH). The sorbitol formed is subsequently oxidized to fructose by sorbitol dehydrogenase with the reduction of NAD^+. Proposed detrimental effects of increased polyol pathway flux include sorbitol-induced osmotic stress, decreased Na^+-K^+-ATPase activity, increased cytosolic $NADH/NAD^+$ and consequent inhibition of glyceraldehydes-3-phosphate dehydrogenase (GAPDH), and decreased cytosolic NADPH. In nerve, aldose reductase has been localized to myelinated fiber Schwann cell cytoplasm. Extraneural sites of aldose reductase localization include skeletal muscle and endothelial cells of blood vessels. Although an unequivocal role for polyol flux in the development of diabetic neuropathy has not been established, accumulation of sorbitol and changes in cofactor levels may compromise Schwann cell metabolism, initiate reduction of Schwann cell-derived neurotrophic factors, and ultimately promote the destruction of this cell. Other consequences include nerve conduction defects, increased triose phosphate concentrations, and decreased reduced glutathione levels.

The primary initiating event in the formation of intracellular and extracellular AGEs is thought to be the generation of glucose-derived carbonyl precursors by auto-oxidation of glucose to glyoxyl, decomposition of Amadori product to 3-deoxyglucosone, and fragmentation of triose phosphates to methylglyoxal. Potential detrimental effects of AGE production are wide ranging. Proteins modified by AGE formation have altered function and structure, with negative consequences for enzyme function, and interaction of extracellular matrix ligands and receptors. Activation of AGE receptors on endothelial cells and macrophages also induces receptor-mediated production of reactive oxygen species.

PKC is a family of 11 isoforms, the majority of which are activated by the triose phosphate lipid second messenger diacylglycerol (DAG). In diabetes, the β and δ isoforms of PKC are activated by hyperglycemia-induced increases in DAG, which are thought to be the consequence of the cytosolic $NADH/NAD^+$ imbalance and consequent inhibition of GAPDH that results in elevated triose phosphate levels. Many of the proposed effects of PKC activation in diabetes are vascular and include blood flow abnormalities resulting from altered expression of endothelial nitric oxide synthase and endothelin-1; changes in vascular permeability and angiogenesis mediated by enhanced vascular endothelial growth factor expression; capillary and vascular occlusion resulting from increased collagen and fibronectin expression; and decreased fibrinolysis due to altered expression of transforming growth factor (TGF)-β and plasminogen activator inhibitor-1, respectively.

Aside from increases in triose phosphates, another consequence of hyperglycemia and hyperglycemia-induced inhibition of GAPDH is increased activity of the hexosamine pathway. Shunting excess intracellular glucose into the hexosamine pathway results in conversion of fructose-6-phosphate diverted from glycolysis into glucosamine-6-phosphate via the rate-limiting enzyme, glutamine:fructose-6-phosphate amidotransferase. The glucosamine-6-phosphate is subsequently converted into UDP-*N*-acetylglucosamine, which is believed to modulate transcription factors responsible for the production of TGF-β and plasminogen activator inhibitor-1 implicated in the vascular abnormalities alluded to previously.

Specific inhibitors of polyol pathway activity, AGE formation, PKC activation, and hexosamine flux have been shown to ameliorate early hyperglycemia-induced biochemical and functional nerve disorders, emphasizing the potential role of these mechanisms in the pathogenesis of diabetic neuropathy. Studies have

implicated oxidative stress as an element common to these mechanisms and emphasized their interrelationship. Others have suggested that oxidative stress is the common element linking these mechanisms of hyperglycemia-induced damage, with each of the four mechanisms reflecting overproduction of superoxide by mitochondrial electron-transport chains. However, despite these contentions, there is little direct evidence supporting an oxidative stress-mediated link between early metabolic events and subsequent structural injury characteristic of diabetic neuropathy. Such evidence is critical for evaluating the overall importance of oxidative stress in the pathogenesis of diabetic neuropathy.

Vascular Consequences

Reduced nerve blood flow and an associated endoneurial hypoxia have been reported in both acute and chronic experimental diabetes and in diabetic patients. In diabetic animals, improvements in electrophysiological deficits occur with any of a variety of agents that improve nerve blood flow. These agents include vasodilators such as α_1-adrenoreceptor blocking agents, calcium channel blockers, drugs that inhibit the renin–angiotensin system, and vasomodulator prostanoids. Other treatments used in experimental animal models of diabetes that can act via vascular-related effects to improve nerve conduction include omega-6 essential fatty acids, antioxidants, aminoguanidine, and ARIs. The fact that so many agents can alter blood flow in both animal models of diabetes and patients with diabetes suggests that dysfunction of blood vessel endothelial cells underlies nerve blood flow deficits. Moreover, the efficacy of ARIs and aminoguanidine in preventing nerve blood flow and conduction deficits argues for a role for the polyol pathway and nonenzymatic glycation in the vascular consequences of endothelial cell dysfunction and the etiology of diabetic neuropathy, as indicated previously.

Dichotic Listening Studies of Brain Asymmetry

K Hugdahl, University of Bergen, Bergen, Norway

© 2009 Elsevier Ltd. All rights reserved.

Dichotic Stimuli

The stimuli typically used in dichotic listening (DL) studies consist of presentations of pairwise combinations of consonant–vowel (CV) syllables that are made up of the six stop-consonants /b/, /d/, /g/, /p/, /t/, and /k/, and the vowel /a/.Thus, examples of DL stimulus pairs are /ba/–/pa/, /ga/–/pa/, and so on. Another often-used variant of the DL test is the so-called fused rhymed words test. These stimuli are computer synthesized and consist of consonant–vowel-consonant (CVC) pairs. The stimuli are synthesized so that the nondistinctive components of each pair are identical (e.g., /aba/–/aka/). The temporal and auditory spectral overlap between numbers of each pair in this test is so great that they fuse into a single auditory percept.

The Dichotic Test Situation

Preparation of dichotic stimulus materials requires computer editing on each trial of the two CV syllables. The most important aspect of the editing procedure is the synchronization of the onset of the energy release in the two syllables in a pair. The syllables are synchronized on both the consonant and vowel segments, which usually requires access to speech synthesis analysis capability. Figure 1 shows a computer display of the syllables /ba/ (top) and /pa/ (bottom) that are synchronized on both the consonant and vowel onset.

DL Paradigms

The most commonly used paradigms in DL laterality studies are the free-report paradigm, the forced-attention paradigm, the fused-rhymed paradigm, and the target-monitoring paradigm. In the free-report paradigm, individuals are required to report the items that they heard on each trial as accurately as possible. Only those trials in which a person can identify one item, but not the other, correctly reveal information about brain laterality. Thus, as a general rule, only single-correct trials should be analyzed. An alternative is to instruct the person to answer only for one item on each trial. The experimenter then calculates number of correct reports from the right and left ears, separately. The free-report paradigm requires that the person has intact speech and can give an oral answer. Thus, the free-report paradigm is less well suited for the study of laterality in clinical populations with speech dysfunctions.

In the target-monitoring paradigm, some of the items in the list to be presented are selected as 'targets,' and the person is instructed to indicate (manually or orally) whenever he/she detects a target. Usually CVC syllables or words are used in the target-monitoring paradigm. The target-monitoring paradigm has the advantage that it can be used also with persons who lack expressive speech.

The fused-rhymed paradigm is similar to the free-report paradigm except for the important distinction that the two sounds presented at the ears fuse into a coherent perceptual unit. A characteristic of the fused-rhymed paradigm is that although individuals subjectively report that they hear only one sound, they report this to be the right-ear item.

The forced-attention paradigm allows for the study of attentional influences on brain laterality. The paradigm involves instructing the individual to pay attention only to the right ear, and report only from that ear in half of the trials, and to pay attention to and report only from the left ear in the other half of the trials. Often there is a third condition included whereby the person is not given any specific instructions. In that case, each instructional condition then applies to a third of the trials.

The Right-Ear Advantage

Irrespective of whether nonfused CV syllables or fused CVC syllables are used, the typical outcome in a standard DL test is a greater percentage of correct reports from the right ear, as compared to the left ear. This is called a right-ear advantage (REA) and is a robust empirical finding in both right- and left-handed persons. The REA is most easily seen in response to the consonant, and is difficult to observe in response to the vowel in a CV syllable. It has thus been argued that the REA might reflect hemisphere specialization for rapidly changing auditory stimuli, such as the rapid formant transition seen in the stop consonants. Figure 2 shows the distributions for correctly reported items from the right-ear (red) and left-ear (blue) stimuli from 694 right-handed adults. Note the apparent shift to the right for the right-ear stimulus distribution.

Attentional Factors

DL also indicates dynamic laterality factors, such as attention, which may modulate a structurally based

Figure 1 Computer display of the CV syllables /ba/ (top) and /pa/ (bottom) synchronized at the energy release at both consonant and vowel onset segments.

Figure 2 Number of adult study participants ('subjects'; *y*-axis) plotted against correctly reported CV syllables presented in the right ear (red distribution) and left ear (blue distribution), respectively. Data from 694 right-handed adults.

laterality when the individual shifts attention to the right or left side in auditory space. In the typical DL test, one-third of the trials involve a 'nonforced' attentional condition, where individuals are not given any particular instructions regarding deployment of attention. In one-third of the trials the person is instructed to attend to and report from the right ear (forced-right attention), and in one-third of the trials the person is instructed to attend to and report from the left ear (forced-left attention). The REA is increased during the forced-right attention condition, and a left-ear advantage (LEA) is observed during the forced-left attention condition. Thus, attentional factors can sometimes override the basic REA asymmetry, providing evidence for a 'top-down' instruction-driven modulation of a 'bottom-up' stimulus-driven laterality effect. Studies in our laboratory have, however, shown that top-down modulation is reduced in children, particularly before literacy, and in psychiatric patients. The switching of an REA to an LEA during forced-left attention is also dramatically reduced in patients with right-sided brain damage.

Neuroanatomical Basis

The REA is believed to be caused by the fact that although auditory input is transmitted to both auditory cortices in the temporal lobes, the contralateral projections are stronger and more preponderant, interfering with the ipsilateral projections. The advantage for the contralateral auditory projections means that the language-dominant left hemisphere receives a stronger signal from the right ear. The contralateral signal from the left ear to the right hemisphere must first pass the corpus callosum in other to be processed in the left hemisphere. Following the same logic, an LEA indicates the right hemisphere to be language dominant, and a no-ear advantage (NEA) indicates a bilateral language dominance.

In an O^{15}-positron emission tomography (PET) study in our laboratory using a DL target monitoring paradigm, we compared brain activation to CV syllables and musical stimuli that were presented dichotically. The CV syllables and musical stimuli showed opposite activation asymmetries in the temporal lobe. Greater activation was observed in the left superior temporal gyrus to the CV syllable stimuli, while greater activation was observed in corresponding right temporal lobe areas to the musical stimuli. Interestingly, overall activation and the intensity of activation were greater in response to the CV syllable stimuli compared with the musical stimuli. This may indicate specialized cortical networks in the left hemisphere for the processing of linguistic stimuli, also including the planum temporale area. The PET data are shown in Figure 3.

Validity and Reliability

The REA to dichotic presentations of CV syllables is usually about 20% in order of magnitude for oral reports, with about 50–70% correct reports from the right ear and 30–50% correct reports from the left ear. The REA is observed in about 85–90% of right-handed persons, and in about 65% of left-handed persons. The magnitude of the REA may, however, vary considerably among individuals within a given ear advantage direction. Scatterplots of DL correct reports from the right and left ears for more than 1000 persons, both children and adults, are seen in Figure 4.

The 85% of right-handed subjects to be identified as left-hemisphere-language dominant by the DL technique is about 10% lower than what is obtained

Figure 3 ^{15}O-PET brain activation data in response to CV syllables and musical stimuli. Note the leftward asymmetry for the CV syllable stimuli, and rightward asymmetry for the musical stimuli. when invasive techniques, like the Wada test, are used. The Wada test involves selective injection of a barbiturate into the right or left hemisphere, 'silencing' the injected hemisphere for about 10 min. The 10% discrepancy between DL and the Wada test probably reflects that DL, in addition to indicating cortical function, also reflects subcortical thalamic influences on language lateralization. DL also picks up perceptual language laterality in addition to expressive speech laterality, whereas the Wada test is an exclusive test of speech laterality. Measures of test–retest reliability vary between 0.70 and 0.90 across different studies. The variation across studies may stem from differences in the reliability index used. However, a study from our laboratory showed that of 17 epileptic patients undergoing both the Wada test for language dominance and DL, 94% of the cases were correctly classified with the DL technique from a stepwise discriminant analysis. The DL results are shown in Figure 5, together with an indication of left- (blue dots) or right- (red dots) hemisphere speech according to the Wada test.

Figure 5 Wada test validation of DL scores from 17 adolescent epileptic patients. Overall, 94% of the group was correctly classified. Data courtesy of Göran Carlsson and Paul Uvebrant, Kiel, Germany, and Göteborg, Sweden.

Calculation of DL Scores

The ear advantage in DL may be calculated in different ways. The most straightforward and simple method is to calculate the number of correct reports from each ear. Since this measure does not compensate for differences in overall performance (i.e., total correct reports) among individuals, some authors favor an index score, where right-ear minus left-ear scores are divided by the sum total of left-ear plus right-ear scores. Still another way of handling DL scores is to display the number of individuals that show a particular ear advantage in scatterplots, as shown in Figure 4.

Arousal and Activation

DL scores may be affected by factors other than brain laterality, and it has been shown that individual differences in arousal or activation may attenuate the REA. Specifically, experimental manipulations whereby the persons are made to believe that they will receive an electric shock to their hand whenever they make an error have been shown to drastically attenuate the REA. This is probably caused by an increase in both brain stem reticular and right-hemisphere activation (right hemisphere being

particularly sensitive for emotional events), which interferes with left-hemisphere processing of the contralateral right-ear signal.

Studies with the forced-attention paradigm have generally revealed that the REA is not an attentional artifact, with right-handed persons attending to the right side in space, which causes the right-ear signal to be better perceived and reported. Experimental manipulations whereby the person is explicitly instructed to turn his/her head and eyes toward the right or left side in space do not seriously affect the REA.

Developmental Effects

The REA to CV syllables can be observed in children as young as 3 years of age, and is frequently reported in 5-year-old children. The magnitude of the REA does not change with age, but stays rather constant. However, the overall level of performance increases with increasing age. Furthermore, preliterate children also report more items from the right ear during testing following instructions to focus attention to the left ear, as in the forced-attention paradigm. The constancy of the REA across different age levels is taken as an indication that brain laterality is not subject to ontogenetic development, and that it is present already at the infant stage.

Sex Differences and Handedness Effects

Males and females differ regarding several cognitive processes (language, visuospatial skills) that are differentially mediated by the left and right hemispheres. The sexes also differ in disorders related to hemisphere differences in brain function. Various disorders such as dyslexia, hyperactivity, and stuttering occur more frequently among boys than girls. Aphasia is also more commonly seen in males than in females after unilateral left-sided lesions. All this evidence points to the hypothesis that females are either less lateralized than males for certain cognitive functions, or that they have a more diffuse cortical organization for cognitive function.

Similar patterns of responding have been obtained in DL tests, with a greater proportion of males than females showing a REA to CV syllables. Males as a group also show a greater mean REA in the standard free-report DL paradigm. It is known that there are differences in cortical organization between right- and left-handers. Only about 65–70% of left-handers are left-hemisphere dominant for language, compared to 95–99% of right-handers. It then follows that right- and left-handers should also differ in their DL performance to CV syllables. Although not all studies have found significant group-mean differences in ear advantage magnitudes between handedness groups, almost every study has reported a tendency for attenuation of the REA in left-handers compared to right-handers. Usually the difference in the magnitude of the REA between right- and left-handers is in the order of 10–15%. The higher proportion of right-handers showing an REA also seem to be independent of the testing procedure or the kind of paradigm used.

Clinical Populations

Commissurotomized patients with sectioning of the corpus callosum show almost complete suppression of the left-ear signal. This is termed 'paradoxical left-ear extinction' and is explained with reference to Kimura's model of suppression of the ipsilateral auditory pathways under dichotic competition. Thus, in a patient with a split brain, the right-ear signal reaches the left temporal cortex unopposed by the ipsilateral right-ear signal. However, the left-ear signal reaches the right hemisphere, and because of the sectioning of the corpus callosum, it cannot be relayed to the left hemisphere for processing.

DL has been used to assess anomalous brain laterality patterns in, for example, stuttering and dyslexia. Although several studies have reported reduced REA magnitudes in these groups, the evidence is not convincing and more research is needed. The DL technique has also been used in studies of schizophrenia and in affective disorders, under the assumption that these disorders are related to left- and right-hemisphere dysfunctions, respectively. The DL data support a notion that schizophrenia may be associated both with left-hemisphere overactivation and with an interhemispheric transfer deficit, although the findings to some extent are controversial.

Nonverbal Stimuli and Lateralization of Affect

Studies of lateralization of affect have involved both the expression of an emotion, as in facial emotional expressions, and the perception of affect, as in the presentation of an emotional stimulus. To summarize, most studies have revealed a right-hemisphere superiority for both expression and perception of affective, or emotional, events. One question that still arouses controversy in the literature is whether the right-hemisphere superiority for emotional processing is valid for both positive and negative emotions.

DL studies of affect have employed either verbal stimuli differing in prosody (vocal intonation), or nonspeech sounds, such as crying or laughing. DL

studies with nonspeech sounds have in general revealed a left-ear advantage in most persons, supporting right-hemisphere processing superiority for these kinds of stimuli. DL studies of differences in prosody to speech sounds have also revealed a larger proportion of persons with an LEA than an REA. However, it is at present unclear whether this is specifically tied to the prosodic component in speech, or whether it is related to an overall right-hemisphere specialization for emotional processing.

Differentiation: The Cell Cycle Instead

Introduction

Generation of the central nervous system (CNS) requires a fine balance between the processes of cell proliferation, cell fate determination, and differentiation, but the coordination between these processes has only relatively recently begun to be understood. One can envisage models in which cell cycle status influences cell differentiation or, conversely, in which the process of differentiation has effects on the cell cycle. However, it is becoming increasingly clear that there are complex multidirectional links between processes at many stages (Figure 1). To understand these links, we must first examine what is known about cell division in the CNS.

Cell Division in the Nervous System

The entire nervous system must be generated from division of a relatively small number of initial precursors during development, and, not surprisingly, a strategy of both symmetrical and asymmetrical cell divisions is adopted. First, neuroepithelial (NE) cells, the stem cells of the mammalian nervous system, can divide symmetrically to generate two identical daughters in what are known as proliferative divisions. Alternatively, they can divide asymmetrically to produce one NE cell and one non-stem cell progenitor or differentiating neuron. Non-stem cell precursors may also divide again to form neurons and/or glia, generating enough cells to populate the nervous system. Neuroepithelial cell progeny can adopt any neural or glial cell fate. However, as development progresses, NE cells divide to produce stem cells with a more restricted range of fate known as radial glial (RG) cells, and most brain neurons are derived from RG cell divisions. Finally, cell proliferation is coordinated with regulated cell death to generate the nervous system.

The progeny of neurogenic divisions (i.e., divisions that generate differentiating neurons) must adopt the correct fate in response to both internal and external cues, and it is becoming increasingly apparent that this process is both coordinated with and influenced by the cell cycle. Indeed, this is obviously essential if the correct number and distribution of neurons and glia are to form in the animal, although the complexity of the relationships involved has meant that, until recently, relatively little has been known about the links between cell cycle and differentiation in the nervous system.

Interestingly, the transition from NE to RG cells and their subsequent progression from proliferative to neurogenic divisions may be influenced by cell cycle length; in particular, G_1 phase elongates as this process proceeds. Experimentally, when a chemical cyclin-dependent kinase (cdk) inhibitor olomucine was used in whole mouse embryo cultures at a dose sufficient to lengthen but not block the cell cycle, this resulted in premature neurogenesis. The 'cell cycle length hypothesis' has been proposed to explain these and other results, where it is suggested that a longer G_1 phase allows factors that promote progression from NEs to RGs to neurons greater time to act. Thus, a lengthened cell cycle will promote these transitions.

Cell Cycle and Cell Fate in the *Drosophila* Nervous System

Important information about the molecular links between cell cycle and cell fate has emerged from studying less complex organisms, which are amenable to genetic manipulation. This is perhaps most vividly illustrated by the differentiation of *Drosophila* neuroblasts, which divide and differentiate in a stereotypical manner that makes them particularly amenable to experimental study. Neuroblasts, the stem cells of the *Drosophila* nervous system, can self-renew but also generate a variety of different neurons and glia; a neuroblast division results in generation of another neuroblast and a smaller ganglion mother cell, which will itself divide again to generate two postmitotic neural or glial daughters. The number of times a neuroblast will divide depends on the expression of a sequential series of transcription factors, which are intimately involved in determining the identity of their progeny. If the cell cycle is blocked prior to neuroblast cell division using a mutant of the cell cycle activator String (cdc25), cells maintain expression of the first transcription factor in the series, hunchback. Therefore, it is passage of the cell cycle and not just passage of time that is needed for the changing pattern of transcription factor expression. However, when both String and Hunchback are knocked out, the cell cycle-arrested neuroblasts do go on to express the normal sequence of transcription factors, so this later phase must be cell cycle independent, indicating the complexity of the situation.

Figure 1 Models linking cell cycle and differentiation processes on the transition from neural precursor (left) to differentiated neuron (right).

Cell Cycle Stage and Cell Fate

The fate of the neurons produced from ganglion mother cell (GMC) divisions is generally determined by expression of transcription factors during the last cell cycle. The same phenomenon may be observed in *Xenopus* retinal progenitors, when transcription factors which determine specific cell fates are upregulated concomitant with a downregulation of cell cycle activator molecules.

Cortical development in mammals shows an unusual 'inside-out' morphology in which the older neurons are found nearer to the ventricular zone, whereas younger-born neurons migrate through to the upper cortical layers, and cells in different layers ultimately adopt specific fates. McConnell and Kaznowski investigated the influence of cell cycle phase on laminar identity in mice. Neuronal precursors from young animals were labeled with tritiated thymidine and then transplanted to an older host. If the cells were transplanted in S phase of the final cell cycle, they were found in layer 3, indicative of an earlier than expected fate, whereas if they were transplanted in mitosis, the cells were ultimately found in layer 6, their expected site. Therefore, it appears that laminar fate is determined in S phase of the final cell cycle and that cell cycle status influences differentiation. There are several ways in which cell cycle stage could influence cell fate, and these may be dependent on events specific to that stage.

Exit from the cell cycle, transiting from G_1 into a G_0 phase, is required for neuronal differentiation. Therefore, it is intuitive that factors influencing the cell cycle will influence differentiation; indeed, cell cycle regulators can directly influence the activity of determination factors. Moreover, there could be cell cycle-dependent expression of transcription factors that influence determination. This is clearly seen, for example, with the homeobox transcription factor prox1, required for determination of horizontal cells in the retina, which is maximally expressed at G_2 phase.

Other characteristics of specific cell cycle phases can also be exploited to coordinate cell fate determination and differentiation. For instance, as described previously, cortical neuronal cell fate seems to be largely determined in S phase. This may be a result of chromatin remodeling which can occur most efficiently at this phase, when complex chromatin structures are opened up to allow DNA replication. This suggestion is supported by evidence that chromatin remodeling complexes play a crucial role in neuronal differentiation. For instance, mice lacking Srg3, a core subunit of the SWI/SNF chromatin remodeling complex, have severe defects in neuronal proliferation and differentiation. Moreover, neurogenin is a central basic helix–loop–helix (bHLH) transcription factor that influences cell fate in many areas of the nervous system, at least in part, by influencing chromatin structure via recruitment of remodeling complexes.

Cell fate can also be determined in mitosis by asymmetrical distribution of determining factors, which is affected by orientation of the mitotic machinery. For instance, in *Drosophila*, Prospero is a transcription factor that is preferentially passed to GMCs and inhibits neuroblast (NB)-specific gene expression. Failure to divide results in repression of NB identity. In addition, blocking the function of the mitotic kinases cdc2 and Aurora A leads to impairment of cell fate determinant localization. Moreover, cyclin E expression may influence symmetry of neuroblast division in the *Drosophila* abdomen, independent of its effects on the cell cycle.

Cell Cycle Genes Regulate Cell Fate and Differentiation in the Nervous System

Differentiation of neurons is likely to be influenced by the proliferation status of the cells. In addition, many instances are now emerging of cell cycle regulators playing a direct role in influencing cell fate and differentiation in the nervous system and even playing a role in some postmitotic aspects of neuronal

function. Although our understanding is far from complete, some interesting themes are emerging, particularly the occurrence of two independent but complementary functions residing within the same cell cycle regulator. Such an approach allows precise coordination between cell cycle exit and differentiation processes and, as such, makes good developmental sense.

The retina is a good system in which to study whether cell cycle influences cell fate because a wide range of different cell types are produced from a single neurogenic precursor type. Normally, early born cell types arise from precursors that exit the cell cycle at an early stage, whereas the converse is true for late-born cell types. Cycling, *per se*, is not essential for producing cell diversity; blocking DNA replication early in retinogenesis still results in production of cells of all the expected histogenic cell types. However, the proportions of these cells are influenced by the cell cycle. For example, atonal-type bHLH transcription factors can influence histogenesis; overexpression of Xath 5 promotes early fates such as the production of retinal ganglion cells. Early cell cycle exit, brought about by co-overexpression of the *Xenopus* cdki Xic1, potentiates this effect, whereas inhibiting the cell cycle by overexpression of cyclin E does the opposite – inhibiting early and biasing toward late cell fates.

Cell Cycle Progression

The cell cycle is driven forward by the action of cdks (Figure 2) that phosphorylate key targets such as initiators of DNA replication, proteins that regulate nuclear envelope breakdown and spindle formation, and so on to bring about cell cycle transitions. Different cdks act at different phases of the cell cycle, and their activity depends on their binding to specific cyclins. Cyclins, in turn, are regulated not only by transcription but also at the level of protein stability.

Figure 2 The cell cycle. Cell cycle regulators act at different phases of the cell cycle and also influence cell fate and differentiation in the nervous system.

For instance, the transition from G_2 to M phase is brought about primarily by the activity of cylin B/cdc2. To exit mitosis, cells must degrade cyclin B, and this is effected by ubiquitin-mediated proteolysis controlled by the anaphase-promoting complex (APC), bound to cdc20. Cyclin B levels are kept low in G_1 phase by the continuing activity of the APC, this time bound to cdh1.

Another key transition point in the cell cycle occurs in G_1 and is known as the restriction point (R). After cells have passed R, they can traverse the rest of the cell cycle without any further external stimulus, and passage through R corresponds to the phosphorylation and inactivation of the retinoblastoma protein. Alternatively, cells can exit the cell cycle before R and enter G_0, a process that is facilitated by the activity of cyclin-dependent kinase inhibitors (cdkis). After cell cycle exit into G_0, cells undergo differentiation (Figure 2).

Cyclin-Dependent Kinase Inhibitors

The role of cdkis in neuronal differentiation of mammals has been reasonably well studied, particularly using an oligodendrocyte model system. O-2A cells are bipotential progenitors that have the ability to differentiate into type 2 astrocytes or oligodendrocytes. Differentiation in the presence of mitogens is regulated by an internal clock that measures time rather than cell divisions, and the cdki p27Kip1 (Kip1) is a component of this clock; Kip1 levels rise progressively through O-2A cell divisions and then reach a plateau at the time of cell cycle exit and differentiation. Experimentally, the speed of the clock can be altered by growing cells at different temperatures. This works by changing the levels of Kip1, a protein whose stability is controlled by ubiquitin-mediated proteolysis. Interestingly, the cdki p21Cip (Cip1) is also involved in O-2A differentiation; Kip1 is needed for cell cycle arrest, but Cip1 may have a role in differentiation independent of its ability to control cell cycle progression. In mice, it has been shown that Kip1 can independently promote neural differentiation and migration in the cerebral cortex and at least some of these functions are independent of its ability to inhibit cdks. A third mammalian cdki, p57 Kip2 (Kip2), can regulate differentiation of neurons where it has been shown to play two roles in amacrine cell differentiation – promoting cell cycle exit and then postmitotically influencing amacrine subpopulation development.

Indeed, although the most well-established function of cdkis is to inhibit the kinase activity of cyclin-dependent kinases, many studies have demonstrated that cdk activity can directly affect neuronal

differentiation as well as affect postmitotic neuronal functions. Nerve growth factor (NGF)-induced differentiation of PC12 cells into neurons is associated with a decrease in cdc2 and cdk2 activity, and strikingly, inhibition of cdc2 and cdk2 activity alone is sufficient to trigger PC12 cell differentiation. Normally, Cip1 levels rise dramatically on PC12 cell differentiation, and indeed, ectopic expression of Cip1 alone is enough to mimic NGF-induced differentiation and trigger the formation of neurons.

The Cdki *Xenopus* Xic1 has complementary but independent roles in regulating other functions independent of its ability to arrest the cell cycle. Müller glial cells are the last cells to be born in the *Xenopus* embryonic retina, and this coincides with accumulation of the highest levels of Xic1. Overexpression of Xic1 in the retina strongly promotes formation of Müller glial cells at the expense of neurons. Mutational analysis of Xic1 has demonstrated that this activity resides near its N-terminus and is independent of its ability to arrest the cell cycle or inhibit overall cdk kinase activity. Similarly, Xic1 is required for differentiation of primary neurons in *Xenopus*, the first neurons to differentiate out of the neural plate. Again, this activity is independent of cell cycle effects and found near the N-terminus. Interestingly, in this case Xic1 has been shown to act at an early stage of neurogenesis, in parallel with the bHLH transcription factor neurogenin, where it may influence neurogenin protein stability. Such cell cycle-independent functions of cdkis in the mammalian nervous system have also recently emerged.

Cyclins and Cyclin-Dependent Kinases

Different levels of cyclins have interesting influences on neuronal cell fate and differentiation. Increasing the level of cyclin E in the developing *Xenopus* retina promotes late-born cell fate types. In mammals, cyclins D1 is found at high levels in proliferating cells of the retina and cerebellum, whereas cyclin D3 is found specifically in differentiating retinal Müller glial cells. Cyclin D2 knockout mice have a decrease in granule cell number and have no stellate interneurons. However, basket and Golgi interneurons are unaffected in the mice even though they come from the same precursor, suggesting that cyclin D2 influences cell type as well as cell cycle. Cyclin D1 null mice have reduced thickness of all retinal cell layers, possibly the result of a reduction in proliferation and specific apoptosis of photoreceptors. Surprisingly, cyclin D1 levels rise on differentiation of PC12 cells, but because there is apparently no increase in associated cdk4 kinase activity, the role of this is unclear.

Cdk5 is unusual among the cdks in that it does not seem to play a direct role in cell cycle progression. Instead, it has important functions in postmitotic neurons, in which it complexes with the p35 and p39 proteins to regulate differentiation and neurite outgrowth. However, because cdk5 can also complex with cyclin D and Kip1, it may also have influences on the cell cycle, although these have been poorly investigated. However, one study has shown that cdk5 can phosphorylate and stabilize Kip1 protein in postmitotic neurons, in which it is required to regulate neuronal migration.

The Anaphase Promoting Complex

Cell cycle progression is driven forward by the action of cdks, which are activated by binding to cyclins. To drive the cell cycle in one direction, cyclins must be cyclically destroyed and this is brought about via their ubiquitin (Ub)-mediated proteolysis. The APC is an E3 ligase required to facilitate conjugation of Ub to a variety of substrates, including cyclin B. In mitosis, APC is activated in part by the presence of a cdc20 subunit to target mitotic substrates, whereas this is replaced by cdh1 in G_1, in which the APC still has E3 Ub ligase activity. Remarkably, APC/cdh1 is highly expressed in postmitotic neurons, and a cdh1 knockdown has been shown to promote neurite outgrowth. Moreover, APC/cdh1 controls synaptic size in *Drosophila* via its ability to control stability of the liprin protein. Again, we see a protein complex with dual roles in controlling the cell cycle and other aspects of neuronal differentiation/function.

The Retinoblastoma Protein

One of the key targets for phosphorylation by cdks that allows them to control cell cycle progression is the retinoblastoma protein (Rb). Rb is required to regulate the passage through G_1 phase. At its most simple level, underphosphorylated Rb protein, found in early G_1, binds to and represses the transcriptional activity of the E2F family of transcription factors, whose targets include many genes that are essential for progression into S phase. As G_1 proceeds, Rb becomes progressively phosphorylated first by cyclin D/cdk4 and then by cyclin E/cdk2. Phosphorylated Rb is no longer able to bind to E2Fs, so it releases them to allow transcription of E2F-dependent genes and transition into S phase. However, it should be emphasized that this is a very simplified view of Rb function; Rb has been shown to bind numerous proteins besides E2F, where the function of these interactions is often unknown, and there are several members of the Rb family with at least partially overlapping functions.

Rb was first identified as a gene inherited in families with children who develop multifocal retinoblastoma

tumors of the eye, indicating an important role in cell proliferation and/or differentiation of the retina. Because Rb is thought to be a crucial cell cycle regulator in most, if not all, cell types, it is perhaps surprising that we still do not understand why the greatest tumor predisposition is for cancers of the nervous system. Mutations of Rb family members have also been found in astrocytomas, glioblastomas, and gliosarcomas, but it is also clear that Rb heterozygous individuals are susceptible to other nonneurological tumors later in life, particularly osteosarcomas. Indeed, some component of the Rb pathway, although not necessarily Rb, is thought to be mutated in the vast majority of human tumors.

An early function for Rb in the development of the nervous system was inferred from the severe neurological phenotype seen in Rb null mice, which die by embryonic day 14. However, it has been shown that many of these problems arise as a result of placental insufficiency; if Rb null embryos are rescued with wild-type placentas, then they have a relatively normal nervous system. However, Rb is strongly expressed in the CNS and, in common with Kip1, its overexpression alone is enough to induce differentiation of neuroblastoma cells, indicating specific roles in neural tissue.

It seems likely that Rb may influence neuronal differentiation independently of its ability to control cell cycle, and indeed, in some cultured cell systems, regulation of cell cycle and differentiation by Rb can be separated. At a molecular level, our best understanding of how Rb can directly influence differentiation comes from the study of myogenesis. Interestingly, studies mainly of cultured cells have shown that Rb not only facilitates cell cycle exit but also cooperates with the bHLH myogenic factor MyoD to activate the MEF2 transcription factor. It has also been reported that Rb may directly influence bHLH factor function by binding Id2, an inhibitor of bHLHs with which it can dimerize but these resultant dimers can no longer bind to DNA and activate transcription. Moreover, a study has shown that Rb may be a coactivator for the neurogenic bHLH NeuroD1.

The p53 Family

p53 is a transcription factor whose activity is disrupted in a wide range of tumors. p53 can transactivate both Cip1 and genes involved in apoptosis, and it has been implicated in neurogenesis, although its precise function has been difficult to identify. p53 does seem to accumulate in the nucleus of neuronal cells at an early stage of differentiation. Moreover, a dominant-negative form of p53 inhibits the cell cycle exit and differentiation of O-2A cells on treatment with thyroid hormone. p73, another p53 family member, can also induce the expression of Cip1. p73 null mice are missing the earliest sort of neurons, Cajal–Retzius cells. Moreover, retinoic acid treatment induces the differentiation of a retinoblastoma cell line and this results in upregulation of p73. Overexpression of p73 alone will promote differentiation of these cells, whereas a dominant negative form of p73 blocks retinoic acid-induced differentiation; therefore, it seems that p73 can also regulate both cell cycle and differentiation.

Geminin

Geminin is an excellent example of a protein with dual functions in cell cycle and differentiation. The gene was initially identified in two independent screens, one for proteins that could perturb early *Xenopus* neural development and the other searching for proteins that are specifically degraded during mitosis. It has subsequently become apparent that geminin has at least two functions: (1) to regulate the loading of the mini-chromosome maintenance proteins onto prereplicative DNA prior to S phase and (2) to maintain neuronal progenitors in a proliferative precursor-like state. It performs this second function by apparently binding to and blocking the function of Brg1, a component of the SWI/SNF chromatin remodeling complex, which is required to act with the bHLH neurogenic transcription factors Neurogenin and NeuroD to promote neural differentiation. Geminin levels decrease in differentiating neurons and this may be required to trigger neuronal differentiation. Moreover, other studies have shown that geminin can also interact with Six- and Hox-related transcription factors, so its ability to modulate transcription both within and outside the nervous system may be widespread.

Differentiation and Patterning Factors Regulate the Cell Cycle

Based on the evidence described previously, it is clear that both cell cycle status and cell cycle regulators influence many aspects of cell fate choice and differentiation in the nervous system. Conversely, much evidence is emerging that molecules controlling cell fate choice and differentiation also have direct effects on the cell cycle.

A paradigm for what we might expect to occur in nerves is seen during the differentiation of skeletal muscle: the bHLH transcription factor MyoD not only drives expression of muscle structural genes but also upregulates cdkis to promote cell cycle exit. This is complemented by interactions with Rb and

cyclinD/cdk4 that regulate MyoD function. Similar interactions may occur in differentiating neurons. Mouse P19 embryonal carcinoma cells can be differentiated into neurons on overexpression of several neurogenic bHLH proteins, including neurogenin 1 and neuroD2, and this is accompanied by upregulation of Kip1 and cell cycle exit. Moreover, achaete-scute, another bHLH protein, transcriptionally regulates the mitotic phosphatase and CDC25 homolog string. Also in *Drosophila*, Prospero, an asymmetrically distributed homeodomain protein, controls the expression of cyclin E, cyclin A, and string. In addition, it can work indirectly via the bHLH protein deadpan to control levels of dacapo, a *Drosophila* cdki.

Expression of other tissue-specific transcription factors in the nervous system influences cell proliferation but only in the regions where they are usually expressed, indicating a requirement for cofactors; overexpression of Optx2, Six3, and Rx1 results in very large eyes due to extra cell proliferation, whereas loss of Optx2 results in the upregulation of two cdkis. Interestingly, the winged helix transcription factor XBF1 has dual roles, both recruiting cells to a neural fate and controlling their proliferation via regulation of cdki transcription, having different effects at high and low doses.

The internal clock that drives the sequential expression of a series of transcription factors in *Drosophila* neuroblasts, leading their progeny to adopt different fates, has been described previously. This transcription factor series may also be used as a way for NB cells to 'count' their number of cell divisions; prolonged expression of early genes such as Hunchback and Kruppel results in the generation of extra ganglion mother cells of an early type. A similar counting mechanism may exist for NBs in postembryonic flies, in which loss of a coiled coil protein, Mushroom body defect, results in generation of extra progeny.

Signal transduction pathways responsive to extracellular ligands are also known to regulate both cell fate and differentiation and cell cycle coordinately, although the molecular details of these interactions have only recently come to light. The two pathways about which probably the most is known are those of Notch and Hedgehog (Hh) signaling.

The Notch signaling pathway is used widely throughout the nervous system, and its role in allowing scattered neurons to differentiate out from a field of equivalent neural precursors has been particularly well studied. In general, active Notch signaling keeps neural cells in an undifferentiated state and, in several systems, also favors gliogenesis at the expense of neurogenesis. In some contexts, such as the mouse nervous system, Notch signaling keeps cells in cycle, and this has been proposed as a mechanism whereby cells remain undifferentiated. However, in other systems, Notch activation promotes cell cycle exit, such as in the *Xenopus* retina and neural plate. How does Notch signaling influence the cell cycle? Again, this seems to be context dependent. Hes1, a component of the Notch signaling pathway, can repress Cip1 expression in PC12 cells and inhibit NGF-induced differentiation, whereas in the skin, Notch induces Cip1 and promotes differentiation. Confusingly, in the *Xenopus* neural plate, Notch signaling inhibits cdki expression but nevertheless promotes cell cycle exit, possibly by downregulation of cyclin A and cdk2 mRNAs. This may reflect an effect of Notch required to inhibit the differentiation function of the cdki, rather than to influence its cell cycle function. Moreover, Notch may control levels of cdkis post-translationally via effects on the level of E3 ubiquitin ligase SCF Skp2, which can target Kip1 and Cip1 for proteolysis.

The Hh pathway regulates cell proliferation in several areas of the vertebrate CNS, including the hippocampus, cerebellum, forebrain, spinal cord, and retina. Again, the effects of Hh signaling on proliferation seem to be context and species dependent. For instance, upregulation of Hh signaling in the mouse retina results in proliferative cells persisting inappropriately, whereas in the zebrafish loss of Sonic Hh results in inhibition of Kip2 and increased proliferation.

Other signaling pathways influence cell cycle in the CNS. Wnt signaling is also likely to play an important role in precursor cell proliferation by regulating levels of D-type cyclins and c-myc. If the downstream Wnt effector β-catenin is put under a neuron-specific enhancer, these mice develop enlarged brains. Moreover, transforming growth factor-α has a dose-dependent effect on proliferation in the retina. Other pathways, such as fibroblast growth factor and bone morphogenetic protein signaling, influence cell fate and differentiation in the neuroectoderm, and it seems likely that in the future we will obtain a better understanding of their influence over cell cycle events in the CNS.

Conclusions

Neural precursors must proliferate, adopt the correct fate, and then differentiate at the appropriate time. Thus, it seems obvious that there must be constant feedback between these processes for development of the exquisitely patterned CNS, yet our understanding of these links has only recently begun to emerge. One key point has been the realization that several cell cycle regulators have complementary but separable roles in the processes of fate determination, differentiation, and cell cycle control, providing important insight into the

elegant ways that have evolved to coordinate these events. From this base, our understanding is likely to grow considerably in the near future.

Introduction

The complex anatomy of the human brain poses a challenge for neuroscientists to study its functions and for clinicians to diagnose neurological diseases. There are an array of imaging techniques that can examine neuroanatomy at different levels of resolution, from the optic or electron microscope at the cellular and molecular levels to other modern imaging techniques at the levels of tissue or organ. These imaging techniques offer diverse image contrasts that can reveal gene expression, cellular composition, metabolism, and so on. For judging whether an imaging technique is appropriate for a particular application, the resolution and contrast are among the most important criteria. The imaging contrast determines whether we can obtain the information we need, and the resolution determines the amount of detail.

Magnetic resonance imaging (MRI) has been widely used in neuroscience research and clinical diagnosis. The resolution of MRI varies from the millimeter level for clinical imaging to the submillimeter level for animal imaging. It can visualize brain structures and detect lesions in the central nervous system (CNS) noninvasively. One of the advantages of MRI over other imaging techniques, such as computed tomography and ultrasound, is that it provides versatile soft tissue contrasts, which can reveal underlying tissue anatomy and physiological states. Figure 1 shows four conventional MRIs acquired from a healthy volunteer, each demonstrating unique tissue contrasts in the brain. In the proton-density, T1-, and T2-weighted images, the contrast between the white matter (WM) and gray matter (GM) reflects the underlying difference in tissue proprieties, such as water and myelin content. Although the contrast between GM and WM in the diffusion-weighted image is not as sharp as in other images, previous reports have shown that diffusion-weighted images can provide unique information in several pathological conditions, such as stroke and edema in the CNS.

In this article, we assume that readers already have some knowledge of MRI, and we focus on a novel MR-based imaging technique, diffusion tensor imaging (DTI), which provides new tissue contrasts that conventional MRI lacks. First introduced in the early 1990s, it has been quickly adopted in clinics and for neuroscience research to study the macroscopic brain connectivity and pathology of several neurological diseases, such as multiple sclerosis and brain damage following stroke. Many review articles cover the basic and technical aspects of DTI. In this article, we give a brief introduction to the principles and applications of DTI.

What Is Water Molecule Diffusion?

Water molecules undergo random translational motion driven by internal kinetic energy. This phenomenon is referred to as self-diffusion or simply diffusion. Diffusion is different from flow, which is often driven by mechanical pressure or concentration gradient. For flow, most water molecules are moving in a determined direction similar to blood flows in the blood vessels with a pressure gradient. For diffusion, movements of water molecules are random, with no determined directions. Because of this randomness, we use the so-called diffusion coefficient (D) to characterize the diffusion process. With a given diffusion coefficient, the root mean squared distance traveled by a water molecule in one dimension during a measurement time period t_{diff} is $\sqrt{2Dt_{\mathrm{diff}}}$, where t_{diff} is the diffusion time. In three-dimensional space, the root mean squared distance will be $\sqrt{6Dt_{\mathrm{diff}}}$. The Strokes–Einstein equation tells us that the diffusion coefficient in an unbounded solution environment (free diffusion) without exchange is related to the temperature (T) and the molecular friction coefficient inside the medium (f) as $D = kT/f$, where k is the Boltzmann constant, and the friction coefficient depends on the radius of the molecule and the viscosity of the medium. At body temperature, the diffusion coefficient of water molecules in an unbounded environment is approximately $3.0 \times 10^{-5}\,\mathrm{cm^2\,s^{-1}}$, which means that for a time period of 10 ms, the root mean square distance traveled by a water molecule is approximately 5 μm, comparable to the radius of a neuron.

Inside biological tissue, many structures, such as the cell membranes and myelin sheath, can restrict or hinder the movement of water molecules. There also exist exchanges between different tissue water compartments. These changes from free diffusion to restricted or hindered diffusion mean that the root mean square distance traveled by a water molecule depends on its environment (i.e., the existence of barriers to diffusion) and should be shorter than in the case of free diffusion. To characterize the restricted or hindered water molecule diffusion in biological tissues, the so-called apparent diffusion coefficient (ADC) is used.

Figure 1 Axial proton density-weighted (PD-weighted), T1-weighted, T2-weighted, and diffusion-weighted images acquired from one healthy adult volunteer. The white and gray matter can be easily distinguished in these images. For the diffusion-weighted image, the resolution is $2.5 \times 2.5 \times 2.5$ mm. For the other images, the resolution is $1 \times 1 \times 1$ mm.

How to Measure Diffusion by MRI?

MRI can measure water diffusion, or ADC. The effect of water diffusion on nuclear magnetic resonance signals in the presence of magnetic field gradients has been described by Hann, Carr, and Purcell. In his paper on spin echo, Hahn showed that the diffusion of water molecules (spins) attenuates the observed signal amplitude. Carr and Purcell further presented the equations that describe the relationships between spin echo signal attenuation and the diffusion process. Later, Torrey incorporated the effect of diffusion into the Block–Torrey equation. Based on these theories, it is possible to measure diffusion using the Stejskal and Tanner sequence, which adds a pair of diffusion-sensitizing gradient pulses to the standard spin echo sequence.

Figure 2 explains how to use a standard spin echo with the addition of diffusion-sensitizing gradient pulses to measure water molecule diffusion. After a 90° radio frequency (RF) excitation pulse, spins start to rotate at a frequency ω ($\omega = \gamma B$, where γ is the gyromagnetic ratio and B is the main magnetic field). The diffusion-sensitizing gradient pulse after the RF pulse has duration of δ and a magnitude of G. It adds a spatial-dependent phase shift to the spins so that the spin at the position $+r$ along the gradient axis (Figure 2, red circle) is leading the spin at the origin (green circle) in phase, and the spin at the position $-r$ along the gradient axis (blue circle) is behind the spin at the origin in phase. Following the first gradient pulse, the 180° RF pulse along the y axis flips the sign of the spins' phases so that the spins with positive phase (leading) before the 180° RF pulse become spins with negative phase afterwards (lagging), whereas lagging spins will become leading spins. The second gradient pulse will have the same effect on the spins as the first gradient pulse (i.e., adding a spatial-dependent phase shift to the spins). If the spins have not undergone any translational motion between the two gradient pulses (Figure 2(d)), the phase shift introduced by the second gradient pulse will cancel the initial phase shift, and all spins will have the same phase and add coherently to form a signal at the receiver. However, if the spins undergo translational motion along the gradient axis between the two gradient pulses (Figure 2(e)),

Figure 2 Schematic diagram of MR measurement of water molecule diffusion. (a) In a typical MR scanner, the long axis of the magnet (i.e., the direction of the main magnetic field) is designated as the *z* axis. (b) A magnetic gradient along the *y* direction can affect the signals from three spins (red, green, and blue circles; their frequencies and phases) located along the *y* axis. (c) A standard spin echo sequence with diffusion-sensitizing gradients (orange boxes) around the 180° RF pulse. The gradients are placed along the *y* direction. The magnetic field as the gradients are on and off are illustrated below the sequence. (d) In the case of three static spins positioned at $+r$, 0, and $-r$ along the *y* axis, the phase evolution of the three spins is plotted. In the end, all three spins have the same phase. (e) In the case of three nonstatic spins at the same position as in (d), where the spin located at $-r$ (blue circle) diffuses from $-r$ to 0 between the two diffusion-sensitizing gradients, the phase evolution of the three spins is plotted. In the end, the three spins have different phases.

there will be extra phase shifts that cannot be completely canceled by the second gradient pulse, and the additional phase shifts depend on the distance of spin movements (diffusion). As a result, signals from diffused spins (blue circle) will have different phase from those of the static spins (red and green circles) and cannot be added coherently. The acquired signal in Figure 2(e) will have smaller magnitude than the signal acquired in Figure 2(d) (i.e., signal attenuation). If there are no diffusion-sensitizing gradients, spins will all have the same phase disregard of their movement.

Figure 2 is a highly simplified illustration of what happens during diffusion measurement. In a routine imaging experiment, the region covered by a pixel contains millions of spins, and the measured signal attenuation reflects the statistical distribution of spin displacement in the pixel. The images acquired with diffusion gradient pulses are called diffusion-weighted images, and the images acquired without diffusion gradient pulses are called non-diffusion-weighted images. By comparing the diffusion-weighted and non-diffusion-weighted images, we can obtain a map of ADC.

Figure 3 An example of measuring tissue ADC. Diffusion-weighted images with different diffusion weighting (b) were acquired. In these images, the increase in b was achieved by increasing diffusion gradient magnitude from 1 to 13 G cm^{-1}. As b increases, there is increasing attenuation of the image intensity. For each pixel, the signal intensity acquired with different b is fitted to a monoexponential model, which results in a map of ADC. The signal at the red pixel decays more rapidly than that at the blue pixel; therefore, the ADC value at the red pixel is higher than the ADC value at the blue pixel.

Figure 3 illustrates how to measure ADC using the MR sequence described previously. In a simplified monoexponential model, the signal decay follows the equation $S = S_0 e^{-b\mathrm{ADC}}$, where S and S_0 are the amplitudes of signals in diffusion-weighted and non-diffusion-weighted images, respectively, and b is the factor of 'diffusion weighting.' A simplified equation for the b value is $b = \gamma^2 G^2 \delta^2 (\Delta - (\delta/3))$, where γ is the gyromagnetic ratio. According to this equation, the b value, or the diffusion weighting, is determined by the magnitude of the diffusion-sensitizing gradient (G), the duration of the gradient (δ), and the duration between the start of the first gradient and the start of the second gradient (Δ). The contrast in the diffusion-weighted images depends on the tissue diffusion property, relaxation time, and proton density. In order to obtain contrast that depends only on diffusion, it is common to fit the intensity values acquired with different diffusion weightings, or b values, to amonoexponential model (Figure 3). The result is an ADC map.

The sequence shown in Figure 2 is only sensitive to displacements of water molecules along the axis of the diffusion-sensitizing gradients (i.e., the direction with changing magnetic field). An analogy of this property is an altimeter, which is only sensitive to changes in altitude, not changes in latitude or longitude. Figure 4 shows how the sequence can separate displacements in different directions. Suppose the gradient axis is along the x axis (i.e., the magnetic field is changing along the x axis). If spins move along the x axis between the two diffusion gradients (Figure 4(a)), they will have incoherent phases. If spins move along the y axis instead (Figure 4(b)), the phases will be coherent. The bottom panel of Figure 4 demonstrates differences in tissue contrasts in diffusion-weighted images when diffusion gradients are placed along the x, y, and z axes – a phenomenon caused by anisotropic diffusion.

In biological tissues, the ADC along different axes may be different; that is, the ADC depends on the geometrical configurations of diffusion barriers that water molecules encounter. Diffusion which has the same ADCs measured along different axes is called isotropic diffusion; otherwise, it is called anisotropic diffusion. For example, in neuronal fiber tracts, the ADC measured along the trajectory of such tracts is greater than the ADCs measured perpendicular to the trajectory. It is not clear exactly which structure causes anisotropic diffusion. It is possible that the axonal membrane and myelin sheath (in myelinated fiber tracts) act as barriers that restrict water molecule diffusion in the direction perpendicular to the fiber tracts.

What Is Diffusion Tensor?

We have shown that water molecule diffusion along a particular axis can be characterized by ADC measured along the axis. To characterize water molecule diffusion in three dimensions, especially for anisotropic diffusion, it is necessary to measure ADC along multiple axes. Questions arise as to how many axes should we measure and how to quantify and visualize diffusion anisotropy. In order to answer such questions, the concept of diffusion tensor was introduced. A diffusion tensor, in mathematical terms, is a three-by-three, symmetric, positive definite matrix as shown here:

$$D = \begin{bmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{bmatrix} = \begin{bmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{xy} & D_{yy} & D_{yz} \\ D_{xz} & D_{yz} & D_{zz} \end{bmatrix}$$

Figure 4 Measurement of direction-dependent ADC. The arrows at the top represent the magnetic field along the *x* axis. Spins are represented by circles, and their phases are visualized by arrows inside the circles. (a) Displacement of spins (red and blue circles) along the *x* axis will produce incoherent phases, as shown by the arrows in the circles. (b) Displacement along the *y* axis will not produce any phase incoherence. (Bottom) Diffusion-weighted images of a postmortem rat brain, with diffusion-sensitizing gradients along the *x*, *y*, and *z* directions. In these images, the contrast between the external capsule, a WM structure in the rat brain, and surrounding GM changes with diffusion gradients along different axes.

Diffusion tensors can be estimated from a minimal set of seven diffusion-weighted images using regression methods. The set of diffusion-weighted images should include one non-diffusion-weighted image and at least six diffusion-weighted images whose gradient directions are noncollinear and non-coplanar. In clinical scanners, imaging protocols that acquired diffusion-weighted images along multiple directions (>7) are commonly used. Because it is symmetric ($D_{xy} = D_{xy}$, $D_{zy} = D_{yz}$, and $D_{zx} = D_{xz}$), we only need to know the diagonal elements (D_{xx}, D_{yy}, and D_{zz}) and three off-diagonal elements (D_{xy}, D_{xz}, and D_{yz}). The diagonal elements are the ADC along the *x*, *y*, *z* axes, and the off-diagonal elements show the coupling between the three axes. For each diffusion tensor, we can compute three real, positive eigenvalues λ_1, λ_2, and λ_3, which are usually arranged in decreasing order (i.e., $\lambda_1 \geq \lambda_2 \geq \lambda_3$), and three eigenvectors, $\mathbf{v}_1$, $\mathbf{v}_2$, and $\mathbf{v}_3$ that correspond to λ_1, λ_2, and λ_3, respectively. Here, λ_1, λ_2, and λ_3 are the ADCs along the axes defined by $\mathbf{v}_1$, $\mathbf{v}_2$, and $\mathbf{v}_3$, respectively. $\mathbf{v}_1$ is the orientation with maximal diffusion coefficient, and $\mathbf{v}_3$ is the orientation with minimal diffusion coefficient.

One way to visualize diffusion tensor is to use the diffusion ellipsoid. The distance between any point on the ellipsoid's surface to the center of the ellipsoid is proportional to the root mean squared distance that water molecules travel along the line between the points and the center. The $\mathbf{v}_1$, $\mathbf{v}_2$, and $\mathbf{v}_3$ of the diffusion tensor make up the three axes of the ellipsoid, and the length of each axis is the eigenvalue of the corresponding eigenvector. As the ratio between the three eigenvalues changes, the shape of the ellipsoid will also change. When the three eigenvalues have similar values (i.e., $\lambda_1 \approx \lambda_2 \approx \lambda_3$), the shape of the ellipsoid is spherical. When $\lambda_1 \approx \lambda_2 > \lambda_3$, the shape of the ellipsoid is called planar. When $\lambda_1 > \lambda_2 \approx \lambda_3$, the shape of the ellipsoid is called tubular. The diffusion ellipsoid of a voxel that contains a single population of axonal fibers appears as elongated along the orientation of the fiber trajectory ($\lambda_1 \gg \lambda_2$), as shown in Figure 5(a), and therefore is considered as a tubular tensor. In this case, the $\mathbf{v}_1$ of the tensor will have the same orientation as the fibers. When a voxel contains two groups of crossing neuronal fibers or two parallel surface barriers with low permeability, there may be two or more orientations within a plane that show maximal diffusion coefficient. In these cases, the corresponding diffusion ellipsoid has a planar shape (Figures 5(b) and 5(c)), as suggested by several authors.

In more complex cellular environments (Figures 5(d) and 5(e)), anisotropy of water diffusion may disappear and result in a sphere-like diffusion tensor.

Although it is possible to use diffusion ellipsoid to visualize tensor data in three dimensions, it is convenient to have scalar or vector measurements that are easier for two-dimensional display and easy quantification. Diffusion anisotropy is an important measurement because it reflect and existence of well-organized tissue structures. The degree of diffusion anisotropy can be measured by various anisotropy indices. Table 1 lists a few commonly used indices.

In the CNS, WM tracts have a high degree of diffusion anisotropy, and the orientation of fiber trajectory can be depicted by the orientation of maximal diffusivity ($\mathbf{v}_1$) from the tensor. The information on WM diffusion anisotropy and orientation obtained from diffusion tensor can generate unique tissue contrast in the CNS. Figure 6 compares a conventional axial T1-weighted image of human brain with results from DTI. In the T1-weighted image, the region of WM appears rather homogeneous. It is difficult to distinguish a single WM tract in the T1-weighted image. In contrast, the image of diffusion anisotropy reveals considerable contrast within the WM (i.e., WM tracts have varying degrees of diffusion anisotropy). Major WM tracts, such as the corpus callosum and corona radiata, have a high degree of anisotropy and appear as bright structures in the anisotropy image. Adding orientation information into the image, there is additional contrast to distinguish individual WM tracts due to their difference in orientation. To visualize orientation information, we use the direction-encoded color map, or simply color map, in which the anterior–posterior orientation is represented by green, left–right orientation is represented by red, and superior–inferior orientation is

Figure 5 The shape of diffusion tensors and local tissue microstructures. (a) If there is only one group of fibers (blue cylinders for fibers) inside an imaging voxel (the cubic frame), the diffusion tensor acquires a tubular shape. (b, c) If there are two crossing fiber groups (b) or barriers with low permeability (c) blue wireframe surfaces), the diffusion tensor will have a planar shape. (d, e) For more complex local tissue structures, for example, multiple crossing fiber groups (d) or no fibers (e), the diffusion ellipsoids become spherical.

Table 1 Frequently used indices of diffusion anisotropy, their definition using eigenvalues, and references

Anisotropy indices	*Definition*	*Reference*
Fractional anisotropy (FA)	$\mathrm{FA} = \sqrt{\frac{(\lambda_1-\lambda_2)^2+(\lambda_1-\lambda_3)^2+(\lambda_2-\lambda_3)^2}{2.(\lambda_1^2+\lambda_2^2+\lambda_3^2)}}$	Basser and Pajevic (2000)
Relative anisotropy (RA)	$\mathrm{RA} = \sqrt{\frac{(\lambda_1-\lambda_2)^2+(\lambda_1-\lambda_3)^2+(\lambda_2-\lambda_3)^2}{(\lambda_1+\lambda_2+\lambda_3)^2}}$	Alexander et al. (2000)
Linear, planar, and spherical anisotropy indices (CL, CP, and CS, respectively)	$\mathrm{CL} = \frac{\lambda_1-\lambda_2}{\lambda_1+\lambda_2+\lambda_3}, \mathrm{CP} = \frac{2(\lambda_2-\lambda_3)}{\lambda_1+\lambda_2+\lambda_3}, \mathrm{CS} = \frac{3\lambda_3}{\lambda_1+\lambda_2+\lambda_3}$	Westin et al. (2002)

represented by blue, as shown by the color arrows in Figure 6, and the overall intensity proportional to diffusion ansiotropy. WM structures, which are now colored by their orientations and shaded by their degree of anisotropy, can be easily separated from each other. For example, the cingulum, a fiber bundle that travels in the anterior–posterior orientation, is green. The corpus callosum, which connects the left and right hemisphere, is red. The corticospinal tract, which connects the cortex and spinal cord and travels in the superior–inferior orientation, is blue. Furthermore, using this orientation information and diffusion anisotropy measurements, it is possible to reconstruct axonal bundles in three dimensions. The DTI tractography uses streamlines that follow, pixel by pixel, the directions of $\mathbf{v}_1$'s to reconstruct WM pathways (Figure 7). Results from tractography are difficult to validate in humans but have been achieved in animals with manganese. This technique enables clinicians and neuroscientist to see, *in vivo*, the path of major WM tracts and to study the neuronal connectivity between different parts of the CNS. A recent DTI-based atlas on human brain WM may be a useful tool for interested readers.

Figure 6 Axial T1-weighted (left), fractional anisotropy map (middle), and direction-encoded color map (right) from a healthy volunteer. In the fractional anisotropy map, regions of the GM appear dark because the diffusion in the GM is mainly isotropic. Regions of the WM appear bright. The color map, in which orientation of WM structures is encoded in red, green, and blue, provides additional image contrast to distinguish individual WM tracts. cc, corpus callosum; cg, cingulum; cr, corona radiata.

Figure 7 (a) An axial DTI color map image of human brain stem. The medial cerebellar peduncle (mcp) contains axonal fibers that travel along the directions of the arrows. (b) Schematic diagram of fiber tracking. It begins with a number of seed pixels and follows the principal direction of diffusion tensors within regions with values of diffusion anisotropy above a threshold. (c) Fiber tracking results of various white matter tracts in the brain stem. Notice the similarity between mcp reconstructed from DTI results and illustrated in a brain atlas (d). dcn, deep cerebellar nuclei; icp, inferior cerebellar peduncle; ml, medial lemniscus; scp, superior cerebellar peduncle.

Applications and Limitations of DTI

The advantages of DTI make it an ideal tool to study WM structures in the CNS. Because DTI is sensitive to the organization and microstructure of WM, it can be used to detect abnormalities caused by diseases that affect WM and follow the progression longitudinally. It has been shown that DTI can detect Wallerian degeneration in WM caused by stroke and axonal injuries due to multiple sclerosis and amyotrophic lateral sclerosis. Sun et al. showed that loss or damage to myelin can also result in a decrease in diffusion anisotropy. Although both axonal injury and myelin injury will result in loss of anisotropy, detailed examinations show that the axial diffusivity (i.e., λ_1 from the tensor) is sensitive to axonal injury, whereas the transverse and radial diffusivity (i.e., the average of λ_2 and λ_3) is sensitive to myelin injury. One possible explanation is that loss of myelin will enable water molecules to move with less restriction in the transverse directions, whereas loss of axons will pose barriers to water molecules to move in the axial direction.

Another area in which DTI has shown great potential is the study of brain development and maturation. Conventional MRI often produces poor contrast in premature brains, mainly due to lack of myelin at the early stages. This poses a major challenge for neuroscientists to study brain maturation and for clinicians to diagnose injuries in pediatric patients. In comparison, DTI can provide superior WM contrast in neonatal brains. Even without myelin, the early WM tracts possess a relatively high degree of anisotropy. The DTI contrast can be used for delineation of early WM structures and, more important, the measured diffusion anisotropy provides information on WM microstructure and its maturation.

As with any imaging modalities, DTI has its limitations. First, DTI can only provide the path of WM tracts, not the direction of signal transduction. Second, DTI is limited by imaging resolution, which is approximately 2 or 3 mm in humans and 0.08 mm in postmortem animal studies. Therefore, if one does not see a certain WM tract in DTI, this does not mean that it is missing. Validation from histology or other modalities is often necessary. Third, diffusion tensor is a simplified model. It assumes that water diffusion is Gaussian. In the case of two or more fibers crossing in a pixel, DTI cannot distinguish these fibers. To overcome this problem, various data acquisition and postprocessing approaches have been proposed, such as diffusion spectrum imaging, Q-ball imaging, and high angular resolution diffusion imaging.

Anatomy

Mesencephalon

The majority of central dopaminergic projections arise in the midbrain from the ventral tegmental area (VTA; A10), substantia nigra (SN; A9), and retrorubral area (A8) to innervate three principal sets of targets: the striatum (the caudate and putamen), the limbic cortex (medial prefrontal, cingulate, piriform, and entorhinal areas), and other limbic structures (regions of the septum, olfactory tubercle, nucleus accumbens, and amygdaloid complex). These systems are frequently referred to as the nigrostriatal, mesocortical, and mesolimbic dopamine (DA) projections, respectively. Although the A9 cells preferentially innervate the striatum, and the A10 cells mainly target the limbic and cortical regions, Figure 1 illustrates that the projections of the midbrain DA cells are not restricted to these regions. Many of the SN DA neurons give off collateral branches and ramify within more than one region. The projection fields of the A8, A9, and A10 cell groups are collectively known as the mesotelencephalic DA system. This term has been used to refer to the projections from the midbrain DA neurons (A8, A9, and A10) to the striatum and nucleus accumbens. The A8–A10 groups comprise approximately 20 000–30 000 neurons on each side of the rat brain. Also located in the mesencephalon, the rostral linear nucleus is sometimes considered part of the VTA. DA neurons of the rostral linear nucleus and periaqueductal gray region project locally or to different brain regions, such as the central amygdaloid nucleus, bed nucleus of the stria terminalis, sublenticular extended amygdala, and substantia innominata.

It is now known that heterogeneities of DA innervation occur within a region. Thus, the nucleus accumbens can be divided into two cytoarchitectonically, physiologically, and pharmacologically distinct compartments, termed core and shell. The core region and the shell region receive preferential inputs from the A9 and A10 cell groups, respectively. Furthermore, two histochemically distinct compartments within the striatum have been defined, known as 'patch' (or 'striosome') and 'matrix,' which contain different densities of a number of markers for dopaminergic, cholinergic, and peptidergic neurons and represent another level of processing in the basal ganglia. Evidence suggests that the mesostriatal DA input to these compartments arises from distinguishable subsets or 'tiers' of the DA-containing midbrain neurons.

Diencephalon

These systems include the A11–A15 cell groups, which are located in the diencephalon, including regions such as the hypothalamus, caudal thalamus, zona incerta, and preoptic region. These neurons project principally within the diencephalon and have been divided into periventricular, incertohypothalamic, and tuberohypophyseal systems. There are approximately 2000–4000 DA neurons on each side of the brain in the rat diencephalic A11–A15 groups. An additional long-length system is the descending projections from the A11 group in the diencephalon to the spinal cord, where a dopaminergic innervation is apparent in the dorsal horn at all levels of the cord.

Other Systems

Among the other DA systems are the short-length interplexiform amacrine-like neurons, which link inner and outer plexiform layers of the retina. There is also a population of periglomerular DA neurons in the olfactory bulb, which link mitral cell dendrites in separated adjacent glomeruli.

Function

The different locations of the various DA systems in the brain dictate that they have different afferent and efferent connections, which in turn determine the roles they play in brain function. These are reviewed here. It should also be appreciated, however, that it is not possible to completely segregate the motor, motivational, and cognitive behaviors that are often attributed to the nigrostriatal, mesolimbic, and mesocortical DA systems, respectively.

Nigrostriatal System

Dopaminergic innervation of the basal ganglia plays an essential role in many aspects of motor control, cognition, and emotion. The striatum is one of the principal input structures of the basal ganglia. The importance of the DA input to the striatum is evident from the motor abnormalities (e.g., bradykinesia, rigidity, and tremor) exhibited by patients with Parkinson's disease, which is characterized by a marked loss of nigrostriatal DA neurons. DA innervations to limbic and cortical regions are also affected in Parkinson's disease but to a lesser extent than the

Figure 1 Schematic diagram illustrating the distribution of the main neuronal pathways containing DA in the central nervous system. The cell groups are named according to the 1965 nomenclature of Dahlstrom and Fuxe. Different colors denote the terminal field projections of the A8, A9, and A10 cell groups. Recent investigations have established that collaterals of ascending DA neurons also provide innervation of the subthalamic nucleus, thalamus, and globus pallidus.

striatal input. DA release in the striatum modulates activity in two striatopallidal circuits ('direct' and 'indirect'), which in turn exert control over thalamocortical circuits essential for voluntary control of movement. The signs of Parkinson's disease do not appear until a large majority (approximately 80%) of nigrostriatal DA neurons have been lost, as surviving DA neurons efficiently increase their activity to compensate for the damage. It is now apparent that nigrostriatal DA neurons do not merely allow motor behavior to occur but that they also play an important role in the selection and initiation of actions and establishing motor skills and habits. Current treatments for Parkinson's disease typically involve administration of the DA precursor, dihydroxyphenylalanine (L-dopa), or DA receptor agonists. Future treatments are likely to include restoration of dopaminergic tone by transplantation of fetal DA neurons or stem cells or by gene therapy.

Mesolimbic System

The function of the mesolimbic dopaminergic system, particularly the projection from the VTA to the nucleus accumbens, has been strongly implicated in goal-oriented (motivated) behaviors, in addition to reward, attention, and pharmacologically induced locomotion. Enhancement of DA transmission in this system has been linked with the addicting, reinforcing, and sensitizing effects of repeated exposure to psychostimulant drugs of abuse. Furthermore, the therapeutic effects of antipsychotic drugs used in the treatment of schizophrenia may depend on the inhibition of mesolimbic DA neuron activity that these drugs induce. The ability of antipsychotic drugs to block DA receptors and thereby reduce DA transmission is central to the 40-year-old DA hypothesis of schizophrenia, which posits that the disease is related to excessive central DA activity. Imaging studies in patients have provided support for the existence of disrupted DA transmission in schizophrenia. A revision to the hypothesis is the concept of underactivity in cortically projecting DA neurons together with overactivity in subcortical DA systems. Persuasive evidence implicates developmental, functional, and structural abnormalities in schizophrenia, involving other transmitter systems besides DA, such as glutamate and γ-aminobutyric acid (GABA).

Mesocortical System

The prefrontal cortex has rich connections with other neocortical regions, limbic regions, and other subcortical regions. The prefrontal cortex has been implicated in a wide variety of cognitive functions, and it particularly appears to be involved in directing

appropriate attention, prioritizing the significance of stimuli, monitoring the temporal sequence of stimuli, referencing stimuli to internal representations or cues, and devising abstract concepts. The well-defined DA projection to the prefrontal cortex has been suggested to be involved in short-term and 'working' memory. It has been hypothesized that the mesoprefrontal DA system is involved in the pathophysiology of schizophrenia and that defects in this system, or its associated neuronal connections, may be responsible for the negative and cognitive deficits that characterize the disorder.

Diencephalon Systems

DA neurons in posterior dorsal hypothalamus and periventricular gray of central thalamus (A11) project to spinal cord and appear to have a role in sensory and nociceptive processing and sensory integration. Tuberoinfundibular DA neurons (A12) are located in the arcuate nucleus and periventricular nucleus of mediobasal hypothalamus and project to the external layer of median eminence. They play an important role in inhibiting the release of prolactin from the anterior lobe of the pituitary. Incertohypothalamic DA neurons (A13) reside in the rostral portion of medial zona inserta and terminate in the central nucleus of amygdala, horizontal diagonal band of Broca, and paraventricular nucleus of the hypothalamus. Their functions are not clear but probably involve integration of autonomic and neuroendocrine responses to sensory stimuli. Two subpopulations of A14 neurons have been distinguished. The periventricular–hypophysial (tuberohypophyseal) DA neurons terminate in the intermediate lobe of the posterior pituitary and inhibit secretion of α-melanocyte-stimulating hormone and pro-opiomelanocortin-derived peptides such as β-endorphin. DA neurons also innervate the neural lobe, but their origin is controversial. The other defined group of A14 DA neurons is located in the periventricular hypothalamic nucleus. Fibers of these neurons extend into the medial preoptic nucleus and anterior hypothalamus. Females possess greater number of these neurons than males, and these neurons are believed to play a role in gonadotrophin secretion in females and reproductive behavior in males. DA neurons in the ventrolateral hypothalamic comprise the A15 cell group, and they extend processes to the lateral hypothalamus and caudal supraoptic nucleus, suggesting a role in oxytocin and/or vasopressin secretion.

Other Systems

Retinal DA neurons in vertebrates appear to be particularly involved in contrast sensitivity and light adaptation. In 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated parkinsonian monkeys, a loss of retinal DA occurs, along with spatial frequency-dependent abnormalities in both the pattern electroretinogram and the visual evoked potential. In Parkinson's disease, abnormalities occur in ocular motor control, visual evoked potentials, electroretinograms, color vision, and visual contrast sensitivity. Changes are also possible in the acquisition and perception of visual information.

In addition to the DA systems in the brain and pituitary, DA appears to have a restricted role in the periphery. The best defined role for peripheral DA neurons is in renal regulation of sodium homeostasis, and impairment of this function may underlie development of hypertension.

Life Cycle

Figure 2 is a schematic model of a dopaminergic nerve terminal illustrating the life cycle of DA and the regulatory mechanisms that modulate the synthesis, storage, and release of this important neurotransmitter. A brief description of this idealized nerve terminal and model synapse will help to summarize the present state of knowledge concerning the life cycle and regulatory control of DA in a typical DA synapse and possible sites at which drugs and chemicals can influence dopaminergic transmission.

Synthesis

Blood-borne tyrosine, derived from dietary proteins and from phenylalanine metabolism, enters the brain by a low-affinity amino acid transport system. Tyrosine in brain extracellular fluid is taken up into DA neurons by high- and low-affinity amino acid transporters. The relative circulating levels of tyrosine and phenylalanine can affect central catecholamine metabolism because these amino acids compete for transport into the brain and for transport into the neuron. DA is synthesized from tyrosine in two enzymatic steps. The first reaction is catalyzed by the enzyme tyrosine hydroxylase in the cytosol. Because this step is rate limiting, it sets the pace for the conversion of tyrosine to DA and is the step most susceptible to physiologic regulation and pharmacologic manipulation. Short-term activation of tyrosine hydroxylase involves phosphorylation of the regulatory domain by protein kinases. The activated form of tyrosine hydroxylase is thought to have a lower K_m for its pterin cofactor and a higher K_i for DA, which effectively reduces end product inhibition. The activity of the enzyme dihydropteridine reductase is indirectly linked to DA biosynthesis because this enzyme catalyzes the recycling of the

Figure 2 Schematic model of a dopaminergic nerve terminal illustrating the life cycle of dopamine (DA) and the mechanisms that modulate its synthesis, release, and storage. Invasion of the terminal by a nerve impulse results in the Ca^{2+}-dependent release of DA. This release process is attenuated by release-modulating autoreceptors. Increased impulse flow also stimulates tyrosine hydroxylation. This appears to involve the phosphorylation of tyrosine hydroxylase (TH), resulting in conversion to an activated form with greater affinity for tetrahydrobiopterin cofactor and reduced affinity for the end product inhibitor DA. The rate of tyrosine hydroxylation can be attenuated by (1) activation of synthesis-modulating autoreceptors, which may function by reversing the kinetic activation of TH, and (2) end product inhibition by intraneuronal DA, which competes with cofactor for a binding site on TH. Release- and synthesis-modulating autoreceptors may represent distinct receptor sites. Alternatively, one site may regulate both functions through distinct transduction mechanisms. The plasma membrane DA transporter (DAT) serves an important physiological role in the inactivation and recycling of DA release into the synaptic cleft. The vesicular monoamine transporter (VMAT) transports cytoplasmic DA into storage vesicles, decreasing the cytoplasmic concentration of DA and preventing metabolism by MAO. VMAT modulates the concentration of free DA in the nerve terminals. Reproduced from Cooper JR, Bloom FE, and Roth RH (2003) *The Biochemical Basis of Neuropharmacology*, 8th edn. New York: Oxford University Press, with permission from Oxford Press.

quinonoid dihydrobiopterine to tetrahydrobiopterine, which is an essential cofactor of tyrosine hydroxylase. In addition, the synthesis of tetrahydrobiopterine is dependent on the activity of another enzyme, GTP-cyclohydrolase-1. The second step is catalyzed by L-dopa decarboxylase in the cytosol. This enzyme is also referred to as aromatic amino acid decarboxylase because it catalyzes the decarboxylation of several endogenous aromatic amino acids. This enzyme so avidly decarboxylates L-dopa that the levels of this amino acid in brain are very low under normal conditions.

Metabolism

DA can be metabolized in brain by several enzymatic reactions, which are summarized in Figure 3. The major mammalian enzymes of importance in the metabolic degradation of catecholamines are monoamine oxidase (MAO) and catechol *O*-methyltransferase (COMT). MAO converts catecholamines to their corresponding aldehydes. This aldehyde intermediate is rapidly metabolized, usually by oxidation by the enzyme aldehyde dehydrogenase to the corresponding acid. In some circumstances, the aldehyde is reduced by aldehyde reductase. MAO is located on the outer membranes of mitochondria and thus, in brain, is present primarily in nerve terminals and glia. Separate genes encode two isoforms of MAO (types A and B), which can be distinguished by substrate specificity and sensitivity to the irreversible selective inhibitors. In brain, MAO-A is preferentially located in dopaminergic and noradrenergic neurons, whereas MAO-B appears to be the major form present in serotonergic neurons and glia. MAO is a particle-bound protein localized largely in the outer membrane of mitochondria. Usually considered to be an interneuronal enzyme, it also occurs in abundance extraneuronally.

The second enzyme of importance in catabolism of catecholamines is COMT. This is a relatively nonspecific enzyme that catalyzes the transfer of methyl groups from *S*-adenosylmethionine to the *m*-hydroxyl

Figure 3 Main pathways of catabolism of DA. Enzymes involved (shown in italics) are monoamine oxidase (MAO), catechol-*O*-methyltransferase (COMT), aldehyde dehydrogenase (ALD-D), aldehyde reductase (ALD-R), and alcohol dehydrogenase (ADH). Cofactors for the enzymes are shown in parenthesis; SAM, *S*-adenosyl-L-methionine. In addition, dopamine (DA) and metabolites are substrates for phenolsulfotransferase; sulfation occurs on the 3-position, indicated on the structure for DA. In brain, DA is metabolized mainly to acidic (DOPAC and HVA) metabolites, with less formation of alcoholic metabolites (DOPET and MOPET); in the periphery, the alcohol metabolites may be metabolized further by alcohol dehydrogenase. In the periphery, glucoronyltransferase is able to form glucoronide conjugates of DA and metabolites.

group of catecholamines and various other catechol compounds. There are two isoforms of COMT, a membrane-bound form and a soluble form. Membrane-bound COMT is the major form found in the central nervous system (CNS), has a higher affinity for catecholamines, and is located principally in neurons. The soluble form has a lower affinity for catecholamines and is the major form expressed in the periphery, but it is present also in CNS glia. The membrane-bound isoform of COMT, having a high affinity for DA, is expressed at neuronal dendritic processes in cortex and striatum, but the expression and activity of COMT are higher in frontal cortex than in striatum. Relevant to this is evidence that in the prefrontal cortex DA transporter (DAT) is rarely expressed within synapses and exerts minimal influence on DA flux in the prefrontal cortex. Thus, COMT activity appears to have a more important function in regulating DA neurotransmission in the frontal cortex than in other regions. In fact, it has been estimated that the flux of DA through the COMT pathway exceeds 60% in the prefrontal cortex but only 15% in the striatum, where DAT is the chief mechanism for terminating the action of DA. The importance of COMT to the actions of DA in the prefrontal cortex is strongly supported by the finding that compared with wild-type mice, COMT knockout mice have increased DA levels in prefrontal cortex, but not in striatum, and that such mice perform better on prefrontal cortex-dependent behavioral tasks. Another interesting facet to the role of COMT in frontal cortex is the finding that the COMT gene contains a polymorphism (Val158Met) that affects the *in vivo* activity of the enzyme. Met158 homozygotes have approximately one-third less COMT enzyme activity in prefrontal cortex than Val158 homozygotes. Consistent with its role in modulating prefrontal cortex DA levels, the Val158Met polymorphism is associated with performance on tests of working memory and executive function, which depend on prefrontal cortex function. Thus, the high-activity Val158 allele is linked with relatively poorer performance on such tasks, relative to the Met158 allele, presumably as a result of increased DA metabolism. The COMT polymorphism has been implicated in a number of neuropsychiatric phenotypes. In particular, there is evidence to support an association between COMT allele frequency and the genetic risk of schizophrenia. Working memory is highly dependent on DA function in the prefrontal cortex, and working memory dysfunction is a cardinal feature of schizophrenia.

The major DA metabolites found in brain differ, depending on the species under study. In general, however, acidic rather than neutral metabolites predominate. In rodents, the primary metabolites of DA found in the CNS are 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) and a small amount of 3-methoxytramine. DOPAC usually predominates. In addition, a considerable proportion of these metabolites in rodent brain are found in the form of conjugates. In both human and nonhuman primates, however, the major DA metabolite is HVA, and only a small amount is found in the conjugate form. It is well documented that in the rat, short-term fluctuations in DOPAC and HVA concentrations in the striatum, nucleus accumbens, and prefrontal cortex provide a useful index, respectively, of alterations in impulse flow in the nigrostriatal, mesolimbic, and mesocortical DA pathways.

Transporters

Presynaptic vesicles or granules present in the nerve terminals are specialized for the uptake and storage of DA, thus protecting it from degradation by the enzyme MAO found in mitochondria present in the nerve terminal. The storage granules contain a vesicular monoamine transporter (VMAT2) that has a pharmacology distinct from the plasma membrane DAT found on the nerve terminals. The Na^+- and Cl^- dependent DAT actively transfers the DA from the synaptic cleft back into the presynaptic cell, where it can be stored and reused. DA is concentrated to approximately 0.1 M in the storage vesicles, 10–1000 times higher than the level in the cytosol.

The tuberoinfundibular, tuberohypophysial, olfactory bulb, mesoprefrontal, and mesoamygdala DA neurons appear to differ from the other DA systems described by the absence, or diminished expression, of a high-affinity DA uptake (transport) mechanism. High-affinity DA uptake serves to recapture released DA and limits the concentration and actions of DA in the synapse. Importantly, neurons equipped with a high density of DATs are especially susceptible to drugs that target this site, such as cocaine and the parkinsonian neurotoxins, 6-hydroxydopamine and MPTP. In fact, the toxicity of MPTP is dependent on the function of MAO-B, DAT, and VMAT2. Once inside the brain, MPTP is metabolized by MAO-B to the actual toxic species, MPP+, which is a substrate for DAT. Whereas DAT is responsible for transport of the toxin into DA neurons, VMAT2 aids in sequestering the toxin and diminishing its detrimental impact on mitochondria in the neuron. Thus, the DAT-to-VMAT2 ratio should be a determinant of the susceptibility of a given brain region to MPTP-induced toxicity.

Since the original studies on DA uptake, it has been known that DA is a good substrate for the NE transporter. However, not until relatively recently has the importance of this been appreciated. While in regions, such as striatum and nucleus accumbens, in which DA neurons express a high density of DAT and there is a relatively sparse NE innervation, DA uptake depends primarily on DAT. However, in regions such as the prefrontal cortex, in which DA neurons express low levels of DAT and there is a rich NE innervation, DA uptake depends strongly on the norepinephrine transporter. In fact, it has been suggested that DA can be co-released with norepinephrine by norepinephrine neurons as a result of nonspecific uptake of DA by the norepinephrine transporter and/or because DA is a precursor in the biosynthesis of NE.

Regulation

Much effort has been directed toward elucidating the regulatory mechanisms that control the function of the various DA systems because this may lead to an understanding of the vulnerability of certain DA systems to disease and may also enable drugs to be developed that target specific DA projections. Some aspects of regulation were discussed in relation to the life cycle of DA. Here, other important controls of DA neurotransmission are reviewed.

Firing Pattern

Electrophysiological studies have shown that DA cells fire in two different modes, either single spiking or burst firing, which have a marked impact on the release of DA. Phasic levels of DA are mediated primarily by bursting events at the level of the cell body and lead to a much larger DA release (150–400 nM in striatum) than when these neurons fire in a slow, irregular single spike mode associated with tonic levels (5–10 nM in striatum). Because cells are able to switch between these levels, the transition in activity is a mechanism for altering the impact of DA neurotransmission on receptive cells. Bursting activity of DA neurons is thought to represent a key component of reward circuitry, signaling a reward, or indicating to what extent a reward occurs differently than predicted. Alterations in tonic levels of DA efflux occur on a much slower time scale than changes in phasic levels and enable function on a variety of motor, cognitive, and motivational processes, which are deficient in Parkinson's disease and which can be restored by DA replacement therapy.

Autoreceptors

A receptor sensitive to the transmitter secreted from the cell on which the receptor is located is termed an

'autoreceptor.' Autoreceptors exist on most portions of DA cells, including the soma, dendrites, and nerve terminals, so that autoreceptors are responsive to both terminal and dendritic DA release. Stimulation of DA autoreceptors in the somatodendritic region slows the firing rate of DA neurons, whereas stimulation of autoreceptors located on DA nerve terminals results in an inhibition of DA synthesis and release. Somatodendritic autoreceptors may also regulate DA release and synthesis by changing impulse flow. Thus, somatodendritic and nerve terminal autoreceptors work in concert to exert feedback regulatory effects on dopaminergic transmission. Three types of autoreceptors can be defined according to their functional effects: impulse-modulating, release-modulating, and synthesis-modulating autoreceptors. In general, all DA autoreceptors can be classified as D2-like DA receptors. The terminals of all midbrain DA neurons examined to date have been found to possess release-modulating autoreceptors. This is not the case for synthesis- and impulse-modulating autoreceptors. Whereas most DA neurons located in the SN and many DA neurons in the VTA possess somatodendritic impulse-modulating and nerve terminal synthesis-modulating autoreceptors, the DA neurons that project to the prefrontal and cingulate cortices and amygdala appear to have either a greatly diminished number, or none, of these receptors. Some of the differences in responsiveness among various midbrain DA neurons may be explained, in part, by differences in their autoreceptor function. Data suggest distinct differences in the autoreceptor regulation of hypothalamic DA neurons. Thus, in contrast to the incertohypothalamic DA neurons, tuberoinfundibular DA neurons appear to lack synthesis-modulating autoreceptors. The activity of tuberoinfundibular DA neurons is regulated by circulating levels of prolactin.

Co-localized Peptides and Proteins

Another interesting intrinsic feature that may contribute to the variable susceptibility of DA neurons to toxicity is the presence of intracellular calcium-binding proteins, such as calretinin and calbindin. These proteins are preferentially expressed in DA neurons that are spared from degeneration in Parkinson's disease and MPTP-treated animals, possibly by buffering calcium overload and protecting cells against excitotoxic damage. DA is co-localized in some neurons with neuropeptides and nontransmitter proteins. Certain midbrain DA neurons contain the peptide cholecystokinin, whereas another subpopulation of mesencephalic DA neurons contains the peptide neurotensin, and a third group of DA neurons in the VTA contains cholecystokinin, neurotensin, and DA. Similarly, DA is co-localized in certain mesencephalic neurons with nontransmitter proteins, including acetylcholinesterase, vesicular glutamate transporter, protein *O*-carboxymethyltransferase, cytochrome P450 reductase, and a vitamin D-dependent calcium-binding protein. The functional significance of such co-localization is not clear. DA neurons in which neuropeptides are co-localized may be regulated by peptide autoreceptors in a fashion analogous to DA autoreceptors. Furthermore, because it appears that release mechanisms for DA and co-stored peptides may be dissociated under certain conditions (e.g., dependent on the firing pattern and firing frequency of the neuron), co-localized peptides may be part of a cascade of regulatory features that exist in dopaminergic neurons. For example, nerve terminal autoreceptors in the prefrontal cortex have been shown to exert reciprocal effects on DA and neurotensin release. Stimulation of DA autoreceptors diminishes DA release and enhances neurotensin release, whereas blockade of DA receptors augments DA release and diminishes neurotensin release. Such differential release of DA and neurotensin could conceivably allow the prefrontal cortex DA neurons to differentially modulate the physiological activity of cortical postsynaptic follower cells.

It appears likely that co-localization of peptides or nontransmitter proteins and DA will distinguish certain subpopulations of DA neurons. For example, cholecystokinin–DA co-localized neurons of the VTA project to the caudal, but not rostral, nucleus accumbens. Such distinctions may have important implications for the regionally specific function of DA in psychiatric and neurological disorders and also for the response of specific DA systems in these pathological conditions to pharmacological treatment.

Extrinsic

The different DA systems also vary in the nature of their interaction with other neurotransmitter systems that impinge on the DA neurons. At the cell body level, afferent inputs into the VTA and SN have been most extensively investigated. Many studies have suggested that these cells can be differentially modulated by afferent inputs. DA neurons are also regulated by neurotransmitter interactions that occur at the level of the nerve terminals. However, a detailed description of such interactions is outside the scope this article.

Postsynaptic Signaling

There are known to be at least six different forms of the DA receptor. The D_1 class of DA receptor has been divided into D_1 and D_5 receptor subtypes, and

the D_2 class comprises D_{2short}, D_{2long}, D_3, and D_4 receptor subtypes. The pharmacological profile and regional distribution in brain of each subtype are different, with the exception of D_{2short} and D_{2long}, which appear to be identical in these respects. Although these different receptors are reviewed elsewhere, certain interesting or novel aspects of DA signaling are discussed here.

Neuromodulation

It is now generally accepted that DA is not a classical, fast ionotropic neurotransmitter like glutamate acting at α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) or *N*-methyl-D-aspartate (NMDA) receptors or GABA acting at GABA-A receptors that elicit excitatory or inhibitory postsynaptic potentials that last a few milliseconds. All the DA receptors are G-protein-coupled receptors that are slow, metabotropic receptors with response times exceeding 100 ms and function to modulate other receptor systems and/or ion channels. Thus, DA is thought of as a neuromodulator and cannot be classified as either an excitatory or an inhibitory neurotransmitter, which may explain why DA does not yield identical effects under all experimental conditions.

Volume Transmission

Neurons may operate via two modes of communication, the synaptic mode and the mode of communication involving short- to long-distance diffusion of chemical signals in the extracellular fluid pathways (volume transmission). The process of volume transmission has been defined as a functionally significant association of release and receptor sites via extrasynaptic diffusion. It is now clear that in certain regions DA functions by volume transmission. The retina provides the clearest example of DA-mediated volume transmission. In the SN, DA receptors are located extrasynaptically, indicating that volume transmission is the predominant form of intercellular communication mediated by DA in this region. In the striatum, volume transmission appears not to play a major role in DA transmission since most DA terminals establish synaptic contacts, and the high density of DA terminals express a high density of DAT. Volume transmission may be more important in maintaining dopaminergic signaling in the striatum after partial loss of nigrostriatal DA neurons, as occurs in Parkinson's disease. With the degeneration of dopaminergic terminals and consequent loss of DAT, DA that is released from the remaining neurons may diffuse in the striatal extracellular fluid to reach supersensitive high-affinity DA receptors.

Somatodendritic Release

There is good evidence that DA can be synthesized and released from dendrites and cell bodies in the SN. The release is vesicular and mediated by exocytosis, as it is in axon terminals. Somatodendritic release is calcium and depolarization dependent in a variety of paradigms. In dendrites, DA appears to be stored both in classical vesicles and in saccules of smooth endoplasmic reticulum, consistent with the expression of VMAT2 in both of these organelles. The function of DA released in the SN in this manner is probably to interact with autoreceptors to control the firing rate of DA neurons, in addition to signaling via DA receptors located on non-DA neurons in the region.

Long-Term Potentiation and Long-Term Depression

DA has a critical role in two distinct forms of plasticity, called long-term depression (LTD) and long-term potentiation (LTP). In regions such as the striatum and prefrontal cortex where DA modulates glutamate signaling, combined stimulation of both glutamate and DA receptors is able to induce either enhancement or weakening of synaptic transmission, depending on the parameters of the stimulation and the receptor subtypes that are activated. These mechanisms may lead to more permanent changes, such as the construction of new connections (synapses). Such plastic changes are thought to have an important role in learning and memory (hippocampus and prefrontal cortex) and acquisition of complex motor skills (striatum).

Pyramidal Cell Dendritic Spines

DA also plays a critical role in the modulation of pyramidal cell dendritic spine synapses and spine density. Several studies have demonstrated that the loss of DA in the striatum results in decreased dendritic length and spine density. Employing multiphoton imaging, selective elimination of glutamatergic synapses on striatopallidal neurons has been observed in Parkinson disease models. It has clearly been shown that DA depletion leads to a rapid and profound loss of spines and glutamatergic synapses on striatopallidal medium spiny neurons but not on neighboring striatonigral medium spiny neurons. This loss of connectivity is triggered by an interesting mechanism – dysregulation of intraspine Cav1.3 L-type Ca^{2+} channels. The disconnection of striatopallidal neurons from motor command structures is likely to be a key step in the emergence of pathological activity that is responsible for symptoms in Parkinson's disease.

DA modulation of pyramidal cell dendritic spines and synapses has been extended to the prefrontal cortex, where work has shown that selective lesion of the DA innervation of the prefrontal cortex caused a decrease in dendritic spine density in pyramidal cells in the prefrontal cortex. It is noteworthy that atypical antipsychotic drugs which cause a large increase in synaptic DA reverse the DA depletion-induced dendritic spine loss in prefrontal cortical pyramidal neurons. In schizophrenia, the prefrontal cortex DA innervation is compromised and postmortem studies have reported decreased dendritic spine density. Taken together, these data suggest that disruption of dopaminergic signaling may be the proximate cause of dendritic remodeling in the prefrontal cortex in schizophrenia. Excessive DA input may have the opposite effect because chronic cocaine or amphetamine use has been shown to increase spine density in nucleus accumbens and prefrontal cortex and increase synapse number in the prefrontal cortex.

Introduction

The dopamine (DA) systems of the brain have been the topic of intensive investigation since the first report of this neurochemical as an independent neurotransmitter in the brain nearly 50 years ago. The DA systems have drawn the attention of investigators due to their known role in a variety of neurological and psychiatric disorders, including Parkinson's disease, schizophrenia, and drug addiction. In this article, we review the principal electrophysiological characteristics of DA neurons, as well as the intrinsic and extrinsic regulation of their activity and firing patterns.

Anatomy of DA Neuron Projections

As with most monoamine systems, individual DA neurons are believed to exhibit dense collateralizations, with single neurons giving rise to 500 000 to 1 000 000 synaptic terminals. However, unlike other monoamine neurons, midbrain DA neurons have discrete, topographic projections to their target regions. Three major DA neuronal systems have been identified that project to forebrain regions: (1) the nigrostriatal DA neuron projection, which arises from the substantia nigra (SN) and projects to the dorsal striatum; this system is involved in motor control and is known to degenerate in Parkinson's disease; (2) the mesolimbic DA projection, which arises from the ventral tegmental area (VTA) and projects to limbic structures such as the ventral striatum, nucleus accumbens, amygdala, and other regions involved in control of affect and likely play a role in schizophrenia and drug abuse; and (3) the mesocortical DA system, which also arises from the VTA and projects primarily to frontal cortex; this projection system is believed to be involved in higher processes related to the control of executive function.

Electrophysiology

Identification

Since the ventral mesencephalon is a heterogeneous region, the first challenge in examining the neurophysiology of DA systems is to ensure that the neurons recorded are indeed DAergic in nature. The first extracellular recordings from putative DA neurons were performed in the 1970s. Through an examination of the neurophysiological characteristics of DA neurons and subsequent histochemical verification, it was determined that DA neurons can be identified based solely on their electrophysiological characteristics. As such, one of the most distinct features of DA neurons is the broad extracellular spike waveform they produce (Figure 1). Such waveforms are biphasic (+/−), with an inflection in the rising phase (representative of the initial segment spike). They have a pronounced negative phase to the action potential, as well as a long time course (>2 ms). More specifically, action potentials consist of a short-duration, smaller-amplitude initial segment spike, followed by a larger and longer duration somatodendritic spike. Much of this unique waveform is a consequence of the active membrane properties of the neuron, causing a train of action potentials to be variable from one waveform to the next, and readily distinguishable by the long-duration negative phase, although such differences can be obscured if improper filter settings are employed.

Passive Membrane Properties

Intracellular recordings from identified DA neurons have provided important insights into the mechanisms underlying action potential generation in these neurons. Interestingly, DA neurons recorded from mesencephalic slices after severing of afferent processes continue to exhibit spontaneous activity that is derived from the active membrane properties of the neuron. One factor associated with spike generation in DA neurons is a large-amplitude (10–15 mV), pacemaker-like slow depolarizing potential that brings the membrane potential from rest (*c.* –55 mV) to the comparatively high action potential threshold (*c.* –40 mV). This slow depolarization is mediated by both sodium and calcium conductances, as it can be blocked by tetrodotoxin (TTX) or cobalt, both of which also inhibit spontaneous spike firing. The resultant spike is followed by a negative shift in membrane potential accompanied by an inhibition of spike firing, or an afterhyperpolarization. This afterhyperpolarization is voltage dependent and mediated by a calcium-activated potassium conductance, as it can be blocked by tetraethylammonium (TEA) and attenuated by the calcium chelator ethylene glycol tetraacetic acid (EGTA). Furthermore, it is believed that the rebound from this hyperpolarization triggers the calcium and sodium conductances comprising the slow depolarization. It is this cycle that has

Figure 1 Electrophysiological trace of an action potential recorded extracellularly from an identified VTA DA neuron. The unique characteristics are the biphasic (+/−) waveform with an inflection in the rising phase, pronounced negative phase, as well as a long time course (>2 ms). Scale bar = 1 ms.

been proposed to underlie spontaneous pacemaker firing of midbrain DA neurons observed *in vivo* and *in vitro*.

DA Neuron Activity States

DA neurons of the brain typically display four different states of activity. The first is an inactive, hyperpolarized state suggested to result from GABAergic inhibition (see the section titled 'Intrinsic regulation of DA neuron firing'). These spontaneously inactive neurons have a higher resting membrane potential (*c.* –65 to –75 mV) and can be activated by direct glutamate application or administration of haloperidol (IV). A separate inactive state has been demonstrated following chronic neuroleptic treatment. This state has been termed 'depolarization block,' caused by hyperexcitation and characterized by a depolarized membrane potential. In contrast to hyperpolarized inactive DA neurons, glutamate application will not activate DA neurons following depolarization block, and the restoration of spontaneous activity is achieved by the direct application of the 'inhibitory' transmitter, γ-aminobutyric acid (GABA).

Spontaneously active DA neurons, recorded *in vivo*, typically display two main firing patterns: a slow, irregular single-spike firing pattern and a faster bursting mode. It is the alternation between these two states that is thought to result in different levels of DA release in terminal regions, with irregular spike firing regulating extracellular, 'tonic' DA levels and burst firing leading to transient synaptic 'phasic' DA levels. Accordingly, much research has focused on the regulation of these two types of firing patterns and the mechanisms that lead to the transition from one pattern to the other.

Irregular, Single-Spike Firing

DA neurons recorded *in vivo* commonly display firing rates between 2 and 8 Hz, with an average of approximately 4 Hz, and seldom fire at rates lower than 1 Hz or exceeding 10 Hz. While in single-spike firing mode, DA neuron interspike intervals (ISIs) are fairly long (200–250 ms) and follow a normal distribution. It is thought that the slow single-spike firing pattern of DA neurons is driven by the intrinsic pacemaker depolarization, as well as the prolonged afterhyperpolarization discussed above. Interestingly, although DA neurons recorded *in vitro* display a highly regular pacemaker firing pattern, DA neurons recorded *in vivo* possess a significantly more irregular pattern of activity. This pattern of activity is likely to be associated with variations in calcium entry into the neuron during spontaneous spike firing, since the intracellular injection of EGTA into an irregularly firing neuron causes a transition to a pacemaker pattern.

Burst Firing

The firing rates of DA neurons fall into a fairly limited range, usually 2–8 Hz, which consequently might limit the flexibility of DA neurons to release differential amounts of DA in terminal regions. However, this is overcome by a change in firing pattern from single-spike firing to burst firing. Burst firing in DA neurons induces increases in DA release that are 2–3 times that of increases in tonic firing rates of the same magnitude. Moreover, DA released during burst firing has been demonstrated to be localized to the synaptic cleft and is considered the functionally relevant signal sent to postsynaptic sites. These bursts are comprised of a series of spikes that display accommodation, with decreasing amplitude and increasing action potential duration (Figure 2). DA neuron bursts are typically comprised of two to eight spikes which ride on top of a membrane depolarization. While the first two of these spikes are separated by an ISI of 80 ms or less, following spikes tends to have increasing ISIs of up to 160 ms. As such, DA neurons firing in burst tend to display a bimodal ISI distribution (Figure 3). Bursts of DA neurons tend to be different from bursting described for neurons in other regions in three primary ways: (1) they cannot be elicited by short, depolarizing current pulses; (2) they have a much larger ISI than is typical for bursting neurons; and (3) they can be blocked by intracellular calcium chelators such as EGTA.

The transition from irregular single-spike firing to burst firing is dependent on an excitatory amino acid, since activation of glutamatergic afferents or direct microiontophoretic application of glutamate induces burst firing in DA neurons *in vivo*. Furthermore, direct application of competitive *N*-methyl-D-aspartate

Figure 2 Extracellular recording of a single burst of action potentials recorded from a burst firing DA neuron. These bursts are comprised of a series of spikes that display accommodation, with decreasing amplitude and increasing action potential duration. Scale bar = 50 ms.

Figure 3 An ISI histogram from a burst-firing DA neuron depicting the characteristic bimodal distribution. Diamonds represent individual bin values, and the line is the fitted average curve. The early peak is the ISI within the burst, and the later peak is the time between bursts.

(NMDA) receptor antagonists potently blocks spontaneous burst firing. Taken as a whole, there is a significant literature demonstrating a primary role for NMDA receptor-mediated glutamatergic transmission in the regulation of DA neuron burst firing. On the other hand, glutamate alone is not sufficient to mediate burst firing. Thus, DA neurons recorded from mesencephalic slices obtained from adult rats, in which afferent input has been severed, display a regular pacemaker firing pattern and cannot be made to fire in bursts in response to glutamate agonist administration or alterations in membrane potential alone.

Based on the role of Ca^{2+} and K^{+} conductances in the generation of burst firing *in vivo*, the first reported instance in which burst firing was observed *in vitro* was in the presence of apamin, a toxin derived from bee venom and a potent and irreversible inhibitor of small conductance (SK) Ca^{2+}-activated K^{+} channels (gKCa). Interestingly, in studies that include apamin in the perfusate, DA neuron activity more closely resembles that seen *in vivo* with a decreased regularity of firing and the potential to display burst firing in response to depolarizing current injections and NMDA application. Taken as a whole, these data suggest that DA neuron burst firing is regulated by at least two mechanisms, the first being a permissive inactivation of the SK Ca^{2+}-activated K^{+} channels that by itself does not necessarily induce burst firing but is required for burst firing to occur, and the second being an afferent-derived glutamatergic drive. Interestingly, these mechanisms are not necessarily mutually exclusive, since recent reports have demonstrated a Ca^{2+}-mediated feedback loop whereby SK channels can regulate NMDA-dependant Ca^{2+} influx within individual dendritic spines. Afferent inputs that may be responsible for altering membrane conductances and allowing for the shift from single-spike, irregular firing mode to bursting mode are reviewed below.

Electrical Coupling

Electrical coupling between DA neurons was suggested following the observation that intracellular injection of Lucifer yellow dye into a single DA neuron can result in the labeling of adjacent DA neurons. Further evidence for electrical coupling stems from the fact that some DA neurons located in close proximity have been shown to fire in nearly synchronous firing patterns (with ISIs on the order of 2–3 ms). Administration of D2 receptor blockers such as haloperidol is reported to increase the incidence of simultaneous spike discharge among DA neurons. Furthermore, near-synchronous firing seems to occur more frequently during burst firing patterns. More recently, direct evidence for DA neuron coupling has been observed by simultaneous patch-clamp recordings from DA neuron pairs. This study demonstrated that depolarization of a DA neuron can result in an increased firing frequency of a neighboring electrically coupled DA neuron. In summary, there is significant evidence for electrical coupling between adjacent DA neurons that may result in synchronous firing under appropriate conditions.

Afferent Input to Midbrain DA Neurons

Given the importance of the VTA in encoding reward prediction or indicating incentive salience, it is perhaps not surprising that this region is a site of extensive integration of afferent information. As such, early anatomical studies demonstrated a widespread convergent input to the VTA. This afferent input has since been confirmed and extended using more selective and sensitive techniques. Thus, afferent inputs to the VTA from a large number of regions have been described, which include the prefrontal cortex, nucleus accumbens, ventral pallidum (VP), lateral preoptic area, lateral hypothalamus, and brain stem regions including the pedunculopontine tegmentum (PPTg) and laterodorsal tegmentum (LDTg), among other areas. In addition, the VTA is a heterogeneous structure containing GABAergic interneurons and dendritodendritic synaptic appositions. As such, the output of the VTA is a function of its intrinsic organization as well as regulation by extrinsic factors.

Intrinsic Regulation of DA Neuron Firing

Autoreceptor-Mediated Inhibition

DA neurons display an autoregulatory mechanism important in the determination of their activity levels. DA neuron dendrites in the VTA contain tyrosine hydroxylase (the rate-limiting enzyme in DA synthesis), contain D2 autoreceptors located near the cell body, and DA has been shown to be released in a calcium-dependent manner from the somatodendritic region of DA neurons. Furthermore, investigations using a number of different methods have shown that somatodendritic DA release in the VTA is altered under different behavioral and pharmacological conditions. This local DA release provides a potent autoinhibitory role in the VTA by decreasing DA cell firing rate via activation of D2 receptors. Iontophoresis of DA onto DA neurons causes inhibition of neural activity. Moreover, low doses of DA agonists administered systemically will preferentially activate these highly sensitive somatodendritic D2 autoreceptors. Moreover, application of D2 antagonists enhances DA neuronal firing even following transection of feedback pathways from postsynaptic targets, suggesting a tonic level of autoreceptor activation of DA neurons. D2 antagonists also block DA-induced suppression of DA neuron firing. These data therefore demonstrate a potent autoinhibitory role for DA within the nigrostriatal and mesolimbic DA system.

GABA

The midbrain DA neuron regions are heterogeneous structures containing not only DAergic and non-DAergic projection neurons, but also a number of GABAergic interneurons. Investigations into the effects of these intrinsic GABAergic neurons on DA neuron firing patterns demonstrated the somewhat surprising observation that systemic administration of a GABA agonist (muscimol) actually increases DA neuron firing rate *in vivo*. Further study determined that this 'paradoxical excitation' was correlated with a decrease in firing rates of non-DA neurons. Moreover, DA neurons recorded intracellularly *in vivo* have been shown to be under a constant bombardment with large-amplitude GABAergic inhibitory postsynaptic potentials (IPSPs). These data demonstrate that the increase in DA neuron firing induced by systemic muscimol is secondary to the inhibition of tonically active GABAergic interneurons, and thus demonstrates a tonic role for local inhibitory regulation of DA neuron firing.

Afferent Connectivity

GABAergic Inputs

As stated above, intracellular recordings from identified DA neurons of the rat midbrain *in vivo* have demonstrated that these neurons are constantly bombarded by GABAergic IPSPs. Indeed, it has been suggested that up to 50% of the midbrain DA neurons are quiescent due to GABAergic-mediated hyperpolarization. Moreover, these IPSPs are not observed *in vitro*, suggesting a prominent and tonically active GABAergic tone to this region in addition to that supplied by intrinsic interneurons. One region providing such input is the pallidal complex; a GABAergic structure that receives GABAergic inputs from the striatum and nucleus accumbens (among other regions) displays relatively high rates of spontaneous activity and exerts a powerful tonic inhibitory influence over efferent structures. Since anatomical studies have demonstrated a substantial projection from the globus pallidus to the SN DA neurons and from the VP to the VTA, the pallidum is well positioned to influence DA neural activity. Investigations have demonstrated that inactivation of the VP results in a dramatic increase in the number of spontaneously active DA neurons observed per electrode track (a standard measure of DA neuron population activity) that is correlated with a significant increase in extracellular 'tonic' DA release in the nucleus accumbens. Taken as a whole, these data demonstrate a prominent tonic inhibition of DA neuron firing by the VP.

Glutamatergic Inputs

As mentioned above, the transition from irregular single-spike firing to a burst firing pattern has been

largely attributed to increased glutamatergic input. As such, direct microiontophoretic application of glutamate has been demonstrated to increase burst firing in DAergic neurons. This effect has largely been attributed to actions at the ionotropic NMDA receptor, since it is blocked by MK-801, a highly potent and selective noncompetitive NMDA receptor antagonist. Furthermore, it has been suggested that glutamatergic transmission is required for burst firing *in vivo* since both glutamate-induced and natural burst events can be blocked by inactivation of glutamatergic afferents or the administration of glutamatergic or NMDA receptor antagonists. There is significant literature suggesting a primary role for NMDA receptor-mediated glutamatergic transmission in the regulation of DA neuron burst firing. Given that DA neuron burst firing is considered to be the functionally relevant signal sent to postsynaptic sites to encode reward prediction or indicate incentive salience, glutamatergic inputs to the VTA have garnished significant attention. Such inputs have been demonstrated to arise from the prefrontal cortex, PPTg, and lateral preoptic-rostral hypothalamic area.

The prefrontal cortex is a region associated with planning complex cognitive behaviors such as executive function and expression of appropriate social behavior. A significant literature has been accumulated implicating the medial prefrontal cortex (mPFC) in the regulation of DA neuron burst firing. Thus, chemical stimulation of the mPFC increases burst firing in a proportion of DA neurons, whereas inactivation of this area has been found to reduce spontaneous burst activity. Furthermore, electrical stimulation of the mPFC induces events that resemble natural burst firing in a subset of DA neurons. It is important to note that recent anatomical studies have demonstrated that terminals from the mPFC synapse exclusively onto mesocortical DA neurons, suggesting that glutamatergic inputs from the mPFC provide direct regulatory control over an important subset of VTA DA neurons.

Another major excitatory input to the VTA arises from the PPTg, a glutamatergic/cholinergic region driven by limbic afferents, including the prefrontal cortex and extended amygdala. The PPTg is activated by auditory, visual, and somatosensory stimuli, and has been demonstrated to directly regulate burst firing of DAergic neurons. Thus, electrical stimulation of the PPTg produces time-locked bursts of action potentials in DA neurons that resemble natural bursts. Furthermore, chemical activation of the PPTg induces a significant increase in DA neuron burst firing. Taken as a whole, the PPTg serves as a site of convergence whereby a variety of sensory inputs can modulate DA neuron burst firing.

Association between GABA and Glutamatergic Inputs

Given that the midbrain DA system is a site of extensive integration of afferent inputs, it is perhaps not surprising that in addition to providing independent control over distinct DA neuron activity states, afferent pathways also interact to modulate DA neuron responsivity. For example, it has been suggested that activation of excitatory inputs to the VTA results in burst firing only in DA neurons that are already spontaneously active. Thus, DA neurons that are inactive, presumably due to GABA-mediated hyperpolarization, are unresponsive to activation of glutamatergic afferents, likely attributable to Mg^{2+} blockade of the NMDA receptor-channel complex. This suggests the presence of a unique interdependence of the GABAergic and glutamatergic VTA inputs, that is, only neurons that are not under GABA-mediated hyperpolarization are capable of entering a burst firing mode in response to a glutamatergic input. Indeed, we have previously reported that the hippocampus can gate phasic DA transmission by regulating the number of spontaneously active DA neurons that can be further modulated by excitatory inputs to induce a graded phasic response. Hence, although independent inputs to the VTA can regulate distinct DA neuron activity states, these afferents also interact to regulate DA neuron responsivity.

Regulatory Inputs

Although there is significant literature demonstrating a primary role for NMDA receptor-mediated glutamatergic transmission in the regulation of DA neuron burst firing, glutamate alone is not sufficient to induce burst firing in DA neurons recorded from mesencephalic slices *in vitro* (in which afferent processes have been severed). As reviewed above, in contrast to what is seen *in vivo*, DA neurons recorded *in vitro* from mesencephalic slices do not exhibit burst firing under baseline, depolarization, or glutamate-stimulated conditions. Thus, although glutamatergic transmission is critical, it is not the sole determinant of the generation of burst firing *in vivo*.

Therefore, we have recently demonstrated that a critical factor required to allow spontaneous and glutamate-driven burst firing *in vivo* depends on tonic drive from the LDTg. After baclofen/muscimol inactivation of this region, DA neuron discharge patterns more closely resemble those observed *in vitro*; as pacemakers that lack spontaneous burst firing. Interestingly, neither activation of the PPTg nor direct glutamate iontophoresis *in vivo* are capable of inducing burst firing following LDTg inactivation. Taken

as a whole, these data demonstrate that a functional input from the LDTg is essential for DA neuron burst firing *in vivo*.

Neuromodulatory Inputs

As discussed above, the predominant excitatory and inhibitory neurotransmitters, glutamate and GABA, respectively, potently and dramatically regulate DA neuron activity states. It is important to recognize, however, that there are also significant inputs to the VTA that contain biogenic amines, neuropeptides, or nonclassical transmitters (i.e., nitric oxide or arachadonic acid derivatives). Moreover, a number of these have been shown to modulate DA neuron firing patterns. These include cholinergic, adrenergic, serotonergic, and peptidergic inputs arising from a number of regions. Given the large number of neuromodulators present in the VTA, it would not be possible to discuss them all in this review; as such, we focus on the two that have been at the center of recent significant advances, namely, the cannabinoids and the orexins.

Cannabinoids

Research into the neurobiological actions of cannabis has demonstrated that the active ingredient of marijuana, Δ9-tetrahydrocannabinol (Δ9-THC), increases extracellular DA efflux in the accumbens. In addition, further research demonstrated that systemic administration of Δ9-THC (and other cannabinoid agonists) increases the firing rate and burst firing of identified VTA DA neurons. Interestingly, in contrast to the mechanism of action of classical neurotransmitters, endocannabinoids appear to act in a retrograde manner. As such, it is believed that endocannabinoids are released from postsynaptic neurons due to membrane depolarization, and that they migrate to adjacent presynaptic targets where they can modulate neurotransmitter release by activating presynaptic CB1 receptors. This retrograde neurotransmitter function of endocannabinoids has been identified recently in the VTA. Therefore, the activity-dependent release of endocannabinoids in the VTA has been suggested to act as a regulatory feedback mechanism to modulate presynaptic glutamatergic and GABAergic release. As a result, it is likely that endogenous cannabinoids act to provide an additional level of autoregulatory feedback in the VTA.

Orexin

Orexins are neuropeptides that are found in neurons of the lateral hypothalamus associated with arousal, feeding, and appetitive behaviors. Due to the significant orexigenic input from the LH to DA neurons of the VTA, it has been suggested that orexin modulates DAergic neurotransmission. Indeed, the direct application of orexin increases the firing rate of DA neurons recorded *in vitro*, suggesting a role for the orexin system in the modulation of DA neuron activity. More recent data have expanded previous observations and demonstrated a unique role for these neuropeptides in the regulation of DA neuronal activity. Specifically, the application of orexin *in vitro* has been shown to augment NMDA neurotransmission by inducing the insertion of NMDA receptors into the membrane of DA neurons. Such findings provide evidence for a role of the endogenous orexin system in the regulation of DA neuronal activity and plasticity.

Conclusion

The functional output of a brain region is dependent on both the intrinsic properties of the neurons and its regulation by extrinsic inputs. Here we illustrate that VTA DA neurons display distinct patterns of activity and furthermore that these activity states can be dynamically regulated by intrinsic and extrinsic inputs. This ability to integrate a variety of incoming signals and dynamically regulate DA neural firing patterns therefore provides the flexibility essential for the role of the VTA in the regulation of cognitive and motivational behaviors.

Introduction

The traditional account of the central dopaminergic system includes the important role for dopamine (DA), a catecholamine neurotransmitter, in the regulation of a myriad of neurobiologic, physiologic, and pathophysiologic processes, including cognition, motivation, memory, salience detection, motor disturbances of Parkinson's disease (PD), depression, schizophrenia, and hypophyseal function. The central dopaminergic system comprises three major and well-described tracts, all of which originate in ventral mesencephalic neurons. The mesolimbic and mesocortical pathways both originate in DA neurons of the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc) and project to structures in the ventral striatum, hypothalamus, nucleus accumbens and other limbic structures, and the prefrontal association cortex. These projections are implicated in mediating many motivated behaviors, addiction, and salience detection. The nigrostriatal pathway connects the substantia nigra with the striatum (caudate and putamen) and is implicated in movement and the pathogenesis of PD. In addition to the three major central dopaminergic tracts described here, several other dopaminergic systems exist, including the diencephalic A11–A15 cell groups, which include the tuberoinfundibular pathway that regulates the release of prolactin from the anterior pituitary; the retinal interplexiform cells (A16); the periglomerular cells of the olfactory bulb (A17); and the wake-active DA neurons located in the ventral periaqueductal grey (vPAG) (Figure 1).

In contrast to other monoaminergic and cholinergic systems, the central DA system has historically been ascribed only a limited role in the regulation of sleep–wakefulness and cortical arousal. Similarly, in the past, DA has been assigned only a marginal role in mediating the effect of wake-promoting therapeutics. Here, we review recent work, including our own, that has challenged this popular conception. In addition to firmly establishing an important role for DA in the regulation of both sleep–wake behavior and electrocortical arousal, this work has identified, for the first time, the neuroanatomical locus of wake-active DA neurons.

Sleep Regulation: Wake-Active Dopamine Neurons

The role of DA in the regulation of sleep–wakefulness as well as the neuroanatomical locus of wake-active DA neurons has only recently been established. As described previously, the DA neurons of origin for the mesocorticolimbic and nigrostriatal projections are distributed in several midbrain areas (designated A8–A10) that include the VTA (A10), the SN (A9, including the pars reticulata and pars compacta), and the retrorubral area (A8). Whereas the A8 and A9 cell groups form the origin of the projections to the striatum (predominantly the caudate and putamen), the A10 group projects most heavily to limbic forebrain areas, including the medial prefrontal cortex (PFC) and septal area. Because A10 (and to some extent A9) neurons respond to alerting stimuli, mesocorticolimbic DA transmission originating in these cell groups has been implicated in both behavioral and EEG arousal. Yet, surprisingly, neurotoxic lesions of the A10 cell group do not decrease behavioral wakefulness. Moreover, recording studies have revealed that the firing patterns of mesencephalic DA neurons do not correlate with overall levels of behavioral wakefulness. By contrast, all other monoaminergic cell groups exhibit robust state-dependent activation. Although these results seem to suggest a limited role for midbrain DA neurons and mesocorticolimbic DA transmission in sleep regulation, an important role for DA in the regulation of sleep–wakefulness is nevertheless indicated by several findings. First, it has been demonstrated that DA transporter (DAT) knockout mice have approximately 20% more wakefulness than control mice and are refractory to psychostimulant-induced (presumably DA-mediated) arousal. A similar phenotype (i.e., increased wakefulness) results from mutation of the *Drosophila* DAT gene. Second, administration of exogenous dopaminomimetics affects the sleep–wake state in a complex dose- and receptor-dependent manner. For example, in general, lower dopaminomimetic doses have a soporific effect, presumably mediated by presynaptic D2-like inhibitory autoreceptors, whereas higher doses (which typically promote an attendant increase in locomotor activity and suppress rapid eye movement (REM) sleep) enhance arousal, likely via postsynaptic D1-like receptors. Third, patients with PD who have extensive loss of DA neurons in the SN (A9), and less extensive loss of DA neurons in the VTA (A10), often demonstrate

Figure 1 (a) The afferent and efferent projections of the midbrain dopaminergic (A8–A10) system, including the ventral periaqueductal area (vPAG) dopaminergic neurons. The wake-active vPAG DA neurons are reciprocally connected with several components of the sleep regulatory and arousal systems, including the ventrolateral preoptic nucleus (VLPO), the locus coeruleus (LC), the pontine laterodorsal tegmental nucleus (LDT), the lateral hypothalamic (LH) orexin neurons, the midline and intralaminar thalamus, the basal forebrain (BF) cholinergic cells, and the prefrontal cortex (PFC). (b) The projections of the diencephalic dopaminergic system, including the descending subparafascicular thalamus (A11) projection to the dorsal horn at all levels of the spinal cord.

excessive daytime sleepiness (EDS), which is made worse by D2 receptor agonist (which activates inhibitory presynaptic autoreceptors on DA neurons and therefore inhibits the firing of DA neurons). Finally, arousal and waking behaviors are associated with increased forebrain DA secretion.

Work has uncovered a previously unrecognized group of wake-active DA neurons in the vPAG that may provide the long-sought ascending dopaminergic waking influence (Figure 2). In this study, 6-hydroxydopamine-induced lesions of vPAG DA neurons (sparing intermingled dorsal raphe serotonergic neurons, the VTA, and SNc) resulted in an increase in total daily sleep (non-REM and REM) by approximately 20%. Importantly, the magnitude of this increase in sleep seen following vPAG DA lesions is significantly larger than that produced by lesions of other monoaminergic and cholinergic cell groups thought to be important in arousal, including the locus coeruleus (LC), lateral dorsal tegmentum (LDT), dorsal raphe (DRN), lateral hypothalamic (LH) orexin neurons, basal forebrain cholinergic neurons, and the histaminergic tuberomammillary nucleus (TMN). Interestingly, DA neurons in the vPAG have been identified previously in humans and rats. Yet because the vPAG DA neurons share many efferent projections with A10 DA neurons, such as the ventral striatum and PFC, they have long been considered a rostral extension of the A10 DA group. Anatomical and physiological characteristics of the vPAG DA neurons suggest, however, that these cells constitute a functionally distinct neuronal population. For example, unlike VTA DA neurons, vPAG DA neurons project heavily to the central and extended nucleus of the amygdala as well as to the ventrolateral preoptic nucleus (VLPO), a critical

Figure 2 Photomicrograph showing the distribution of DA neurons in the ventral periaqueductal area (vPAG). Aq, aqueduct.

sleep-promoting center. These vPAG DA neurons also project heavily to (and receive reciprocal innervations from) most of the major components of the sleep–wake and arousal systems, including the VLPO, basal forebrain, LH orexin cells, LC, the LDT cholinergic cells, and the midline and intralaminar thalamus. Also, as mentioned previously, unlike the vPAG DA neurons, VTA DA neurons do not demonstrate state-dependent changes in firing. Taken together, these findings indicate that vPAG DA neurons contain a functionally distinct group of DA neurons which likely form the origin of a potent dopaminergic arousal system. Thus, for example, loss/dysfunction of vPAG DA neurons may underlie EDS in PD. Although it remains unclear how DA influences sleep regulation and arousal, it is likely through both inhibition of sleep active neurons in the VLPO and activation of the basal forebrain and monoaminergic systems (i.e., as part of the extrathalamic cortical arousal system).

A role for DA in REM sleep (also called 'paradoxical sleep' and 'active sleep') control has also been indicated by several studies. REM sleep is a behavioral state characterized by activation of the cortical and hippocampal EEG, REM, and muscle atonia, although the neurobiologic significance of this behavioral state remains unresolved. Nevertheless, electrophysiological work has revealed increased bursting activity of VTA (A10) DA neurons during REM sleep. DA levels are also elevated in the PFC during REM sleep. It remains unclear, however, if the A10 bursting is linked to the increase in DA in the PFC. Additional work suggests that DA may also directly regulate the activity of REM active neurons located in the peri-LC alpha. Specifically, Sakai and colleagues have shown that microdialysis of DA in the peri-LC alpha inhibits REM sleep in cats, likely via adrenergic α_2 receptors. Finally, numerous cholinergic receptors have been found in the midbrain DA neurons, indicating that PPT cholinergic neurons may influence the midbrain DA system, particularly during wake and REM sleep states. Collectively, these findings provide further evidence linking changes in the activity of DA neurons with changes in behavioral state.

Dopaminergic Disorders and Sleep: PD

Patients with PD suffer a progressive loss of DA neurons, largely in the SNc and VTA, leading to a marked reduction in DA content in the basal ganglia and ultimately manifesting in motor abnormalities that include akinesia, rigidity, resting tremor, and postural instability. In addition to motor disturbances, PD patients often complain of sleep disturbances ranging from sleep fragmentation to abnormal motor activity and EDS. These problems tend to worsen with disease progression. During the early stages of PD, dopaminomimetic drugs such as L-3,4-dihydroxyphenyalamine (L-DOPA) can treat these sleep disturbances; unfortunately, patients become refractory to L-DOPA treatment during the more advanced stages of PD.

Ascertaining the contribution of central DA dysfunction to the sleep disturbances of PD is complicated by several factors. First, patients with PD also exhibit neurochemical changes in cholinergic and monoaminergic systems, both of which are implicated in sleep regulation. Second, medications used to treat PD may alter sleep. Third, nocturnal tremors and inappropriate phasic motor bursting may produce fragmented sleep. Nevertheless, several compelling lines of evidence provide support for the concept that DA dysfunction significantly contributes to the pathological sleep disturbances of PD, the most common of which are EDS and nocturnal sleep disruption in the form of involuntary motor disturbance (e.g., REM sleep behavior disorder (RBD)).

Significant hypersomnia in PD, manifesting as EDS, is common and yet underrecognized with respect to diagnosis and treatment. Clinic-based objective

measurements of sleepiness employing the standardized Multiple Sleep Latency Test has revealed a high rate of EDS (approximately 20–50%) in PD patients. As indicated previously, the determinant(s) of EDS in PD is difficult to resolve because EDS is likely secondary to severe sleep fragmentation in PD, which itself may be attributable to other motor (e.g., abnormal nocturnal movements) or respiratory (e.g., central/obstructive sleep apnea) disturbances that accompany the pathology of PD.

Perhaps a more insidious form of sleep disruption that has been tacitly linked to central DA dysregulation is RBD. RBD is a parasomnia that typically manifests as 'dream enactment' behavior – that is, involuntary nocturnal movements that include kicking, punching, shouting, and screaming during REM sleep. RBD may represent an early pathophysiologic manifestation of evolving PD and other Lewy body diseases (LBDs) (e.g., dementia with Lewy bodies, multiple systems atrophy, and pure autonomic failure). Indeed, RBD typically manifests a decade prior to the motor and cognitive sequela of PD, and thus the diagnosis of RBD may provide an early therapeutic window for delaying or preventing the full development of PD.

Of note, because Lewy bodies and Lewy neurites are composed of α-synucleinopathies, these disorders are termed 'synucleinopathies.' Although the brain stem is clearly implicated in RBD pathogenesis, the identity of the neural networks that become dysfunctional to manifest RBD is unknown. Because approximately 50% of people with RBD develop PD or dementia with Lewy bodies and the majority of PD patients have RBD, it has been suggested that the intrinsic pathology of PD (i.e., severe nigrostriatal DA neuron loss) may contribute to the development of excessive nocturnal movement, particularly RBD. Despite the intuitive appeal of this hypothesis, however, studies have linked RBD to dysfunction of brain stem REM sleep circuitry. These structures include the subcoeruleus region (SC; equivalent to the sublateral dorsal nucleus (SLD) in rats) and, possibly, the intermediate region of the ventromedial medulla; both structures appear critical for generating atonia during REM sleep. SC/SLD dysfunction, as the neuropathologic substrate for RBD, is seemingly consistent with the temporal pattern of neuronal degeneration in PD and other LBDs, which starts in the brain stem and includes the coeruleus–subcoeruleus complex in stages I and II of PD and progresses inexorably rostrally toward the forebrain. The temporal pattern of lesions (i.e., caudal-to-rostral progression) is also consistent with RBD (secondary to SC/SLD degeneration) as an early manifestation of these neurodegenerative conditions. Nevertheless, although SC/SLD dysfunction has been demonstrated in PD, it remains unclear if RBD in evolving PD is caused by SC/SLD degeneration or loss of critical inputs such as DA nigrostriatal projections.

Dopamine and Stimulant-Induced Arousal

Drugs such as amphetamines and amphetamine-like stimulants (e.g., cocaine, methylphenidate, and methamphetamines) have potent wake-promoting effects. These drugs are thought to produce their arousal effects by blocking DA reuptake/transport (i.e., acting on the cell membrane DAT and/or stimulating DA release), resulting in increased synaptic DA concentrations. Determining DA's contribution to behavioral arousal in this context has nevertheless been complicated by the fact that psychostimulant administration also promotes the synaptic accumulation of other monoamines, particularly norepinephrine (NE). This is particularly true at higher doses, where amphetamines interact with vesicular monoamine transporter-2 to increase the cytoplasmic pool of monoamines. In fact, for many years, the wake-promoting effect of amphetamine-like stimulants was attributed almost exclusively to NE mechanisms since adrenergic signaling is known to modulate arousal state. Further reinforcing this notion is the fact that LC neurons (the major source of brain NE) display robust state-dependent activity and discharge most rapidly during enhanced arousal. Although, taken together, these observations suggest NE signaling might form the molecular basis for the wake-promoting actions of psychostimulants, several studies have suggested a more dominant role for DA than NE in this regard. Centrally acting DA antagonists, for example, cause drowsiness, and drugs that selectively block the DAT are more effective in promoting wakefulness than drugs that selectively block the NE transporter (NET). Indeed, both desipramine and nisoxetine, two potent and selective NET blockers, have minimal effects on EEG arousal in narcoleptic canines (even at high doses which suppress REM sleep). The wake-promoting effect of amphetamine-like stimulants is also abolished in mice with deletion of the DAT gene. Conversely, the wake-promoting effect of amphetamines is preserved following lesions of the LC (and hence a dramatic reduction in central NE) in cats and following chemical ablation of NET-bearing NE forebrain projections from the LC in mice. The potency of most wake-promoting psychostimulants is also best predicted by binding affinity to DAT. Finally, elevated arousal levels correlate with increases in synaptic DA but not NE. Taken together, these findings support the concept that presynaptic modulation of DA transmission (at least at the level of the forebrain) is the key pharmacological mechanism

by which amphetamines and their derivatives mediate cortical and behavioral arousal.

The anatomical substrates for DA's effects on arousal also remain unresolved, although several lines of experimental evidence suggest this may occur through inhibition of sleep-promoting systems. For instance, as previously indicated, a mutually inhibitory circuit between wake-active vPAG DA neurons and sleep-active neurons of the VLPO has been elucidated. Moreover, *in vitro* administration of DA inhibits neurons of the VLPO. Curiously, however, DA-mediated inhibition of the VLPO is blocked by α_2 receptor antagonists but not by D2 receptor antagonists. Although these findings appear difficult to reconcile, they likely indicate, at a minimum, cross-talk between these central nervous system catecholaminergic systems. Thus, for example, the drug modafinil (which shares the wake-promoting properties of traditional psychostimulants) hyperpolarizes VLPO neurons *in vitro*, presumably by blocking the NET. Yet DAT knockout mice are unresponsive to modafinil treatment, suggesting instead that DA neurotransmission (i.e., blockade of the DAT) underlies the wake-promoting effect of modafinil. Combined, these findings suggest a possible dual mode of action for modafinil (i.e., interference with both NE and DA uptake), and this may explain why modafinil can exert its wake-promoting effects without inducing dopaminergic side effects such as addiction. Indeed, data indicate that modafinil may produce its arousal effects through dopaminergic-dependent adrenergic signaling. For example, DA may function as a physiological ligand at adrenergic receptors. In support of this concept, DA stimulation of NE receptors has been documented previously in the pontine brain stem. However, the mechanism of action by which DA produces its effects on cortical and behavioral arousal remains unresolved.

In addition to inhibiting VLPO neurons, amphetamine-like stimulants may also promote wakefulness by activating, for example, the wake-promoting basal forebrain cholinergic neurons and LH orexin neurons. To this end, DA has been reported to stimulate cholinergic cells in the basal forebrain by D1-like receptors (i.e., D1 and D5) *in vitro*. Research has also uncovered an extended network of basal forebrain and preoptic sites that mediate amphetamine-induced increases in behavioral and electrocortical arousal. Remarkably, however, although the anatomical resolution of this mapping study was limited, close inspection of the data reveals that infusion of amphetamine into the region best approximating the location of the VLPO produced one of the largest increases in arousal, providing further support for the concept that the VLPO may be a critical structure for mediating the arousal-promoting effects of amphetamines and amphetamine-like stimulants.

Summary

Work during the past decade has firmly delineated an important role for DA in sleep–wake regulation (both normal and pathologic) and behavioral and electrocortical arousal. Wake-active DA neurons of the vPAG likely exert their potent arousal influence through a mutually inhibitory interaction with the VLPO as well as less well-defined interaction with components of the ascending arousal system (e.g., basal forebrain, LC, and lateral hypothalamus). Based on recent findings, it is tempting to speculate that alterations in DA neurotransmission may underlie the excessive sleepiness of evolving PD as well as the manifestation of abnormal nocturnal movements in the form of RBD. Finally, a critical role for DA in mediating the wake-promoting effects of psychostimulants has begun to emerge, although the indirect or direct mechanism by which this occurs remains to be clarified.

Dopamine in Perspective

P Foley, Prince of Wales Medical Research Institute, Sydney, NSW, Australia

Dopamine (systematic: 1,2-benzenediol, 4-(2-aminoethyl)-9CI; 3-hydroxytyramine or 3,4-dihydroxyphenylethylamine; $C_8H_{11}NO_2$; abbreviated DA) is a biogenic amine, catecholamine neurotransmitter, and pituitary hormone; it is also an intermediate in the synthesis of norepinephrine and epinephrine. DA was long known as 3-hydroxytyramine; Russell Dale proposed the name 'dopamine' in 1952 in order to avoid confusion with 5-hydroxytryptamine, as well as to underscore the relationship between the amino acid (DOPA) and the amine. 'Dopamine' did not, however, become the standard designation until the mid-1960s.

DA is the principal transmitter of several central nervous system (CNS) pathways, particularly those originating in the midbrain, and also acts as a neurotransmitter in several peripheral neurovegetative systems. In the CNS, dopaminergic (DAergic) systems are critically involved in the control and modulation of motor activity, learning, and motivation, and regional disruptions of these systems have been implicated in a number of disorders, including Parkinson's disease and schizophrenia. Several important classes of therapeutic agents are correspondingly active in CNS DAergic systems. DA itself is unable to cross the blood–brain barrier, for which reason L-DOPA and, more recently, DA receptor agonists are employed to increase CNS DAergic tone.

DA Synthesis and Catabolism

DA is synthesized in nervous tissue and adrenal gland by aromatic amino acid decarboxylase, a cytosolic enzyme which requires the cofactor pyridoxal phosphate (vitamin B_6), from the amino acid L-DOPA (3,4-dihydroxyphenylalanine); the rate-limiting step in DA synthesis, however, is the conversion of the amino acid tyrosine to L-DOPA by tyrosine hydroxylase (TH; Figure 1). DA is then sequestered in synaptic vesicles or particles following uptake by the relatively nonspecific ATP-dependent vesicular membrane transporter 2 (VMAT-2), which can be irreversibly blocked by the alkaloid reserpine (see below). Depolarization of the nerve terminal elicits a calcium-dependent fusion of vesicles with the terminal membrane and release of DA into the synaptic cleft (exocytosis), where it interacts with a variety of postsynaptic membrane protein receptors, initiating diverse biochemical responses in the postsynaptic cell. The released transmitter also interacts with presynaptic autoreceptors, thereby inhibiting depolarization-induced DA synthesis and release. DA synthesis and release in the CNS are tightly coupled; free DA (and other catecholamines) inhibit TH activity directly, competing for the cofactor binding site, while depolarization and activation of DAergic autoreceptors leads to phosphorylation of TH by a variety of kinases, reducing its sensitivity to catecholamine-related inhibition. Reduced nerve stimulation and release can thus lead to increased DA synthesis in cells bearing DA autoreceptors (Figure 2).

The principle mechanism for termination of DA-mediated transmission involves transmitter reuptake along its concentration gradient by a specific presynaptic Na^+- and Cl^--sensitive membrane DA transporter (DAT). Diffusion of DA away from the synapse and stimulation of more distant receptors is termed volume transmission, and a local extracellular DAergic 'tone' has been described in certain brain regions.

There are two major enzymes involved in DA catabolism in mammalian nervous tissue: mitochondrial outer membrane monoamine oxidase (MAO) in the nerve terminal, and extracellular catechol-*O*-methyl transferase (COMT), whereby the latter is not regarded as playing a major role in the regulation of CNS DA (Figure 3). Mammalian MAO exists in two forms; MAO-A is primarily responsible for DA metabolism in rodents, whereas type B is more significant in this capacity in humans, a difference attributable more to regional enzyme abundance than to differences in enzyme specificity. The first specific MAO-B inhibitor (selegiline) was synthesized in the USA and Hungary in the early 1960s, but this specificity was recognized only in the early 1970s. The major DA metabolite in humans is homovanillic acid (HVA), whereas dihydroxyphenylacetic acid (DOPAC) is more abundant in rodents. Levels of these metabolites have been monitored in the laboratory as indicators of DA turnover in specific brain regions of experimental animals; in humans, DA metabolites, as measures of CNS DA turnover, are assayed in cerebrospinal fluid to exclude products of peripheral DA catabolism.

DA Biochemistry: History

DA played a particularly significant role in the history of neurochemistry: following a series of investigations between 1957 and 1965, commencing in the laboratory and completed in the clinic, chemical

Figure 1 The major catecholamine synthetic pathway. The basic catecholamine structure is most easily seen in DA, consisting of the 1,2-dihydroxlated benzene ring (catechol or, more properly, pyrocatechol), to which is attached at the 4-position the aminoethyl group. The conventional numbering of the carbons in catecholamines, however, is referenced to phenylethylamine; DA is thus 3,4-dihydroxyphenylethylamine. The designation of the carbons in the aminoethyl chain is also shown. TH, the rate-limiting enzyme in catecholamine synthesis from tyrosine, is nearly saturated by the amino acid at normal physiological concentrations. AADC (also referred to as DOPA decarboxylase), which also decarboxylates the serotonin precursor 5-hydroxytryptophan, is found not only in DAergic and serotonergic nerve tissue, but also in kidney and vascular tissue.

neurotransmission and its significance for normal CNS function was first demonstrated in the case of DA. While chemical (as opposed to electrical) neurotransmission in peripheral nervous pathways had been recognized since the 1920s, the central role of so-called neurohumoral agents in the CNS remained a matter of vigorous dispute until the early 1960s. But before this unparalleled chain of investigations was conceptually possible, DA had principally been invoked in the context of general catecholamine research stretching back to the beginning of the twentieth century.

DA was first synthesized (from vanillin) in 1909–10 during investigations of the adrenal medulla in Berlin and London. In comparison with the 'major catecholamines,' adrenaline and noradrenaline, DA ('aminoethyl-catechol') was a weak vasopressor agent, and consequently sank into relative obscurity until the 1930s.

The DA precursor L-DOPA was first isolated from the broad bean (*Vicia faba*) by Torquati in 1911, but Markus Guggenheim (Hoffmann-La Roche, Grenzach) published the first major paper on its physiological properties in 1913. Guggenheim discovered by self-administration that it was "not completely innocuous," and for many years he sought a physiological role for L-DOPA as part of his investigation of what he termed the "biogenic amines"; ironically, he died in the year that L-DOPA was commercially launched as a medication for parkinsonism. Bruno Bloch (Basle) reported in 1917 that L-DOPA was involved in the synthesis of melanin from tyrosine in pigmented cells; he also discovered that it was the substrate for an oxidative reaction catalyzed by 'dopaoxydase' (tyrosinase).

Naturally occurring DA itself was first isolated from the broom plant (*Sarthamnus scoparius*) by two Hamburg chemists in 1931. By this time, it was widely assumed that L-DOPA was a precursor in adrenaline synthesis – elucidating the catecholamine synthetic pathway was one of the central problems of physiological chemistry until the late 1950s – but ignorance of how the amino acid might be converted to an amine *in vivo* left the question open. Much of the work which determined the biochemical pathway involved was published in a series of landmark papers by Peter Holtz (Rostock; after 1945: Frankfurt am Main). In 1937, he demonstrated that 'DOPA decarboxylase' in kidney rapidly decarboxylates L-DOPA (but not D-DOPA) to DA, and by 1939 had proposed the now-accepted catecholamine synthetic pathway (Figure 1). Proof that amino acid decarboxylation actually occurred *in vivo* was delivered by Holtz in 1941 and 1942 by administering L-DOPA to guinea pigs and humans and then isolating DA from their urine. In 1952, Holtz reported that pyridoxal-5-phosphate activates adrenal cortex DOPA decarboxylase, and that a similar activator was present in cortex, thus identifying the cofactor for the enzyme. By 1956, the presence of DA in a number of tissues

Figure 2 Schematic depiction of the synthesis, storage, release, and metabolism of DA in a DAergic nerve terminal. ① DA synthesis. TH activity can be inhibited by α-methyl-p-tyrosine, or elevated by increasing levels of its cofactor tetrahydrobiopterin. ② Vesicular storage effected by VMAT, the activity of which can be inhibited irreversibly by reserpine or irreversibly by tetrabenazine. ③ Exocytotic, Ca^{2+}-dependent DA release into synaptic cleft stimulated by depolarization of the nerve terminal. D-Amphetamine at high doses increases effective DA release. ④ DA binds postsynaptic G-protein-associated DA receptors, the varieties of which are broadly classified into the D_1 and D_2 receptor families, and thereby elicits a variety of specific intracellular biochemical events in the postsynaptic cell, including activation of adenylyl cyclase, various kinases, and modulation of ion channel states. Agonists and antagonists of varying specificity for particular DA receptors are employed experimentally and clinically to modify the activity of DAergic systems. ⑤ Binding of DA to presynaptic D_2 autoreceptors inhibits DA synthesis (by inhibiting TH activity, which is also reduced by nerve depolarization) and release. ⑥ Reuptake of DA into the presynaptic terminal by DAT is the primary means for ending DAergic stimulation of the postsynaptic cell. DAT activity can be inhibited by D-amphetamine, cocaine, and nomifensine. ⑦ Intracellular catabolism of DA by MAO and extracellular metabolism by COMT can be reduced by enzyme inhibitors of varying specificity.

had been demonstrated, but not its active accumulation. Most significantly, Schümann, working in Holtz' laboratory in Frankfurt, had identified DA in sympathetic nerves and ganglia, and he suggested that much of what had hitherto been recognized as adrenaline in these tissues was probably DA.

Nagatsu, Levitt, and Udenfriend (Bethesda) provided in 1964 the final essential link in the catecholamine synthetic pathway when they reported the first direct evidence for the presence of tyrosine hydroxylase in brain. Further, Kenneth Shaw and his group (Salt Lake City) had established in 1957 that HVA was present in normal human urine, and their experiments led them to propose the now-accepted metabolic pathway for DA (Figure 3).

DA Function in the CNS: History

By the mid-1950s, the possibility of at least a limited role for chemical transmission in the CNS was being discussed, with acetylcholine, histamine, and substance P seen as the likeliest candidates, while

Figure 3 The major catabolic pathways of DA. Both DOPAC and HVA can be further metabolized to sulfate conjugates prior to excretion in urine. MAO, monoamine oxidase; COMT, catechol-*O*-methyltransferase.

Bernard Brodie and his group (NIH, Bethesda) believed that serotonin (5-HT) was particularly significant. Most researchers, however, believed that the physiological significance of DA lay not in its circulatory or sympathomimetic capacity, but rather in its role as precursor for noradrenaline, adrenaline, and melanins.

This view was challenged about this time by Hermann ('Hugh') Blaschko (Oxford). In 1937, he had discovered (mono)amine oxidase and found that it metabolized both DA and noradrenaline, and in 1939 had independently proposed the catecholamine synthetic sequence. In 1956, Blaschko noted that DA was not stored in adrenal chromaffin tissue, consistent with its putative role as a metabolic intermediate, but that this was not true for adrenergic nerve endings, so that DA here might possess in its own right hitherto unrecognized regulatory functions. The investigations which would be employed to explore this hypothesis were made possible by the development of more sensitive assays which exploited the fact that DA is liable to oxidation under controlled laboratory conditions, and in particular by adaptations of the fluorometric techniques introduced by Brodie's laboratory for the assay of serotonin.

In 1956, the Swedish pharmacologist Arvid Carlsson and colleagues reported that the plant alkaloid reserpine, then employed in the clinic as an antipsychotic agent, depleted catecholamine stores in adrenal medulla and brain tissue. Further, they demonstrated that stimulation of sympathetic nerves after reserpine treatment no longer elicited catecholamine release, and Carlsson hypothesized that this was relevant to the central hypotensive effect of reserpine. This view placed him at odds with his respected mentors Brodie and Shore, with whom he had recently spent a year as postdoctoral fellow, who attributed its effects to its release of serotonin. Carlsson sought to resolve the issue by replenishing central monoamine stores in reserpinized animals by administrating their amino acid precursors; peripherally administered DA and serotonin do not appreciably penetrate the blood–brain barrier. In experiments which would prove to among the most important in catecholamine history, Carlsson found that treatment with racemic

DOPA, but not 5-hydroxytryptophan, quickly reversed reserpine-induced tranquilization of mice and rabbits, but without elevation of noradrenaline levels. He therefore concluded that DA depletion underlay reserpine sedation, and that DA was thus critically involved in CNS neurotransmission.

The history of neurochemistry is, like the history of brain function since the nineteenth century, largely a history of the localization of particular functional elements. It was necessary, before any function could be ascribed to DA or the other catecholamines in the CNS, to establish not only that they occurred in brain, but also that they were localized to specific regions of the brain. It is possible that CNS DA was first detected by the cardiologist Wilhelm Raab (Vermont) in 1947 as 'encephalin.' The unknown catechol substance detected in 1957 by Katharine Montagu (Wickford, Essex) in brain, 'substance X,' may have partially consisted of DA, but Montagu did not appear to recognize the significance of this finding. In contrast, Carlsson's group concluded in 1958 that the levels of DA measured in rabbit brain were inconsistent with its being merely an intermediate. Two of Carlsson's doctoral students, Bertler and Rosengren, reported that in eight mammalian species CNS DA was predominantly localized in the striatum, distinctly different from the distribution of noradrenaline, also examined using the fluorescent techniques then being introduced in Carlsson's laboratory. On the basis of this distribution, and the fact that drugs which modulated its levels also affected motor performance, the authors concluded that "dopamine is concerned with the function of the corpus striatum and thus with the control of motor function." At the First International Catecholamine Symposium (1958), Carlsson also compared the effects of reserpine-induced DA depletion with the symptoms of parkinsonism, and suggested that the deficit could be compensated by administration of either the transmitter precursor or of a sympathomimetic amine. In early 1959, the neurologist Isamu Sano (Osaka) published a detailed analysis of DA distribution in human brain which indicated that the highest concentrations here were also in the striatum.

At the CIBA Foundation Symposium on Adrenergic Mechanisms (March 1960), many doyens of physiology remained unconvinced that catecholamines played a major role in CNS neurotransmission. Marthe Vogt, for example, who in 1954 had published a landmark paper on the localization of catecholamines in the dog brain, argued that any central catecholamine effects were attributable to general or local hypertensive effects. During a vigorous discussion of the question at the end of the symposium, where Carlsson advanced the role of catecholamines and Brodie that of serotonin in modulating behavior, Vogt concluded that any theories linking central DA or 5-HT levels with behavior would not have a long life.

On the contrary, results accrued from various laboratories during the next few years which confirmed the significance of CNS biogenic amines. But the conclusive evidence for the role of DA was ultimately provided by a series of clinical experiments. During the 1950s, reserpine was a commonly employed sedative, particularly in psychiatric patients, but extrapyramidal reactions ranging to a parkinsonian-like state were an occasional but unwelcome side effect. In 1958, Rudolf Degkwitz and colleagues (Frankfurt am Main) commenced experiments in which they administered L-DOPA to reserpine-treated patients, and reported in 1960 that the amino acid rapidly abolished the lethargy and feelings of exhaustion which had hitherto plagued their patients. Similarly, Sano reported in February 1960 the experimental treatment of parkinsonian patients with infused D,L-DOPA. Sano had found the DA levels in specific brain regions of a deceased parkinsonian patient to be significantly reduced when compared with normal levels, most dramatically in substantia nigra and striatum. The results of his experimental D,L-DOPA therapy were promising, but Sano did not pursue this phenomenon further.

Convincing, direct evidence for disturbed monoamine function in Parkinson's disease was provided in Vienna by the pharmacologist Oleh Hornykiewicz and the neurologist Walther Birkmayer. Hornykiewicz had 18 months' valuable experience under the tutelage of Blaschko in Oxford, where he had acquired the best available methodologies for measuring catecholamines in biological tissues. After reading the 1959 Bertler/Rosengren paper, Hornykiewicz and Herbert Ehringer found the highest human CNS DA concentrations in the caudatus and putamen, with moderately high levels in the substantia nigra and area postrema, confirming the results of Carlsson and Sano. More exciting was what he observed in brains from parkinsonian patients, as captured by Hornykiewicz' 1992 reminiscence of the moment of discovery: he could literally see with the naked eye the basal ganglia DA deficiency in Parkinson's disease, as the total absence of the pink reaction elicited by DA in control brains.

Shortly after Hornykiewicz had identified the basal ganglia DA deficit in the parkinsonian brain, he proposed that Birkmayer treat parkinsonian patients with L-DOPA. In July 1961, Birkmayer intravenously administered 50 mg L-DOPA to a female postencephalitic parkinsonian patient, with dramatically positive effects on her parkinsonian symptoms, particularly her akinesia. The simplest explanation was that the hypothesis that the striatal DA deficit was responsible

for parkinsonian akinesia and that L-DOPA administration was capable of ameliorating this deficit, was correct. But the initial response to these findings was lukewarm, and Hornykiewicz designated the period 1960–67 the "seven lean years" of DA research. Despite the promising start at the end of the 1950s, interest in DA remained restricted in the early 1960s to a small group scattered across the world.

Hornykiewicz wished to improve the new therapy by expanding the theoretical basis upon which it was built, while Birkmayer applied his observational skills to determining whether theoretical expectations were reflected by clinical reality. At this point Hornykiewicz was invited to write a review article on DA and Parkinson's disease for the leading German medical journal, the *Deutsche Medizinische Wochenschrift*, the first review concerning DA in a major medical journal.

The foundations for studies of the anatomical basis of CNS DAergic transmission were also laid in the early to mid-1960s. André Barbeau and Theodore L Sourkes (Montréal) had independently investigated L-DOPA therapy for parkinsonian patients in 1961, basing their approach on reduced urinary DA levels in parkinsonian patients. More significantly, Sourkes and Louis J Poirier reported in 1964–65 that interruption of nigrostriatal fibers reduced striatal catecholamine levels. It is easy to forget that the concept of 'dopaminergic' and other transmitter-defined pathways was remarkable at the time; neural tracts were spatially defined by histological techniques according to biochemical reactions unrelated to transmitter content. Some residual suspicion persisted regarding the Sourkes–Poirier results in light of the originality of their integration of experimental neuroanatomy, neurochemistry, and behavioral studies; further, the existence of the nigrostriatal pathway contradicted long-standing neurohistological orthodoxies. These doubts were soon allayed by functional investigations which provided further evidence for a direct DAergic nigrostriatal connection.

The visualization of the pathway was also achieved in 1965, by Carlsson, Nils-Åke Hillarp, and Kjell Fuxe (Karolinska Institute, Stockholm), using the sensitive condensation-fluorescent detection method which had been developed since 1959 by Hillarp, Bengst Falck, and Georg Thieme. The perfection of this method and its employment to demonstrate CNS catecholaminergic neurons was of fundamental importance to modern neurochemistry. As Carlsson noted in 1987, the discoveries of DA deficits in parkinsonism and the beneficial effects of L-DOPA were important, but the real breakthrough came with the histochemical techniques visualizing the cellular localization of the monoamines by means of the fluorescence microscope.

The importance of this work for neurochemistry cannot be overestimated, not only for its contribution to the theoretical analysis of Parkinson's disease but also because, as Poirier and Sourkes noted in retrospect, it stimulated studies aimed at the identification of neurochemically defined pathways and their role in behavioral and psychoneuroendocrinological phenomena.

The first unequivocal demonstration of a unity between physical lesion, neurochemical changes, and behavioral abnormalities was a major step forward in establishing neurochemical investigations as the dominant research paradigm in the further investigation of CNS function and disease. For his particularly significant contributions of his group to these developments from 1956 onward, Carlsson was one of the three recipients of the Nobel prize for physiology or medicine in 2000.

The outcome of these investigations was that residual skepticism regarding the role as CNS transmitters of catecholamines, and of DA in particular, was largely assuaged. In subsequent years, increasingly sophisticated neuroanatomical techniques were employed to precisely map CNS pathways associated with DA and other transmitters, revealing functional connections not apparent on the basis of classical, structural neurohistology, as well as interactions between these systems and the integration of CNS information and its exchange. The further development of visualization techniques has similarly permitted the elucidation of the structural characteristics of DAergic neurons and synaptic structures. Further, increasingly sensitive electrochemical procedures have been applied to the assay of DA in biological fluids, both *ex vivo* and in specific brain regions of living research animals. Finally, animal studies and the correlation of neurochemical and neurohistological findings with clinical data have allowed the illumination of the functional significance of DA for human emotion, behavior and motor performance.

Functional Significance of CNS DA

DA was initially thus identified as being involved in the regulation of certain motor functions. The link between deterioration of the nigrostriatal DAergic pathway and the consequent loss of striatal DA and the akinesia of parkinsonism represented the first association of a specific neurochemical deficit with a CNS disorder, and thus the first conclusive implication of a chemical neurotransmitter in CNS function. Pharmacological treatment of Parkinson's disease has since been directed at compensating for reduced extrapyramidal DA release by administration of the DA precursor L-DOPA (usually in

combination with a blood/brain barrier-impermeable decarboxylase inhibitor, in order to minimize peripheral L-DOPA metabolism), of direct-acting DA receptor agonists, or of inhibitors of DA-metabolism, particularly MAO-B inhibitors.

In the ensuing four decades, further CNS DAergic pathways and systems have been identified, and the palette of functions linked with DA correspondingly expanded. The major DAergic CNS pathways are the following: (1) the nigrostriatal system, projecting from the substantia nigra to the striatum, involved in control of voluntary movement, as discussed above; (2) the mesocortical–mesolimbic system, projecting from the ventral tegmentum to the nucleus accumbens, tuberculum olfactorium, amygdala, area entorhinalis, and septum, involved in control of motivational behavior and probably also of learning and memory; and (3) the tuberoinfundibular system, projecting from the hypothalamic nucleus arcuatus and inhibiting hormone release (principally of prolactin) from the anterior pituitary.

That excessive DAergic activity is involved in the etiology of psychosis and schizophrenia was first explicitly hypothesized by Carlsson and Lindqvist in 1963, who demonstrated that phenothiazine-class antipsychotic agents acted principally by blocking DA receptors. This hypothesis, since rendered more precisely as hyperactivity of the mesolimbic DAergic system, is consistent with the observation that releasing agents which increase extracellular DA levels, such as cocaine (an uptake blocker) and amphetamine, can elicit psychotic symptoms. On the other hand, reduced DAergic function in the prefrontal cortex, where DAergic neurons contribute to regulating the flow of information from other CNS regions, is associated with deficits in memory and attention processes, and has been implicated both in the negative symptoms of schizophrenia as well as in attention-deficit disorders.

The mesocortical–mesolimbic DAergic system, particularly the ventral tegmentum-nucleus accumbens projection, has similarly been implicated in phenomena relevant to reward, motivation, and drug reinforcement/addiction, and thus also in problems of psychostimulant drug withdrawal. Although the concept of DA as a reward chemical is on overly simplistic interpretation of these phenomena, the appropriate regulation of DAergic function in this pathway is undoubtedly important for proper emotional performance as well as for goal-directed behavior. DA appears to be particularly critical for establishing a "conditioned tendency to re-approach environmental stimuli that have been associated with most primary rewards, and for maintaining habit strength once a task has been learned" (Wise, 2004).

The role of DA outside the CNS is not as clear cut. DA-containing neurons and DA receptors have been identified in a variety of tissues, and DA is the most abundant plasma catecholamine, presumably related to peripheral autonomic activity, its levels being increased by a number of physiological stressors. DA elicits hypotension subsequent to direct vasodilation and reduced vascular resistance (via stimulation of D_1-type receptors) and indirect vasodilation (D_2-type receptor-mediated reduction of sympathetic tone) in renal, pulmonary, coronary, and mesenteric vascular beds, and stimulates cardiac contractility (via activation of β_1-adrenergic receptors). Identification of specific DA receptor types by molecular biological techniques also suggests that DAergic activity plays roles in the regulation of immune activity, in blood lymphocytes, and in the lung. DA plays an important role in renal function, increasing perfusion as well as enhancing natriuresis and diuresis, and defective renal DA function has been suggested to underlie age-related declines in kidney function, with implications for the pathogenesis of hypertension and diabetes.

Intravenous DA is employed in the clinic for its direct (β_1-adrenergic receptor agonist) and indirect (noradrenaline releasing) sympathomimetic effects. At low ('renal') doses it is administered as a renal and visceral vasodilator, while at higher dosages it is utilized as an inotropic agent. It has thus been used in cardiac emergencies, hypotension, shock, and kidney failure. The utility of 'renal dose' DA, however, has been increasingly questioned in recent years; critics note that evidence for its clinical effectiveness from large-scale controlled trials has not been forthcoming, and that the potential deleterious effects of systemic DA administration (impaired rather than enhanced mucosal blood flow via activation of α_1 receptors, aggravation of reduced gastric motility, impairment of pulmonary function) also suggest caution, particularly as the precise mechanisms of DAergic renal regulation, for instance, remain to be defined. The significance of DA-induced negative changes in endocrine (central hypothyroidism following suppression of anterior pituitary function) and immune function also requires clarification.

Dopamine Neurons: Reward and Uncertainty

W Schultz, University of Cambridge, Cambridge, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The classic view of dopamine functions derives from the clinical neurologist examining a human parkinsonian patient who suffers from severe problems with ocular, facial, and skeletal movements, resting tremor, and muscular rigidity. Likewise, experimental dopamine depletions by lesions or drugs, or dopamine receptor blockade, result in severe behavioral deficits of movement initiation and execution. Further investigations of humans and animals with dopamine depletions have revealed an even larger spectrum of behavioral deficits, including many cognitive and motivational disabilities. However, electrophysiological studies of the impulse activity of single dopamine neurons have revealed primarily a role in the processing of information related to reward and uncertainty. These studies could not confirm active dopamine involvement in the large variety of functions deficient after their lesion, including movements, suggesting that the crucial role of dopamine in these processes consists of enabling postsynaptic neurons that actively encode these specific functions. This article describes the electrophysiological activity of single dopamine neurons in relation to reward and uncertainty.

Behavioral Theories of Reward and Uncertainty

Public perception associates rewards primarily with happiness and special gratification, but behavioral research suggests wider functions. Rewards are any objects or events that generate approach behavior and consumption, produce learning of such behavior, and constitute outcomes of economic decision making. Rewards are of crucial importance for individual and gene survival, and they support elementary processes such as drinking, eating, and reproduction. Rewards are polysensory and do not engage specialized reward receptors, and the brain extracts the reward information from visual, auditory, somatosensory, olfactory, and other sensory information. Thus, the functions of rewards are not defined by the physics and chemistry of their inputs but by the behavioral reactions they induce.

The laws of mechanics, optics, acoustics, and biochemistry define the key functions of primary sensory systems in the brain. The dedicated physical and chemical receptors of these systems translate environmental energy and information into neural language. By contrast, there are no dedicated receptors for reward, and the information enters the brain through the touch, taste, visual, and auditory receptors of primary sensory systems. The functions of rewards cannot be derived entiely from the physics and chemistry of input events and are based primarily on behavioral effects. Thus, the investigation of reward functions requires behavioral theories that can conceptualize the different effects of rewards on behavior. Animal learning theory and economic decision theories provide coherent frameworks for the investigation of neural reward mechanisms. The central tenets of these theories are based on observable behavior and, superficially, on the behaviorist approach, although mental states of representation and prediction are included.

Learning

Rewards induce changes in observable behavior and serve as positive reinforcers by increasing the frequency of the behavior that results in reward. In Pavlovian, or classical, conditioning, the outcome follows the conditioned stimulus irrespective of any behavioral reaction, and repeated pairing of stimuli with outcomes leads to a representation of the outcome that is evoked by the stimulus and elicits the behavioral reaction. Thus, Pavlovian conditioning produces outcome predictions. By comparison, instrumental, or operant, conditioning requires the subject to execute a behavioral response; without such response, no reward occurs. Instrumental conditioning increases the frequency of those behaviors that are followed by reward by reinforcing stimulus–response links. Instrumental conditioning allows subjects to influence their environment and determine their rate of reward. However, there is general agreement that the stimuli used in instrumental conditioning have become reward predictors through Pavlovian learning.

Associative learning depends crucially on the discrepancy between the occurrence of a reward and its prediction. The importance of such prediction errors is derived from Kamin's blocking effect, which postulates that a reward that is fully predicted does not contribute to the learning of a stimulus or action, even when it has been repeatedly paired with the stimulus or action. This is conceptualized in the associative learning rules, according to which learning advances only to the extent to which a reinforcer is unpredicted and slows progressively as the reinforcer becomes more predicted. The omission of a predicted

reinforcer reduces the strength of the conditioned stimulus and produces extinction of behavior. So-called attentional learning rules in addition relate the capacity to learn (associability) in certain situations to the degree of attention evoked by the conditioned stimulus or reward.

Approach Behavior and Decision Making

Rewards elicit approach and consummatory behavior. This is due to the objects' being labeled with appetitive value through innate mechanisms (primary rewards) or, in most cases, classical conditioning, after which these objects constitute, strictly speaking, conditioned reinforcers. Nutritional rewards derive their value in addition from hunger and thirst states (drive), and satiation of an animal reduces the reward value and consequently the behavioral reactions.

Conditioned, reward-predicting stimuli also induce preparatory or approach behavior toward the reward. In Pavlovian conditioning, subjects automatically show nonconsummatory behavioral reactions that would otherwise occur after the primary reward and which increase the chance of consuming the reward, as if a part of the behavioral response has been transferred from the primary reward to the conditioned stimulus (Pavlovian response transfer).

In instrumental conditioning, the action becomes associated with reward and thus obtains a value. Decision-making mechanisms are based on the action values of the different available options. Furthermore, a reward can become a goal for instrumental behavior if the reward is represented at the time the behavior is being prepared and executed and if there is a systematic relationship between the specific action leading to the reward.

When more than one option is available, animals show preferences for specific options, expressed as the probability of choosing one option over all others. Choices are crucially based on predictions of outcomes. Without predictions, agents can only guess, as they do not know what they will get when making the choice. This gives the Pavlovian learning of reward predictors a key role in decision making. The reward function in decision making is thus indirect: rewards serve for predictive Pavlovian learning, and the acquired prediction directs the choice. Reward itself is the outcome of the overt choice, and its evaluation is used to update the prediction used for the next decision.

Quantification of Reward Value and Uncertainty

Decision mechanisms maximize the outcome of choices by comparing the values of all available options and choosing the option with the highest value. The values of options are compared on the basis of their probability distributions. The expected value of a probability distribution denotes the summed product of each reward value weighted by its probability and provides a single numeric measure of the outcome. However, additional factors play important roles, and outcomes are better quantified by the utility they have for the individual decision maker. Utilities are assessed by preferences in overt choice behavior, resulting in the quantification of outcomes as single scalar variable: expected utility $= \sum u(x) \times p$ (u is utility, x is value, and p is probability).

A major factor influencing utility is uncertainty. In risk averse subjects, uncertainty reduces the utility of a reward (a reward has less value for me if I am afraid that I won't get it), whereas risk seekers find higher utility in an uncertain reward (I like the uncertainty and thus prefer risky rewards over safe ones), all other reward parameters being equal. The influence of uncertainty on outcome utility becomes apparent when doing the Taylor series expansion of expected utility.

Pleasure

Subjective feelings of pleasure and the resulting positive emotion represent key functions of rewards. However, it is unclear whether the pleasure can have a reinforcing causal effect for behavior (I feel good because of the outcome I got and therefore will do again what produced the pleasure) or is simply an epiphenomenon (my behavior gets reinforced and, in addition, I feel good because of the outcome). Although recent theories propose a distinction between the (unconscious, unpleasurable) wanting and the (conscious, pleasurable) liking of rewards, animal experiments investigating the issues of subjective feelings of pleasure run into obvious problems because of the lack of common language. Other than for specific investigations, the issue may be left aside when studying the neural mechanisms of reward in controlled behavioral neurophysiological experiments on animals.

Motivational Valence

Punishers have valence opposite that of rewards, induce withdrawal behavior, and act as negative reinforcers by increasing the behavior that results in decreasing the aversive outcome. Avoidance can be passive when subjects increasingly refrain from doing something that is associated with a punisher, or it can be active by increasing an instrumental response that is likely to reduce the impact of a punisher. Punishers induce negative emotional states of anger, fear, and panic.

Reward Signals in Dopamine Neurons

A prime goal in the investigation of neural processes of reward is to identify an explicit neuronal reward signal, just as retinal responses to visual stimuli constitute starting points for investigating the neuronal processes underlying visual perception. The search for a 'retina of the reward system' has located brain signals related purely to reward value irrespective of sensory and motor attributes in midbrain dopamine neurons and in select neurons of orbitofrontal cortex, dorsal and ventral striatum, and possibly amygdala. Reward signals influence neural decision processes in cortical and subcortical structures underlying behavioral actions and thereby contribute to economic choices.

Most midbrain dopamine neurons show phasic activations following primary food and liquid rewards; visual, auditory, and somatosensory reward-predicting stimuli; and physically intense visual and auditory stimuli. They are briefly depressed in their activity by reward omission and by stimuli predicting the absence of reward. They respond very little to aversive stimuli and not at all to inedible objects and known neutral stimuli unless these stimuli are very intense or large. The subsecond dopamine reward response may be responsible for the reward-induced dopamine release seen with voltammetry but would not easily explain the 300–9000 times slower dopamine fluctuations with rewards and punishers seen in microdialysis.

Reward Prediction Error

The response to reward appears to code the discrepancy between the reward and its prediction ('prediction error') such that an unpredicted reward elicits an activation (positive prediction error), a fully predicted reward elicits no response, and the omission of a predicted reward induces a depression (negative error, Figure 1). The prediction error response is sensitive to both the occurrence and the time of the reward, as a delayed reward induces a depression at its original time and an activation at its new time.

The positive and negative reward prediction error responses are graded such that a partial prediction error induces a smaller error response. Prediction errors covary in a monotonic fashion with both reward magnitude and probability and thus reflect the expected value of the probability distribution of reward magnitudes relative to prediction.

The reward prediction error response appears to normalize to the predicted range or standard deviation of the prediction error. For example, when three visual stimuli predict different binary distributions of equiprobable reward magnitudes, the larger magnitude always elicits the same positive response, even with a tenfold difference in prediction error,

Figure 1 Reward prediction error response of a single dopamine neuron. CS, conditioned stimulus; R, reward. Reprinted from Schultz W, Dayan P, and Montague RR (1997) A neural substrate of prediction and reward. *Science* 275: 1593–1599, with permission from AAAS.

although the same neurons are sensitive to unpredicted magnitudes. As a result of this gain adaptation, the neural response discriminates between the two likely outcomes equally well, regardless of their absolute magnitude difference.

The hypothesis that dopamine neurons report reward prediction errors can be tested formally by paradigms developed by animal learning theory, using the Rescorla–Wagner learning rule. In the blocking test, a stimulus is not learned when it is paired with an already fully predicted reward, indicating the importance of prediction errors for learning. After pairing with a fully predicted reward, the blocked stimulus does not come to predict a reward. Accordingly, the absence of a reward following the blocked stimulus does not produce a response in dopamine neurons as no prediction error is elicited, and the delivery of a

reward does produce a positive prediction error response. By contrast, after a well-trained reward-predicting stimulus, reward omission produces a depressant neural response, and reward delivery does not lead to a dopamine response.

In the conditioned-inhibition paradigm, a test stimulus is presented simultaneously with an established reward-predicting stimulus, but no reward is given after the compound, making the test stimulus a conditioned inhibitor which predicts the absence of reward. Reward omission after a well-learned conditioned inhibitor does not produce a prediction error response in dopamine neurons, even when a well-learned reward-predicting stimulus is added. By contrast, the occurrence of reward after the inhibitor produces an enhanced dopamine response, as the prediction error represents the difference between the actual reward and the negative prediction from the inhibitor.

Taken together, the data from these formal tests suggest that dopamine neurons show bidirectional coding of reward prediction errors, described by the following equation:

$$\text{Dopamine response} = \text{reward occurred} - \text{reward predicted}$$

Thus the dopamine response seems to convey the crucial learning term (λ-V) of the Rescorla-Wagner learning rule and complies with the principal characteristics of teaching signals of efficient reinforcement models.

Neuronal computations using prediction errors may contribute to the self-organization of behavior (Figure 2). Brain mechanisms establish predictions, compare current inputs with predictions from previous experience, and emit a prediction error signal once a mismatch is detected. The error signal may act as an impulse for synaptic modifications that lead to subsequent changes in predictions and behavioral reactions. The process is reiterated until behavioral outcomes match the predictions and the prediction error becomes nil. In the absence of a prediction error, there would be no signal for modifying synapses, and synaptic transmission remains unchanged and stable.

Reward-Predicting Stimuli

Dopamine neurons acquire responses to reward-predicting visual and auditory stimuli that covary with the expected value of reward but occur irrespective of spatial position; sensory stimulus attributes; and arm, mouth, and eye movements. The responses are modulated by the motivation of the animal, the time course of predictions, and the animal's choice among rewards. Activations do not occur when the conditioned stimulus (CS) is predicted by another stimulus in time ranges of seconds. These responses conform to temporal difference learning models that conceptualize prediction errors irrespective of primary or conditioned reinforcers and view a CS response as reflecting an error in the prediction of the CS. Although discriminating between reward-predicting CSs and neutral stimuli, dopamine activations have a non-negligible propensity for generalization.

Physically intense stimuli induce activations in dopamine neurons which are enhanced by stimulus novelty, although smaller visual stimuli that become effective for driving dopamine neurons after pairing with reward do not induce saliency or novelty responses before conditioning, suggesting that novelty *per se* is not sufficient to activate dopamine neurons. As intense stimuli have attention-inducing and reinforcing functions, the dopamine responses to rewards themselves might be due to the attention-inducing rather than the reinforcing functions of the rewards. However, other strongly attention-inducing stimuli, including primary and conditioned aversive events, reward omission, and conditioned inhibitors, are rather ineffective in producing the characteristic, short-latency activation of dopamine neurons. Thus, the dopamine responses to rewards and intense novel stimuli do not appear to be due to a general

Figure 2 Learning viewed as change of action following change of prediction. The error signal would be transmitted by dopamine neurons and would influence synaptic processes in dopamine target structures such as striatum and orbitofrontal cortex.

alerting or attention-generating function of these stimuli. The occurrence of intensity responses may be due to a combined sensitivity of dopamine neurons to both rewarding and intense events, may reflect the known rewarding and approach-generating functions of intense stimuli, or may be related to less-well-known forms of attention attached to rewards and intense novel stimuli but not to punishers.

Uncertainty Signal in Dopamine Neurons

Rewards occur in most natural situations with some degree of uncertainty. The uncertainty of reward can be tested by delivering rewards with different probabilities and separating expected value (linearly increasing from $p = 0$ toward $p = 1$) from uncertainty expressed as the variance of the probability distribution of magnitudes (inverted U function with peak at $p = 0.5$). More than one-third of dopamine neurons show a relatively slow, sustained, and moderate activation between the reward-predicting stimulus and the reward which covaries with variance. This activation occurs in single trials in single neurons and does not propagate during learning from reward back to the conditioned stimulus, as assumed by some implementations of temporal difference reinforcement models. The uncertainty-related activation contrasts with the responses to reward-predicting stimuli and reward prediction errors that covary with expected value and occur with different time courses (Figure 3). The two responses are uncorrelated in strength across individual neurons. In a separate experiment, the delivery of two equiprobable rewards with different magnitudes influences the variance while keeping the entropy constant at 1 bit. Increasing variance in this procedure leads to an increased uncertainty response, suggesting that variance is an effective measure of uncertainty for dopamine neurons.

Figure 3 Separate uncertainty and reward signals in dopamine neurons. Data show averages responses from a population of dopamine neurons. CS, conditioned stimulus; US, unconditioned stimulus.

The distinct neural coding of reward value and uncertainty is consistent with the separation of expected utility into these two components suggested by financial decision theory and found in human brain imaging. However, the separation contrasts with the combined coding as scalar variable generally assumed by classic microeconomic expected utility theory.

Comparisons with Other Reward Centers

Information about rewards is processed also in a number of other brain structures and in different ways. Such reward signals are found in brain structures to which the axons of dopamine neurons project, including the orbitofrontal cortex, striatum, and amygdala. Rewards influence the action-related activity of neurons in additional structures, including the prefrontal and parietal cortex. Additional brain structures influenced by reward include the supplementary motor area in the frontal lobe, the rhinal cortex in the temporal lobe, the pallidum and subthalamic nucleus in the basal ganglia, and a few others. These activations are seen in neuronal recordings not only from behaving animals, mostly monkeys, but also in human brains, via functional magnetic resonance imaging.

Orbitofrontal Cortex

Orbitofrontal neurons show activations following reward-predicting stimuli, during the expectation of reward, and after reward reception. Orbitofrontal responses to rewards and reward-predicting stimuli are related to the motivational value rather than the more sensory properties of reward objects, as satiation with specific rewards reduces the neuronal responses. They constitute pure reward signals by reflecting only reward and not spatial or visual object features. Orbitofrontal reward signals distinguish between reward and punishment, change with reversal of stimulus–reward associations, discriminate between different volumes of liquid reward, and encode the economic value of rewards for decision making irrespective of the actual reward objects. Different neurons in this structure show more-sustained activations preceding the expected delivery of liquid or food reward. Besides these pure reward-related responses, a few other orbitofrontal neurons respond to visual or spatial object properties or are activated in relation to movements.

Orbitofrontal neurons do not appear to be specialized for particular reward objects but seem to discriminate between different rewards depending on their current availability. A reward that is effective for activating an orbitofrontal neuron may lose its

efficacy when the distribution of available rewards changes and the initially effective reward changes its level of preference. By encoding economic value rather than specific reward objects, these responses appear to adapt to the current probability distribution of reward values. A change in this distribution changes the neuronal responses. The apparent dependence of responsiveness on a set point corresponds to a basic tenet of prospect theory indicating that outcomes are valued relative to movable references rather than absolute physical characteristics.

Pure Reward Signals in Striatum and Nucleus Accumbens

The slowly firing medium spiny neurons in striatum and nucleus accumbens and the tonically active striatal neurons (TANs) respond to the reception of food and liquid rewards. Other striatal and accumbal neurons show phasic activations following visual reward-predicting stimuli and more-sustained activations during the expectation of rewards. Changes of existing reward expectation during learning lead to adaptations of reward expectation-related activity to the currently valid expectation in parallel with the animal's behavioral differentiation. The TANs discriminate between rewards and air puff punishers, and many slowly firing striatal neurons distinguish reward from no reward and discriminate between different rewards and reward magnitudes irrespective of visual object properties, spatial information, and movements. Neurons in the ventral striatum show a higher incidence of reward responses and reward expectation activities compared with caudate and putamen neurons and, their larger spectrum of task-related activity. Thus, subpopulations of striatal neurons appear to process pure reward signals.

Reward Influences on Action-Related Activity in Striatum

Similar to prefrontal neurons, the action-related activity of a population of neurons in the striatum (caudate and putamen) is influenced by predicted rewards. These neurons are activated during the preparation and execution of specific arm and eye movements toward different spatial targets and discriminate between movement and nonmovement reactions. At the same time, these action-related activities are differentially influenced by the predicted presence versus absence of reward and by different predicted types, magnitudes, and probabilities of reward. This activity can predict the animal's choice toward a rewarding outcome. The reward-differentiating nature of the activations develops and adapts during learning while differential reward expectations are being acquired. Similar specific action–reward activities exist also in another basal ganglia structure, the subthalamic nucleus.

The activations in the striatum and cortex mentioned above do not simply represent outcome expectations; they differentiate in addition between different behavioral reactions for the same outcome (e.g., movement vs. nonmovement, different spatial targets), and they not only reflect different behavioral reactions but differentiate also between the expected outcomes. The combined action and reward coding by striatal neurons complies with theoretical notions of action values by which specific behavioral actions become associated with a rewarding outcome through operant learning. These activities may constitute neuronal correlates of goal-directed behavior as they appear to reflect neuronal representations of the reward for the specific action while this action is being prepared and executed.

The combined coding of action and reward contrasts with the earlier described pure reward signals in dopamine neurons and in some neurons of orbitofrontal cortex and striatum, which reflect the predicted or received reward irrespective of other stimulus or behavioral components. In demonstrating the influence of predicted reward on action-related activity, action–outcome coding may represent the next processing stage downstream from pure reward signals toward overt choices. Action–outcome coding may be a component of mechanisms by which reward signals are translated into behavioral choices for obtaining reward through action. Information about the value of each possible action in choice situations would constitute important inputs for decision-making mechanisms.

Prefrontal Cortex

In addition to generating specific signals, rewards also influence ongoing action-related activity. The prediction of different food or liquid rewards modifies the typical, spatially discriminating delay activity of neurons in dorsolateral prefrontal cortex and influences movement-specific cue responses in medial prefrontal cortex. These prefrontal neurons carry signals related to the memory of movement cues and the preparation of movement and at the same time encode the expected reward. Only a small population of prefrontal neurons is preferentially activated by aversive stimuli.

Other Cortical Areas

Predicted rewards also influence activity related to arm and eye movement in other cortical areas, including parietal cortex and anterior and posterior

cingulate. Similar reward effects in premotor and supplementary motor cortex may reflect the motivating functions of rewards on movements coded in this part of the motor system.

Amygdala

In rats, reward-predicting stimuli and unpredicted liquid, food, cocaine, and intracranial electrical stimulation elicit responses in central and basolateral amygdala, the responses being differentiated against aversive and neutral outcomes. Responses discriminate between reward magnitudes and change with outcome reversal. Responses correlate with orbitofrontal responses during early discrimination learning and decrease after orbitofrontal lesions. Reward studies on monkeys demonstrate satiety-sensitive gustatory responses and responses to liquid or food-predicting visual stimuli which decrease with increasing behavioral requirements.

Dopamine Receptors and Antipsychotic Drugs in Health and Disease

P Seeman, University of Toronto,Toronto, ON, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The discovery of dopamine receptors is intertwined with the discovery and development of antipsychotic drugs. The research in this area started with the development of antihistamines after World War II, particularly with H Laborit using such compounds to enhance surgical analgesia. In patients receiving these medications, Laborit noticed a 'euphoric quietude,' and that the patients were "calm and somnolent, with a relaxed and detached expression." Of this series of Rhône-Poulenc compounds, RP4560, now known as chlorpromazine, was the most potent.

Chlorpromazine was tested by many French physicians for use in various medical illnesses. Although Sigwald and Bouttier were the first to use it as the sole medication for a psychotic patient, their work was not reported until 1953, after a 1952 report by Delay and colleagues that chlorpromazine alleviated hallucinations and stopped internal 'voices' in eight patients. A significant aspect of the action of chlorpromazine was that it was effective within 3 days. This rapid improvement, especially during the first week of antipsychotic treatment, has been observed in many studies and summarized in reviews by S Kapur and O Agid.

The clinically successful action of chlorpromazine stimulated the search to identify chlorpromazine's mode of action. The assumption then, as now, was that the discovery of such a mode of action would open the avenue to uncovering the biochemical cause of psychosis and possibly of schizophrenia.

Early Days: Before Discovery of Dopamine Receptors

In searching for the mechanism of chlorpromazine action in the 1960s and 1970s, many types of electrophysiological and biochemical experiments were done. Because high doses of chlorpromazine and other antipsychotics (or 'neuroleptics,' as they were then called) also elicited parkinsonism as a side effect, the basic science quickly focused on the action of antipsychotics on dopamine pathways in the brain. The rationale for examining brain dopamine regions was based on the finding by H Ehringer and O Horniekiewicz that the parkinsonism of Parkinson's disease was associated with a massive loss of brain dopamine. It was felt, therefore, that the unwanted side effect of chlorpromazine-induced parkinsonism, as well as the antipsychotic action itself, might arise by antipsychotics interfering with dopamine neurotransmission. The working assumption was that if the brain targets for antipsychotics could be found, then perhaps it could be determined whether these sites were overactive or underactive in psychosis or schizophrenia.

A variety of mechanisms were explored for the mode of action of chlorpromazine, including its action on mitochondrial enzymes, sodium–potassium-ATPase, and related enzymes, and its membrane-stabilizing action, such as its strong potency to inhibit membrane action potentials and to stabilize cellular and subcellular membranes from releasing their contents. It also became clear in 1963 that all antipsychotics were surface active, readily explaining their hydrophobic affinity for membranes. Some of these nonreceptor-related findings, such as the surface activities of the antipsychotics, showed an astonishingly excellent correlation with clinical antipsychotic potencies.

Therapeutic Concentrations of Antipsychotics

All of the early experiments in the 1960s revealed that the *in vitro* active concentrations of the antipsychotics were generally between 20 and 1000 nM. These concentrations, however, were found in 1971 to be far in excess of the nanomolar concentrations (e.g., 1–2 nM for haloperidol) that exist in the spinal fluid in patients being successfully treated with these medications.

In Vivo Experiments

In parallel with the *in vitro* experiments, there were many *in vivo* experiments by F Bloom, by G Aghajanian, and by B Bunney, showing that dopamine agonists can excite or inhibit neurons in the nigrostriatal dopamine pathway. Moreover, other workers (WD Heiss, J Hoyer) showed that direct application of dopamine on neurons also stimulated or inhibited snail neurons, and that haloperidol or fluphenazine could block these actions (H Struyker Boudier). These studies provided evidence for the existence of distinct dopamine receptors on neurons.

Additional work *in vivo* showed that chlorpromazine and haloperidol increased the production of normetanephrine and methoxytyramine, metabolites of epinephrine and dopamine, respectively. To explain the increased production of these metabolites,

Carlsson and Lindqvist suggested that "the most likely [mechanism] appears to be that chlorpromazine and haloperidol block monoaminergic receptors in brain; as is well known, they block the effects of accumulated 5-hydroxytryptamine.…" In other words, they proposed that antipsychotics might block all three types of receptors for noradrenaline, dopamine, and serotonin, but they did not identify which receptor was selectively blocked or how to identify or test any of these receptors directly *in vitro*. This study in 1963 by Carlsson and Lindqvist is often mistakenly cited as discovering 'the dopamine receptor' and that antipsychotics are selectively acting on this receptor. However, N-E Andén, a student of A Carlsson, had a different view, and proposed that "chlorpromazine and haloperidol delay the elimination of the (metabolites).…" Moreover, 7 years later Andén reported that antipsychotics increased the turnover of both dopamine and noradrenaline, but he could not show that the antipsychotics were selective in blocking dopamine; for example, chlorpromazine enhanced the turnover of noradrenaline and dopamine equally. Therefore, it remained for *in vitro* radio-receptor assays to detect the dopamine receptor directly and to demonstrate antipsychotic selectivity for the dopamine receptor.

The Dopamine D1 Receptor

With the advent of assays for adenylate cyclase in the 1960s, J Kebabian found that dopamine stimulated adenylate cyclase in the superior cervical ganglion. This receptor was later named the dopamine D1 receptor, selectively labeled by [^{3}H]SCH23390, and subsequently cloned by three research groups in 1990.

The dissociation constants at D1 for dopamine agonists and antagonists of medical therapeutic interest are given in Tables 1 and 2. There is no correlation between the antipsychotic clinical doses and the dissociation constants of the antipsychotic antagonists at D1, as illustrated in Figure 1. These data suggested that D1 was not the major or common target for antipsychotics, in addition to the fact that the antipsychotic molarities at D1 are between 10 and 10 000 nM, far in excess of the therapeutic concentrations in the spinal fluid of treated patients.

In addition to the lack of targeting D1 receptors by clinical doses of the common antipsychotics, D1-selective compounds have not been found to be effective as antipsychotics (Figure 2).

Discovery of the Antipsychotic Dopamine Receptor, or the Dopamine D2 Receptor

In 1974 and 1975, in order to detect and discover the dopamine receptors on which the antipsychotics presumably acted, it was essential to label a receptor with a ligand, such as radioactive haloperidol, having an affinity (or dissociation constant) of ~1 nM, because this was the haloperidol therapeutic concentration found in the spinal fluid or plasma water of treated patients. For this to occur, the specific activity of [^{3}H]haloperidol would have to be at least 10 Ci mmol^{-1}. Although the [^{3}H]haloperidol donated in 1971 by Janssen Pharmaceutica (J Heykants, J Brugmans) had a low specific activity of 32–71 mCi mmol^{-1}, I R E Belgique (M Winand) custom synthesized [^{3}H]haloperidol at even lower specific activity (10.5 Ci mmol^{-1}) for Seeman's laboratory by June 1974. Specific binding of this new [^{3}H]haloperidol to brain striatal tissue was readily detected in 1975, and the following concentrations of compounds were found to inhibit the binding of [^{3}H]haloperidol by 50%: 2 nM for haloperidol, 20 nM for chlorpromazine, 3 nM for (+)butaclamol, and 10 000 nM for (–) butaclamol.

The stereoselective action of butaclamol and the good correlation between the $IC_{50\%}$ values and the clinical doses, as shown in Figure 3, indicated that the 'antipsychotic receptor' had finally been discovered. Equally important, of the endogenous compounds tested, dopamine was the most potent in inhibiting the binding of [^{3}H]haloperidol, indicating that the antipsychotic receptor was actually a dopamine receptor (see Table 1). Using sequences related to the β-adrenoceptor, the antipsychotic/dopamine receptor, now named the dopamine D2 receptor, was finally cloned in 1988; its amino acid sequence is shown in Figure 4. Using the cloned D2 receptor, values for the dissociation constants for agonists and antagonists can be determined (Table 1).

It is now known that therapeutic levels of antipsychotic drugs occupy 60–80% of brain D2 receptors, as shown by L Farde and colleagues. In fact, using the antagonist dissociation constants in Table 1, the concentrations necessary to occupy 75% of D2 receptors can be calculated and are essentially identical to the free molarities of the antipsychotics found in either the plasma water or the spinal fluid of treated patients, as shown in Figure 5.

Because radiolabeled raclopride is less tightly bound to D2 receptors than radiolabeled spiperone, which in turn is less tightly bound to D2 receptors than radiolabeled nemonapride, the dissociation constant for any antagonist at D2 receptors is lowest when using radiolabeled raclopride, but rises when using radiolabeled spiperone, or rises higher still when using radiolabeled nemonapride (see Table 1). This dependence of the dissociation constant on the ligand is also seen in positron emission tomography studies, where it has been found, for example,

when monitoring patients with [^{11}C]raclopride, that therapeutic doses of clozapine occupy ~50% of D2 receptors but that there is much less occupancy of D2 receptors when using [^{11}C]methylspiperone or [^{18}F]fluorethylspiperone, both of which bind more tightly to D2 receptors than raclopride (see Table 2).

The correlations in Figures 3 and 5 remain a cornerstone of the dopamine hypothesis of psychosis or schizophrenia, and the dopamine hypothesis is still the major contender for an explanatory theory of schizophrenia etiology.

Two Classes of Dopamine Receptors

The D1 site and the [^{3}H]haloperidol/dopamine receptor binding site were soon considered as distinct, because B Roufogalis found that the sulpiride antipsychotic did not block dopamine-stimulated adenylate cyclase. Two general classes of dopamine receptors were recognized,

Figure 1 There is no correlation between the clinical antipsychotic doses and the antipsychotic dissociation constants (or concentrations) that inhibit the binding of a D1 ligand ([^{3}H]SCH23390) at dopamine D1 receptors in homogenized striatal tissue. The high concentrations inhibiting the D1 receptor are far higher than those found clinically in the plasma water or spinal fluid. Adapted from Seeman P (1987) Dopamine receptors and the dopamine hypothesis of schizophrenia. *Synapse* 1: 133–152, with permission from John Wiley & Sons Inc.

Figure 2 Amino acid sequence of the dopamine D1 receptor. The two hydroxyls of dopamine are presumed to be associated with the two serine residues, while the tertiary nitrogen atom is presumed to be associated with the aspartic acid residue (D in transmembrane 3).

Figure 3 The clinical antipsychotic doses correlate with the concentrations that inhibit by 50% the specific binding of [^{3}H]haloperidol in homogenized caudate nucleus tissue (calf). These concentrations are similar to those found in the plasma water or spinal fluid in patients treated with antipsychotic drugs. Adapted from Seeman P, Lee T, Chau-Wong M, et al. (1976) Antipsychotic drug doses and neuroleptic/dopamine receptors. *Nature (London)* 261: 717–719, with permission from Nature.

Figure 4 Amino acid sequence of the dopamine D2 receptor. The variants or polymorphisms of D2 include an alanine instead of a valine at position 96 (~1% of population), an insertion of a 29-amino-acid polypeptide (D2Long) at the position shown by the lower left arrow, a serine instead of a proline at position 310, and a cysteine instead of a serine at position 311. Dopamine is presumed to be associated with the two serines (S) in transmembrane 5 and the aspartic acid (D) in transmembrane 3 (see **Figure 2**).

Figure 5 The therapeutic antipsychotic concentrations in the spinal fluid or in the plasma water in treated patients are essentially identical to the antipsychotic concentrations that occupy approximately 75% of the D2 receptors *in vitro*. The concentrations in the plasma water were obtained by correcting for the amount bound to the plasma proteins. The concentrations to occupy 75% of D2 were calculated as being three times higher than the dissociation constant at D2. Adapted from Seeman P (2002) Atypical antipsychotics: Mechanism of action. *Canadian Journal of Psychiatry* 47: 27–38.

Figure 6 Early version of dopamine receptors before clones of receptors became available. The D1 receptor (dopamine-stimulated adenylate cyclase) was stimulated by ~3000 nM dopamine and inhibited by high concentrations of butyrophenones such as 2000 nM spiperone. The D2 receptor, or the [^{3}H]haloperidol binding site, was highly sensitive to spiperone, but required ~5000 nM dopamine to inhibit adenylate cyclase. The D3 site was a site labeled by [^{3}H]dopamine and, therefore, very sensitive to dopamine at 3 nM, but required very high concentrations of antipsychotics to be inhibited. The D4 site was defined as being sensitive to both the agonists and the antipsychotic antagonists. While these definitions for the D3 and D4 sites are no longer used, the D1 and D2 properties are still valid for the cloned D1 and D2 receptors, with the additional point being that both D1 and D2 have high- and low-affinity states.

therefore, coupled or uncoupled to adenylate cyclase. These two classes were named D1 and D2 by J Kebabian and D Calne.

Nomenclature of Dopamine Receptors

The data for the pattern of binding of [^{3}H]haloperidol identifying the antipsychotic/dopamine D2 receptor were very different from those for the pattern of [^{3}H] dopamine binding described by studies in the mid-1970s. For example, the binding of [^{3}H]haloperidol was inhibited by ~5000 nM dopamine, while that of [^{3}H]dopamine was inhibited by ~3 nM dopamine, as summarized in Figure 6. For several years, this latter [^{3}H]dopamine binding site was termed the 'D3 site,' a

term which is not to be confused with the later discovery of the dopamine D3 receptor.

Dopamine D2 Receptor Variants

As noted in Figure 4, there are several variants of D2, the most important of which are the short form and the long form of D2, the latter having an additional 29 amino acids. There is also a D2Longer form where a dipeptide, valine–glutamine, is inserted into the intracellular loop, as shown in Figure 7.

There are at least three polymorphisms in D2 (Figure 4): alanine replaces valine at position 96 in about 0.8–1% of some populations, serine replaces proline at position 310 in ~0.4% of people, and cysteine replaces serine at position 311 in approximately 3–4% of the population. The variants at 310 and 311 are markedly less effective in inhibiting the synthesis of cyclic AMP than is the more common form of D2. Silent polymorphisms have also been found in the DNA code for D2, but there is no change in the amino acid (leucine at 141, histidine at 313, and proline at 319).

There are also polymorphisms in the noncoding regions of D2, including an A-to-G at position –241, a C insert at position –141, an A-to-G before transmembrane 1 (*Taq*1B polymorphism), an A-to-G in the intron within transmembrane 2 (*Taq*1D polymorphism), an A-to-C in the intron before transmembrane 4, a G-to-A in the intron before transmembrane 6, and an A-to-G situated ~10 kb beyond transmembrane 7 (*Taq*1A polymorphism). A further mutation in D2 occurs in individuals with hereditary autosomal dominant myoclonus dystonia, with valine replaced by isoleucine at position 154 at the beginning of the fourth transmembrane segment of D2 (see Figures 4 and 7).

D2 Function and Distribution

A wide variety of psychomotor functions, including biochemical, physiological, and pathological, have been attributed to D2. Specifically, D2 inhibits action potentials by eliciting a prolonged 'inhibitory postsynaptic potential' (IPSP), inhibits adenylate cyclase, and inhibits the entry of calcium ions into cells, thereby inhibiting many aspects of stimulus–response coupling in a variety of neurons and cells. D2 receptors are located on presynaptic terminals and, therefore, can readily inhibit the release of dopamine. These presynaptic receptors appear to be predominantly D2Short, while D2Long receptors are mostly postsynaptically located on dendritic spines. The genetic absence of D2 receptors leads to animals that are akinetic and Parkinson-like.

Figure 7 Amino acid sequence of D2Longer. Compared to D2Short and D2Long (Figure 4), D2Longer has an extra valine–glutamine dipeptide (as indicated by the arrow) that is usually spliced out in D2Short and D2Long.

In alcoholics, it has been reported that the prevalence of the *Taq*1A polymorphism is about twofold higher than in control subjects. In schizophrenia, it has been found in 27 studies, comprising 3707 patients and 5363 controls, that the serine311cysteine polymorphism was significantly associated with schizophrenia. Furthermore, the number of D2 receptors in the caudate-putamen is elevated in schizophrenia, as measured *in vivo* (Corripio) or in postmortem samples *in vitro* (Figure 8). Although Figure 8 shows that the density of D2 receptors in postmortem human schizophrenia tissues is elevated, some of this elevation may have resulted from the antipsychotic administered during the lifetime of the patient. The postmortem tissues from half of the patients with schizophrenia revealed elevated densities of [^{3}H]spiperone-labeled D2 receptors in the caudate-putamen tissue. The other half of the postmortem schizophrenia tissues were normal in D2 density, even though most of the patients were known to have been treated with antipsychotics during their lifetime.

Such findings have long been controversial, because the D2 density is not elevated in schizophrenia when using [^{11}C]raclopride. It should be noted, however, that the number of D2 receptors is significantly elevated in healthy identical co-twins of individuals with schizophrenia, suggesting that an elevation of D2 may be a necessary but not sufficient requirement for schizophrenia.

Figure 8 Bimodal pattern of D2 receptors in postmortem striata from individuals who had schizophrenia during life. The control individuals had died of nonneurological disorders. The bimodal pattern was found in the schizophrenia tissues, regardless of whether the individuals had received antipsychotics or not. Each square indicates a different postmortem human brain (caudate nucleus or putamen regions). Adapted from Seeman P and Niznik HB (1990) Dopamine receptors and transporters in Parkinson's disease and schizophrenia. *FASEB Journal* 4: 2737–2744, with permission from Federation of American Societies for Experimental Biology.

The distribution of D2 receptors within the various brain regions is reflected in the gene expression pattern of D2, as shown in Figure 9. An additional unique feature is that D2 receptors are organized in bands in the normal human temporal cortex, but these bands are not found in brains of patients with Alzheimer's disease. Finally, the density of D2 is not constant over one's lifetime, but slowly falls by about 2% per decade, as shown in the postmortem human tissues in Figure 10. There is a sharp transient rise during ages 1–3, but this is followed by a gradual pruning of neurons with D2 receptors.

The Dopamine D3 Receptor

Using methods similar to those used for cloning the D2 receptor, the D3 receptor was cloned in 1990; its sequence is shown in Figure 11. D3 has several polymorphisms, including a serine replacing glycine at position 9 in ~28% of the population (see Figure 11). In addition, there are nonfunctional forms of D3, where the amino acid chain stops after transmembrane 2, after transmembrane 3, or before transmembrane 6, the latter being found in, but not diagnostic for, Alzheimer's disease and schizophrenia.

Although BP897 is a partial agonist at D3, with a selectivity for D3 of about 100-fold higher than that for D2, this drug (at 10 mg day^{-1}) did not appear effective against schizophrenia symptoms. Other drugs moderately selective for D3, such as S33138 and A437,203, are currently being tested in schizophrenia patients. The highly D3-selective drug, FAUC 365, has not yet been tested in this disease. It is possible that the D3-selective compounds may be helpful in treating drug abuse.

The Dopamine D4 Receptor

The dopamine D4 receptor was cloned in 1999; its sequence is shown in Figure 12. The D4 receptor probably has more polymorphisms than any other protein in the body. For example, the intracellular loop contains repeat forms of a 16-amino acid polypeptide, the number of repeats varying from person to person. Most people have four such repeats, but up to ten repeats are known. Moreover, the precise sequence within each repeat usually varies from person to person, with at least 20 different types of repeat units known, thereby resulting in a massive number of polymorphisms in the human population.

An unusual polymorphism in D4 occurs at position 194, where glycine replaces valine in 13% of Africans

Figure 9 Anatomical location for gene expression of dopamine receptor genes in human brain. abbreviations: CX, cerebral cortex; L, lateral ventricles; C, caudate nucleus; P, putamen; G, globus pallidus; AC, nucleus accumbens; O, olfactory tubercle; H, hypothalamus; AM, amygdala; Hipp, hippocampus; VTA, ventral tegmental area; SN, substantia nigra; ICG, Islands of Calleja.

and Caribbeans (Figure 13), but not in Caucasians. This mutant form of D4 markedly reduces its sensitivity to dopamine. One young man in the Caribbean was found to be homozygous for this V194G polymorphism, but no medical abnormalities were found. Another D4 polymorphism occurs when the GASA sequence is missing at position 21.

Interestingly, clozapine has a higher affinity at D4 than at D2, as shown in Table 2. Nevertheless, despite clozapine's selectivity for D4, clozapine occupies the necessary 60–70% of brain D2 receptors at clinical doses (~400 mg day^{-1}), compatible with the idea that D2 is the therapeutic target for clozapine, as with all the other antipsychotics. It may be noted that isoclozapine causes catalepsy, in contrast to clozapine, which does not elicit catalepsy. Both drugs have dentical affinity for D4, but isoclozapine has higher affinity for D2 (see Table 2), and, therefore, causes catalepsy.

Although the gene expression of D4 was found to be elevated in the frontal cortex of schizophrenia tissues, selective D4 antagonists, such as sonepiprazole and L-745,870, did not have any antipsychotic action. Some evidence suggests that the longer forms of D4, such as D4.7, with seven repeats, or D4.9, are found in hyperactive individuals or in those persons who take unusual risks, but this is controversial.

Figure 10 Postmortem human D2 densities in the striatum. After an initial rapid growth period in the first 3 years of life, the D2 receptor density is rapidly pruned before age 10, and thereafter decays by 2.2% every 10 years. Adapted from Seeman P, Bzowei NH, Guan H-C et al. (1987) Human brain dopamine receptors in children and aging adults. *Synapse* 1: 399–404, with permission from John Wiliy & Sons Inc.

Figure 11 Amino acid sequence of the human cloned dopamine D3 receptor. A polymorphism occurs at position 9, where glycine replaces serine. When a frame shift occurs in the cytoplasmic loop, as shown, the receptor is nonfunctional.

The Dopamine D5 Receptor

The dopamine D5 receptor was cloned in 1991 (Sunahara), and its sequence is shown in Figure 14. There are two pseudogenes of D5, where the amino acid sequence stops at position 154. Although D5 is essentially D1-like in sequence and function, the characteristic feature of D5 is that it is more sensitive to dopamine than D1 is, as indicated in Table 1 for the K50 values.

Regulation of Dopamine Receptors

Each of the five dopamine receptors has a state of high affinity and a state of low affinity for dopamine, an example of which is shown in Figure 15 for the D2 receptor in anterior pituitary tissue. Dopamine receptors belong to a group of more than 1000 receptors known to be associated with G-proteins. The binding of an agonist to such a G-linked receptor occurs in two concentration ranges. Low nanomolar

Figure 12 Amino acid sequence of the human dopamine D4 receptor and its polymorphisms. The cytoplasmic loop has repeat units of 16 amino acid polypeptides. Different humans have different numbers of repeats. Shown are four repeats (D4.4), the most common, and seven repeats (D4.7).

concentrations of the agonist binds to the high-affinity state of the receptor, while high micromolar concentrations bind to the low-affinity state of the receptor. Generally, it is the high-affinity state of the receptor that is the functionally active state of the receptor, because the agonist affinities for the high-affinity state are usually identical to the concentrations that elicit the physiological action of the agonists. This holds for many neurotransmitter receptors, including dopamine D2 receptors, cholinergic muscarinic receptors, α_2-adrenoceptors, and β_2-adrenoceptors.

$D2^{High}$ is the functional state in the anterior pituitary, upon which dopamine and other dopamine-like drugs (bromocriptine) act to inhibit the release of prolactin. $D2^{High}$ is presumably also functional on the terminals of the dopamine-containing terminals, and these receptors are usually referred to as presynaptic receptors. Although it has been reported that 90% of the D2 receptors in brain slices are in the $D2^{High}$ state, the proportion of D2 receptors in the high-affinity state in homogenized striatum *in vitro* is generally between 15% and 20%. The $D2^{High}$ state can be quickly converted into the $D2_{Low}$ state by guanine nucleotide, as illustrated in Figure 15 for anterior pituitary tissue and in Figure 16 for the striatum. Furthermore, as shown in Figure 16, the high-affinity state of D2 is most readily detected by dopamine competing with [^{3}H]domperidone, but not [^{3}H]raclopride or [^{3}H]spiperone, which are less sensitive to the competitive action of dopamine. In fact, it is known that the physiological concentration of dopamine in the synaptic space (between neurons) is 2–4 nM, matching the known dissociation constant of 2 nM for dopamine at the $D2^{High}$ receptor. This latter value of 2 nM is obtained from the dopamine/[^{3}H]domperidone competition curve in Figure 16, using the standard Cheng–Prusoff equation to correct for the ligand concentration and the [^{3}H]domperidone K_d.

There are at least two views of the physical existence of the high-affinity state. The traditional view is that

Figure 13 Additional polymorphisms of the human dopamine D4 receptor. Approximately 13% of Africans and Caribbeans have a glycine replacing valine at position 194. Approximately 8% of Italians have an additional ASAG peptide inserted at the position shown.

Figure 14 Amino acid sequence of the human dopamine D5 receptor. Two polymorphisms of D5 exist where the sequence abruptly stops to create a sequence of 154 amino acids instead of the full-length sequence of 477 amino acids.

the high-affinity state of the receptor exists when the receptor, R, is associated with the G-protein, and the agonist, D, binds to this high-affinity state to form the 'ternary complex,' namely DRG. This view of the receptor proposes that the low-affinity state occurs when the G-protein is not associated with the receptor. However, there are many significant shortcomings with this view of the high-affinity state of the

Figure 15 The high-affinity state of the dopamine D2 receptor, or $D2^{High}$, occurs at low nanomolar concentrations of dopamine in inhibiting the binding of [^{3}H]spiperone to anterior pituitary tissue (Ant. Pit.; porcine). The low-affinity state of the D2 receptor, or $D2_{Low}$, occurs at high concentrations of dopamine, as shown. However, the presence of 200 μM guanilylimidodiphosphate converts all the $D2^{High}$ receptors into the $D2_{Low}$ form.

receptor in the ternary complex model. For example, the ternary complex suggests that RG should have a transient existence. This is not the case, however, because it has been found that the purified muscarinic RG is stable. Moreover, the purified muscarinic receptor, free of G and GDP, clearly shows high-affinity and low-affinity states.

An alternate view of the high-affinity state of the receptor is the 'cooperativity' model, as worked out by J Wells and colleagues. The cooperative model proposes that the receptor cooperates with other receptors to form either a dimer, a tetramer, or a larger oligomer. The receptor is in the high-affinity state when it is vacant and unoccupied by the agonist. However, when the agonist binds to the vacant receptor, the occupied receptor interacts or 'cooperates' with the other receptors (within the tetramer) such that the affinity of the other receptors for the agonist is markedly reduced. This reduced affinity for the agonist is a result of 'negative cooperativity' between the receptors, and corresponds to the low-affinity state of the receptor.

In other words, if there is very strong negative cooperativity, then the second, third, and fourth receptors (within the tetramer) would hardly bind the agonist, and only the high-affinity sites would be observed in the competition between, say, dopamine and [^{3}H]domperidone, all taking place at the first receptor. These events are depicted in a diagram in Figure 17.

D2 Interactions with Other Receptors

The D2 receptor is known to interact with the D1 receptor as well as with other receptors, such as the adenosine A2 receptor. Many D1/D2 interactions occur at all levels, including the molecular level, where D1 and D2 can form functional heterodimers with one another. Such interaction also occurs at the cellular level, where the block of D1 (by SCH23390) unmasks the high-affinity state of the D2 receptor, $D2^{High}$, as shown in Figure 18. This experiment shows that D1 normally inhibits or suppresses the high-affinity state of D2.

Psychosis and the $D2^{High}$ Basis of Dopamine Supersensitivity

The dopamine hypothesis of psychosis or schizophrenia was first outlined by J. Van Rossum in 1967:

> The hypothesis that neuroleptic drugs may act by blocking dopamine receptors in the brain has been substantiated by preliminary experiments with a few selective and potent neuroleptic drugs. There is an urgent need for a simple isolated tissue that selectively responds to dopamine so that less-specific neuroleptic drugs can also be studied and the hypothesis further tested. . . . When the hypothesis of dopamine blockade by neuroleptic agents can be further substantiated it may have fargoing consequences for the pathophysiology of schizophrenia. Overstimulation of dopamine receptors could then be part of the aetiology.

Figure 16 Low nanomolar concentrations of dopamine readily inhibit the binding of [^{3}H]domperidone at the high-affinity state of dopamine D2 receptors (between 1 and 100 nM), in contrast to [^{3}H]raclopride and [^{3}H]spiperone, which are less sensitive to competition by dopamine. The high-affinity state, $D2^{High}$, is converted to the low-affinity state, $D2_{Low}$, by guanine nucleotide. Adapted from Seeman P, Tallerico T, and Ko F (2003) Dopamine displaces [^{3}H]domperidone from high-affinity sites of the dopamine D2 receptor, but not [^{3}H] raclopride or [^{3}H]spiperone in isotonic medium: Implications for human positron emission tomography. *Synapse* 49: 209–215, with permission from John Wiley & Sons Inc.

As noted earlier, it has not been clearly established that D2 receptors are elevated in psychosis or schizophrenia, although studies using brain imaging of healthy co-twins of schizophrenia individuals, as well as single-photon brain imaging of nonmedicated psychotic patients in at least one study, have shown significant elevations of D2.

At present, the most promising direction in this field is to examine the molecular basis of dopamine supersensitivity, because up to 70% of patients are supersensitive to either methylphenidate or amphetamine at doses which do not affect controls. Moreover, a wide variety of brain alterations in animals (lesions, birth injury by C-section, amphetamine or phencyclidine treatment, knockouts of a variety of receptors) all lead to the final common finding of behavioral dopamine supersensitivity and elevated proportions of D2 receptors in the $D2^{High}$ state in the striatum. For example, repeated administration of amphetamine to animals or humans leads to behavioral dopamine supersensitivity. While the density of D2 receptors in the striatum does not change in such studies, it is remarkable that the density of $D2^{High}$ receptors increases dramatically by several fold, as shown in Figure 19.

A similar situation occurs in animals that receive hippocampal lesions neonatally. Such animals, as adults, reveal behavioral dopamine supersensitivity, and the striatum contains a marked increase in the proportion of D2 receptors in the high-affinity state, as shown in Figure 20. Therefore, the molecular control of the high-affinity state of D2 is emerging as a

Figure 17 (a) The cooperativity model for the dopamine D2 receptor, according to J Wells and colleagues. The receptor is proposed to exist as an oligomer of D2 receptors, such as a tetramer of D2. Each of the vacant receptors is in the high-affinity state, $D2^{High}$. When dopamine first attaches to one of the vacant D2 receptors in the tetramer, the occupied D2 then interacts with the other three receptors within the tetramer to reduce their affinity for dopamine (i.e., negative cooperativity). (b) One molecular explanation for dopamine supersensitivity is that an unknown factor may reduce the negative interaction between the D2 receptors, thereby allowing more dopamine to occupy more $D2^{High}$ receptors.

Figure 18 Regulation of $D2^{High}$ by the D1 receptor. (a) Dopamine inhibited the binding of [^{3}H]raclopride to D2 receptors at dopamine concentrations higher than 100 nM. However, in the presence of SCH23390 to block D1 receptors, the binding of [^{3}H]raclopride was readily inhibited by 1–100 nM, corresponding to the presence of $D2^{High}$. These data suggest that D1 actively suppresses the existence of the functional $D2^{High}$ state. (b) In comparison to 100 nM SCH23390 unmasking the $D2^{High}$ state (a), other drugs do not lead to such unmasking of $D2^{High}$. L745,870 is a dopamine D4 receptor antagonist. Adapted from Seeman P and Tallerico T (2003) Link between dopamine D1 and D2 receptors in rat and human striatal tissues. *Synapse* 47: 250–254, with permission from John Wiley & Sons Inc.

central problem in this field. At present, there is uncertainty as to whether this high-affinity state of D2 is controlled through G_o or one of the G_i proteins, because this varies from cell to cell.

Figure 19 Repeated administration of amphetamine to rats leads to behavioral dopamine supersensitivity. While the total density of D2 receptors was normal in the striata of such supersensitive rats (about 26 pmol g^{-1}), the density of $D2^{High}$ receptors was markedly elevated by 355%, from a control value of 2.9 pmol g^{-1} to the elevated level of 10.3 pmol g^{-1}. Nonspecific binding of [^{3}H]raclopride was done in the presence of 10 μM *S*-sulpiride. In the presence of 200 μM guanilylimidodiphosphate (G.N.), all the $D2^{High}$ receptors were converted to $D2_{Low}$. Adapted from Seeman P, Tallerico T, Ko F, et al. (2002) Amphetamine-sensitized animals show a marked increase in dopamine $D2^{High}$ receptors occupied by endogenous dopamine – Even in the absence of acute challenges. *Synapse* 46: 235–239, with permission from John Wiley & Sons Inc.

According to the negative cooperativity model (Figure 17), the increased number of D2 receptors in the high-affinity state, $D2^{High}$, found in the striata of supersensitive animals, may be attributed to a reduction in the overall negative cooperativity between the receptors, as illustrated in Figure 17. Thus, in order to determine the molecular mechanism of dopamine supersensitivity, it will be essential to determine the factors that reduce negative cooperativity among the D2 receptors or that alter the association of the receptor with its G-protein. The role of guanine nucleotides in regulating the overall sensitivity of the dopamine D2 receptors would be to alter the extent of the receptor–receptor negative cooperativity.

Current Clinical and Basic Research on Dopamine Receptors

Of the five dopamine receptors and their many variants, the D2 receptor and its properties continue to be most actively investigated, because D2 is the main clinical target of antipsychotics and of dopamine agonist treatment of Parkinson's disease. The D1 receptor, however, also has an important clinical role in treating Parkinson's disease because the stimulation of D1 synergizes with the stimulation of D2, possibly via D1/D2 heterodimers or cell–cell interactions. A current active area of clinical research on dopamine receptors is to measure the occupancy of D2 receptors both in the striatum and outside the striatum in individuals taking antipsychotic medications. Some researchers find that the same D2 occupancy occurs in both striatal and limbic regions, while others find a lower occupancy in the limbic regions.

Figure 20 Rats with lesions made neonatally reveal behavioral dopamine supersensitivity when they become adults. Such supersensitive animals reveal a marked increase of 3.7-fold in the proportion of D2 receptors in the high-affinity state, $D2^{High}$. Nonspecific binding of [^{3}H]domperidone was done in the presence of 10 μM *S*-sulpiride. Adapted from Seeman P, Weinshenker D, Quirion R, et al. (2005) Dopamine supersensitivity correlates with $D2^{High}$ states, implying many paths to psychosis. *Proceedings of the National Academy of Sciences of the United States of America* 102: 3513–3518.

As previously noted, therapeutic doses of antipsychotics occupy 60–80% of the D2 receptors in psychotic patients, while D2 occupancies higher than 80% are associated with elevated serum prolactin and parkinsonism. The new aripiprazole antipsychotic tends to occupy more than 80% of D2 but does not seem to cause parkinsonism at these higher levels. This may be a result of the fact that aripiprazole, like clozapine and quetiapine, quickly desorbs from the D2 receptor (in under 60 s *in vitro*), minimizing prolactin elevation and parkinsonism. Rapid desorption permits the dopamine neurotransmission to proceed more normally. However, if the antipsychotic drug dose or antipsychotic concentration in the plasma remains high, then the antipsychotic drug will readsorb. In effect, fat-soluble antipsychotics remain adsorbed to D2 in patients for 1 or 2 days or even more, while the plasma concentration falls. Less fat-soluble antipsychotics such as clozapine or quetiapine remain attached to D2 in patients for only 6–12 h, immediately falling in D2 occupancy as the plasma concentration falls.

Probably the most central question in determining the basis of psychosis or schizophrenia is to determine the molecular basis of dopamine supersensitivity and to determine which proteins or genes regulate the maintenance of D2 receptors in their high-affinity state.

Dopamine: Cellular Actions

G Bernardi and N B Mercuri, Università di Roma 'Tor Vergata', and IRCCS Fondazione Santa Lucia, Rome, Italy

© 2009 Elsevier Ltd. All rights reserved.

There is a plethora of experimental and clinical evidence indicating that dopamine (DA) is a key element in promoting and regulating the reward and motivation processes occurring in the brain. Therefore, the state of pleasure and well-being that one might derive from everyday activities such as playing, eating palatable food, drinking, listening to a melody, smelling a perfume, and having sex certainly rely on the correct operation of this catecholamine at the neuronal level. On the other hand, DA plays a significant role when an altered behavior is instituted. Hence, drug abuse and craving, compulsive acts, and affective problems could depend on maladaptive changes in DA neurotransmission. This catecholamine is synthesized by discrete groups of cells (mesencephalic, ipothalamic, and retinal). It is noteworthy that the main source of DA for the central nervous system arises from the population of neurons originating in the ventral mesencephalon (ventral tegmental area, substantia nigra pars compacta) and mainly terminating in the cerebral cortex, accumbens, and striatum.

The diffuse projections of the dopaminergic neurons suggest that DA is able to act in different brain areas to induce motivation and reward. Accordingly, behavioral, pharmacological, and clinical studies have demonstrated that the cerebral regions principally involved in incentive and behavioral activation are the prefrontal cortex, the ventral/dorsal striatum, and the ventral mesencephalon itself. Indeed, these regions are the richest in DA.

Therefore, in order to better understand the reward processes, it is of crucial importance to understand the functions of DA at the cellular and synaptic level within the different areas indicated previously. Another important aspect to be considered for the clarification of DA action is that the catecholamine stimulates subtypes of specific receptors that cause distinct effects on neurons. There are two families of G-protein-linked DAergic receptors, D1 and D2. While the D1 family (constituting the D1 and D5 receptors), linked to Gαs, stimulates adenylate cyclase, the D2 family (constituting the D2, D3, and D4 receptors), linked to Gα0/i, inhibits adenylate cyclase. Usually, the D1-mediated effects are cyclic adenosine monophosphate (cAMP)- and protein kinase A-dependent, while the D2-mediated effects depend on the inhibition of cAMP and protein kinase A (PKA), eventually the activation of phospholipase C-inositol triphosphate (IP3), and changes in intracellular Ca^{2+}. The dichotomy in the formation of cAMP results in opposite consequences on neuronal excitability. In addition, by stimulating either similar or different receptors, DA might exert competing presynaptic and/or postsynaptic actions to modify neuronal responsiveness.

In the present article we reexamine the electrophysiological actions of DA on neurons located in those brain areas that are linked to the reward processes.

Dopamine Actions in the Frontal Cortex

DA in the frontal cortex has implications in reward, the psychomotor and hedonic effects of drug abuse, drug seeking, and certain forms of memory formation linked to salience. Electrophysiological data have extensively shown a variety of effects caused by DA and DAergic agonists in this structure. Although there is a consensus that DA inhibits cortical neurons, several studies have also reported DA-mediated neuronal excitation. DA might have different effects on the excitability of pyramidal neurons by reducing either persistent voltage-dependent sodium currents or voltage-dependent potassium currents. It has been also reported that the stimulation of D1 receptors can activate firing rate by modulating synaptic strength. In fact, some authors have shown that DA significantly enhances excitatory postsynaptic current (EPSC) amplitudes in the pyramidal cells. Recent data have also suggested that DA potentiates the late postsynaptic responses in an excitatory postsynaptic potential (EPSP) train evoked by a sustained presynaptic stimulation. However, a combined activation of D1 and D2 receptors could also determine a reduction of the efficacy of excitatory synaptic transmission at synapses onto pyramidal cells. Moreover, contrasting effects of DA on neuronal responsiveness to glutamate agonists have been reported. Thus, bath application of *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and the D1 agonist SKF 38393 induces concentration-dependent excitability increases, whereas the D2 receptor agonist quinpirole causes a concentration-dependent excitability decrease. Furthermore, opposing D1- or D2-mediated actions, depending on DA concentrations, have been shown to modify the inhibitory drive on cortical neurons. As a result, a nanomolar concentration of DA might enhance the inhibitory postsynaptic currents (IPSCs) via D1 receptors while a micromolar concentration could decrease the IPSCs via D2 receptors. In contrast, it has been reported that the stimulation of presynaptic D1-like receptors

decreases the IPSCs in layer II–III of neocortical pyramidal cells.

In addition, DA could induce important changes in the local network connections of pyramidal cells with γ-aminobutyric acid (GABA)ergic interneurons. Thus, the activation of D1 receptors reduces the amplitude of the EPSPs or causes a reversible membrane depolarization in the fast-spiking (FS) interneurons. On the other hand, the stimulation of D4 receptors, limiting interneuronal excitability, favors multiple spike discharge of pyramidal cells.

Furthermore, DA has been shown to sustain enduring changes of the synaptic signals. Thus, the long-term potentiation (LTP) of the excitatory transmission on pyramidal neurons requires D1 receptor stimulation. This could activate PKA and increase the surface expression of GluR1 in prefrontal cortex neurons. On the other hand, a constant presence of DA in the extracellular space might facilitate long-term depression (LTD). It is supposed that these DA-mediated persistent changes in synaptic responses (LTP-LTD) could be important in processes linked to reward.

Dopamine Actions in the Ventral and Dorsal Striatum

A sizable body of evidence considers the ventral striatum (nucleus accumbens) as a fundamental station for the DA-regulated reward processes. In fact, accumbens DA modulates motivation and cognitive aspects related to incentives. In addition, DA effects in this structure are particularly important in mediating the activating and addictive effects of psychostimulants.

As in the cerebral cortex, accumbal DA might change the activity of medium spiny neurons by involving multiple mechanisms. It has been shown that this catecholamine causes a membrane hyperpolarization that is due to the activation of D1 receptors and is associated with an increase in potassium conductance. However, DA also causes a membrane depolarization that is generated by the stimulation of D2 receptors and sustained by a decrease in potassium conductance. In addition, D2 receptors seem to reduce the direct excitability of medium spiny accumbal neurons by inhibiting evoked Na^+ spikes through the involvement of slow A-type K^+ currents, while reported effects of DA on inward rectification and 'leak' K^+ currents could favor excitability. D2 receptors could also cause an enhancement of voltage-sensitive sodium currents mediated by the suppression of the cyclic AMP/PKA cascade and the facilitation of intracellular Ca^{2+} signaling. In addition, D1 receptor stimulation appears to suppress N- and P/Q-type Ca^{2+} currents by activating a cAMP/protein kinase A/protein phosphatase signaling system, presumably leading to channel dephosphorylation.

Moreover, a coactivation of D1 and D2 receptors and signaling through G-protein $\beta\gamma$ subunits and PKA could enhance spike firing in nucleus accumbens shell medium spiny neurons.

Referring to the DA-induced changes of synaptic functions, there are data supporting an inhibitory role of this catecholamine on the EPSP-IPSP sequences The depression of the EPSP appears to be mainly mediated by a D2 receptor-induced decrease of AMPA currents, while the inhibition of the EPSCs progressively diminishes; the inhibition of the IPSCs seems to be persistent. The resultant effect could cause an increased excitability of these neurons.

Activation of D3 receptors is also reported to suppress the efficacy of the inhibitory synaptic transmission in the nucleus accumbens by increasing the phospho-dependent endocytosis of GABA-A receptors.

Interestingly, DA also attenuates the neuronal responses to repetitive activation of glutamatergic afferents and thereby could block LTP. On the other hand, the accumbal LTD requires, among other factors, dopamine D1 receptor stimulation and cAMP-PKA activation. DA-mediated plastic adaptations of the neural synaptic functions in the nucleus accumbens caused by psychostimulants might control the development and long-term maintenance of sensitization to abused drugs.

The increase of extracellular DA in the dorsal striatum of humans (caudoputamen) related to self-reported measures of liking and the feeling of a 'high' (euphoria) implies that this structure is an essential element of the circuitry responsible for the control of motivated behavior and reward. However, in spite of the recognized importance of DA in reward-related locomotor activation, the precise nature of the modulation that DA exerts on striatal neurons remains largely elusive.

There are early electrophysiological studies demonstrating a predominant inhibitory effect of DA on low-firing medium spiny striatal cells. Thus, the most common responses produced by DA on these cells are the decrease of voltage-dependent inward conductances and the modulation of the corticostriatal synaptic transmission. The DA-mediated inhibition of firing activity seems to be mediated by the activation of D1 receptors. The stimulation of D1-like receptors initiates a cascade of intracellular events, including cAMP formation and activation of cAMP-dependent PKA that reduce excitability and possibly activate the neuronal changes linked to reward. An additional stimulation of D2 receptor reduces glutamate- and GABA-mediated currents.

Some authors have also described a reduction of AMPA-mediated postsynaptic current caused by D2 receptors in medium-sized striatal neurons. In contrast, the stimulation of D1 receptors could potentiate the NMDA-induced currents and reduce GABA-evoked currents by activating a PKA/dopamine- and cAMP-regulated phosphoprotein (DARPP-32)/protein phosphatase 1 signaling cascade. It must also be considered that the cholinergic interneurons are affected by DA. While the stimulation of D1 receptors depolarizes and excites the cells, the stimulation of D2 receptors reduces the GABAergic and cholinergic inputs on these interneurons. With regard to the synaptic function, the two main subclasses of DA receptors contribute in the formation of the long-term changes (LTD/LTP) occurring at the corticostriatal terminals. Therefore, D1-like and D2-like receptors interact synergistically to allow LTD formation. A form of LTD in the striatum is also bidirectionally modulated by D2 receptors and requires the regulation of mGluR-dependent endocannabinoid release. The LTP is blocked by dopamine depletion but is not affected by a D2 antagonist. Furthermore, the use of knockout mice with the ablation of D1 receptors has demonstrated a disrupted corticostriatal LTP, whereas pharmacological blockade of D5 receptors prevented LTD in these animals. Interestingly, DA-dependent stimulation of DARPP-32, a small protein expressed in the spiny neurons which acts as a potent inhibitor of protein phosphatase-1, is necessary for the expression of both corticostriatal LTD and LTP and is required for the full expression of the behavioral response to cocaine and amphetamine. On this basis, a role for neostriatal DA in the formation of a pathological drug habit has been hypothesized.

Dopamine Actions in the Ventral Mesencephalon

There is homogeneous experimental material demonstrating that DA, released from the dendrites, has an inhibitory action on the dopaminergic cells located in the ventral tegmental area and substantia nigra pars compacta. This inhibition is D2-mediated and is due to a membrane hyperpolarization depending on a G-protein (Go/i)-activated potassium current (GIRK). Therefore, by modifying firing discharge of the DAergic cells, the catecholamine might encode the salience of stimuli linked to natural and artificial rewards. Although there is evidence that the dopaminergic neurons fire during reward anticipation, encoding errors in reward prediction, the inhibition of firing mediated by locally released DA could play part of the reward processes. Therefore, a delicate balance of activity in different subsets of DA cells could regulate the timing of the various expressions of reward. In addition, DA, by modifying the strength of the excitatory transmission in the ventral mesencephalon, might contribute to enhancing memory processes linked to salience. Thus, DA could block the induction of LTD in the ventral midbrain via activation of D2-like receptors. This DA-dependent modulation of the synaptic code could be a substrate of memory traces linked to reward. Of note is the fact that the DA-mediated long-term alterations in the strength of the excitatory transmission have been reported to occur after treatments with psychomotor stimulants. Since the development of addictive behaviors shares common features with traditional learning models, these DA-dependent modifications of synaptic plasticity could represent an important substrate for the acquisition of reward-related behaviors.

Conclusions

It is believed that the multiple and, in some instances, opposite effects of DA on cerebral neurons could account for the whole range of behavioral modifications linked to reward processes. However, in spite of the large amount of experimental work so far available, we have to admit that the overall picture describing the actions of DA on single cells and groups of cells is rather complex. Undoubtedly, there is a certain unpredictability in the neuronal responses to DA that could likely depend on competing presynaptic, postsynaptic, and nonsynaptic mechanisms, the type of receptor involved, and the type of neuron. Notwithstanding these limitations, future effort in studying the function of DA should be concentrated on individuating and eventually correcting the processes that control reward at the cellular level.

Pharmacological Treatment of Parkinson's Disease

Parkinson's disease (PD) is a common neurodegenerative disorder, affecting approximately 3% of people older than 65 years. Considerable advances have been made in identifying the etiopathogenesis of PD. In recent years, different gene mutations have been identified as causing familial forms of PD, accounting for nearly 2% of cases. Despite this, the large majority of cases are 'sporadic–idiopathic' and are thought to be the outcome of complex interactions between the environment and the genetic background. Cardinal features of PD are represented by resting tremor, rigidity, bradykinesia, and impaired balance, often complicated by autonomic, cognitive, and emotional disturbances. The main neuropathological characteristic of the disease is a loss of pigmented dopaminergic cells in the substantia nigra pars compacta that produces a massive depletion of dopamine in the basal ganglia (mainly striatum). Neuropathological findings have also demonstrated degenerative processes in the serotoninergic, noradrenergic, cholinergic, and peptidergic pathways.

Although there is currently no cure for PD, because no therapy has been definitely shown to halt its progression, there are medications available to treat the motor symptoms, which can certainly improve the quality of life of affected patients. These are mainly based on a dopamine replacement strategy.

L-DOPA in PD

The dopamine precursor L-DOPA (L-3,4-dihydroxyphenylalanine, also called levodopa) is still the 'gold standard antiparkinsonian agent' because a drug superior to it has not been produced after more than four decades of use. Long-lasting observations in clinical practice have undoubtedly demonstrated that orally administered L-DOPA is a more 'potent' symptomatic antiparkinsonian drug than any dopaminergic agonist thus far introduced in the therapeutic armamentaria. It has been also reported that it increases life expectancy in PD patients.

The superiority of L-DOPA is very likely due to its special feature that allows *de novo* synthesis of dopamine mainly in the surviving dopamine-containing neurons, thus raising the level of this catecholamine in the striatum. L-DOPA is converted in dopamine by the enzyme aromatic L-amino acid decarboxylase (AADC) that is present not only in the brain but also in many peripheral organs and vessels. It has been recognized that the peripheral transformation of L-DOPA by AADC only permits a small percentage of L-DOPA to reach the dopaminergic neurons in the brain. Therefore, in order to obtain valid therapeutic concentrations, a huge dose of L-DOPA was administered. This caused important side effects, including hypotension, nausea, and vomiting. Opportunely, the coadministration of L-DOPA with two compounds (benserazide and carbidopa), which block AADC but do not cross the blood–brain barrier, has increased the availability of this dopamine precursor to the brain, thus diminishing its dosage and reducing side effects.

It has been suggested that the initial excellent therapeutic response to L-DOPA depends on the fact that newly synthesized dopamine can be released mainly at the synaptic contacts under a stimulus-dependent control. Thus, the newly formed catecholamine might be, at least initially, released respecting neurochemistry and the cytoarchitecture of the remaining dopaminergic neurons. As a result, despite a neuronal degeneration in PD, a phasic and a tonic release of dopamine could still be sustained by oral administrations of L-DOPA. Thus, this L-DOPA-induced dopamine release adequately stimulates dopaminergic receptors. At least six different dopamine receptor subtypes have been cloned. These receptors are divided in two classes: the D1 class comprises D1 and D5 receptor subtypes, whereas the D2 class includes D2 (D2S and D2L isoforms), D3, and D4 receptors. It has been demonstrated that the D2 receptors are mainly involved in the regulation of striatal motor functions. Interestingly, all dopaminergic receptors cloned from the brain are also present in tissues outside the central nervous system (CNS), mainly in the cardiovascular system, the kidney, as well as sympathetic ganglia and the adrenal glands.

Whereas the phasic release of dopamine might control the transitory activation of the motor system during movement, the tonic release might prepare and set the motor programs. Therefore, both the phasic and the tonic release of dopamine induced by L-DOPA should correct the disturbances of muscle tone and the alterations of motor performances in Parkinsonian patients. Another important aspect, which might account for L-DOPA's superiority with respect to other drugs, is the possibility that L-DOPA is not only the precursor of dopamine's synthesis but also regulates the formation of noradrenaline and, eventually, the release of serotonin and trace

amines in the extracellular space. Unfortunately, the 'optimal' activation of different receptor systems obtained with L-DOPA in an early phase fades. Thus, the 'honeymoon' with the use of the drug vanishes as more dopaminergic neurons degenerate. Therefore, despite L-DOPA administration, because the surviving dopaminergic cells cannot produce enough dopamine in advanced Parkinsonian patients, not only a phasic but also a tonic stimulation of dopaminergic receptors is no longer possible. Consequently, the Parkinsonian symptoms worsen.

Important negative side effects also develop during long-term L-DOPA treatment of PD (3–5 years), including attenuation of drug efficacy, motor fluctuations, and psychoses. Along with disease progression, and the consequent loss of dopaminergic terminals, the duration of clinical benefit derived from each L-DOPA dose shortens and patients begin to experience motor fluctuations such as 'end of dose deterioration' or the 'wearing off' phenomena. The 'off' periods do not necessarily respond to an increased frequency of L-DOPA intake. Indeed, the clinical response to L-DOPA becomes unpredictable and the patient may frequently switch from 'on' condition to off states. Accordingly, the plasma levels of L-DOPA fluctuate as well and exceed the therapeutic range, producing excessive, involuntary movements (dyskinesias). With further progression of the disease, dyskinesias become even more complex in pattern, with the occurrence of 'peak-dose dyskinesias,' and also 'end-of-dose dyskinesias.' Currently, the pathogenesis of these motor fluctuations is elusive, although both pre- and postsynaptic mechanisms likely play a critical role. Similarly, psychoses are a common side effect of long-term use of L-DOPA, affecting nearly 20% of treated patients. Managing psychotic symptoms is a very difficult challenge in terms of pharmacological treatment and for daily nursing.

For these reasons, some authors claim that it is preferable to avoid treating patients in the early phase of PD with L-DOPA and that, instead, it should be used later when the administration of dopaminergic agonists no longer controls symptoms. Nevertheless, there is not a consensus on this therapeutic approach because the optimal time for initiating L-DOPA therapy is still debated.

Variations in the L-DOPA's pharmacokinetic and alterations of the presynaptic and postsynaptic components in the dopaminergic system might account for the unpredictable responses to L-DOPA in individual patients. The unwanted effects of L-DOPA can be reduced by modifying the therapeutic schedule. For instance, it is important to avoid excessive fluctuations of L-DOPA concentrations in the blood and consequently in the brain. Thus, continuous stimulation of dopaminergic receptors should be obtained in order to attain an acceptable therapeutic outcome.

Several attempts have been made to reduce the oscillations in the extracellular concentrations of L-DOPA: (1) the number of daily administrations of L-DOPA has been increased; (2) the dietary intake of proteins has been reduced to favor a better penetration in the brain (the amino acids and L-DOPA compete on the same carrier at the blood–brain barrier); (3) although not practical, a continuous duodenal or intravenous infusion of L-DOPA has been used to diminish 'on–off' events; and (4) sustained-release preparations of L-DOPA have been used to avoid excessive plasmatic and cerebral peak concentrations of L-DOPA. This has been done to prolong the actions of each single dose of L-DOPA. However, there is no clear evidence that these formulations of L-DOPA reduce side effects.

It is also important to mention that established clinical studies have recognized that L-DOPA has a short-duration response (hours) and a long-duration response (days). It has been reported that the long-duration response is observed when consistent single doses of this drug are orally administered. Therefore, therapeutic regimens that use small and divided dosage during the day, as is currently done in clinical practice, might not achieve the beneficial long-duration response.

Other strategies, via the use of different pharmacological agents, have also been used to enhance the availability of L-DOPA in the brain. All these approaches reduce the degradation of L-DOPA, thus prolonging its effects.

It has been shown that inhibition of the catechol-*O*-methyltransferase enzyme potentiates L-DOPA efficacy. In fact, two inhibitors have been coadministered with L-DOPA to parkinsonian patients – tolcapone, which is centrally and peripherally acting, and entacapone, which does not cross the blood–brain barrier. These inhibitors prolong the effects of the drug, increasing on-time and reducing off-time. Of note, tolcapone has been associated with severe liver toxicity and hepatic failure, which represent a significant limitation to its clinical use. Thus, hepatic functions have to be carefully monitored during treatment.

It has been also shown that inhibition of the monoamine oxidase B mitochondrial enzyme, caused by the irreversible and selective inhibitor L-deprenyl (selegiline), reduces the on–off side effects of L-DOPA and produces modest symptomatic positive actions on Parkinsonian symptoms.

Some authors have also claimed that L-DOPA is toxic to the dopaminergic cells due to its oxidative metabolism. On the contrary, others have suggested that it might be neuroprotective. There is clear clinical

evidence demonstrating that L-DOPA is not toxic and possibly increases the lifetime of Parkinsonian patients.

L-DOPA and L-DOPA-Sensitive Dystonia

It has been shown that L-DOPA has a dramatic therapeutic action in reducing the symptoms of a form of primary dystonia, the DOPA-responsive dystonia (DYT5). This disease is caused by a deficit in the synthesis of dopamine. This fact explains the remarkable positive response to L-DOPA therapy. Interestingly, the therapeutic response to L-DOPA is maintained for years with a low incidence of motor fluctuations, which instead are often observed after long-term treatment in Parkinsonian patients.

Dopaminergic Agonists

Use of dopamine receptor agonists to treat PD has increased dramatically in the past two decades. In the CNS, dopaminergic receptors are involved in a wide range of functions, including locomotion, cognition, emotion, and endocrine responses. Whereas the D1 receptors are mainly distributed in the medium spiny striatal cells, giving rise to the so-called direct pathway projecting to the globus pallidus interna and substantia nigra pars reticulata, the D2 receptors are preferentially localized in the striatal neurons, giving rise to the indirect pathway projecting to the globus pallidus externa. Experimental and clinical studies have provided evidence that activation of D2 receptors exerts a central role in mediating the beneficial effects of dopaminergic agonists, although stimulation of both classes (D1 and D2) of receptors has been shown to be necessary for optimization of the clinical response. The dopaminergic agonists introduced in PD therapy exert their pharmacologic effects by directly activating dopaminergic receptors with different affinities (Table 1).

The use of dopamine receptor agonists has proven effective in the management of motor symptoms occurring in PD as adjunctive therapy to L-DOPA in advanced phases of disease. Moreover, compelling evidence supports the valuable role of dopaminergic agonists as a monotherapy in the early stages of PD. Although still a matter of debate, it is believed that early treatment with dopaminergic agonists could prevent or substantially reduce the neurochemical changes underlying the development of the disabling motor fluctuations commonly observed in the course of long-term L-DOPA therapy. Indeed, a significant advantage of dopaminergic agonists, compared to L-DOPA, is that they do not require metabolic conversion to an active compound to produce effects. Rather, they directly stimulate postsynaptic dopaminergic receptors, thus circumventing the synthetic processes of dopamine at degenerating nigrostriatal terminals. Moreover, these dopaminergic compounds have a significantly longer half-life compared to both standard and controlled-release formulations of L-DOPA, allowing a more continuous, rather than pulsatile, stimulation of target dopaminergic receptors. Another advantage compared to L-DOPA is that dopamine receptor agonists do not compete for both absorption and transport across the blood–brain barrier with circulating plasma amino acids. Prolonged stimulation of the D3 receptors by a selective dopaminergic agonist has been reported to activate neurogenesis of the dopaminergic system in a rat model of PD. These experimental results may have very important clinical relevance if confirmed in PD patients.

The concept of an initial monotherapy with a dopaminergic agonist, or an early combination of an agonist with L-DOPA, in an attempt to postpone disabling motor complications has been shown to be, at least to some extent, valid. Prospective long-term clinical trials have shown that early symptomatic treatment with a dopamine receptor agonist is associated with a significantly lower risk of developing motor

complications compared to L-DOPA therapy. Despite these encouraging results, the clinical efficacy of dopaminergic agonists has been shown to decrease over time, along with disease progression, so that the number of patients receiving these agents as monotherapy rapidly decreases to 50% after 2–4 years of treatment and to less than 20% after 5 years. In such circumstances, it is mandatory to introduce L-DOPA. In some cases, switching dopaminergic agonists could be a strategy to maintain a clinical response or to avoid specific adverse events. Moreover, another aspect deserving consideration is the combination of two dopamine receptor agonists, which appears to be an attractive alternative to delay initiation of L-DOPA therapy. This dual agonist's treatment has been shown to reduce the time spent in 'off' conditions and to improve the motor scores by nearly 20%. However, only few controlled and well-designed trials have been conducted in an attempt to compare the efficacy of the different marketed dopaminergic agonists in clinical practice.

Indeed, the way in which dopamine receptor agonists stimulate dopaminergic receptors appears to produce a tonic stimulation of the dopaminergic system (although this is an oversimplification); thus, a phasic stimulus is still necessary. Therefore, small amounts of L-DOPA (that might provide a phasic stimulus on dopaminergic receptors and, eventually, activation of other receptorial systems) are eventually required in patients treated with only direct dopaminergic agonists. This clinical observation highlights the importance of a phasic (neuronal-driven) stimulation of dopaminergic receptors that could be provided by L-DOPA, but it also suggests that the best way to activate striatal (and perhaps extrastriatal) dopaminergic receptors is by combining L-DOPA and dopaminergic agonists in the treatment of PD.

It is worth mentioning that a central dopaminergic dysfunction has also been implicated in a disease (restless leg syndrome) characterized by periodic limb movements during sleep that lead to severe insomnia. Therefore, this syndrome has an excellent response to low doses of direct dopaminergic agonists.

Ergoline Derivatives

Dopamine receptor agonists are classified into two major categories: ergolines, which are derivatives of ergot alkaloids that may be referred to as first-generation agents, and non-ergolines, more recently introduced in the pharmacotherapy of PD. Ergolines were introduced into clinical practice in the early 1970s. Bromocriptine, a bromo-substituted derivative of the natural peptide ergot alkaloid ergocryptine, was introduced for the treatment of hormonal disturbances, particularly for the treatment of prolactinomas, and was found to have anti-PD properties at higher dosages. It was first utilized as adjunctive therapy to L-DOPA in advanced PD patients experiencing motor fluctuations, and later it was proposed as monotherapy in the early stages of disease. A large controlled, 10 year trial directly compared bromocriptine with L-DOPA in early PD. At 3 years, patients receiving bromocriptine had lower disability scores than those in the L-DOPA arm of the trial; however, the difference was not significant at 9 years. Also, in two Cochrane reviews, patients receiving L-DOPA for 3 years were more likely to develop dyskinesias than patients receiving bromocriptine, although several patients from the bromocriptine group had to drop out because of intolerable side effects.

The second agonist introduced, lisuride, had initially been employed in the prevention of migraine attacks and then was approved for the treatment of PD. Similar to bromocriptine, lisuride has been utilized both as adjunct to L-DOPA and as monotherapy. Notably, subcutaneous lisuride infusion by means of micropumps has been shown to provide benefit in advanced PD patients. In a 4 year study comparing patients receiving subcutaneous lisuride and those receiving conventional L-DOPA and/or dopaminergic agonists, a significant reduction in both 'off' time and motor complications was obtained in the group treated with lisuride, with a long-term beneficial effect for the duration of the study.

The clavine derivative pergolide is a potent dopamine receptor agonist used as adjunct to L-DOPA therapy to retard the clinical progression of PD or to delay the occurrence of L-DOPA-induced motor complications. Several studies have been conducted comparing the efficacy of the ergot derivatives (bromocriptine and pergolide) as adjunctive therapy to L-DOPA. Despite many methodological differences within the study design, these trials have confirmed the efficacy of the combined approach in reducing the appearance of motor fluctuations. In fluctuating PD patients, these dopaminergic agonists may shorten the 'off' periods and increase the time spent in 'on' condition. Comparative studies among different dopamine receptor agonists have revealed that pergolide is more effective than bromocriptine as adjunctive therapy to L-DOPA in advanced PD patients. Both drugs proved to be effective compared to L-DOPA monotherapy, although pergolide treatment resulted in a more sustained improvement in terms of motor activity and quality of life, probably because of its longer half-life. The efficacy of pergolide has also been shown as monotherapy in early stages of PD.

Dihydroergocryptine is another ergoline derivative, showing affinity for D2 and partially for D1 receptors.

Controlled trials have been conducted both as monotherapy and as adjunctive to L-DOPA treatment.

The newest marketed ergoline derivative is the lysergic acid amide derivative cabergoline, which shows a higher affinity for D2 receptors. The main feature of this drug is its longer half-life (nearly 65 hours) compared to those of all other agonists, allowing a single daily intake. In adjunct to L-DOPA, cabergoline has been proven effective in ameliorating motor symptoms, compared to placebo, and in reducing the daily dosage of L-DOPA. Moreover, a controlled clinical trial conducted in patients in an early stage of PD showed that the incidence of motor fluctuations was significantly lower in the cabergoline group compared to the group treated with L-DOPA.

Non-Ergoline Derivatives

Two dopaminergic agonists with no relation to ergot derivatives have been introduced in the pharmacotherapy of PD: the indole derivative ropinirole and the benzothiazol derivative pramipexole.

Ropinirole has high affinity for both D3 and D2 dopaminergic receptors, with little affinity for D1 receptors. Rapidly absorbed and well tolerated, it was reported to be as efficacious as bromocriptine in reducing motor fluctuations and decreasing L-DOPA daily dosage. As monotherapy, ropinirole was proven effective in treating tremor in PD patients. Several studies have demonstrated that ropinirole is effective both in the early and in the advanced phases of PD. A 5 year controlled clinical trial in newly diagnosed PD patients has been conducted comparing the effects of ropinirole to L-DOPA. After 5 years, the occurrence of dyskinesias was 20% in the group of patients receiving ropinirole compared to 45% in the L-DOPA group.

Pramipexole, a non-ergoline derivative, features a preferential affinity for D3 over D2 dopamine receptor subtypes. Its efficacy and safety have been investigated in several clinical trials, which have demonstrated that pramipexole utilized both as adjunct to L-DOPA and as monotherapy has beneficial effects on motor symptoms, significantly reduces the periods spent in 'off' condition, and allows a reduction in the daily dosage of L-DOPA. In particular, patients with pronounced resting tremor derived a clear benefit from pramipexole use compared to L-DOPA.

Among non-ergot derivatives, the most recent agent introduced in the pharmacotherapy of PD is the aminotetraline derivative rotigotine, considered as a D3/D2/D1-preferring dopamine receptor agonist. Indeed, rotigotine showed agonistic activity on dopaminergic receptors with higher affinity (approximately 20-fold) for the D3 compared to the D2 (approximately 100-fold) and the D1 receptor. Despite the short duration of rotigotine efficacy on oral administration, the ability of the drug to act after transdermal application has provided a means of developing its clinical potential. Based on the pharmacologic profile of the agent and its effect in experimental models, subsequent clinical investigation has shown that transdermal rotigotine is an effective and long-acting treatment for the control of motor symptoms in PD. In two large clinical trials, early PD patients receiving rotigotine experienced a significant improvement in motor symptoms compared to placebo. Moreover, patients in more advanced disease stage, utilizing rotigotine as adjunctive therapy with L-DOPA resulted in a significant reduction in the time spent in 'off' condition.

Concerning the achievement of satisfactory results with dopaminergic agonists, the route of delivery is gaining importance more than their supposed receptor affinity. A 'continuous dopaminergic stimulation' concept of the treatment of PD suggests that the use of long-acting dopaminergic agonists, such as transdermal patches or continuous subcutaneous infusion, may indeed produce effective control of motor symptoms, accompanied by a reduction of the motor fluctuations induced by L-DOPA.

In the past decade, there has been renewed interest in apomorphine. The tetracyclic apomorphine is a morphine derivative but without opiate-like effects. It was introduced in the late nineteenth century for the treatment of intoxications because of its powerful emetic effects. It is a short-acting dopaminergic agonist with receptor affinity similar to that of dopamine, thereby representing the only agonist with a pharmacological profile comparable to that of dopamine. Apomorphine is commonly prescribed for subcutaneous use as bolus injection or continuous infusion by micropumps. The subcutaneous injection is commonly used in clinical practice as a confirmatory, diagnostic test for PD. Moreover, apomorphine is currently utilized for the management of severe, refractory 'off' periods in fluctuating PD patients because of its rapid onset and good efficacy. Several studies have also demonstrated that continuous subcutaneous infusion of apomorphine results in reduced 'off' periods, reduced occurrence of dyskinesias, and reduced daily L-DOPA dosage. Despite compelling evidence of both efficacy and safety, the validity of apomorphine as an important adjuvant in the advanced stages of PD is still underestimated.

Side Effects

Despite a significantly different affinity for the distinct classes of dopamine receptor subtypes, the beneficial

clinical and side effects of dopaminergic receptor agonists are remarkably similar, independent of their chemical structure (Table 2). Indeed, expectations of clinical improvements claimed on the basis of their biochemical and pharmacological profile have not been met.

Experimental and clinical evidence indicates a central role for the pharmacokinetics of dopaminergic agonists in the development of side effects. The commonly observed undesired effects, such as nausea, dizziness, somnolence, emesis, and orthostatic hypotension, are not in fact directly related to the effective plasma levels but, rather, seem to be triggered by the rapid increase in drug level in the blood, probably related to drug bioavailability and individual susceptibility. Although in some PD patients the occurrence of these side effects requires the discontinuation of the drugs, in a much larger number of patients ongoing treatment with slowly increasing dosages of agonists permits the development of tolerance for the undesired effects while preserving the beneficial actions. To some extent, the use of antagonists of peripheral dopamine D2 receptors, such as domperidone, is helpful in preventing some of the side effects caused by the dopaminergic agonists and enables a more rapid titration of the drugs within a few weeks. However, despite these therapeutic precautions, serious side effects may occur, and they may be comparable to those observed with L-DOPA therapy. These also include psychiatric symptoms, such as hallucinations, paranoia, vivid dreams, mood alterations, compulsive gambling, and compulsive sexual behavior, and they appear to be more frequent in elderly patients or in patients with preexisting cognitive impairment. Similarly, excessive daytime somnolence is very common and often complicated by sudden sleep attacks. Sleep attacks have been shown to occur with virtually all of the dopaminergic agonists.

Ergoline derivatives have also been associated with pleuropulmonary and retroperitoneal fibrosis, so careful patient selection is required. Thus, during treatment patients should be monitored for persistent cough, dyspnea, chest and abdominal pain, and cardiac failure. Pergolide and cabergoline have been associated with a significantly higher incidence of valvular heart disease, which will certainly limit their use in clinical practice. Thus, in the course of ergot-derived agonist treatment, an annual screening with chest x-rays, blood tests, and echocardiographic examination should be warranted.

Conclusion

Considering all the points discussed in this article, we believe that the dosage of administered L-DOPA and dopaminergic agonists should be customized to the needs of the individual patient on the basis of the clinical response and the profile of adverse events.

Dopaminergic Differentiation

A Rosenthal and J C Lin, Rinat Neuroscience Corp., South San Francisco, CA, USA

Introduction

Dopaminergic (DA) neurons in the mammalian midbrain region are critically affected in several neuropsychiatric disorders, such as schizophrenia, and they are specifically lost in Parkinson's disease (PD). This article reviews how the DA neurons are generated through the interactions of multiple extrinsic and intrinsic factors during embryogenesis. The molecular identities and the mechanisms of action of an increasing number of such factors have been elucidated. Many of the same factors have been successfully used to induce efficient differentiation of DA neurons *in vitro* from embryonic or neural stem cells. These advances promise to have significant impacts on science and medicine in the future.

Overview: The Medical Importance of DA Neuron Development

Dopamine is a major catecholamine neurotransmitter of the mammalian central nervous system (CNS). It is also present in noradrenergic and adrenergic neurons as a biosynthetic precursor to noradrenalin and adrenaline. Several distinct populations of DA neurons can be identified in the CNS. They include a subset of interneurons in the olfactory bulb, a subset of amacrine interneurons of the retina, distinct neuronal groups in the hypothalamus, and the ventral mesencephalon, which includes substantia nigra (SN, the so-called nigrostriatal system), and ventral tegmental area (VTA, the so-called mesolimbic system). Medically, the most important group of DA neurons, which is also the largest population by number, of the mammalian CNS is in the ventral mesencephalon. The nigrostriatal DA neurons are selectively lost in PD, whereas dysfunction of the mesolimbic DA neurons is implicated in obsessive–compulsive disorder, schizophrenia, and substance abuse.

Since PD is marked by progressive loss of the nigrostriatal DA neurons, 'dopamine supplementation' therapy such as L-dopa and dopamine receptor agonists has been the mainstay of the symptomatic management of this most common movement disorder. However, the standard dopamine supplementation gradually becomes ineffective after the first 2–4 years of treatment, presumably due to the inexorable loss of nigrostriatal DA neurons and eventually their synaptic targets. Even when effective, the current DA agonist medications are frequently accompanied by fluctuations, dyskinesias, and psychotic side effects, which can be attributed at least in part to improperly regulated and ectopic dopamine transmission. Consequently, the concept of 'DA cell replacement' gradually emerged as a potential alternative to dopamine supplementation. Transplantation of DA neurons or their precursors in the striatum or in the substantia nigra may restore physiologically regulated and anatomically precise dopamine release. However, there are severe technical and ethical constraints on the use of human tissue for transplantation. As a result, attention has been directed increasingly toward deriving DA neurons from embryonic stem (ES) cells as well as from adult-derived neural stem cells. Understanding the mechanism by which normal mesencephalic DA neurons develop, therefore, has become important, not only as a model of neuronal subtype differentiation in neural development, but also for its medical implications. This article focuses on the developmental mechanism of DA neurons in the ventral midbrain.

Extrinsic Factors in Mesencephalic DA Neuron Development

Mesencephalic DA neurons are generated in the mid–hindbrain boundary (MHB) under the influence of two major signaling centers, the floor plate and the isthmus, of developing embryos. Sonic hedgehog (Shh) and fibroblast growth factor-8 (FGF-8) are the principal secreted signals underlying the activity of each of these signaling centers, respectively. Shh determines the location of DA neurons along the dorsal–ventral axis, whereas FGF-8 positions the mesencephalic DA neurons along the anterior–posterior axis of the neural tube. The Gli proteins are a conserved family of zinc finger transcription factors that function as both activators and repressors in transducing the Shh signal inside the cells. Forced Gli-1 expression in transgenic mice induced ectopic mesencephalic DA neurons while Gli-2-deficient mouse embryos failed to develop mesencephalic DA neurons. These results further underscore the importance of the Shh signaling pathway in the development of mesencephalic DA neurons.

How do these early patterning signals originate during embryogenesis? Shh expression in the floor plate was shown to be controlled by the forkhead transcription factor FoxA1/HNF3β in mouse and zebra fish, the basic helix-loop-helix (bHLH) and PAS domain containing transcription factors Sim-1 and -2 in the mouse, and directly by TGFβ family factor Cyclop in

the zebra fish. Likewise, FGF-8 expression in the MHB is controlled by a complex network of regulatory genes including a key homeodomain transcription factor Pax2. These early developmental events that initiate, refine, and maintain the pattern and signaling centers along the anterior–posterior and dorsal–ventral axes in the MHB have been reviewed extensively elsewhere.

In addition to the patterning signals intersecting at the ventral MHB of the early embryo, several other secreted factors can induce the differentiation or support the survival of DA neurons *in vitro* and *in vivo*. Among them, glia-derived neurotrophic factor (GDNF) is the most potent trophic factor for mesencephalic DA neurons. The GDNF−/− mice initially develop a full complement of midbrain DA neurons, but these mice die soon after birth, precluding the analysis of later survival and function of DA neurons in the absence of GDNF. When transplanted into the striatum of a 1-methyl-4-phenyl-1,2,3, 6-tetrahydropyridine-lesioned wild-type mouse, the GDNF mutant (−/−) donor tissues exhibit a greatly reduced survival of DA neurons compared with the wild-type (+/+) donor tissues. Moreover, such a defect can be rescued by immersion of the GDNF−/− donor tissues with a high concentration of GDNF prior to transplantation. Thus GDNF is needed for continued survival of mesencephalic DA neurons in the adult. This is particularly significant in view of early promising clinical studies in which continuous and localized delivery of recombinant GDNF into the SN by a pump led to a rapid and significant rescue of the DA neurons of PD patients. Significant technical hurdles, such as efficient drug diffusion in the striatum, remain to be resolved in order to achieve optimal outcome in such applications of a potentially neuroprotective or regenerative agent.

Intrinsic Factors in Mesencephalic DA Neuron Development

Once the DA neuronal fate is induced by the extrinsic signals in the ventral MHB region, several cell-autonomous transcription factors are required for initiation and maintenance of the expression of DA cell-specific genes as well as for survival of DA neurons. They include several homeodomain transcription factors (En1, En2, Msx1, Lmx1a, Lmx1b), a bHLH transcription factor (Ngn-2), and a nuclear receptor family transcription factor (Nurr1) as described below in more detail.

Two homeodomain transcription factors, En-1 and En-2, are highly expressed in the developing and mature mesencephalic DA neurons as well as other cell types in the MHB. Although the midbrain DA neurons are initially specified in single- or double-En knockout mice, their survival requires the En1 and -2 genes in a dosage-dependent manner. In the En1/En2 double knockout mice, a very small population of TH-positive mesencephalic DA neurons remains, but the expression of α-synuclein, a gene mutated in a familial form of PD, is completely lost in the ventral midbrain, suggesting that En genes may directly regulate α-synuclein expression in the DA neurons. The loss of α-synuclein expression, however, is unlikely to be responsible for the loss of DA neurons in the En1/En2 double knockout mice since the α-synuclein knockout mice maintain a full complement of midbrain TH neurons.

A LIM homeodomain transcription factor, Lmx-1a, and another homeodomain protein, Msx-1, are specifically turned on by Shh in the ventral MHB. Lmx-1a is sufficient and required to induce DA neuron differentiation *in vivo*. One function of Lmx-1a is to induce the expression of Msx-1, which further turns on the proneural gene Neurogenin-2. The absence of Neurogenin-2 in mice resulted in progressive loss of DA neurons in both the SN and the VTA. It is important to note that forced expression of Lmx-1a can drive robust DA cell differentiation in ES cell culture. It is intriguing to note that Lmx-1a and Msx-1 are both expressed in dorsal neural tube and required for the development of the roof plate. These two dorsal factors are somehow co-opted to serve in the development of a ventral cell type, that is, the DA neurons, specifically in the MHB region.

Lmx-1b, another LIM homeodomain transcription factor, is initially highly expressed in the MHB and the dorsal neural tube and later expressed in developing and adult mesencephalic DA neurons. The early expression of Lmx-1b is induced and/or maintained by FGF-8, and retroviral-mediated Lmx-1b expression is able to induce ectopic Wnt-1 expression, another secreted signal of the MHB. In the absence of Lmx-1b, the ventral mesencephalic DA neurons retain expression of Nurr1 and TH, but most of them lose the expression of a homeodomain transcription factor Pitx3. These results suggest that Lmx-1b and Pitx3 form a regulatory cascade independent of the expression of Nurr1 or TH in DA neurons.

Another gene that attracted significant attention is Nurr1, an orphan nuclear receptor that is widely expressed in the CNS including in the mesencephalic DA neurons. In the absence of Nurr1, mice initially still develop a group of Pitx-3-, Lmx-1b-, and HNF3β-expressing cells in the ventral MHB region but fail to initiate TH expression. These 'prospective' DA cells eventually degenerate and disappear, resulting in a complete loss of mature DA neurons. Conversely, forced expression of Nurr1 in the adult hippocampus-derived progenitors can induce TH expression without affecting other DA-specific genes,

suggesting a direct regulation of TH expression by Nurr1. Furthermore, overexpression of Nurr1 can induce the differentiation of a mature DA neuronal phenotype by a cerebellum-derived immortalized cell line in the presence of the type 1 astrocytes. Therefore, Nurr1 appears to be a transcriptional regulator of TH expression and is essential for DA neuronal differentiation and survival.

Development of Distinct Subtypes of Mesencephalic DA Neurons

The mesencephalic DA neurons are mainly distributed in two distinct anatomical structures, SN DA neurons, innervating the striatum, and VTA DA neurons, innervating the nucleus accumbens and the prefrontal cortex. Little is known about how these two groups of DA neurons develop since they largely express a common set of genes. Raldh-1 (class 1 aldehyde dehydrogenase) is one of the first genes characterized to exhibit a subgroup-specific expression in mesencephalic DA neurons. The Raldh-1-expressing axonal terminals form a gradient in the striatum and nucleus accumbens such that its density is highest in the rostral and dorsal region of the basal forebrain. Such a graded distribution suggests that Raldh-1 is preferentially expressed in the DA neurons of SN instead of those of the VTA. Given the importance of retinoic acid in early embryogenesis, hindbrain patterning, and spinal motor neuron development, such a striking expression pattern of a retinoic acid-synthesizing enzyme suggested that retinoic acid and/or its derivatives may play a role in the development of subsets of DA neurons.

Some other genes, while not necessarily exclusively expressed in any specific subset of DA neurons, are nevertheless required for the development or maintenance of only a subpopulation of mesencephalic DA neurons. Genetic deletion of mouse transforming growth factor-α (TGF-α), for instance, leads to a selective reduction of DA neurons in SN, but not in VTA. This appears to reflect an early, possibly a developmental, requirement of TGF-α since such a defect was already present in the newborns. Neither the site of expression nor the mechanism of TGF-α action in a subset of the SN DA neurons is known.

The brain-derived neurotrophic factor (BDNF) and its receptor trkB are expressed in the mesencephalic DA neurons. BDNF can promote DA neuronal survival and differentiation in experimental culture conditions. When researchers conditionally deleted the BDNF gene by crossing the floxed allele of BDNF and a Wnt–Cre line, BDNF expression was nearly completely abolished in the MHB region. Such mouse mutants exhibit a ~23% reduction in tyrosine hydroxylase (TH)+ DA neurons in the substantia nigra compacta but not in the VTA, indicating a preferential requirement of BDNF in DA neuron development of the SN.

One transcription factor that regulates the differentiation or maintenance of a subset of DA neurons is Pitx-3/Ptx-3, a paired-type homeodomain transcription factor that is expressed almost exclusively in all the mesencephalic DA neurons. It is interesting that the number of DA neurons fell dramatically in the SN, but not the VTA, in the Aphakia mutant mice that are deficient in the Pitx-3 gene. This is accompanied by ~90% loss of dopamine in the dorsal striatum and significant deficits in sensorimotor coordination behaviors. These deficits can be reversed by peripheral administration of L-dopa. Finally, the Aphakia mutant mice also displayed denervation hypersensitivity to L-dopa in the dorsal striatum, making Aphakia one of the best mouse models with all the major symptomatic and pharmacologic characteristics of the early clinical stages of PD.

The Control of DA Axonal Development

DA neurons project their axons in the rostral direction to form the medial forebrain bundle (MFB) before reaching the final targets in the forebrain, which include the corpus striatum, nucleus accumbens, and the prefrontal cortex. MHB and DA neuron co-culture experiments have shown that the MHB tissue alone is not repulsive to the DA axons, suggesting that no localized repulsive signal from the MHB and rostral hindbrain region prohibits the DA axons from entering the hindbrain. In contrast, the DA axons do turn abruptly when forced to grow into a stratum of the reverse polarity, suggesting that locally distributed directional cues guide the rostral projection of DA axons to their precise positions in their physiological targets. The absence of repulsive signals in the hindbrain suggests that the DA axons may turn rostrally in response to attractive guidance cue(s) distributed in the vicinity of ventral midbrain.

Unlike many ascending axons originating from the spinal cord and elsewhere, the mesencephalic DA axons never cross the midline. Once turned rostrally, the DA axons join additional ascending axons to form the MFB, a symmetrical pair of axonal bundles running in parallel to the ventral midline of the forebrain. Studies in the *Drosophila* embryo have shown that longitudinal axonal pathways are kept from crossing the midline and maintained at a constant distance from the midline by the repulsive signal Slit. Similarly, mammalian Slit-1 and Slit-2 are both expressed in the ventral midline of the CNS. The TH-positive axons, as well as other axons in the MFB, are displaced ventrally in Slit2−/− mutant mice

and frequently enter the hypothalamus in Slit1−/−; Slit2−/− double mutants. Therefore, the repulsive Slit signals contribute to the maintenance of DA axonal trajectory in the ventral forebrain.

Finally, DA axons invade selected targets in the forebrain, that is, the striatum and the prefrontal cortex, in a topographic manner. The SN DA axons preferentially innervate the dorsal striatum, while the VTA DA axons the ventral striatum (mainly nucleus accumbens) and the prefrontal cortex. The Eph receptor–ligand system has been implicated in the formation of the DA topographical map. EphB1 is preferentially expressed in the SN DA neurons, while its ligand ephrin-B2 shows a graded expression in the DA axonal targets, with the highest level in the ventral striatum. Furthermore, ephrin-B2 specifically inhibits neurite outgrowth of SN but not VTA, suggesting that repulsive interaction between EphB1 and ephrin-B2 may underlie at least in part the formation of the DA topographic map. This proposal awaits confirmation by gain and loss of function experiments *in vivo*.

DA Neuron Differentiation *In Vitro*

Current understanding of the mechanisms by which the mesencephalic DA neurons are generated during normal development has been successfully extended to useful methods of promoting DA neuronal differentiation from the totipotent ES cells. Addition of Shh and FGF-8 to the ES cell culture increases the efficiency of DA cell differentiation from ~5% to 20–30%. Similar results were also obtained with clonal ES cell lines derived from nuclear transplantation of adult donor cells (ntES cells). It is interesting that different ntES cell lines produced DA neurons at highly variable frequencies, with one line generating 50% DA neurons, suggesting that the inherent potential of DA neuron differentiation is ES cell line-dependent.

Such intrinsic factors with the ability to influence DA neuron differentiation have been identified, including Lmx-1a and Nurr1. As mentioned earlier, Lmx-1a expression in mouse ES cells can drive up to 60% TH+ neuronal differentiation in the presence of basic fibroblast growth factor, FGF-8, and Shh. Essentially all these TH+ neurons also express the correct mesencephalic DA neuronal phenotype, including dopamine transporter, Lmx1a, En, Nurr1, and Pitx3. A separate study found that the efficiency of DA differentiation can be increased up to 80% by adding Shh and FGF-8 to an ES cell line forced to express Nurr-1. The DA cells derived from these experimental protocols express not only dopamine-synthesizing enzymes and dopamine receptor and transporter but also molecular characteristics that are specific to the differentiating and mature mesencepahlic DA neurons (e.g., cRet, Pitx-3, En-1). When transplanted into the striatum, these cells can correct the amphetamine-induced ipsilateral rotation of rats whose mesencephalic DA neurons were ablated by 6-hydroxydopamine in one side. Moreover, animals grafted with Nurr-1-expressing ES cells not only exhibited contralateral turning on amphetamine stimulation but also manifested spontaneous contralateral rotations. This phenomenon, which results from overproduction of dopamine in one side of the brain, demonstrates a robust differentiation of Nurr-1 ES cells into functional dopamine-producing DA neurons *in vivo*.

Given the success in inducing ES cells to the DA lineage, promoting the differentiation of adult or fetal mesencephalic neural progenitor cells would seem conceptually straightforward. This approach, however, has generally achieved a lower percentage of DA neuron production compared with ES cells. One possible explanation for this discrepancy relates to the fact that the tissue oxygen pressure in the developing and adult brain ranges from 1–5% whereas the standard techniques expose the neural progenitor cells to the ambient 20% of oxygen pressure. Lowering the tissue culture condition to 3% oxygen significantly increases the proliferation of mesencepahlic progenitor cells, decreases their death, and most important, enhanced efficiency of their differentiation into DA neurons by up to 56% (compared with 18% at the regular 20% oxygen condition). Nurr-1 and Shh expression levels were not altered by low oxygen, but FGF-8, vascular endothelial growth factor (VEGF), and erythropoietin (EPO) messenger RNA levels are significantly increased by low oxygen tension. Neither adding nor blocking VEGF affected DA differentiation. However, FGF-8 exposure enhanced mesencephalic progenitor proliferation and delayed the differentiation of TH+ cells. It is interesting that recombinant EPO protein increased the yield of DA neurons from mesencephalic progenitors at 20% oxygen environment in a dose-dependent manner, and an EPO-neutralizing antibody partially abolished the efficiency of DA differentiation at the 3% oxygen condition. It will be interesting to learn whether and how EPO acts as an inducer of DA neurons *in vivo* as well as in the ES cell culture system.

Conclusion

In the past decade, considerable advances have been made at an ever accelerating pace in understanding the cellular and molecular mechanisms controlling the development of mesencephalic DA neurons. Indeed the extrinsic and intrinsic signals underlying native DA neuron development have turned out to be

highly relevant and useful in efforts at directing DA differentiation from ES cells *in vitro*. Conversely, new observations from *in vitro* culture systems have revealed unexpected molecular mechanisms influencing DA neuron differentiation, which will inspire further studies of their roles *in vivo*. While the recent progress was fueled by the expectation that *in vitro* production of DA neurons would be useful as a form of cell replacement therapy for PD, it is quite possible that 'neuroprotective' or 'regenerative' medicines for PD can also derive from the knowledge of DA neuron development.

An update on latest advances is as follows:

1. DA neurons were found to be greatly reduced in mice in which Dicer, a critical enzyme essential for micro-RNA formation, has been conditionally deleted in DA neurons. Furthermore, a specific micro-RNA, miR133b, is enriched in the midbrain DA neurons and can negatively regulate Pitx3 expression and the maturation of dopaminergic neurons.
2. As a definitive confirmation of the importance of GDNF in DA neuronal development and maintenance, conditional deletion of GDNF in adult mice resulted in severe hypokinesia and loss of DA neurons.

Introduction

The dorsal root ganglia (DRG) are a collection of cell bodies of the afferent sensory fibers, which lie between adjacent vertebrae. Unlike motor neurons, the soma is on a side branch of the main axon and receives little synaptic input and has sometimes been written off as unimportant and uninteresting, perhaps simply working as the metabolic factory of the neuron. Access to the soma for techniques such as patch clamp is relatively easy and can provide excellent recording conditions, making it a convenient model neuron. A substantial body of work during the past two decades has shown that changes in excitability of DRG neurons are representative of functional changes in the associated fibers, and that these alterations are of importance in many pathological conditions. In addition, these studies have increased our understanding of the very different roles particular ion channels play in influencing excitability of DRG and also how they may alter firing behavior in other neurons in which they are expressed or misexpressed. One field of research that has been especially revealing is the study of sodium channel subtypes in DRG, and this article draws on examples from this area to illustrate the control of excitability in DRG by plasticity of these proteins.

Expression of Multiple Ion Channel Subtypes

It has been known for some time that it is possible to link the conduction velocity of the dorsal root fibers with DRG cell size and to classify these neurons into four main groups of decreasing velocity: Aα, 30–55 m s^{-1} Aβ, 14–30 m s^{-1}; Aδ, 2.2–8 m s^{-1}; and C, <1.4 m s^{-1}. These fibers relay information from muscle and skeletal mechanoreceptors (Aα and Aβ), cutaneous and subcutaneous mechanoreceptors (Aβ and Aδ), and nociceptors (Aδ and C). The slower velocity fibers are generally associated with small cells, and the action potential duration is broader, often displaying a hump on the falling phase. Some of these characteristics are obviously related to the intrinsic behavior of, for instance, a myelinated axon versus a nonmyelinated one, but it has become increasingly clear that the excitability of these fibers, and the plasticity of that excitability, is directly related to the subtypes and combinations of ion channel that they express. In particular, differential expression and modulation of sodium channels, which are responsible for subthreshold depolarizations, as well as the upstroke of the action potential, have been demonstrated to be important modulators of excitability.

Initial clues came from studies of C-fibers (e.g., from sciatic nerve) that generated a slow sodium-dependent spike that was resistant to tetrodotoxin (TTX). Subsequently, this phenomenon was linked to the presence of TTX-R sodium channels and later to the specific isoform responsible for the current, $Na_v1.8$. Multiple studies have now shown that there are large variations in sodium current parameters in DRG neurons linked to expression of a heterogeneous population of sodium channels. Apart from pharmacological intervention using TTX, one can further dissect the channels by using parallel methods of immunohistochemistry and electrophysiological recording, giving insight into the expression patterns and possible roles. A convenient classification method is to use cell size. Using immunocytochemical techniques, large DRG cells have been shown to predominantly express TTX-S channels, such as $Na_v1.6$ and $Na_v1.1$, with some TTX-R $Na_v1.8$ expression. Small cells, which are likely to be nociceptive in nature, predominantly express the TTX-S $Na_v1.7$ channel, in conjunction with TTX-R $Na_v1.8$ and $Na_v1.9$ channels. These findings have been further corroborated using intracellular recording, together with immunohistochemistry, to show the expected distribution of channels in particular fiber types, such as $Na_v1.9$, which is almost exclusively confined to nociceptive fibers (Figure 1).

Several studies have shed light on the distinct roles of the different sodium channel isoforms in DRG neurons. The TTX-S currents of large DRG neurons tend to have relatively fast recovery from inactivation (repriming) characteristics, which correlates with the predominant expression in these neurons of $Na_v1.6$, an isoform that displays this characteristic when expressed and studied in isolation in DRG. In contrast, small DRG neurons tend to have slow repriming, which corresponds to the expression of $Na_v1.7$. $Na_v1.6$ is a channel that has been linked in some cell types with production of a resurgent current, an inward current that occurs upon repolarization. In line with this is the observation that many large DRG neurons can produce resurgent current, whereas small neurons do not.

As mentioned previously, the action potential of many small DRG neurons is broad and the upstroke has been associated with the presence of the kinetically

Figure 1 Putative roles of sodium channel subtypes in DRG action potentials. Subthreshold responses and overshooting action potentials are shown from small and large DRG neurons. In the small neuron, Na$_v$1.7 (and Na$_v$1.9 in some cells) is likely to bring the neuron toward threshold, whereas Na$_v$1.8 is the main channel responsible for the overshooting action potential. Note the large depolarization necessary for action potential activation, due to the depolarized characteristics of Na$_v$1.8. In contrast, larger DRG neurons are likely to have a more hyperpolarized threshold for action potential overshoot, in line with the predominance of TTX-S (Na$_v$1.1 and Na$_v$1.6) channels requiring less depolarization for activation. RMP, resting membrane potential.

slower TTX-R Na$_v$1.8 current. Thus, the majority of nociceptive fibers predominantly rely on current via Na$_v$1.8 for the upstroke of the action potential, rather than completely on TTX-S currents, as is the norm in the majority of excitable cells. Na$_v$1.8 carries a current which has very depolarized voltage dependence of activation and inactivation and is extremely resistant to depolarization. However, TTX-S currents do still play a role in the action potential, especially around threshold. One of the major candidates is Na$_v$1.7, which has been suggested to amplify subthreshold generator potentials. This is due to one specific property – the slow onset of inactivation. It is thought that under conditions in which there is slow depolarization, this particular channel would tend to remain available for activation, in comparison with other channels. This would make it a prime candidate to be able to produce ramp currents (responses to small, slow depolarizing stimuli), and this isoform has indeed been shown to produce a robust ramp current in response to slow depolarizations. Mutations in this Na$_v$1.7 have helped to demonstrate its role as a threshold channel that can interact with Na$_v$1.8 to produce repetitive firing behavior, as discussed in further detail later.

The role of Na$_v$1.9 in firing behavior of nociceptive DRG is unclear. Na$_v$1.9 produces a TTX-R, persistent current, which may be active around the resting membrane potential (RMP) due to hyperpolarized midpoints of steady-state inactivation and activation that lead to a large predicted window current. Modeling studies suggested that Na$_v$1.9 can depolarize the RMP of a neuron and may amplify depolarizing inputs. Subsequent *in vitro* experiments supported the predictions, in which the current was activated via G-proteins, and also showed that the presence of Na$_v$1.9 tends to lower threshold. In contrast, studies from knockout animals suggest that RMP may be unaffected or even hyperpolarized by a mechanism that is not yet understood, although the current may play a role in the sustained depolarization required for repetitive firing involving Na$_v$1.8 since this was eliminated in many cells of the knockout animals.

Excitability of Injured DRG Neurons

Chronic constriction injury (CCI) and axotomy of the sciatic nerve both cause a downregulation in Na$_v$1.8 and Na$_v$1.9 and an upregulation in Na$_v$1.3 expression in nociceptive DRG neurons. Na$_v$1.3 is normally only expressed during early stages of development and is practically undetectable in the adult. These changes are thought to be related to changes in access of axotomized DRG neurons to neurotrophic factors such as nerve growth factor and glial-derived neurotrophic factor because these effects can be reversed by increasing their levels.

The effect of replacement of Na$_v$1.8 and Na$_v$1.9 by Na$_v$1.3 in injured DRG neurons on firing behavior provides an excellent example of the effects that plasticity of ion channels can have on a neuron. As previously stated, the TTX-S current of small, nociceptive DRG normally recovers from inactivation slowly, and this current has largely been correlated to Na$_v$1.7 expression. The current produced when Na$_v$1.3 is expressed in a cell line or in DRG neurons reprimes rapidly and may boost subthreshold responses due

to a robust ramp current. Therefore, previously subthreshold inputs may generate action potentials in the presence of $Na_v1.3$ and, in addition, high frequency firing may be more sustained.

Inflammatory Pain

Additional factors may also be involved in inflammatory pain. Here, long-term chronic changes in expression may occur in addition to shorter term acute alterations in behavior of existing channels. Models of inflammatory pain, such as carrageenan injection into the hindpaw, produce an upregulation of TTX-S channels $Na_v1.3$ and $Na_v1.7$ in DRG after a few days, together with a parallel increase in the TTX-S current. This is in addition to an increased expression of $Na_v1.8$ and a boosted TTX-R current. In contrast, $Na_v1.6$ and $Na_v1.9$ are unaffected in the inflammatory response. These changes would amplify previously subthreshold inputs ($Na_v1.3$ and $Na_v1.7$) and help in sustaining repetitive firing under prolonged depolarization ($Na_v1.3$ and $Na_v1.8$). $Na_v1.8$ is also likely to be involved in acute inflammatory pain because administration of agents such as prostaglandin E_2 (PGE_2) and 5-HT produces an increase in current amplitude and a hyperpolarizing shift in activation, both likely to increase excitability. Evidence also points toward the involvement of $Na_v1.9$ in the inflammatory response. Acute administration of the inflammatory mediator PGE_2 causes a large increase in the steady-state current amplitude of $Na_v1.9$, a channel which, when knocked out in the mouse, produces deficits in the inflammatory response. These data suggest that $Na_v1.9$ may play a significant role in the increased excitability of nociceptive fibers during inflammation, either by RMP effects or by sustaining depolarization. Taken together, the previous findings indicate that changes in multiple ion channels due to either levels of expression or modulation of the existing isoforms can have profound effects on the firing behavior of DRG and suggest that particular isoforms may be more important targets for treatment at different stages of a pathology.

Demyelination and Multiple Sclerosis

Misexpression of ion channels may also be of importance in demyelinated peripheral axons, such as that which occurs during multiple sclerosis, leading to slowing of conduction and conduction block. $Na_v1.6$ is normally concentrated at nodes of Ranvier along myelinated axons, but subsequent to demyelination, the channel can be found expressed along the long lengths of some axons, including the centrally projecting axons of DRG neurons within the dorsal columns. With normal development, $Na_v1.2$ is often the initial sodium channel at immature nodes of Ranvier, which is then replaced by $Na_v1.6$ at later stages. $Na_v1.2$, which is normally expressed along the lengths of premyelinated axons, also reemerges along some demyelinated axons, including the axons of DRG neurons within the dorsal columns. When the properties of these channels have been compared by expression studies in DRG neurons, $Na_v1.6$ has been found to have a greater persistent current. This current may provide a sustained sodium conductance that can drive the reverse Na^+/Ca^{2+} exchanger which contributes to axonal degeneration. Consistent with this, the Na^+/Ca^{2+} exchanger has been found to be co-localized with $Na_v1.6$ in injured axons, whereas it was co-localized with $Na_v1.2$ in axons that did not display signs of injury. In addition, $Na_v1.2$ was found to have more depolarized voltage dependence of activation and inactivation than $Na_v1.6$ in DRG. $Na_v1.2$ may therefore allow a damaged and depolarized neuron to continue to fire action potentials, thus sustaining function. These observations suggest that specific expression patterns of these two isoforms can have profound effects on the survival or degeneration of particular axons and also on maintenance of the signal-carrying function following demyelination.

Ion Channel Mutations Associated with DRG

As mentioned previously, an important characteristic of $Na_v1.7$ is its behavior in response to slow ramp depolarizations which mimic natural small depolarizations such as generator potentials. $Na_v1.7$ displays a larger ramp current than other sodium channel isoforms so that it may function as a threshold channel.

Inherited erythromelalgia (also known as erythermalgia), a disorder in which patients suffer burning pain in their extremities, has been linked to mutations in $Na_v1.7$. These mutations tend to cause a negative shift in the voltage dependence of activation, often accompanied by an increased ramp current. When the effects of these mutations on firing behavior of DRG were examined, there was a lowering of threshold for single action potentials and high-frequency firing. These mutations in $Na_v1.7$ may also cause a depolarization of a neuron in which they are expressed, possibly due to the larger persistent current around the RMP. This depolarization could inactivate many TTX-S channels with relatively hyperpolarized steady-state characteristics, a factor that would tend to decrease excitability. However, $Na_v1.8$ is responsible for the overshooting action potentials in the majority of small DRG neurons and has very depolarized activation and

inactivation properties compared to other isoforms. This suggests that even if some of the erythromelalgia mutations caused a depolarization of DRG neurons, the essential $Na_v1.8$ channel would still be available for action potential firing and, in fact, the neuron would be closer to the activation of those channels, which would decrease the threshold for firing. Conversely, this implies that neurons which do not express $Na_v1.8$ would display hypoexcitability in response to mutant $Na_v1.7$ expression rather than hyperexcitability.

This hypothesis has been tested directly in a study in which the effects on firing behavior of expression of an erythromelalgia mutated $Na_v1.7$ channel were compared to those of wild type in DRG neurons and in superior cervical ganglion (SCG) sympathetic neurons (the other type of neuron in which $Na_v1.7$ is expressed), which do not express $Na_v1.8$. The mutation caused an $\sim$5 mV depolarization in resting membrane potential in both types of neurons. The threshold for firing of single action potentials and high-frequency firing was decreased in DRG neurons (hyperexcitability). However, the opposite occurred in SCG neurons, in which an overall reduction in excitability was seen, presumably due to inactivation of sodium channels essential for the action potential upstroke. Subsequent addition of $Na_v1.8$ into SCG neurons allowed these cells to fire action potentials despite the depolarization. This suggests that channelopathies in general may have very different effects on firing properties, dependent on the other channel isoforms present where the mutations are expressed.

Modulation of Excitability by Cofactors and Phosphorylation

Thus far, we have mainly discussed alterations in firing behavior caused by differential expression of specific sodium channel isoforms in a specific cell type, DRG neurons. Studies have revealed that the cellular background in which particular channels are expressed is an important determinant of behavior of the isoform. These differences are likely caused by selective expression of particular associated proteins.

One such factor is contactin, a cell adhesion molecule that has been shown to associate with $Na_v1.2$, $Na_v1.3$, and $Na_v1.9$, probably by the intracellular C- and N-termini, via a linker protein such as β_1 so that it enhances the channel density at the plasma membrane. The interaction with $Na_v1.3$ may play a role in accumulation of the channel within the neuroma and DRG of a transected sciatic nerve and therefore the emergence of a rapidly repriming sodium current. In a nonpathological setting, recordings from DRG of contactin knockout animals suggest that contactin does not affect the channel density of the TTX-S currents present (likely $Na_v1.6$ and $Na_v1.7$) but does increase the amplitude of both the slow and persistent TTX-R currents (produced by $Na_v1.8$ and $Na_v1.9$) in a subset of neurons. These data demonstrate that contactin is likely to influence the trafficking and expression of particular sodium channel isoforms to selected compartments and thus influence their firing properties.

Other proteins have been shown to not only boost the channel density at the plasma membrane but also to change the properties of the channel. This has been shown, for example, for fibroblast growth factor homologous factor 2A (FHF2A) and -2B (FHF2B). These proteins associate with $Na_v1.6$ via the C-terminus of the channel, and both cause an increase in current density in cells in which they are co-expressed. FHF2B causes a moderate and FHF2A a large positive shift in the voltage dependence of inactivation, but the largest difference is demonstrated with recovery from inactivation. FHF2A drastically inhibits repriming of $Na_v1.6$, leading to a large accumulation of inactivation during repetitive stimulation. In contrast, FHF2B allows a quicker recovery of channels. These effects would likely influence the response of a neuron to sustained depolarization, where FHF2A would be expected to inhibit repetitive firing. Interestingly, FHF2B is selectively expressed at nodes of dorsal root sensory but not ventral root motor axons, whereas FHF2A is localized in unmyelinated fibers which originate from small DRG neurons. The differential expression of FHF2B may contribute to differences in the electrogenic properties of motor versus sensory fibers. The presence of FHF2A in small DRG neurons may help explain the anomalous observation that TTX-S current is slowly repriming in small DRG, despite $Na_v1.6$ as well as $Na_v1.7$ being present in these cells. A protein such as FHF2A may be responsible for slowing the recovery from inactivation of $Na_v1.6$ current in these cells.

Sodium channels of DRG can also be modulated by phosphorylation. The current density of $Na_v1.6$ is reduced upon activation of p38 mitogen-activated protein (MAP) kinase, which has been shown to be upregulated in certain pain conditions. Phosphorylation is via a single site on the intracellular linker connecting domains I and II of the channel, but the mechanism of the change in current density is not known. One study found that $Na_v1.8$ may also be modulated by p38 but in the opposite direction. Tumor necrosis factor-α (TNF-α) is a proinflammatory cytokine that has been linked to enhanced sensitization during inflammation. Mechanical sensitization due to TNF-α was found to likely occur via an increased TTX-R ($Na_v1.8$) current in a p38 MAP kinase-dependent manner. As previously mentioned, $Na_v1.8$

current can also be increased via the protein kinase A cascade (whereas $Na_v1.2$ is decreased); thus, TTX-S and TTX-R channels may display differential modulation by phosphorylation.

Conclusions

Excitability of DRG can be affected by changes during development and by a variety of pathologies and injuries. However, the control of firing behavior has increasingly been linked to alterations in expression of specific isoforms with different biophysical characteristics or modulation of existing ion channels. Sodium channels, which were once thought to be uniform in terms of biophysical properties and responsible for a single characteristic (the rising phase) of an action potential, have been shown to be able to play multiple roles in electrogenesis and thus can finely tune the behavior of excitable cells. Not unexpectedly, alterations in expression or physiological properties of sodium channels thus contribute to altered function of neurons such as DRG neurons following injury.

Introduction

Diffuse subcortical band heterotopias (SBHs) are neuronal migration disorders that have been described pathologically as well as on clinical and imaging basis under the names of double cortex, bicortical lissencephalies, partial lissencephalies, subcortical laminar heterotopia, or laminar band heterotopias (OMIM #300067). In this brain malformation, two cortical plates, separated by white matter, coexist: one cortical plate is in a normal superficial position while the other one is located in a deep heterotopic position and is separated from the lateral ventricle by another area of white matter. This malformation is generally isolated without any other malformation although in a few occasions it can be associated with pachygyria. A large spectrum of clinical manifestations can be observed in this condition: reported patients have usually moderate to severe developmental delay and an early onset of medically refractory seizures but other patients can have relatively mild clinical manifestations. Mutations in DCX gene (or XLIS gene; OMIM #300121) are responsible for an X-linked neuronal migration disorder where females display SBH (or double cortex syndrome) (Figure 1) and males have lissencephaly (Figure 2). This gene encodes a protein, doublecortin, which is a microtubule-associated protein (Map) expressed by migrating and differentiating neurons. The majority of cases of SBH have been found to be linked to abnormalities in DCX. Some genotype–phenotype correlations for SBH patients are being proposed.

Genetic Bases

Recent studies suggest that almost all familial cases of SBH are linked to mutations of DCX, while up to 80–85% of sporadic female cases and about 25% of sporadic male cases of SBH are linked to mutations in the same gene. DCX mutations are generally associated with anterior greater than posterior migration abnormalities. DCX is located on the long arm of the X-chromosome (Xq22.3–q23) and is inherited in an X-linked dominant manner. In general, affected hemizygous males have a more severe phenotype (lissencephaly) than affected heterozygous females (SBH). This observation, which is classical for X-linked dominant diseases, could suggest that in female patients, due to random X-inactivation, neocortical neurons expressing the mutated DCX will fail to migrate properly while neurons expressing the nonmutated DCX will migrate to the superficial cortical plate. In contrast, in male patients, due their obligate homozygous status for DCX, all neocortical neurons will fail to migrate properly.

In addition, DCX mutations have been described in male patients with SBH and in female patients with anterior greater than posterior lissencephaly. Male patients with SBH and associated DCX mutations were recently shown to exhibit somatic mosaicism of these DCX mutations in hair root cells. Although brain mosaicism for DCX mutation remains to be confirmed in these patients, one can make the hypothesis that this somatic mosaicism underlines the less-severe migration disorder in these male patients.

For what concerns female patients with lissencephaly associated with DCX mutations, one potential explanation would be a skewed inactivation of DCX in migrating neurons. Analysis of lymphocytes has failed to support such a skewed inactivation of DCX but analysis of brain tissue would allow testing this hypothesis directly.

Mutations of LIS1 gene are associated with isolated type 1 lissencephaly or with Miller–Diecker syndrome. Lissencephaly observed in male patients with DCX mutations has an anterior greater than posterior distribution while type 1 lissencephaly due to mutations of LIS1 gene has a posterior greater than anterior distribution. Of note, some male patients with posterior greater than anterior SBH have been shown to have mosaic mutations of LIS1.

Reported mutations in DCX include deletions, nonsense mutations, and missense mutations, leading to truncated protein or amino acid changes. Most of these reported mutations cluster in two hot spot regions of DCX called R1 and R2. These R regions code internal tandem repeats which are both required for assembly of Dcx with microtubules.

Imaging Studies

As mentioned above, migration disorders associated with mutations in DCX have an anterior-predominant distribution while migration disorders associated with mutations in LIS1 have a posterior-predominant distribution.

Figure 1 Diffuse subcortical band heterotopia imaged by MRI in three separate female patients with mutations in DCX gene. (a) Courtesy of Dr. Thierry Duprez, Service de Radiologie, St-Luc Hospital, University of Louvain Medical School at Brussels, Belgium.

Figure 2 Lissencephaly imaged by MRI in a male patient with mutation in DCX gene.

SBH associated with DCX mutations can be divided into three different classical groups according to severity: (1) generalized thick SBH with an anterior greater than posterior gradient; (2) generalized thin SBH with an anterior greater than posterior gradient; and (3) thin SBH restricted to frontal lobes. Interestingly, patients with generalized (thin or thick) SBH tend to have more severe mutations in DCX than patients with SBH restricted to frontal lobes. A recent imaging comparison of male and female patients with SBH revealed that some female patients displayed more frequently classical anatomical types such as diffuse SBH or SBH with anterior predominance while some more unusual anatomical subtypes such as posterior SBH associated with anterior pachygyria or diffuse SBH with posterior predominance were more frequently or exclusively observed in male patients.

Functional magnetic resonance imaging (fMRI) has been performed in a few patients with SBH, yielding interesting results. Using simple motor tasks and/or sensory stimulus, different groups were able to show that motor and sensory tasks induce activation of the

SBH. In addition, when compared to controls, these tasks induce the recruitment of bilateral primary areas and more numerous higher-order association normotopic cortices, suggesting the need for a more widespread network to perform simple tasks in patients with SBH. Positron emission tomography (PET) scan with [18F]-fluorodeoxyglucose performed in a patient with SBH revealed that band heterotopia had the same degree of glucose metabolism as that of the overlying cortex.

Neuropathology

At the macroscopic level, SBH appears in females as nodular or confluent masses of gray matter forming a contiguous subcortical band. This laminar band is clearly separated from the overlying cortex (which looks normal except in cases associating SBH and pachygyria) and the lateral ventricle by white matter tracts. The extent of this band can be variable with bilateral or unilateral laminar heterotopia and diffuse or local laminar heterotopia. Also, the thickness of these laminar heterotopia can be thick or thin. As mentioned above, in DCX mutations, the distribution of this laminar heterotopia shows an anterior versus posterior predominance.

At the microscopic level, SBH does not exhibit any typical histological feature except for an increased number of neurons in the superficial layer, and a smaller appearance of pyramidal neurons in some cases. Between both layers, a large zone of hypomyelinated brain parenchyma containing neurons can be observed. Neuronal nodules appear surrounded by normally myelinated fiber tracts.

Most of male patients with DCX mutations display lissencephaly rather than SBH. Until recently, it was considered that the DCX-linked migration lissencephaly was similar to the lissencephaly associated with mutations in LIS1 and observed in isolated type 1 lissencephaly or Miller–Diecker syndrome. However, imaging studies comparing patients with DCX and LIS mutations have revealed different distribution patterns of lissencephalies (anterior vs. posterior predominance). Similarly, neuropathological studies comparing patients with DCX and LIS mutations have revealed different distribution patterns of agyria–pachygyria (anterior vs. posterior predominance). Sylvian fissures are abnormal, due to hypoplasia of the frontal opercula, and sometimes of the frontal lobes. The lack of primary and secondary sulci predominates in the frontoparietal areas. On coronal sections, the corpus callosum is short and thick, but the basal ganglia appear as normal. The cortical ribbon is poorly demarcated from the white matter (Figure 3).

Neuropathological studies have shown that, although brains with LIS1 deletions exhibited the classic inverted four-layer lissencephalic architecture, male patients with DCX mutations and lissencephaly had unique cytoarchitectural findings distinct from LIS1 including a roughly ordered six-layer lamination (Figure 3). The molecular layer is paucicellular, the layer II (external granular cell layer) is absent, and replaced by a highly cellular and thick band of medium-sized and large, often inverted, pyramidal neurons devoid of laminar organization. Under a paucicellular layer III, layer IV is also thick and composed of small-sized neurons. In the underlying white matter, multiple clusters of heterotopic neurons arranged in a columnar fashion are observed (layer V), as well as nodules (layer VI) located in the vicinity of the ventricular wall. The striatum is disrupted by the columns. Brain stem structures are generally normal, although decreased basis pontis neuronal populations and olivary pachygyria have been described. The deep cerebellar nuclei are dysplastic and the cerebellar white matter contains heterotopic nests of Purkinje cells.

Clinical Aspects

A large spectrum of clinical manifestations can be observed in this condition: reported patients have usually moderate to severe developmental delay and an early onset of medically refractory seizures but other patients can have relatively mild clinical manifestations. Epileptic manifestations, if present, are often partial complex seizures or atypical absences with focal or regional onset.

A study comparing male and female patients with SBH showed that the range of clinical phenotypes in male patients greatly overlapped that in female patients. However, female patients tend to have mild to moderate clinical symptoms while male patients tend to have less severe or more severe clinical symptoms than females. This gender-related distribution of clinical signs is globally correlated with the gender-related distribution and severity of anatomical abnormalities.

Genotype–phenotype correlations for SBH are emerging but remain weaker than those observed for lissencephaly. More severe mutations tend to be observed in sporadic cases when compared to familial cases.

Genetic counseling remains a difficult area in SBH. In SBH cases with DCX mutations, a variable penetrance (potentially due to random X-inactivation-induced somatic mosaicism, modifying genes and/or environmental factors) has been observed. Furthermore, silent carriers of DCX mutations have been reported. In the case of silent carrier, it is suggested

Figure 3 Lissencephaly in a male patient with mutation in DCX gene. (a) Macroscopic coronal section of the telencephalon passing through hippocampic gyri, showing the poor delineation between gray and white matter, with an inverted ratio gray/white matter. (b) Representative microphotograph of the frontal lobe: the cortical ribbon is extremely thick as well as the corpus callosum. (c) Higher magnification showing the superficial cortical layers. (d) Higher magnification showing the deep cortical layers with periventricular heterotopic neuronal nodules (right) and neuronal columnar heterotopias (left).

that there is a 10% risk to have a second child affected after the diagnosis of the first, the real risk being linked to the level of mosaicism and whether germ cells are involved by the mutation. Finally, in male patients, DCX mutations are only responsible of a fraction of cases of SBH, suggesting the existence of other genes involved with potentially different transmission and penetrance than DCX mutations.

Pathophysiology

Studies over the last decade have identified several molecules involved in the control of neuronal migration and targeting of neurons to specific brain regions. These molecules can be divided into four broad categories (Figure 4): (1) molecules of the cytoskeleton which play an important role in the initiation (filamin-A and Arfgef2) and ongoing progression (Dcx, Lis1, 14–3-3epsilon, Map1B, Map2, and Tau) of migration; (2) signaling molecules playing a role in lamination (Reelin, Disabled-1 (Dab1), ApoE receptor 2, and very low density lipoprotein receptor (Vldlr); p35, cdk5, and Brn1/Brn2); (3) molecules modulating glycosylation (protein *O*-mannosyltransferase, protein *O*-mannose β-1, 2-*N*-acetylglucosaminyltransferase, and Fukutin) which seem to provide stop signals for migrating neurons; and (4) other factors which have been shown to modulate neuronal migration (glutamate, γ-aminobutyric acid (GABA), brain-derived neurotrophic factor (BDNF), thyroid hormones, molecules deriving from peroxisomal metabolism, and environmental factors such as ethanol and cocaine). Recent studies have highlighted significant cross talk between the groups of molecules.

Neuronal migration involves two distinct phases: extension of the leading process and movement of the cell body and nucleus (nucleokinesis). Movement of the centrosome (microtubule organizing center) in the leading process, in front of the nucleus, precedes movement of the nucleus toward the centrosome. Nucleokinesis requires, among others, the dynein/Lis1/Ndel1 complex, Map's including Dcx, signaling molecules (cdk5, which phosphorylates Dcx and Fak), and stop molecules (Fak). The positioning of the centrosome in the leading process and the dynamic coupling and uncoupling of the nucleus to the microtubule network and centrosome seem to be key events of neuronal migration.

Figure 4 Schematic representation of some critical molecular modulators of neuronal migration illustrating the cross talk between different groups of molecules including cytoskeletal proteins, signaling molecules of the Reelin pathway, NMDA receptor-mediated pathway, and peroxisome-derived factors. This scheme highlights the central position of Dcx and Lis1 in the cytoskeletal machinery controlling migration.

Several recent studies have focused on the mechanisms of action of Dcx. Although mutations in DCX are responsible for SBH, the precise role of Dcx in the control of neuronal migration is not yet totally understood. Dcx could act as a molecular link between microtubule and actin cytoskeletal filaments. As mentioned above, two R (R1 and R2) regions coding internal tandem repeats are required for assembly of Dcx with microtubules. Dcx microtubule affinity is regulated by a balance of kinase and phosphatase activity. In addition, two other reports suggest roles of Dcx which are not directly related to microtubules. Dcx interacts with c-Jun N-terminal kinase (Jnk) and Jnk interacting protein (Jip), suggesting the involvement of Dcx in a signaling pathway. Dcx was also shown to interact with the ubiquitin-specific protease *Drosophila* fat facets related on X-chromosome (Dffrx), which prevents degradation of different molecules including β-catenin by the proteasome, suggesting a potential role of Dcx in the regulation of cell adhesion.

Further confirming the role of Dcx in neuronal migration, *in utero* electroporation of plasmids encoding short hairpins RNA to create interference (RNAi) of Dcx protein in embryonic rats induces two types of neocortical neuronal migration defects: many neurons stop their migration in the intermediate zone (prospective white matter) and form an SBH; in addition, many neurons migrate into inappropriate cortical layers within the normotopic cortical plate. Interestingly, SBH contains transfected pyramidal neurons as well as nontransfected cell types, suggesting that affected cells also influence the migration of neighboring neurons expressing normal levels of Dcx. Cells in the SBH display a multipolar stage, which occurs as bipolar progenitor cells become radially migrating neurons. This multipolar stage seems to be a critical checkpoint of migration and therefore a vulnerable stage for disruption of neuronal migration.

Two other animal models of SBH are currently available: the ibotenate-induced laminar heterotopia in the newborn hamster and the tish (telencephalic internal structural heterotopia) rat. Focal injections of ibotenate (a glutamate analog mainly acting on *N*-methyl-D-aspartate (NMDA) receptors) into the brain of hamsters on the day of birth (a stage where neurons destined to the superficial cortical layers are migrating) induces different types of migration abnormalities, including SBH, focal periventricular

nodular heterotopia, or intracortical arrests of migrating neurons. The tish rat is a spontaneously mutant animal exhibiting a bilateral laminar band heterotopia which predominates in the frontal and parietal cortex. The laminar heterotopia seems to be secondary to the combination of abnormal neuronal migration and heterotopic neurogenesis. Affected rats exhibit spontaneous recurrent electrographic and behavioral seizures.

Introduction

Down syndrome (DS) is caused by trisomy (i.e., the presence within the genome of three copies) of chromosome 21 (HSA21). Infants with DS constitute about 1 in every 700 live births in the United States. Not surprisingly, the presence of an extra copy of nearly 300 genes results in many abnormalities. DS affects many organ systems: cardiovascular, digestive, endocrine, immune, reproductive, musculoskeletal, and nervous systems (Figure 1).

DS is a lifelong condition, often resulting in multiple medical interventions and ongoing management of chronic disease and disability. Many individuals with DS need special education and residential, medical, and social services for the duration of their lives. They have often been stigmatized and marginalized in society. Even during the twentieth century, they were subject to harsh institutionalization practices and medical neglect. Deinstitutionalization and the development of community care models, coupled with medical and scientific advances, have dramatically increased the quality of medical care, education, and the life expectancy for people with DS.

In addition to its consequences for the health and well-being of affected individuals, DS exacts a significant economic cost to society through the provision of medical and social services. The total yearly cost (i.e., both medical and nonmedical) is estimated to be $54–123 billion for the USA (350 000 cases at $156–353 000 per case). Furthermore, the increase in life expectancy for people with DS has been quite remarkable. The median age at death for people with DS has increased from 2 years in the 1950s to 50 years in the 1990s. While much has been accomplished in improving not only the longevity but also the quality of life for people with DS, increased life expectancy has given rise to medical and social concerns related to the aging of this population.

In the sections that follow, we first trace some of the historical, epidemiological, and etiological aspects of DS. We then discuss its clinical manifestations. Focusing on the nervous system, we point to recent research advances in pathophysiology and outline some prospects for future research and therapeutic interventions.

History

Although DS was recognized and represented in the arts as long ago as 1500 BC, its conception as a distinct and natural entity was formed within the emergence of specialty asylums in England and Wales in the mid-nineteenth century. These types of institutions were built in a time of optimism with regard to rehabilitation and training of those deemed cognitively deficient.

J. Langdon Down of the Earlswood Asylum (UK), in the 1860s, is credited for having identified the syndrome that later carried his name. He formalized his concept of 'Mongolian imbecility' in 1866. He characterized the population according to his perception of how they looked in ethnic and racial terms, identifying those who are now regarded as afflicted with DS not only as looking remarkably alike one another, but also resembling Mongols. Drawing from the social evolutionary theory of his day, Down theorized that these people were evidence of regression to a lower racial state in a hierarchy of races, a spontaneous reversion of individuals to earlier 'premoderns.'

Down's racial argument held sway for several decades until successfully challenged by Lionel Penrose. Penrose argued that there was no evidence of increased 'Mongol' blood in persons with DS, using statistical analysis and extensive blood investigation. He was perhaps the first to reject the name 'Mongolism' in the 1930s; however, it was not until 1966 that the World Health Organization officially replaced the name with 'Down syndrome' (note: per a 1974 *Lancet* article, the singular, rather than possessive, form of 'Down' is preferred).

The latter half of the 1950s was a watershed for genetic inquiry and for the conceptualization of DS. In 1959, Jérôme Lejeune of France published his observations that there was an extra chromosome present in the smooth muscle tissue of people with DS. Immediately following, Patricia Jacobs also linked the disorder to an extra copy of chromosome 21. This model of the DS chromosomal anomaly was used as a foundation in identifying other autosomal disorders and was a landmark discovery for medical genetics. The research on DS reached its climax in 2000 when the complete sequence of human chromosome 21 was published by Hattori and colleagues.

Over the past 40 years, parental and professional advocacy have dramatically affected the lives of persons with DS, impacting institutional practices, education, work opportunities, and clinical care. Advances in pediatric medicine have been especially

Figure 1 Schematic representation of systems affected in Down syndrome. Text colors indicate the assigned frequency of occurrence of each feature.

important in identifying and treating the conditions associated with DS, facilitating survival and longevity.

Epidemiology

Humans are highly susceptible to numerical abnormalities in chromosomes (i.e., to aneuploidy). It has been estimated that around 20% of human oocytes and 1–2% of sperms are aneuploid. As a result, it is estimated that approximately one-third of all miscarriages in humans involve abnormal numbers of fetal chromosomes. This mechanism of natural elimination leads to a drastic reduction in the number of aneuploid liveborn babies). Only 0.3% of newborns are aneuploid.

The most important risk factor for aneuploidy in humans is the age of the mother. At the maternal age of 20 years, around 0.058% of liveborn infants are diagnosed with DS. This elevates to 4.12% at the maternal age of 46 years – a 70-fold increase in incidence rate. Unlike sperm cells, after entering into meiotic prophase I before birth, oocytes enter into an extended meiotic arrest which lasts till ovulation. This makes meiosis I very vulnerable to endogenous and exogenous factors. This is supported by the fact that in the majority of cases (65%), human trisomy 21 is due to errors in maternal meiosis I.

According to the United States Department of Health and Human Services, Centers for Disease Control and Prevention, the prevalence of DS from

1983–90 was found to be 9.2 per 10 000 liveborn infants in the 17 states studied. It estimated that 3000–5000 children are born with DS in the USA each year. The annual per-capita cost of $27 000 for children with DS between 0 and 1 year of age, approximately $135 million, will be spent for DS each year due to new cases.

The causes of death for people with DS include congenital circulatory defects, dementia, hypothyroidism, digestive system abnormalities, epilepsy, leukemia, and respiratory illnesses. In the United States, the number of deaths of people with DS is estimated to be 5.6 deaths per 10 000 total deaths (1983–97). As mentioned, life expectancy has increased dramatically for people with DS and is now nearly 60 years. From 1983 to 1997, the average median age at death for people with DS has increased 1.7 years per year – from 25 to 49. The death rate for children with DS presenting with heart abnormalities was reduced from 10.6 per 1000 in years 1988–93 to 1.7 per 1000 in 1994–99 in California.

Clinical Features

The most frequent DS manifestation in newborns is hypotonia. The clinical features of DS are dysmorphic changes involving craniofacial, neck, and limb abnormalities. Manifestations include, but are not limited to, brachycephaly, oblique palpebral fissures, epicanthic folds, flat nasal bridge, folded or dysplastic ears, open mouth, narrow palate, protruding and furrowed tongue, abnormal teeth, short neck with loose skin on nape, short and broad hands, incurved fifth finger, transverse palmar creases, gap between first and second toe, and hyperflexibility. Brushfield spots on the iris and hypotonia are also characteristic for people with DS. Cardiac malformations, thyroid dysfunction, digestive system abnormalities, and seizures are less prevalent (Figure 1), but have greater consequence for individuals with DS. Acute megakaryoblastic leukemia is the most common form of myeloid leukemia in DS and is present at rates reflecting a 466-fold increase in this population. Most males with DS are infertile, probably due to defects in spermatogenesis. Although females with DS often have reproductive system dysfunction, it is possible for them to become pregnant.

Individuals with DS face many medical problems. Perhaps the most important among them is nervous system dysfunction. In addition to hypotonia and seizures, virtually all individuals manifest intellectual disabilities (commonly known as 'mental retardation') to varying degree. The severity of intellectual disability is typically moderate, with Intelligent Quotient (IQ) averaging 40, with a range of 20–70. Children with DS often experience delays in the acquisition of developmental milestones as well as delayed disappearance of primitive reflexes (e.g., the grasp reflex and the Moro response). There are cognitive abnormalities attributable to the abnormal function of the hippocampus and prefrontal cortex (e.g., organizing verbal material according to its categorical structure and active retrieval of stored information); these are significantly impaired in DS. This is in contrast to implicit or nondeclarative memory, which is normal in DS. Pain and temperature sensations are abnormal for these individuals, as the peripheral nervous system is also affected. It is unclear to what extent peripheral nervous system involvement contributes to the burden of the disorder.

Neuroimaging studies in children and nondemented adults with DS complement clinical observations by revealing that their brains are often smaller in relation to their overall body weight. After accounting for the decrease in the size of the brain, the volumes of the hippocampus and cerebellum were smaller while those of the parahippocampal gyrus and subcortical gray matter were increased.

Adults with DS show additional manifestations of central nervous system (CNS) dysfunction. After the age of 40 years, virtually all DS patients develop a neuropathology indistinguishable from that of Alzheimer's disease (AD). Many, but perhaps not all, also show progressive cognitive decline resulting in dementia. It has been shown that the prevalence of dementia in institutionalized DS patients is about 8% in patients 35–40 years old, 55% in patients 55–59 years old, and 75% in DS patients older than 60 years. With increasing life expectancy, the disorders that affect brain aging with DS will become a significant source of medical and social concern.

Etiology

The genetic foundation for DS is HSA21 trisomy. Three hypotheses have been suggested to explain the link between genes and DS phenotypes: (1) the 'gene dosage effect' hypothesis proposes that dosage imbalance of specific genes or sets of genes on HSA21 causes specific DS phenotypes, (2) the 'sensitization model' states that specific phenotypes arise from one triplicated gene, or a small set of specific triplicated genes, but only when many other triplicated genes are also present and active, and (3) the 'developmental instability' hypothesis predicts that small, nonspecific effects of large numbers of genes at increased dose are responsible for DS phenotypes.

Neurobiological Bases for Nervous System Dysfunction in Down Syndrome

Human Studies

Due to the scarcity of postmortem material from humans with DS, the structural and functional bases for intellectual disability in DS are yet to be fully explored. Nevertheless, a number of observations have been made. Macroscopically, prenatal brain weight and shape, fronto-occipital diameter, and the sizes of the brain stem and cerebellum do not distinguish DS brains from controls. At birth, brain weight is generally decreased by approximately 12% in relation to controls and by age 3 to 5 months it is decreased even further. At this age there is shortening of the anteroposterior diameter due to a relative reduction in the size of the frontal lobes, flattening of the occipital poles, and a smaller brain stem and cerebellum. Other postnatal changes in DS include a narrow superior temporal gyrus and diminished sulcation. *In vivo* magnetic resonance imaging studies confirm these changes.

Microscopically, DS brain exhibits changes in synaptic structure and function and in basal forebrain cholinergic neurons.

Synaptic structure and function It has long been believed that synaptic dysgenesis contributes to the cellular basis for mental retardation in DS. If so, the consequences for neuronal circuit function would be significant. Focusing on an important set of structural indicators of synapses, dendritic spine density and morphology, dendritic length, and dendritic complexity have been examined. One caveat to the interpretation of such studies is the paucity of well-preserved tissue for analysis, resulting in relatively few careful studies and a still incomplete characterization of the changes present. Nevertheless, decreased synaptic density in the sensorimotor cortex was detected as early as 32–34 weeks of gestation and included a shift from intermediate contacts to primitive ones in the DS brain. A reduced number of spines, including in hippocampus and cortex, has been reported in both children and adults with DS. Sachio Takashima and colleagues studied a large number of pre- and postnatal DS cases. Although they failed to detect differences in the number of spines in fetal cases, they reported a significant reduction in the number of spines in visual cortex of infants with DS. Echoing this finding are reports on dendritic length in the neocortex: while there are no obvious changes in DS fetal cases, shorter lengths have been recorded in children with DS.

Using the Sholl analysis, Laurence E Becker studied the effects of age on the growth of dendritic length in DS and normal children. It was found that the total dendritic length per cell in layer 3 of the visual cortex was increased by 65% in the control group in transition from the infantile (6 months to 2 years old) to juvenile (>2 years old) period. However, the DS group showed a 50% decrease in the same period. Structural alterations in synapses are assumed to have functional consequences. Unfortunately, the only published physiological studies of human tissue are those of Brain S Scott and colleagues on dorsal root ganglion cells of the peripheral nervous system.

Basal forebrain cholinergic neurons Cholinergic neurochemical markers appear to be intact in prenatal stages of DS. Examining the brains of 3- to 12-month-old DS infants, the activities of the cholinergic enzymes choline acetyltransferase (ChAT) and acetylcholinesterase (AChE) are found to be normal. Remarkably, however, in DS cases ranging in age from 16 to 56 years, there is a significant reduction in the number of neurons and in nucleolar size in the nucleus basalis of Meynert. Of note, these changes are most marked in the oldest patient, who also showed AD-like pathology, drawing a further parallel between the two disorders. Early, preliminary tests of the cholinergic hypothesis have been carried out clinically through treatment with donepezil, an AChE inhibitor. In one trial, adults aged 20–41 years were entered in an open-label treatment with the AChE inhibitor donepezil. While some improvement in expressive language was recorded, the study suffered from a very small number of patients and from lack of a control group. In a more recent trial in children, aged 8–13 years, the same investigators examined the effects on language function of donepezil in an open-label study for 16 weeks in a small number of patients. Improved language performance has also been found in one test.

Mouse Models of Down Syndrome: Defining Nervous System Abnormalities

The development of animal models for disorders with strong genetic components is extremely useful for understanding underlying genetic and molecular mechanisms for pathogenesis. Studies in humans have helped to suggest chromosomal regions and genes that may contribute, but the ability to resolve the basis of important neurological phenotypes is limited. In contrast, recent studies in mouse models are providing important new insights.

The models are of three types. In the first, mice have been created that are trisomic for segments of the mouse chromosomes that are syntenic to HSA21.

In the majority of cases, DS is caused by triplication of the entire HSA21. At least 300 known and predicted genes have been mapped to HSA21. A comparison with the mouse genome shows that a majority of HSA21 orthologs are mapped to the distal end of MMU16 (about 23.2 Mb). Smaller numbers of genes are mapped to mouse chromosomes 17 (1.1 Mb) and 10 (2.3 Mb). It is noteworthy that some human genes are not present in the mouse genome and, correspondingly, that some mouse genes within these regions are not present in the human genome. Given this, it is clear that mouse genomic sequences cannot mirror precisely the genetics of DS. The second type of model consists of mice that carry an extra copy of all or part of HSA21. While of obvious benefit for research studies, such mice are much more difficult to produce and much less data exist concerning DS-relevant phenotypes. The third model includes transgenic mice overexpressing individual genes mapped to HSA21 or MMU16 (e.g., *App*, *Dyrk1A*, *Sod1*, *Sim2*, and *S100β*.

Mice Trisomic for Mouse Orthologs of HSA21

Ts16 and Ts65Dn mice Initial studies were carried out in mice trisomic for the entire sixteenth chromosome. In the first step toward developing a mouse model for DS, mice trisomic (Ts16) for the entire MMU16 were generated. These mice demonstrated a number of biochemical and structural changes similar to those of DS, including basal forebrain cholinergic neuron abnormalities. However, Ts16 mice do not survive beyond birth (Figure 2).

To produce a better model, Muriel T Davisson and colleagues, using γ-radiation, induced reciprocal translocation of T(16C3–4;17A2) and generated a mouse segmentally trisomic for MMU16 called Ts65Dn. These mice, which have normal life spans, have three copies of a fragment of MMU16 extending from *Znf295* to *Mrp139*. In behavioral analyses, Ts65Dn mice reveal significant deficits in hippocampally mediated cognition – spatial and nonspatial learning disabilities, as shown by the hidden platform

	Down syndrome	Tc1	Ts16	Ts65Dn	Ts1Cje	Ms1Cje/Ts65Dn	Ms1Rh1/Ts65Dn	Ts1Rh1
Number of triplicated genes	261–364	240–334	731*	104–132	81–85	22–46	70–98	33
Viability	+	+	–	+	+	+	+	+
Cognitive deficits	Moderate	Severe	ND	Severe	Moderate	Mild	ND	ND
Change in brain structure/function	+	+	+	+	+	ND	ND	ND

Figure 2 Schematic representation of triplicated segments of chromosome 21 (HSA21) in Down syndrome and MMU16 in different mouse models of DS. The asterisk indicates predicted genes for Ts16 (includes many nonorthologs to HSA21); ND, not determined. Based on data from Antonarakis SE, Lyle R, and Dermitzakis ET (2004) Chromosome 21 and Down syndrome: From genomics to pathophysiology. *Nature Reviews Genetics* 5: 725–738; O'Doherty A, Ruf S, Mulligan C, et al. (2005) An aneuploid mouse strain carrying human chromosome 21 with Down syndrome phenotypes. *Science* 309: 2033–2037; Mural RJ, Adams MD, Myers EW, et al. (2002) A comparison of whole-genome shotgun-derived mouse chromosome 16 and the human genome. *Science* 296: 1661–1671; and Olson LE, Richtsmeier JT, Leszl J, et al. (2004) Direct testing does not support a chromosome 21 critical region as the cause of Down syndrome phenotypes when triplicated. *Science* 306: 687–690.

and probe tests in the Morris water maze (MWM). Furthermore, Ts65Dn mice recapitulate a variety of morphological changes detected in the DS brain and are increasingly used as mouse models of DS.

Ts1Cje and Ms1Ts65 mice A second segmentally trisomic mouse was generated by CJ Epstein and colleagues. Ts1Cje mice are trisomic for a fragment of MMU16 extending from *Sod1* to *ZNF295,* but not including a functional copy of *Sod1*. In contrast to Ts65Dn mice, to which they can be compared, Ts1Cje mice are hypoactive; they do show abnormalities in spatial learning and memory but these are less severe than in Ts65Dn mice. Ms1Ts65 mice are produced by crossing Ts65Dn mice with T(12:16)1Cje mice. They are segmentally trisomic for the genetic segment from *Mrp139* to *Sod1,* but not including a functional copy of *Sod1*. Thus, they represent a genetic complement to the Ts1Cje mice. Though little characterized, they show changes in spatial cognition that are significantly less severe than in Ts65Dn mice. This suggests that genes in both the centromeric and telomeric regions of Ts65Dn contribute to changes in hippocampal-dependent learning.

Ts1Rhr and Ms1Rhr mice A recent study examined the hypothesis suggested by human studies that triplication of a 5.4-Mb specific region of chromosome 21, referred to as the Down syndrome critical region (DSCR), causes many DS phenotypes. Using chromosomal engineering, Lisa E Olson and colleagues generated two lines of mice – Ms1Rhr and Ts1Rhr; the former is monosomic for the region of interest (about 33 genes conserved between mice and humans) while the latter is trisomic for it. Ms1Rhr mice crossed to Ts65Dn mice produced animals that were trisomic for most of the genes trisomic in Ts65Dn, but had only the normal two copies of the critical segment. No results of nervous system function have yet been reported, but studies on craniofacial features showed that the DSCR was neither necessary nor sufficient to produce the phenotypes present in Ts65Dn. These studies are important because they chart the direction that future studies will take in examining the contribution of gene segments and individual genes.

Mice Trisomic for HSA21

The limitations encountered by genetically modeling DS through triplication of mouse genes led A. O'Doherty and colleagues to attempt to produce a mouse genome containing an extra copy of HSA21, using the irradiation microcell-mediated chromosome transfer method. The mice appear to carry three copies of about 90% of HSA21 genes. Abnormalities in hippocampal-dependent learning and memory were detected and decreased long-term potentiation (LTP) was detected in physiological studies in dentate gyrus. In addition, there was a reduction in neuron density in the cerebellum. One shortcoming of this model is a high degree of mosaicism within tissues (e.g., in the brain, approximately one-third of cells were not trisomic).

Mice Transgenic for Individual Genes

In order to link DS features to specific genes, transgenic mice have been developed that overexpress single human HSA21 genes or their mouse orthologs. To date, mice overexpressing one of the following genes have been examined: *App*, *Cbs*, *Dscr1*, *Dyrk1A*, *Ets2*, *Hmg14*, *PfKl*, *S100β*, *Sim2*, and *Sod1*. Nervous system phenotypes including defects in learning and memory have been detected in mice transgenic for *App*, *Dyrk1A*, *S100β, Sim2*, and *Sod1*. For instance, mice overexpressing *App* show decreased working memory and learning in the water maze task.

The shortcoming in studies using only one transgene is that the genetic interactions characteristic of DS may not be replicated. Nevertheless, such studies are informative with respect to the possible contributions of individual genes. They make an even more compelling contribution when included in studies in which phenotypes of interest are examined both in the presence of a single gene as well as in mice in which only the third copy of the gene of interest is deleted. Using this paradigm, it may be possible to demonstrate whether an individual gene makes a contribution to a phenotype that is necessary and sufficient.

Defining and Characterizing Nervous System Abnormalities in Mouse Models of Down Syndrome

Synaptic Structure and Function

Pre- and postsynaptic structural and functional abnormalities have been detected in both Ts65Dn and Ts1Cje mice. Although less severe in Ts1Cje mice, both models exhibit significant alterations in spine structure, including a reduction in the density of dendritic spines, enlargement of spine heads, and reduced length of spine necks. Mara Dierssen and colleagues have studied dendrite morphology in 10-month-old Ts65Dn and control mice. They found a significant reduction in the area and number of dendritic branches, length of dendritic branches, and spine density, and in the basal dendritic arbors of layer III pyramidal cells in Ts65Dn mice. Alterations

in spines in the hippocampus were associated with failure to induce LTP in the dentate gyrus and CA1 areas of the hippocampus in Ts65Dn mice.

Basal Forebrain Cholinergic Neurons

Basal forebrain cholinergic neurons (BFCNs, the principle source of cholinergic innervation to the entire cortex and hippocampus) undergo degeneration in DS patients. Studies of BFCNs in Ts65Dn mice and Ts1Cje mice have been carried out. Using the p75 neurotrophin receptor ($p75^{NTR}$), a reliable marker of BFCNs, there was a significant reduction in the number and size of $p75^{NTR}$-positive BFCNs in Ts65Dn versus diploid (2N) controls at 12 months of age, and this was more marked at 18 months. These data have been replicated in several laboratories and using different markers for BFCNs. Nerve growth factor (NGF) plays a critical role in the maintenance of BFCN phenotype, and the changes in BFCN morphology replicate those in which BFCNs are deprived of NGF. NGF signaling was examined in Ts65Dn and Ts1Cje mice and their 2N controls. A series of experiments showed that failed NGF signaling was due to decreased axonal transport rather than to failure in binding or internalization of NGF–NGF receptor complexes. Very recent studies show that the defect in transport is not general, since no decrease in the retrograde transport of fluorogold is detected. This suggests that a specific failure in NGF retrograde mechanisms is causative in Ts65Dn mice.

One gene that is found in three copies in Ts65Dn mice and that has been linked to neurodegeneration is that for the amyloid precursor protein (APP); the *App* gene, the mouse ortholog of the human gene *APP*, is present in the centromeric portion of the trisomic segment in Ts65Dn. Examining NGF retrograde transport in these mice showed a drastic reduction in Ts65Dn mice. A significantly greater level of transport was detected in Ts1Cje mice and the changes in BFCNs were not detected. Interestingly, Ts65Dn mice with only two copies of *App* (Ts65Dn:$App^{+/+/-}$) achieved transport levels for NGF that were more than 50% of those in 2N mice. Thus, deleting one copy of *App* markedly reduced the severity of diminishment of NGF transport, similar to that in Ts1Cje mice. Morphological analysis of BFCNs revealed that while the area of BFCN cell bodies in Ts65Dn (with three copies of *App*) was markedly reduced, in Ts65Dn with only two copies of *App*, it was indistinguishable from that of 2N mice. These results are compelling evidence that increased gene dose for *App* contributes significantly to the disruption in NGF transport and atrophy of BFCNs in Ts65Dn mice. They suggest that the human gene plays the parallel role in people with DS.

Hippocampal Functions

LTP and long-term depression (LTD) are commonly used as models of synaptic plasticity involved in learning and memory. These parameters have been measured in several subregions of the hippocampus in Ts65Dn (e.g., dentate gyrus and CA1 areas). It appears that failed LTP induction in the dentate gyrus is mainly due to increased inhibition, since suppressing inhibition with picrotoxin, a γ-aminobutyric acid (GABA)-A receptor antagonist, LTP elicitation could be restored.

Cerebellum

DS patients show significantly smaller cerebellar volumes as compared to normal individuals. Olson and colleagues found about a 12% reduction in Ts65Dn mice compared to controls. This may explain failed motor coordination reported in Ts65Dn mice.

Basis of DS Therapy

At present there are no proved treatments for cognitive dysfunction in people with DS. Linking individual genes to particular manifestations of DS is relevant to the goal of understanding and treating its cognitive dysfunction. The goal of linking specific genes to neurological phenotypes is now much closer to realization. In the future, it may be possible to define many more such linkages, thus enhancing opportunities for both understanding the genetic and cellular mechanisms of nervous system dysfunction in people with DS and for treating them effectively.

Introduction

With an incidence of 1 in 800 live births, Downs syndrome (DS) is the most common congenital cause of mental retardation. DS is caused by trisomy of chromosome 21, and it is believed that overexpression of chromosome 21 genes is responsible for the mental retardation and other phenotypic abnormalities of DS. Individuals with DS are typically microcephalic and have characteristic facial features, hypotonia, and small stature. Other phenotypes include congenital heart defects, premature aging, and leukemia. Although its severity may vary, mental retardation remains the most striking and consistent feature of DS. Recent advances in mapping the human genome and constructing mouse models have accelerated progress toward understanding the etiology of the neurobehavioral phenotype in DS. Evidence suggests that mental retardation in DS is associated with both pre- and postnatal events and that neurogenesis, cell division, and survival may be common abnormalities in the DS central nervous system (CNS).

DS children have different degrees of developmental brain abnormalities associated with CNS maturation defects and cortical and hippocampal dysgenesis in particular. Although a wide range of studies have found no differences in terms of shape, weight, and morphology of the DS brain at birth, gross neuropathological differences between DS and control brains have been consistently observed postnatally. For example, the anterior–posterior diameter of brain hemispheres is smaller in postnatal DS brain. In early infancy, narrowing of the superior temporal gyrus is noted together with diminished size of the brain stem and cerebellum. Architectonic abnormalities of the cerebral cortex are also found in infant and adolescent DS brains. Since normal cortical development requires the generation and migration of cells from the ventricular and subventricular zones to the cortical mantle, delayed and disorganized cortical lamination observed in fetal DS brain are believed to be due, in part, to changes in neuronal proliferation and migration. In addition, areal measurements of the dentate gyrus and pyramidal cell layers in the fetal and adult hippocampus indicate that these structures are significantly smaller in DS brain than those in control subjects. For example, a recent high-resolution magnetic resonance imaging (MRI) study gathered quantitative neuroimaging data in children and young adults with DS and reported significantly smaller hippocampal volume in DS groups. These system-level defects reflect abnormalities in histogenesis, axonal and dendritic arborization, and synaptic development which may underlie many of the cognitive deficits seen in DS individuals.

Although conspicuous morphological abnormalities begin to be apparent in postnatal DS brain, reduced expression of synaptosomal-associated proteins in the fetal DS brain indicates that fetal life in DS starts with impaired dendritic spines and synaptosomal structures; these anomalies are manifested in postnatal brain as shortened basilar dendrites and a decreased number of spines with altered morphology. These changes during early life culminate in delayed myelination, fewer neurons, and lower neuronal and synaptic density in the adult DS brain. Although the main underlying factors for these synaptic changes remain to be fully identified, a major hypothesis is that prenatal abnormalities in corticogenesis precede the synaptic abnormalities. Brain development occurs via highly regulated stages of proliferation, migration, differentiation, and synaptogenesis, and each stage must be successfully and expeditiously completed before onset of the next stage to result in proper development and cognitive function. As such, the anatomical and cytological findings in DS and the progressive changes in cognitive function are all consistent with abnormalities during the early stages of embryonic brain development. It is entirely possible that the changes in the histogenesis of the DS brain may be unrelated to the synaptic abnormalities which develop later. Alternatively, it is possible that these two phenomena are linked. This issue has not yet been resolved due to the lack of appropriately staged DS and control tissue. However, considerable evidence in support of the early embryonic etiology of mental retardation in DS has been provided by analyses in several mouse models of DS (Figure 1). Therefore, the relationship(s) between prenatal histogenetic abnormalities and later cognitive dysfunction can now be investigated in animal models of DS.

Ts16

The trisomy 16 (Ts16) mouse model of DS, developed using spontaneous Robertsonian translocations to generate aneuploidy for mouse chromosome 16, take advantage of the substantial homology between human chromosome 21 and mouse chromosome 16. Ts16 fetuses have a number of phenotypic characteristics

Figure 1 Comparison of triplicate chromosome regions in mouse models of DS with the location of specific genes on human chromosome 21 (HSA21). Regions of HSA21 are syntenic with MMU16, MMU17, and MMU10 (mouse chromosomes 16, 17, and 10). The Ts16 model contains an extra copy of the entire MMU16, whereas Ts65Dn, Ts1Cje, and Ms1Cje have smaller segmental translocations.

similar to those of DS subjects including growth retardation, edema, cardiac defects, and anasarca. A wide range of studies on prenatal brain development demonstrate that Ts16 fetuses exhibit altered corticogenesis. In particular, Ts16 neocortical development is described by a delay in radial expansion of the dorsal telencephalic wall and altered timing of neurogenesis of subplate pathfinding neurons. These delays are primarily due to abnormal proliferation of the ventricular zone and subventricular zone stem and progenitor cells, including longer duration of S-phase of the cell cycle and a delay in neuron-generating divisions. Moreover, reduced numbers of neocortical founder stem cells and slowed tangential expansion of the neuroepithelium in Ts16 result in microcephaly. Consequent to the delayed development of the Ts16 neocortex, a reduction in the number of thalamocortical axons is observed just prior to birth in Ts16 mouse embryos. Thus, disturbances in the rate of neocortical histogenesis, found to be due to abnormalities in the proliferating stem cell populations, result in delayed connectivity between the neocortex and subcortical structures.

Intriguingly, these histogenetic changes, which occur during the initial neurogenesis period in Ts16, are compensated for before birth; there is a massive production of neurons during the late stages of neurogenesis, eventually yielding the proper number of neurons. This observation of a histologically normal neocortex at birth is highly reminiscent of findings in DS. However, despite the fact that the Ts16 cortex is of normal thickness at birth, the transient delay during neurogenesis may predispose trisomic embryos to abnormalities in early synaptogenesis. Taken together, studies in Ts16 demonstrate that perturbations in the timing of neuron generation before the final numbers of neurons are produced can lead to subsequent neocortical abnormalities similar to those found in DS. Unfortunately, Ts16 embryos die perinatally, so research on this model has been limited to fetal stages of development. In addition, the Ts16 model also includes genes on mouse chromosome 16 that are not syntenic with human chromosome 21, opening the possibility that some phenotypes observed in Ts16 may not be relevant to DS. Together, these drawbacks of the Ts16 model limit the investigation of links between transient histogenetic delays and mental retardation in DS.

Ts65Dn

The Ts65Dn mouse may be a more relevant trisomy mouse model of DS as it has only a segmental trisomy of chromosome 16 that is orthologous to the DS critical region (DSCR) on human chromosome 21. In contrast to Ts16 animals, Ts65Dn mice live into adulthood and thereby provide the opportunity to test the embryonic theories of DS etiology. Although the genes triplicated in Ts65Dn represent most of those in the DSCR, these mice do not show all of the gross abnormalities frequently observed in DS, including cardiovascular abnormalities and senile plaques or neurofibrillary tangles in aged animals. Nevertheless, Ts65Dn mice display many phenotypic similarities with DS including altered craniofacial structure, obesity, growth retardation, premature aging, and behavioral deficits. Cognitively, there are significant deficits in the development of a number of sensory and motor tasks and defects in learning and memory mediated by the hippocampus in Ts65Dn. These cognitive deficits are analogous to the mental retardation seen in DS individuals. Complementing the behavioral findings, physiological analyses demonstrate a marked suppression of long-term potentiation in the CA1 and dentate gyrus of Ts65Dn hippocampus. In addition, long-term depression is augmented in Ts65Dn CA1 hippocampal neurons. Alterations in inhibitory tone have been hypothesized to underlie these changes in synaptic plasticity.

Stereological morphometric studies demonstrate irregularities in selected regions of the postnatal Ts65Dn mouse brain. Reductions in the volume of CA2, neuronal density in the CA3 and dentate gyrus, and synaptic density in CA1, CA3, and dentate gyrus suggest that altered neurogenesis and/or survival in the Ts65Dn hippocampus may combine with impaired synaptic connectivity to cause the cognitive

impairments. Intriguingly, aged (13–15 months) mice show reduced proliferative capacity in the dentate gyrus, suggesting that postnatal neurogenesis may also be affected in Ts65Dn. In the neocortex, Ts65Dn pyramidal cells are smaller and exhibit less dendritic branching compared to control littermates and these effects parallel those obtained in humans. High-resolution MRI and histological analyses also reveal neuroanatomical parallels between DS and Ts65Dn in the cerebellum. For example, cerebellar volume is decreased in Ts65Dn mice due to fewer granule cells in both the internal granule layer and the molecular layer. Recently, the origin of the granule cell deficit in Ts65Dn cerebellum has been traced to precursors in early postnatal development. These precursors show a substantially reduced mitogenic response to sonic hedgehog (Shh) signaling protein. Purified cultures of trisomic granule cell precursors show a reduced but dose-dependent response to Shh *in vitro*. Interestingly, systemic treatment of newborn Ts65Dn mice with an agonist of Shh pathway increases mitosis and restores granule cell precursor populations *in vivo*. Thus, there is substantial evidence for histogenetic changes being observed during both embryonic and postnatal development in both of these mouse models of DS. Future work will determine whether delays similar to those found during corticogenesis in Ts16 are also present in Ts65Dn, and this will allow a frank examination of the hypothetical links between early histogenetic abnormalities and later cognitive deficits in DS. Altogether, it is now clear that developmental abnormalities in histogenesis and synaptogenesis precede the synaptic and functional deficits which eventually present as mental retardation in DS. These animal model studies now provide a system to test the hypothesis that early abnormalities in CNS formation may underlie the later functional, synaptic, and cognitive deficits found in models of DS.

Basal Forebrain Deficits

Significant abnormalities are observed during development and maturation of the basal forebrain in DS, and in Ts16 and Ts65Dn animal models. DS individuals have fewer cholinergic neurons in the nucleus basalis of Meynert compared to age-matched controls. Similarly, Ts16 mice exhibit a reduction in cortical cholinergic activity and a reduced number of cholinergic cells in the basal forebrain. These cells appear to cease proliferation prematurely, particularly in those regions projecting to the hippocampal formation. Although the number and size of basal forebrain cholinergic neurons (BFCNs) is similar in Ts65Dn and diploid mice during development, adult Ts65Dn mice show an atrophy and progressive loss of BFCNs. Moreover, Ts65Dn mice develop septohippocampal cholinergic neuron degeneration at 12 months of age. These cellular changes are compensated for by increases in choline acetyltransferase (CHAT) enzyme activity of the remaining cholinergic terminals in the hippocampus. Nevertheless the loss of medial septum projections to the hippocampus in Ts65Dn mice may be a causative factor in the learning and context discrimination deficits found in Ts65Dn. Similar to Ts65Dn mice, DS infants appear to have normal septohippocampal cholinergic system and degeneration of this system only appears with aging.

Apoptosis in DS

Substantial evidence suggests that increased apoptosis is involved in many of the abnormalities in DS. DS neurons display an increased rate of apoptosis *in vitro* which may be due to overexpression of the chromosome 21 transcription factor Ets2. Similar to DS, neuronal cell loss is found to be accelerated in Ts16 neuronal cultures as cultured Ts16 hippocampal neurons display an inherited defect in survival response mediated by low concentrations of glutamate; this accelerated neuronal death in Ts16 occurs by caspase-mediated apoptosis. *In vivo* evidence also suggests an increased rate of prenatal apoptosis in DS and Ts16 neocortex. Since normal CNS development involves the sequential differentiation of multipotent stem cells, any alteration of the numbers of stem cells, their self-renewal ability, or their proliferative capacity is likely to have major effects on the appropriate development of the nervous system.

Ts1Cje and Ms1Cje Mouse Models of DS

Ts1Cje and Ms1Cje are recently described partial trisomy 16 mouse models of DS that contain smaller regions of chromosome 16 than the Ts16 or Ts65Dn models. Although few studies on histogenesis and neuron proliferation have been conducted on these newer mouse models, detailed investigation of cerebellar phenotypes has revealed a reduction in granule cell density in both Ts1Cje and Ms1Cje. Moreover, the Ts1Cje hippocampus has reduced long-term potentiation and increased long-term depression, suggesting that abnormal synaptic plasticity may be a common feature of mouse models of DS.

Dream Function

D Kuiken, University of Alberta, Edmonton, AB, Canada

Introduction

Theories of dream function posit a correspondence between the effects of dreaming and what enables the dreamer, in some sense, to thrive. Perhaps the most common proposal is that dreams metaphorically represent disturbing life events and allow the covert review of self-protective or self-restorative responses. Another long-standing hypothesis is that dreaming distinctively reorganizes memories for newly learned tasks and enhances the retrieval of related knowledge and skills. And, still another conception is that dreaming directly alters attention, evokes feeling, and enhances the flexibility and emotional relevance of postdream thought. As is evident from these broad themes, models of dream function vary considerably in their scope and in the nature of the evidence required to substantiate them.

Contrasting Conceptions of 'Function'

Theories of dream function differ markedly in their articulation of the temporal locus of what is beneficial about dreaming. Researchers have sometimes taken a broad perspective, hypothesizing that dreaming facilitates long-term adaptation (e.g., species survival). In contrast, some investigators have identified immediate and transient dream effects (e.g., postawakening attentional flexibility). Also, theories of dream function are usually presented as though all dreams fulfill a common function. Perhaps dreaming is a sufficiently uniform phenomenon to serve consistently some function (or functions), but, by abandoning strict assumptions about highly general dream effects, the contrasting effects of different dream types – for example, nightmares versus night terrors, or rapid eye movement (REM) dreams versus non-REM (NREM) dreams – have also been fruitfully considered.

Contrasting conceptions of the temporal locus and uniformity of dream effects became important when evaluating the efficacy of REM sleep research protocols during the past half century. Although researchers originally posited an isomorphism between REM sleep and dreaming, it is now widely acknowledged that dreaming in some form occurs elsewhere in the sleep cycle, most notably during sleep onset and stage 2 NREM sleep. The implications of these observations remain controversial. Even though dreaming occurs during NREM sleep, it is still unclear whether dreams reported upon awakening from REM sleep are qualitatively or merely quantitatively different from those reported upon awakening from NREM sleep. If REM dreams are qualitatively different from NREM dreams, comparison of the consequences of REM and NREM sleep deprivation may help to establish the contrasting functions of REM and NREM dreams. On the other hand, if NREM dreams are only somewhat more intense but of the same basic type as REM dreams, the psychological functions of 'typical' dreaming can only be weakly clarified by comparing the effects of REM and NREM sleep deprivation.

Moreover, even if the differences between REM and NREM dreams were clearly established, and REM sleep physiology could confidently be regarded as a useful index of REM dreaming, the use of REM sleep research protocols in studies of dream function would leave unresolved an even more basic issue: the psychological function of REM dreaming is not reducible to the physiological function of REM sleep. Thus, even if REM sleep were reliably associated with a distinct form of dreaming, the challenge of differentiating the physiological effects of REM sleep from the psychological effects of REM dreaming would remain. This issue is far from resolved and contributes to very different perspectives on the significance of REM sleep research protocols for studies of dream function.

Dream Carryover Effects

Awakenings from REM and NREM sleep are followed by a brief period ($\approx$20 min) during which thoughts and feelings are systematically altered. Observations during this period are often thought to reflect the nature of mental activity during the sleep stage that immediately precedes awakening. However, these observations are also appropriately considered as the direct influence of the preceding sleep stage on subsequent waking experience.

Carryover Effects of REM Dreaming

In cats, it has been observed that (1) high-amplitude pontogeniculooccipital (PGO) waveforms accompany the orienting response during waking, (2) comparable high-amplitude PGO waves occur spontaneously during REM sleep, and (3) novel auditory stimuli that elicit the orienting response during waking reliably induce PGO waves in both REM and NREM sleep. Such observations suggest that REM sleep is characterized by persistent and spontaneous activation of the orienting response. Correspondingly, in humans, there is evidence that an automatic, stimulus-induced shift of

attention toward unexpected stimuli occurs more quickly during the period immediately following awakening from REM sleep than it does following awakenings from NREM sleep.

Fluidity of thought Such attentional flexibility helps to explain dreamers' post-REM readiness to entertain infrequently considered possibilities. For example, individuals awakened from REM sleep show greater priming by weakly associated words (e.g., thief–wrong) than by strongly associated words (e.g., hot–cold), whereas individuals awakened from NREM sleep show greater priming by strongly associated than by weakly associated words. Also, individuals awakened from REM sleep use strategies that differ from those used during wakefulness to solve simple problems (e.g., anagrams), whereas, after awakening from NREM sleep, strategies for solving these problems more nearly resemble those used during wakefulness. Finally, after REM deprivation, individuals awakened from REM sleep score higher on fluidity and flexibility in traditional tests of divergent thinking than do those deprived of NREM sleep. In sum, numerous findings support the contention that awakenings from REM sleep are more likely than awakenings from NREM sleep to be followed by a brief period of fluid thinking. Whether this fluidity reflects the lingering effects of REM dreaming, rather than the lingering effects of REM physiology, remains, as indicated earlier, unresolved.

Felt presence The fluid thinking that follows REM dreaming acquires additional significance when it is considered that carryover effects also involve the readiness to see motion where it objectively is not. Individuals awakened from REM sleep are more likely than those awakened from NREM sleep to (1) perceive one dot moving between two positions when two stationary dots are alternately presented (the beta phenomenon) and (2) perceive movement in a static figure after a period of concentration on a rotating spiral (the spiral aftereffect). This 'feeling' of motion is complemented by enhanced 'feeling for' objects. After awakenings from REM sleep, performance on a left-handed tactile-kinesthetic recognition task is better than after NREM awakenings (even though analogous differences are not evident with the enumeration of dot patterns). Together these results suggest that the felt presence of objects – rather than simply their visual appearance – is intensified during the period that immediately follows REM dreaming.

Felt position There is also evidence that REM dreaming accentuates the felt sense of the dreamer's position in relation to the external world. It has been proposed that, during REM sleep, the initiation of bodily movement without corollary proprioceptive feedback (a pattern associated with intensification of the orienting response) precipitates perceived adjustments in bodily position. This possibility is consistent with evidence that REM deprivation increases REM density, the associated sense of self-participation (i.e., active participation in the dream scenario), and also the perception of human movement in ambiguous figures after awakening.

Emotional feeling The carryover of emotional dream feelings might seem to follow directly from the preceding findings. However, emotional feeling is attenuated immediately following awakening from a typical REM sleep period, either because of the lingering atonia of that sleep stage or, more likely, because of the mood-regulating function of REM dreams. Regardless of its origin, imaginative expression (e.g., creating stories in response to ambiguous stimuli) immediately after REM awakenings seems to evoke emotional feeling more than does straightforward dream reflection.

Auxiliary effects Carryover effects of typical REM dreaming are subtle and transient. Nonetheless, post-REM fluidity of thought is sometimes not only greater than after NREM sleep but is also greater than during ordinary wakefulness. Correspondingly, there is evidence that reflection on remembered REM dreams is more likely than reflection on remembered NREM dreams to facilitate feeling expression during insight-oriented therapy. Although the carryover effects of typical REM dreaming may exert their adaptive influence especially through timely and vivid recollection, this auxiliary function of dreaming has considerable practical import.

Carryover Effects of Intensified Dreaming

Sometimes dream carryover effects are intensified during the transition from REM sleep to wakefulness and during the period immediately following REM dreaming. These extreme forms of dreaming sometimes have lasting significance.

Sleep paralysis episodes In sleep paralysis episodes, the general atonia of REM sleep persists despite the capacity for external perception and the presence of consciousness. In this liminal state, the accompanying hallucinatory experiences are of three types. One type involves the felt presence of a spatially distant but threatening figure (accompanied by assorted noises, humanoid apparitions, and sensations of being touched), a second type involves the felt presence

of a spatially near and disturbing figure (accompanied by breathing difficulties, feelings of suffocation, and thoughts of impending death), and a third type involves sensations of linear and angular acceleration (e.g., flying, floating), fictive motor movements (ranging from simple arm movements to apparent locomotion), and feelings of bliss. Consistent with laboratory research on REM sleep carryover effects, these three types of transitional dream experience involve the distinctly felt but nonvisual presence of an 'other' and a keenly felt but anomalous sense of 'self.'

The effects of sleep paralysis episodes on waking thoughts and feelings are often direct and persistent. The lingering 'reality' of these dream experiences, traceable to the compellingly felt presence of external objects and the experience of an unembodied but uniquely positioned self, contribute to beliefs about spirit figures and self-transcendence. Whether these effects are lasting and whether they are beneficial depend upon the cultural context – even when these dreams challenge, rather than merely reflect, the surrounding cultural milieu.

Impactful dreams Significant features of sleep paralysis episodes correspond to empirically established types of impactful dreams. Impactful dreams are defined as those that directly influence postdream thoughts and feelings, most likely through the intensification of REM carryover effects. One type, the nightmare, with features such as intense fear, the avoidance of threatening others, and physical metamorphoses, is followed by externally directed vigilance and apprehension. A second type, the existential dream, with features such as intense sadness, rejection by or separation from significant others, and spontaneous feeling change, is followed by sadness, autobiographical review, and changed self-perception. A third type, the transcendent dream, with features such as surprise, magical accomplishment, and shifts in visual–spatial orientation (floating, flying), is followed by astonishment and reported spiritual change. In forms that are analogous to sleep paralysis episodes, nightmares involve the threatening presence of distant external objects, existential dreams involve the disturbing presence of near external objects, and transcendent dreams involve an anomalously positioned self.

The effects of impactful dreams also seem direct. Dreamers are often reluctant to have them interpreted, and there is evidence that, although they may alter the way dreamers understand their daily lives, they do not provide optimal material for therapeutic dream reflection. However, the auxiliary processes by which such intense dream experiences do exert influence on the dreamer's personal, social, or cultural life have not been systematically investigated.

Memory Consolidation

The long-standing hypothesis that memories are reorganized and stabilized during sleep became more focused during the 1970s when researchers began to examine specifically whether REM sleep was the psychobiological state within which memory consolidation occurs. At that time, the apparent isomorphism between REM sleep and dreaming suggested that the processes by which dreams are formed are also the processes by which memories are consolidated. So, REM deprivation became a common means by which memory consolidation was hypothetically disrupted, and assessing the effects of prior learning on REM sleep parameters was often used to assess increased pressure for REM-dependent consolidation. Although research initially supported the memory consolidation hypothesis among animals but not humans, in recent years, studies of human memory during sleep support the role of REM sleep, and by implication REM dreaming, in memory consolidation among humans.

Memory Consolidation and REM Sleep

A turning point in this research occurred with the realization that REM sleep may play a particularly important role in the consolidation of procedural, as opposed to declarative, memory. Review of the literature indicated that, when a task requires the development of perceptual-procedural, verbal-procedural, or cognitive-procedural skills, REM sleep facilitates learning; when the task requires the retrieval or recognition of generic semantic information, REM sleep does not facilitate learning.

Effects of learning on REM sleep In one commonly used research paradigm, a learning task is presented prior to sleep and then REM sleep parameters (e.g., REM density, percentage of sleep in stage REM) are assessed. For example, when people are required to adapt to lenses that distort their visual field, there is a subsequent increase in the percentage of stage REM sleep. Comparable effects have been found after learning verbal-procedural skills (e.g., second language learning) and cognitive-procedural skills (e.g., solving a conceptual problem that involves recursive steps).

Effects of REM deprivation on consolidation In the frequently used REM deprivation paradigm, people are awakened whenever they enter REM sleep, or, in comparison conditions, whenever they enter NREM sleep. In general, as hypothesized, when people are deprived of REM sleep after learning perceptual-procedural skills (e.g., a complex visual discrimination task) or cognitive-procedural skills (e.g., the recursive cognitive

problem), their performance during retesting is impaired. These findings have sometimes been challenged because deprivation procedures are often confounded with the stress precipitated by repeated awakenings from REM sleep. However, some studies of REM deprivation have demonstrated that performance disruption is still evident several days after the termination of REM deprivation and, hence, after recovery from the related stress or fatigue. Also, REM deprivation during specific temporal windows, sometimes days after the learning task, sometimes disrupts performance even more than does REM deprivation immediately after learning, precluding the possibility that stress associated with REM deprivation accounts for impaired performance.

Convergent findings from other paradigms Other research methods have provided converging evidence that REM sleep facilitates perceptual-procedural and cognitive-procedural memory. Research using functional neuroimaging procedures indicates that specific brain areas activated while learning a serial reaction time task are significantly more active during REM sleep among those who have previously trained on the task than among those who have not. Also, when people who have learned a recursive cognitive skill in the presence of a clicking sound are presented clicks coincident with their rapid eye movements during REM sleep, they perform better on retesting than do people who have learned the skill and then are presented clicks during a period of REM sleep without rapid eye movements or during a period of NREM sleep. These findings suggest a special role for the phasic events of REM sleep in memory consolidation, a possibility bolstered by evidence that hippocampal theta rhythms, which have been implicated in memory consolidation during wakefulness, are not only prominent during REM sleep but also are precipitated by the PGO waveforms that generate the REMs, twitches, and other phasic features of that sleep stage.

However, because hippocampal theta rhythms are especially implicated in the consolidation of declarative rather than procedural memory, the association between hippocampal theta and REM sleep is inconsistent with the notion that REM-mediated memory consolidation is specific to procedural learning. Moreover, there is evidence from a partial sleep paradigm that declarative memory involving emotional information is enhanced by REM sleep. Specifically, when memory is assessed after periods of undisturbed sleep during either the first half of the night (when NREM sleep predominates) or the second half of the night (when REM sleep predominates), the consolidation of emotional declarative memories (e.g., for emotional stories), but not of neutral declarative memories (e.g., for nonemotional stories), is enhanced by late-night (REM-dominated) sleep. These findings suggest that declarative memory for emotional events, although dependent upon hippocampal theta activity, is enhanced during REM sleep by amygdalar modulation of hippocampal function. Since, within any particular learning task, declarative and procedural learning are often mixed, there clearly is need for more refined characterization of the particular kinds of memories that are consolidated during REM sleep.

Memory Consolidation and NREM Sleep

Although there is evidence that sleep stages other than stage REM are implicated in memory consolidation, identification of their distinctive contributions has only begun. There are replicable findings indicating that NREM sleep facilitates performance on motor tasks (e.g., a pursuit rotor task). And, there is evidence that a word-pair association task influences some parameters of early-night (NREM-dominated) sleep (e.g., the number of sleep spindles) and that the disruption of early-night (NREM-dominated) sleep interferes with this type of declarative memory. This might be expected from dual-process theories, which suggest that REM and NREM sleep have specialized memory consolidation functions. However, other evidence (e.g., correlations between retesting performance and time spent in both NREM and REM sleep) suggest that NREM and REM sleep independently contribute to memory consolidation. According to sequential process theories, the orderly succession of NREM and REM sleep is required for memory consolidation, regardless of the nature of the task.

Dream Content and Memory Consolidation

On a few occasions, researchers have directly linked REM-dependent memory consolidation to dream content. For example, individuals who have successfully adapted to lenses that distort their visual field report dreams including visual and motor difficulties, as well as misfortune and confusion. Similarly, among people learning a second language, those performing successfully are among the first to incorporate that second language into their own dream communications. However, there is ample room in this literature for closer examination of the relations between the incorporation of the presleep task (into both REM and NREM dreams) and subsequent task performance.

Such research must take into account the extended temporal reach of dream formation processes. The incorporation of challenging life events into dreams appears to be modulated by a 7-day rhythm. One peak in incorporation occurs for dreams following the event by 1 day (the day-residue effect), and a

second peak occurs 6–7 days later (the dream-lag effect). Dream-lag incorporations (1) seem related to interpersonal problem-solving (interpersonal relationships, positive emotions, and resolved personal problems), (2) are most pronounced among individuals who report that their dreams influence waking thoughts and feelings, and (3) are at least compatible with evidence that REM deprivation during specific, delayed temporal windows disrupts REM-dependent memory consolidation. Documenting the complex processes by which presleep tasks and challenging events are incorporated into dreaming may help clarify the forms of memory reorganization and elaboration that support memory consolidation.

Emotional Adaptation

Studies of dream function often are couched in the language of problem solving. Usually, the proposal is that dreams incorporate aspects of a waking problem, the process of dream formation actively reorganizes material related to that problem, and the dream effect is articulation of a novel solution to the problem, either within the dream or during immediate waking reflection upon the dream images. Whereas research supports the notion that REM dreaming, as a form of fluid thinking that briefly persists after awakening, contributes to the formulation of solutions that are not characteristic of waking thought, generalization from transient nonemotional problems (e.g., anagrams) to enduring emotional problems (e.g., bereavement) is common but problematic. Research procedures suited to the investigation of short-term dream effects cannot simply be extended to studies of the influence of dreaming on long-term emotional well-being. Longitudinal (or quasi-longitudinal) research designs are required.

Within longitudinal designs, the contribution of REM sleep research protocols continues to be significant for two reasons. First, laboratory studies of the immediate effects of REM dreaming often guide articulation of the hypotheses examined in longitudinal studies. Second, sleep laboratory procedures remain crucial when the research question concerns changes in dreaming during the course of the night, contrasts between REM dreams and NREM dreams, etc.

Mood Regulation

The hypothesis that REM sleep has a mood regulatory function is consistent with evidence of an overnight attenuation of either positive or negative mood intensity. An extension of this hypothesis is that nightmares reflect the failure of this regulatory mechanism to subdue disturbing emotions, a proposal that is reminiscent of Freud's suggestion that the function of dreaming is to protect sleep. A recent and modified version of the mood-regulation hypothesis has influenced studies of the role of REM dreaming in the alleviation of depression.

REM sleep and mood regulation during depression There is evidence that early-night and late-night REM sleep stages play different roles in mood regulation during depression. It is well established that depressed individuals show reduced latency to the first REM sleep episode of the night and an increase in REM density during the first REM sleep period, indicating a phase advance of the diurnal cycle. Also, during depression, REM density during the first REM period is negatively correlated with the attenuation of negative mood during the night, whereas REM density during the last REM period is positively correlated with the attenuation of negative mood. Finally, depressed individuals reporting more negative dreams at the beginning of sleep, and fewer negative dreams toward the end of sleep, are more likely to be in remission 1 year later than are those with fewer negative dreams at the beginning of the night and more negative dreams toward the end of the night. Taken together, these findings indicate that, among depressed individuals, the progressive attenuation of negative affect during successive REM periods and the associated attenuation of negative mood in the morning alleviate depression. While it is not clear what normally brings this about, REM deprivation is one intervention that seems to do so.

REM deprivation and depression When acutely depressed individuals (e.g., responding to divorce) undergo selective REM deprivation over several weeks, the phase advance of the diurnal cycle is reversed, leading to sustained remission from depressive symptoms. Preliminary evidence that dreaming is implicated in these improvements includes (1) the attenuation of negative mood on REM deprivation nights, (2) the maintenance of this attenuation during the following day, (3) the vividly dreamlike character of REM mentation early in the treatment period, and (4) dream reports that incorporate emotionally significant aspects of the life event that precipitated the depressive episode (e.g., the former spouse; the children). The preceding pattern is best described as emergent; its various components remain somewhat unstable from study to study. However, the prevalence of depression (including as a complement to other distressing life events, e.g., trauma) makes clarification of this pattern especially important.

This research is a reminder of the procedural complexity that is required in studies of long-term dream function. Among those who are depressed, it is demonstrably important to (1) differentiate the types of dreaming that occur early in the night from those that

occur late in the night, (2) examine the blending of and variations in dream themes between early-night and late-night REM periods, (3) monitor not only the immediate mood carryover effects, but also the waking events that support or obstruct stabilization of these mood changes during wakefulness, and (4) assess individual differences in the patterns of dreaming and dream effects.

Conflict Resolution

In recent years a number of investigators have focused on repeated themes, and their variations, in individual dream series. These repeated themes vary on a continuum, from the reappearance of particular images in a dream series, to the recurrence of analogous dream scenarios, to the repeated replication of overwhelming traumatic moments. In a variety of theories, these repeated themes are understood as indicating the presence of unrecognized and unresolved personal conflicts. Correspondingly, the repetition and variation of these themes are understood as fostering their recognition and resolution.

There is some evidence from research using quasi-longitudinal research designs that is consistent with this formulation. When adults who are presently experiencing recurrent dreams are compared with those who experienced recurrent dreams in the past and with those who have not experienced recurrent dreams, recurrent dreamers report dreams that are more anxious, dysphoric, and conflicted laden; they also have lower scores on several indices of personal well-being (e.g., anxiety, depression, life stress). Past recurrent dreamers report greater personal well-being, as well as more positive dream content, than do recurrent dreamers or nonrecurrent dreamers. These results have been replicated with younger adults among whom past recurrent dreamers were defined as those who had recurrent dreams during late childhood. In this case, past recurrent dreamers did not differ from nonrecurrent dreamers. These studies indicate that the cessation of adult – but not childhood – recurrent dreams is associated with enhanced well-being.

Vestigial Defense

There are two conceptions of dream function that posit their historical rather than current adaptive significance. In an ontogenetic version of this possibility, the capacity of REM dreaming to enhance the consolidation of memories for emotional events may fix traumatic memories in a way that is not adaptive in the dreamer's current life. A prototypic example occurs in posttraumatic stress disorder (PTSD), with its hyperemotional memories, flashbacks, and nightmares. Hypothetically, the enhanced consolidation of declarative memory for overwhelming events (through amygdalar modulation of hippocampal function) consolidates those memories so that they remain easily evoked long after the threat associated with trauma has passed (e.g., in posttraumatic nightmares). Generalization of this hypothesis to more mundane emotional memories may explain the repetition principle – that is, the persistence in dreams of a variety of recurrent themes that are unrelated to current concerns.

In an analogous evolutionary model, dreaming purportedly simulates threatening events of the kind that early humans were likely to encounter frequently (e.g., aggressive interaction with animals) but that contemporary humans typically do not. In hunter–gatherer societies, such dreamed threat simulations may have provided covert rehearsal of a defensive response to actual threatening circumstances, even though they have no contemporary ecological validity. So, when contemporary threats evoke dreams with those primordial characteristics, the threat simulation is likely to be unrelated to, and perhaps even incompatible with, adaptive responses. These conceptions of vestigial dream function may help to explain why dreams related to trauma, or even nightmares that do not have origins in identifiable trauma, often disrupt sleep, prompt hypervigilance, and create lingering distress.

Conclusion

It sometimes seems that theories of dream function are strongly conflicting – as though if one is valid then the others cannot be. However, since short-term dream effects may serve auxiliary functions within more obviously 'adaptive' activities, long-term dream function may be understood as the capacity of a complex self-organizing system that depends upon integration of numerous simpler capacities. From this perspective, the short-term functions of dreaming, when coordinated according to the system's superordinate integrative principles, may subserve a long-term function that is irreducible to any particular dream effect. This integrative possibility remains undeveloped but increasingly plausible.

Dreams and Dreaming: Incorporation of Waking Events

Overview

We all have the intuition that our dreams in some way relate to experiences from waking life. Even in cases in which no specific event presents itself as the likely source of a particular dream, still, our nightly reveries often involve places, persons, or activities which are familiar to us. Indeed, empirical investigations of the effects of presleep experience on dream content support the generally held presumption that mentation during sleep is constructed, at least in part, from memories of both recent and remote experiences. But what does this tell us? Despite decades of research effort, we still have surprisingly little understanding of the cognitive mechanisms controlling incorporation of waking events into sleep mentation, and virtually no understanding of the neural events underlying these processes.

What algorithms determine which recent and remote memories will appear in sleep mentation and what form incorporation of these memories will take? 'Does the incorporation of waking events into dreaming rely on the engagement of particular memory systems, to the exclusion of others? Is the appearance of recent events in dreaming related to neural processes facilitating memory processing during sleep? Might the reexpression of waking events in sleep mentation serve some adaptive function?' Answering these questions not only will provide us with a better understanding of the neural basis of the dreaming process, but may also provide us with insights into the nature of human cognition and memory processing in general.

The definition of 'dreaming' remains a contentious subject, and one that we do not address here. For our purposes, we refer to 'dreaming' as being all sleep mentation of which an individual is aware either during sleep or upon awakening, and we refer to a 'dream' as being the content of that mentation. In addition, we will sometimes use the term 'dream' to refer to the waking report of dream content, and 'dream content' to refer to the content of such reports. We do so only for the sake of clarity in reading, and not to stake out a particular position in regard to the nature of dreaming.

Effects of Presleep Experience on Dream Content

Manipulation of Presleep Experience in the Sleep Laboratory

During the 1960s and 1970s, a considerable amount of research effort was devoted to understanding the relation of waking events to dreaming through laboratory studies manipulating participants' presleep experience. Unfortunately, much of this research was plagued by methodological weaknesses, including frequent failure to employ blind raters and/or reliance on subjective interpretation of symbolic relationships between waking experience and dream content. Overall, the most consistently observed direct effect of waking experience on laboratory-collected dream reports to emerge from these studies was the powerful influence of the laboratory setting on dream content. In an analysis of 813 rapid eye movement (REM) dream reports collected across several studies, Dement and co-workers reported that 22% of reports unambiguously incorporated either isolated elements (e.g., the experimenter, the sleep laboratory itself, electrodes) of the laboratory situation (in 10% of the reports) or more complete representations (e.g., a combination of the previously mentioned elements) of the experimental setting (in 12%).

In contrast to the strong influence of the laboratory setting, experimental manipulations of the presleep experience have often failed to demonstrate clear effects on dream content. In fact, the most striking outcome of such investigations has been the conspicuously rare appearance of content directly related to a particular presleep intervention. Even the use of emotionally salient stimuli (e.g., violent films) or the manipulation of basic biological drives (e.g., the induction of thirst) has rarely resulted in dream content obviously related to the manipulation. In studies in which unambiguous incorporations of experimental stimuli have been reported, the influence of the laboratory environment often greatly overshadows these effects.

In retrospect, this is hardly surprising, given the relative salience of sleeping in a strange place and being awakened during the night to report dreams. The salience of any particular film, activity, etc. introduced to individuals as a part of an experimental protocol likely pales in comparison. At the same time, these findings suggest that emotional salience may be a major determinant of dream content. This conclusion must be

tempered, however, by the fact that the individuals were receiving sensory input from the laboratory environment (e.g., from the recording electrodes) even as they slept, and such concurrent sensations might have dictated their incorporation.

Well-designed experimental investigations utilizing appropriate control groups have had relatively more success in demonstrating statistically significant effects of experimental manipulations when formal or qualitative dream features (e.g., length, affect), rather than content of dreams *per se*, were used as the outcome measure. In short, it has proved to be difficult, if not impossible, to reliably manipulate the content of dreams through presleep interventions administered in a laboratory setting.

Correspondence between Presleep Experience and Dreaming in the Home

Other, nonexperimental approaches, however, clearly show that waking experience is a primary source of sleep mentation content. In an analysis of the possible waking memory sources of 299 home-collected dream reports, Magdalena Fosse and colleagues demonstrated that fragments of recent experience are often seen in dream reports. Of 299 reports, 51% analyzed in this study were judged by individuals to contain at least one feature bearing strong similarity to a recent waking event. In this particular study, participant-identified incorporations were typically direct in nature. As in the case of the aforementioned experimental studies, however, naturally experienced waking events appear to sometimes affect qualitative dream features, as opposed to resulting in direct incorporations of the experience. In an analysis of home dreams collected in the weeks prior to and following the terrorist attacks of 11 September 2001, Ernst Hartmann reported that, although the events of September 11 were not typically incorporated into participants' dreams in the period following the attacks, the emotional intensity of central dream images was significantly increased.

Other lines of research have explored the more general correspondence between sleep mentation and waking life. Calvin Hall, an early cognitive dream theorist, pioneered the use of content analysis to quantitatively assess the content of large sets of mentation reports. This classification system, developed in collaboration with Robert Van de Castle as a response to subjective interpretations of dream content generally employed by psychoanalytic dream theorists, counts the occurrences of various categories of characters, settings, objects, social interactions, etc., as explicitly described in the text of dream reports. Using this system, Hall was able to create surprisingly accurate psychological profiles and histories for psychiatric patients, based solely on blind content analysis of their dream reports. Later work employing this same system of quantifying dream content has reported consistent, statistically significant differences in the dream content of groups of individuals with divergent waking experience (e.g., between males and females, children and adults, and blind and sighted individuals). These investigations have contributed to our understanding of the dreaming process particularly inasmuch as they remind us that, while attempts to predict or control the waking source of specific dream elements have often failed, a broad correspondence between dream content and waking experience is nonetheless transparently obvious. In short, people clearly tend to dream of the same persons, activities, etc. which dominate their waking lives. While psychoanalysts have long presumed that dreaming conceals a hidden message demanding the application of a complex 'decoding' process, this research, on the contrary, suggests that the relationship between dream content and waking experience may be, if not straightforward, at least discoverable without resorting to symbolic interpretation or reference to hidden 'latent' content.

Incorporation of Presleep Experience into Sleep Onset Dreaming

In contrast to the relative difficulty of manipulating dream content later in the night, experimentally administered tasks appear to more clearly affect mentation during the first few minutes of sleep. In a series of studies employing engaging video games as a presleep task, Stickgold has demonstrated a powerful influence of presleep experience on dreaming at sleep onset. In one such study, participants played the video game Tetris in the morning and evening, several hours prior to retiring for the night. Dream reports were then repeatedly elicited from each participant after just 30 s to 3 min of sleep (in Tetris, the gamer must manipulate falling block shapes and fit them together; problematic subjective interpretations of dream imagery were not necessary in this study, as gamers reported clearly related content elements, such as "Tetris shapes" and "tiles fall[ing] down"). All told, 64% of participants reported isolated, unambiguous, Tetris-related images in at least one sleep onset report. In a related investigation utilizing a downhill skiing arcade game, a surprising 88% of participants reported direct incorporation of game features into at least one mentation report collected during the 3-day study. The frequency of direct incorporation in these sleep onset studies, which is dramatically higher than that observed in any previous overnight investigation, suggests that the first minutes of sleep represent the ideal conditions for reexpression of waking experience in dreams. The instance of direct Alpine Racer incorporation, however, is greatly decreased when reports

are collected from a delayed sleep onset period following 2 h of sleep, even when these report collections are matched for time of night with initial sleep onset controls. It may be, then, that direct incorporation of these experiences into initial sleep onset reports is dependent upon the position of the report collection period within the sleep phase, rather than on either simple proximity to waking events or general neurobiological features of the sleep onset state.

Taken together, these data strongly support the common presumption that waking experiences influence dreaming both at sleep onset and later in the night. Yet, the question of 'whether or not' waking experience affects dream content may not be a particularly meaningful one. While empirical verification of the folk psychology presumption that dreams incorporate experience-related content is a necessary step, its confirmation is hardly a revelation, and, more importantly, it tells us little about the neural processes which create dreaming, nor about a possible function for the dreaming process. Instead, a more detailed examination of the nature of the incorporation waking experience, grounded in neurobiological data regarding the engagement of memory systems across states of consciousness, is needed if we are to gain clues to the neural and cognitive processes supporting incorporation of waking experience into sleep mentation.

Form of Waking Experience Incorporations

Even in cases in which mentation reports clearly do include elements originating from a specific spatiotemporal episode, these dreams almost never take the form of an exact replay of a life event. Instead, sleep mentation typically incorporates only isolated elements, or fragments, of a waking episode. These fragments, in turn, may be interleaved with remote and semantic memory material. For example, although Fosse's group found that more than half of the reports in their sample contained individual features with strong similarity to a recent experience, less than 2% of these preserved all of the key elements of the original episode, including the setting, characters, objects, and actions found in the memory of the waking event. Mentation reports following Tetris and Alpine Racer exposure exhibit similar characteristics, with individuals describing seeing clearly identifiable isolated features of the game (e.g., Tetris shapes) without the larger context of the activity (e.g., the computer screen, keyboard, or desk).

The following report from Fosse's group provides an illustrative example of a waking memory source and corresponding report, in which the sleep mentation clearly incorporates fragments of a waking experience, without replicating the original context in which these fragments were embedded:

> Waking Experience: "*When I left Starbucks, we had so many leftover pastries and* ***muffins*** *to throw away or take home.* ***I couldn't decide which muffins to take*** *and which to toss…*"
> Corresponding Sleep Mentation: "*My dad and I leave to go shopping. We go from room to room, store to store. One of the stores is filled with* ***muffins, muffins, muffins*** *from floor to ceiling, all different kinds,* ***I can't decide which one I want****…*"

The various components of a waking episode, then, do not appear to be 'bound' together in the manner that characterizes the 'mental time travel' (as described by psychologist Endel Tulving) of episodic memory recall in waking life. This phenomenological disparity between the appearance of memories in dreams and the recall of recent episodes in waking life suggests that divergent, though likely overlapping, processes underlie these two phenomena. We consider in the following discussion how the fragmented appearance of recent memory in dream reports, interleaved with remote and semantic content, might reflect the consolidation of recent memories during sleep as they become integrated into older cortical memory networks.

Note that it may be precisely the fragmentary nature of event incorporation which frustrated the efforts of so many early presleep-stimulus studies. Investigators have often, for example, exposed study participants to multidimensional film stimuli prior to sleep, expecting to see veridical 'replay' of this stimulus in subsequent mentation reports. The stimuli employed might contain a number of relatively well-learned features (e.g., persons or commonplace objects and activities). If only isolated features of these experiences appeared later in dream reports, their ubiquitous nature may have prevented the recognition as having originated in the presleep manipulation of interest. In contrast, the novel and easily identifiable features of Tetris, for example, provide the optimal conditions for tracking isolated features of waking events in subsequent dreams.

It may be important to note also that, as in the preceding example, isolated dream elements originating from the identified/manipulated presleep experience clearly appear in combination with additional elements derived either from other memory sources or from generalized semantic memory networks (e.g., 'shopping with dad' in the preceding example). Indeed, although participants often cite relatively recent experiences as the source of their mentation content, remote memories from several years or longer ago, as well as generic semantic memories, are

also frequently cited as the mnemonic referent of dream material. In sum, the incorporation of recent experiences into dreams is manifested in the intrusion of isolated, salient features of a presleep experience, intermingled with other content.

Sleep Stages, Waking Memory Sources, and Memory Systems

There appear also to be systematic differences across various sleep states in the types of memories incorporated into dream content. This distribution of memory sources, in turn, may inform us about the engagement of particular memory systems across sleep stages and their participation in the dream creation process. In a series of studies, primarily conducted by researchers at the University of Bologna, Italy, participants identified possible waking memory sources of mentation collected from non-REM (NREM), REM, and sleep onset. Blind raters classified each participant-identified memory source as either 'episodic' (autobiographical episodes taking place in a specific spatiotemporal context) or 'semantic' (elements of general knowledge not tied to a particular spatiotemporal context). Perhaps the most interesting result emerging from this work is that NREM reports, rather than REM reports, are associated with the highest proportion of episodic memory sources. This observation fits well with what we know about regional cerebral blood flow (rCBF) patterns during sleep. Acquisition and retrieval of recent episodic memories rely crucially on the engagement of the hippocampal formation, which is more active during NREM than in either waking or REM sleep. In addition, the low levels of acetylcholine characterizing NREM sleep are hypothesized to preferentially facilitate output from the hippocampus to the cortex.

Consistent with the data of Stickgold, however, reports at sleep onset tend to contain an even greater proportion of episodic memory sources than do NREM reports, as well as to contain a very high proportion of 'day residues' (episodic memory sources originating from an experience during the previous day). Comparatively little is known about the activity of the hippocampal system at sleep onset, although at least one investigation has reported that rCBF in the hippocampus is not significantly decreased at sleep onset relative to waking. However, there is cognitive evidence that the hippocampus is not required for incorporation of recent experience into sleep onset mentation (see later).

When participants, returning to sleep following awakening after the first complete REM cycle, provide dream reports from a delayed sleep onset period, episodic sources in general are still proportionally greater than in either REM or NREM reports. But 'day residues' are significantly less frequent. Though proximity to waking experience has been postulated to account for this decline in incorporation of very recent events into later sleep onset periods, recall that Stickgold et al. observed a similar decline in Alpine Racer game-related content when mentation was collected from a delayed sleep onset phase, even though time of night and time since last game play were both kept constant. Again, this suggests that the disproportionate appearance of recent memories in sleep onset reports is not a function of simple proximity to the daytime experience. Rather, memory processing occurring during the initial hours of sleep may alter the incorporation of recent experiences into subsequent dreams, such as into delayed, as compared to initial, sleep onset periods.

Emotional Value and Waking Experience Incorporation

But what processes determine 'which' memory fragments will appear in subsequent sleep mentation? Though doubtless others operate in tandem, the emotional value of waking experiences appears to be one relevant factor. Analyses of the correspondence between dreamed and waking activities, for example, demonstrate that while some relatively mundane activities consuming a great deal of our waking time (e.g., reading and writing) are underrepresented in dreams, other activities of greater personal significance (e.g., socializing with friends) are overrepresented relative to their frequency during waking. Other lines of research suggest a direct link between the emotional value of specific waking events and their appearance in dream reports. Rosalind Cartwright's work on the adaptive function of dreaming in women experiencing divorce directly addresses personal relevance as a mediator of the incorporation of waking experiences into dream content. Cartwright found that individuals' self-rated concern about their spouse is strongly correlated with the percentage of dream reports containing explicit mention of the spouse. Meanwhile, DeKoninck and Koulack have reported similar findings in a group of individuals viewing a film of work-related accidents prior to sleep. Those individuals reporting increased levels of anxiety following morning film viewing reported significantly more film-related content in their subsequent dream reports. Each of these studies suggests that degree of emotional involvement in waking experiences modulates their incorporation into subsequent dreams.

Recall also that in laboratory studies of the effects of presleep experience, the experimental situation was often more strongly incorporated into mentation reports than any was particular experimentally manipulated stimulus. Presumably, in these situations, the

experience of sleeping in a strange place, being wired with electrodes, and participating in an experiment is far more salient and more important than is any specific presleep experience (e.g., a film or other activity) of interest to the investigators. Again, this general set of findings indicates that those experiences in which an individual is more emotionally involved are more likely to appear in subsequent dreams. We also see this effect dramatically, of course, in the dreams of trauma survivors, who tend to replay the traumatic emotional event in their dreams to such a degree that the disturbing dreams themselves become a clinically significant symptom of posttraumatic stress disorder (PTSD).

Time Course of Incorporations

Incorporation of recent experiences into dream content may follow an organized temporal pattern, examination of which could provide clues to a possible function of dreaming. First of all, very recent events may more often be incorporated into mentation occurring early in the sleep phase. Though only a small handful of studies have examined the effect of time of night on such incorporations, both recency of subject-identified memory sources and the similarity of sleep mentation reports to presleep thoughts have been reported to correlate negatively with time since sleep onset. Meanwhile, Stickgold has reported that, during the first few minutes of sleep, incorporation of Tetris imagery into sleep onset dreams declines linearly as a function of time since sleep onset. Recall also that, overall, very recent experiences are more often incorporated into initial sleep onset mentation than into delayed sleep onset mentation or dream reports later in the night. As discussed earlier, simple proximity to waking events appears to be inadequate to explain these effects, as incorporation of recent events declines later in the sleep cycle, even when time of night is held constant.

Examining the incorporation of waking experience into sleep mentation across longer timescales also suggests that mere proximity to a waking event is a relatively poor predictor of incorporation. Although some studies conducted across multiple nights have reported incorporations occurring most frequently on the night immediately following a presleep experience, others have found that frequency of incorporations peaks only after a delay of $\geq$1 day. Stickgold, for example, found that sleep onset reports of novice game players contained far more Tetris imagery on the second night following initiation of game play than on the first. Cartwright has similarly reported increased incorporation of a sexually arousing film on the second night following viewing the film, though these incorporations were most often 'symbolic' in nature. Roffwarg and colleagues have reported even longer incorporation delays, as in the case of the influence of extended wearing of colored goggles on the perceptual quality of dreams. Here, the incorporation effect was seen most strongly several days after participants began wearing the goggles.

In addition, Tore Nielsen has conducted a series of careful studies that find two distinct postevent time frames in which incorporation is most likely to be identified. In accordance with the findings of several Roffwarg and colleagues, the first of these is on the night immediately following a presleep experience (the 'day residue' effect). Nielsen also finds evidence, however, for a 'dream lag' effect, in which waking experiences are again likely to be incorporated into dreams recalled approximately 7 days after the initial experience. Though broadly consistent with the long incorporation delays reported by Roffwarg et al., this is a relatively novel finding and the cognitive and neurobiological mechanisms that might underlie it remain unknown. Nonetheless, this 'dream lag' effect has remained relatively robust across several studies, and controls have ruled out a number of potential confounds.

On an even broader timescale, the temporal distribution of participant-identified dream memory sources is quite similar to that of experimentally elicited waking autobiographical memory samples. In each case, the largest proportion of memory references is drawn from more recent experiences, with references to more remote memories declining in concert with increased temporal distance. This observation is consistent with the idea that some overlap exists between the neurobiological basis for waking recall of autobiographical episodes and their appearance in dream content, and, contrary to Freudian theories, dreams are relatively infrequently associated with memories from the distant past.

Recent Memories, Dreaming, and Memory Consolidation

A growing body of evidence suggests that sleep, and in particular, NREM sleep, facilitates the offline processing of recent declarative memories (e.g., memories of events and facts). Behavioral studies in humans, for example, suggest that periods of NREM sleep are beneficial for declarative memory performance, relative to periods of wakefulness or REM sleep. Meanwhile, both human and animal studies demonstrate that patterns of neural activity associated with recent hippocampally dependent learning are reexpressed during subsequent NREM sleep. This neural 'replay' of recent episodes during NREM sleep is thought to support consolidation processes that mediate the

transformation of recent memories from an initial hippocampus-dependent labile form into more permanent long-term memories in the cortex.

Naturally, the observation that recent declarative memories are reexpressed in the sleeping brain has prompted speculation that these processes may be related to the content of dreams. Although very little work has directly addressed the possible relationship between dreaming and sleep-dependent memory consolidation, a small group of studies do support the notion that such memory processing is reflected in the content of sleep mentation. For example, Carlyle Smith reported preliminary evidence of dream reports related to a mirror-tracing task learned prior to sleep. These task-related dreams were present to a greater degree in individuals 'cued' during sleep using a sound associated with the learning task, compared to noncued individuals. Fiss has provided evidence of a link between overnight changes in memory performance and dreaming, reporting that dreaming of stories presented to individuals prior to sleep was associated with enhanced morning recall of those stories. Thus, the available cognitive evidence is at least consistent with the notion that sleep mentation may reflect consolidation of memories in sleep.

Neural Basis for Dream Incorporation of Recent Events: Connection to Declarative Memory Consolidation?

Research into the neurophysiological basis of sleep-dependent memory consolidation may shed light on neural mechanisms mediating the relationship between recent experience and dreaming. Models of memory consolidation are grounded in evidence that, although declarative memory recall is initially dependent on the hippocampus, over time, repeated memory trace reactivation enables the cortex to support retrieval without the need of hippocampal involvement. Repeated memory reactivation is thought to be crucial to the process of memory consolidation, and, as noted previously, evidence suggests that this occurs optimally during NREM.

Supporting this general model, a number of studies have demonstrated that neural activity initially established during waking experience is 'replayed' during subsequent sleep. These data primarily derive from studies in rodents utilizing multiple single-neuron recordings. Analogous observations have been reported in humans, however, as patterns of regional brain activation associated with specific learning experiences in wakefulness are again seen during subsequent NREM sleep.

Several key features of the replay of learning-associated neural activity in sleep exhibit interesting parallels with the preceding cognitive data on sleep mentation:

1. The neural replay of recent experiences has most often been reported to occur in NREM sleep. As described earlier, NREM is also the sleep stage during which episodic memories are most often incorporated into sleep mentation.
2. Within NREM sleep, neural replay of recent experience is expressed most strongly immediately after learning. The strength of this reactivation effect then tends to decay quickly across time. Similarly, as already described, sleep mentation may be most strongly related to recent experience early in the sleep cycle.
3. Recent learning is not 'replayed' during sleep in its original form. Following learning, firing sequences established during wakefulness are reexpressed only intermittently during rodent NREM, with relatively low fidelity, and on a faster timescale than the original experience. Similarly, as already described, recent experiences are not 'replayed' in dream content in their original form. Instead, intermittent fragments of recent experience are recalled from sleep, intermingled with other content.

Although far from conclusive, this correspondence between features of neuronal-level experience replay during sleep and dream content is consistent with the hypothesis that subjective experience is derived, at least in part, from memory reactivation supporting consolidation processes in sleep. Though these generalizations are largely based on neural replay of recent events observed in the hippocampus, it is important to note that reexpression of learning-related activity has also been observed in cortical structures. Matt Wilson, for example, recently observed sequential replay of a recent experience in the rodent primary visual cortex. Though the inference that an observed pattern of brain activity is associated with conscious awareness always presents a problematic conceptual leap, experimental stimulation of visual cortex in humans does result in associated visual experience.

Despite these arguments, it must be pointed out that little evidence directly links subjective experience recalled from sleep to neurophysiological and cognitive data on memory replay and consolidation. In fact, the study of Tetris imagery in sleep onset dreaming suggests that, at least at sleep onset, this incorporation likely does not rely on neural processes involved in sleep-dependent declarative memory consolidation. Replay and consolidation of recent

declarative memory during sleep is presumed to depend crucially on involvement of the hippocampus. Remarkably, however, Stickgold found that amnesiac patients with complete loss of hippocampal function incorporated Tetris images into their sleep onset dream reports at rates similar to normal persons. These images appeared even though the patients could neither identify the source of the Tetris imagery nor recall ever having played the game. This observation suggests that, at least at sleep onset, dream incorporation of recent experiences does not rely on the hippocampal processes presumed to underlie consolidation of declarative memory. It seems likely that this is exclusively a sleep onset phenomenon, as sleep onset is a state with distinct neurophysiological and phenomenological features. Alternatively, as described in early studies of dreaming in hippocampal patients, there may be subtle differences in the quality of memory content seen in the dreams of amnesiacs. Certainly, more research is needed before a definitive statement can be made about the relationship between dreaming and memory consolidation in sleep.

A Function for Dreaming?

To the extent that dreaming does turn out to reflect memory consolidation processes, neural activity supporting the dreaming process may serve an important adaptive function. Presumably, the function of memory consolidation, in sleep or in wakefulness, is not only to facilitate long-term retention of information, but also to identify those memories of recent events worth retaining and then to integrate these with memories of related older experiences and with general semantic information, so that this new knowledge can be most adaptively utilized to guide future action. It may be that dreaming is associated both with the identification of valuable memories and with the integration of these memories with remote and semantic information stored in cortical networks.

Supposing that dreaming is indeed associated with such a function, might there be cases in which this function is disrupted? Although we have characterized the incorporation of recent experiences into dream content as a fragmentary process, with elements of the waking event interleaved with remote and semantic content, there are cases in which more veridical, complete replay of experiences is reported. In patients suffering from PTSD, the traumatic experience is often replayed in an abnormally direct manner, and the patients' frequent, near-veridical replay is a persistent symptom of the disorder, which can continue for years. It is conceivable that this abnormal replay of traumatic experiences in the dreams of PTSD patients is reflective of the dysfunctional consolidation of the traumatic memories, perhaps involving a failure to successfully integrate the traumatic experience with existing cortical memory networks.

In closing, it is important to remember that despite this or any speculation on a possible 'function' for dreaming, the question of whether the conscious experience of dreaming *per se*, as opposed to the neural activity associated with it, supports these processes is essentially unapproachable until more is understood about the neural basis of consciousness in general.

Dreams and Nightmares in PTSD

Clinical Significance of Nightmares in Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) refers to symptoms of reexperiencing, avoidance, and hyperarousal that persist for more than 1 month after exposure to a traumatic event. Violent crimes, including rape, physical assaults, and combat exposure, constitute traumatic events that involve threat to integrity of the self or to others and are accompanied by intense fear, helplessness, or horror. Epidemiological studies indicate that community prevalence estimates of PTSD are in the range of 1–10%, with higher estimates reported for victims of interpersonal violence (20–30%) and combat veterans (15–30%). Recommended first-line treatments of PTSD include selective serotonin reuptake inhibitors (SSRIs) and cognitive-behavioral interventions such as prolonged exposure and cognitive restructuring.

Nightmares are a core feature of PTSD. As many as 90% of trauma-exposed individuals who develop PTSD report disturbing dreams that bear varying degrees of resemblance to the actual traumatic event. Growing evidence suggests that trauma-related nightmares may directly contribute to the pathophysiology of PTSD. The persistence of nightmares and sleep disruption 1 month posttrauma increases the likelihood of developing PTSD at follow-up assessments. Moreover, a personal history of nightmares prior to trauma exposure can predict the severity of PTSD and other posttraumatic psychiatric symptoms. Frequent recurrent nightmares about a traumatic event can persist for years and even decades after the trauma. Trauma-related nightmares disrupt sleep and independently contribute to increased severity of daytime PTSD symptoms and increased alcohol use in trauma survivors, and adversely affect quality of life and perceived physical health.

Nightmares and Sleep following Trauma Exposure and in Chronic PTSD

In healthy persons, elaborate dream recall is more prominent following awakening from rapid eye movement (REM) sleep than from awakening from non-REM (NREM) sleep. In trauma-exposed adults, two preliminary studies suggest that disruption of REM sleep, as indicated by increased sleep stage transitions and arousal, as well as increased sympathovagal tone during REM sleep are associated with increased PTSD symptom severity and may increase the likelihood of developing PTSD at follow-up assessments. Thus, REM sleep disruption and increased arousal during REM sleep may increase one's vulnerability to experience vivid nightmares following trauma exposure and to develop PTSD.

REM sleep disturbances have been most consistently reported in patients suffering from chronic PTSD, but other sleep alterations, such as reduction in slow-wave sleep, have also been documented. More general sleep disturbances, such as increased sleep latency, total sleep time, and duration of and number of nocturnal awakenings, have been reported in some, but not all, studies. Polysomnographic studies based on refined objective measures of central and peripheral physiological arousal, such as quantitative electroencephalography and quantitative electrocardiography, have observed indices of heightened central and peripheral arousal during sleep in patients suffering from PTSD. PTSD in patients who report trauma-related nightmares show increased duration of wakefulness after sleep onset in comparison to those who report non-trauma-related nightmares. However, REM sleep parameters, or more global sleep measures, do not correlate with specific aspects of nightmare content. These observations suggest that in chronic PTSD, trauma-related nightmares may represent expressions of a more global sleep disturbance related to heightened arousal.

Dream Recall and Nightmare-Related PTSD

Studies on dream recall frequency following trauma exposure have yielded inconsistent results. Increases in dream recall frequency following a traumatic event have been reported and the hypothesis put forth is that dream recall is facilitated by the intensity, affective charge, and references to the victims' trauma depicted in their dreams. Conversely, significant decreases in dream recall have also been documented. These data, however, are largely based on retrospective assessments conducted many months or even several years following trauma exposure. It is possible that dream recall increases immediately following an individual's exposure to trauma and subsequently diminishes over time. One comparison of high-functioning Holocaust survivors, average-functioning Holocaust survivors, and controls found that the high-functioning survivors reported fewer dreams from REM sleep (33.7%), compared to the average-functioning survivors (50.5%)

and controls (80.8%). A reduction in dream recall may thus reflect improved posttrauma adaptation in this population.

Repetition of Trauma in Dreams

The recall of dreams that replicate the traumatic event experienced by trauma victims has been described in many populations, including war veterans, adults and children exposed to war, witnesses of violence and abuse, burn victims, and individuals exposed to natural disasters. A classification system for trauma-related dreams has been put forth. Posttraumatic dreams refer to the replication of the traumatic event during sleep or the introduction of the encapsulated memory of the trauma during sleep. Modified dreams present distorted themes, elements, or emotions from the trauma. Finally, disguised dreams represent the traumatic event symbolically or metaphorically. These categories form a continuum of replication (according to the extent to which the traumatic event is represented in the dream) and of repetition (i.e., the dream's recurrence). Empirical studies support this classification system. For example, in one study of Vietnam War veterans, 304 of 316 veterans reported combat-related nightmares. An examination of their dream narratives revealed that over half of the veterans reported realistic combat dreams, 21% reported plausible war sequences that they nevertheless had not experienced, and 26% reported dreams that alluded to the war, but also included fantastical and everyday elements. In addition, a laboratory study of war veterans found that only 21% of dreams exactly replicated the traumatic event, while the majority contained distortions related to the traumatic event. Similarly, one study of patients hospitalized following an accident or assault found that 46% of reported dreams replicated the traumatic event, 33% were dissimilar to the traumatic event while containing high levels of distress, and 19% showed little similarity to the trauma or distress.

Taken together, the results reveal changes in dream content with the passage of time and with improvement in the posttrauma reaction. Dreams recalled during the initial posttrauma phase tend to include some type of repetition of the trauma while subsequent phases are characterized by more symbolic representations of the trauma and greater integration of the individual's everyday life in recalled dream content.

Trauma and Dream Content

Several studies have reported salient alterations in the content of trauma victims' dreams. Some data suggest that when compared to the dream reports from controls, dreams recalled by trauma victims tend to be more ordinary and realistic and less salient, bizarre, and imaginative. The 'ordinary' quality of trauma victims' dreams may reflect an alteration in the process of dream construction or may be related to a protective mechanism which keeps traumatic images from intruding into everyday dreams.

Intense emotions have been documented in several studies of trauma victims' dreams. Feelings of horror, anxiety, rage, sadness, and frustration are among the most frequently reported. PTSD patients rate their nightmares as being significantly more distressing than do non-PTSD patients. Emotional preoccupations prior to bedtime may also play a role in the affective content experienced during subsequent sleep. The finding that one's mood prior to sleep is inversely related to positively or negatively experienced dream affect supports the idea that dreams may help regulate emotional equilibrium in traumatized individuals.

Some research has been directed at delineating relationships between measures of dream content and specific types of traumas.

Victims of Physical and Sexual Abuse

Themes of attack, pursuit, and of one's own death are more frequently found in the dreams recalled by victims of sexual abuse than in those recalled by control participants. Episodes of verbal and physical abuse are more evident in the dreams of physically abused women when compared to the dreams of controls. Although themes of violence and aggression often characterize women's nightmares, the nightmares reported by victims of sexual abuse are more likely to include unique themes of blood and dismemberment as well as a higher occurrence of male strangers. In addition, the dreams and nightmares of sexually abused women contain more frequent references to negative sexual activity, including themes concerning lack of trust and shame, guilt, jealousy, anger, and violence. These dreams often depict situations wherein elements of sex and aggression are confounded, in which sexuality is unpredictable and often results in fear. Victims of sexual abuse also frequently report the presence of serpents and worms in their dreams as well as references to both sexual and nonsexual body parts.

Victims of War and Violence

Exposure to an environment of war or violence is associated with dreams containing high proportions of aggressive and hostile human interactions. Themes involving immediate dangers to one's life appear more frequently in the dreams of Holocaust survivors, children that have been kidnapped, and children involved in car accidents than in nontrauma populations. It is not unusual for war veterans to report that their

traumatic dreams entail being killed in the place of their compatriots. A study of war-exposed Palestinian children found that traumatized children had more dreams with threatening strangers. Their dreams were often composed of attacks, anxiety, persecution, hostility, and nondesirable endings. In addition, nontraumatized children report more dreams of school and of their peers than do traumatized children.

That said, conflicting results exist regarding the impact of trauma and PTSD on dream content. For example, in addition to having more dreams with threatening strangers, victims of violence also report more dreams referring to their family, house, affiliations, and human connections than do controls.

Frequency of Dream-Related Disorders

Dream-related disorders, such as posttraumatic dreams, nightmares, bad dreams, and recurrent dreams, are the most frequently reported and most persistent symptoms exhibited by trauma victims. Several factors appear to mediate this association. First, a positive relationship exists between the degree and severity of trauma exposure and the frequency of dream-related disorders. Second, the victim's psychological reaction to trauma (e.g., level of anxiety) positively influences the occurrence of nightmares and other dysphoric dream experiences. Third, the time elapsed since trauma exposure appears to play an important role, with reductions in dream-related disorders occurring over time. However, it should be noted that dream disturbances can nevertheless persist for many years following the trauma.

Functional Hypotheses of PTSD-Related Nightmares

Many contemporary dream theorists suggest that dreaming is functionally significant and may subserve a biologically important function, but some argue that dreams are epiphenomenal to neurophysiological activity during REM sleep and have no value in and of themselves. While this overarching question on the function of dreaming is of phenomenological interest, the resolution of this debate is of little clinical relevance for chronic, frequent, and distressing nightmares in PTSD patients. However, understanding the possible role(s) of nightmares as one of the normal initial reactions to trauma exposure, which may also become a perpetuating condition contributing to maladaptive, chronic trauma response, has direct clinical implications regarding the development and refinement of effective nightmare-specific treatments. The following sections describe the main hypotheses put forth to explain the possible dual role of nightmares occurring posttrauma.

Nightmares and Emotional Adaptation to Trauma

Several neuropsychophysiological hypotheses of the function of dreaming have been adapted to explain the occurrence of nightmares after exposure to a trauma or other significant life events, and the role of nightmares in the pathogenesis and maintenance of PTSD. Freud proposed that nightmares reflect attempts to master anxiety and guilt associated with a traumatic experience, and to integrate traumatic experiences into one's psyche during sleep. Contemporary hypotheses are based on a similar premise – that dreaming serves a function of emotional adaptation to emotionally salient or traumatic events – and combine empirical observations supporting the role of REM sleep (and by association, dreaming) in learning, memory consolidation, emotional processing, and adaptation to stress. Given that REM sleep is associated with muscle atonia, and given the lack of detectable physiological activation during REM sleep episodes preceding awakening from nightmares, dreaming and REM sleep may provide a unique psychophysiological milieu during which traumatic memories can be reexperienced in the absence of physiological arousal. This process could facilitate the attenuation of emotional and physiological responses associated with these memories, leading to desensitization to the trauma-related memories, including a reduction of nightmares. Prospective dream collection studies in combination with repeated objective assessment of sleep patterns and other physiological parameters of central and peripheral arousal in people at high risk for trauma exposure (e.g., disaster workers, police officers, firefighters, deployed military personnel) are necessary to assess the role of nightmares in the recovery of trauma response and PTSD.

Stickgold proposed an explicit REM sleep model of the neurobiological substrates potentially subserving emotional processing and integration of trauma-related memories. Specifically, it is suggested that REM sleep provides a unique neurochemical and neurobiological brain state that allows the transfer of hippocampally mediated episodic traumatic memories and amygdala-dependent salient affect into cortically distributed semantic networks. It should be noted that the possibility has not been evaluated that PTSD-related nightmares may also reflect the failure of compensatory mechanisms aimed at preserving processes such as emotional adaptation, memory consolidation, and sleep continuity.

Sensitization Hypothesis of PTSD Nightmares

While the adaptation process may be successful in individuals who recover from trauma exposure, the persistence of nightmares in those who develop PTSD may, instead, reflect a failure of dreaming and REM

sleep to fulfill their role of emotional adaptation and memory integration. In this perspective, nightmares are the outcome of unsuccessful processing during dreaming and REM sleep. In addition, nightmares may directly contribute to the failure of the adaptation and integration process by promoting sensitization (rather than desensitization) to trauma-related memories. PTSD-related nightmares are often associated with awakenings and are accompanied by intense emotional and physiological arousal. Trauma-related nightmare content, sleep disruption induced by awakening from a nightmare, and heightened physiological and emotional arousal levels that follow such awakenings may contribute to reinforce the occurrence of nightmares and related distress during both wakefulness and sleep. In other words, the recall of nightmares can expose patients to their prior trauma and may even induce retraumatization, since PTSD nightmares often repeat a traumatic situation in whole or in part, whereas habituation to physiological arousal elicited by these memories does not occur.

There is evidence that frequent and distressing PTSD-related nightmares are associated with increased severity of daytime reexperiencing, arousal, and avoidance PTSD symptoms. Alternatively, some PTSD patients who show clinically significant improvements in PTSD following exposure-based therapy also report improvements in trauma-related nightmares, suggesting that habituation to trauma memories during wakefulness can also attenuate nightmare frequency, intensity, and related distress. Desensitization therapy has also been used successfully for the treatment of trauma-related nightmares. These observations support the hypothesis that chronic nightmares without physiological habituation may indeed contribute to the maintenance of PTSD by sensitizing patients to trauma memories.

Potential Psychophysiological and Neurobiological Underpinnings of PTSD-Related Nightmares

While several polysomnographic studies have been conducted in PTSD samples, these sleep measurement methods do not allow the identification of neurobiological underpinnings of trauma-related nightmares or, more generally, of PTSD during sleep. Such an endeavor requires the use of functional sleep neuroimaging approaches. Sleep neuroimaging has not yet been conducted in PTSD patients. However, animal models of the effects of fear conditioning on sleep, and neuroimaging sleep studies in humans, have provided valuable insights into the potential neurobiological underpinnings of altered REM and NREM sleep mechanisms following stress exposure PTSD, and into the neurobiology of normal sleep, respectively. While animal models and sleep imaging in healthy persons limit possible extrapolation of neurobiological underpinnings of trauma-related nightmares, findings derived from these two distinct fields provide evidence for functionally significant overlaps between the neurobiology of fear and sleep regulation.

Functional neuroimaging studies conducted during wakefulness in PTSD patients are consistent with animal models of fear conditioning. PTSD is associated with hyperresponsiveness of the amygdala to threat-related stimuli, and/or a with blunted response of medial prefrontal cortical regions, which exert inhibitory control over the amygdala. Other functional findings include increased thalamic activity with trauma-related stimuli in PTSD compared to non-PTSD subjects, and hyperresponsiveness of the noradrenergic system. Of note, neuronal activity in these structures cannot be captured by conventional sleep measurement methods, which further reinforces the need to use state-of-the-science sleep neuroimaging methods in patients with PTSD.

In rodents, cued fear conditioning increases REM sleep latency, decreases REM sleep duration and number of REM bouts, and increases pontogeniculooccipital (PGO) waves, a marker of alerting mechanisms during sleep and wakefulness analogous to REMs in humans. The effects of fear conditioning on REM sleep in rodents are mediated by amygdalar projections to brain stem regions involved in alerting response and REM sleep generation. Anatomically, the interconnections that the amygdala shares with the basal forebrain, hypothalamus, preoptic area of the anterior hypothalamus, brain stem reticular formation, and solitary tract nucleus allow the amygdala to influence both wakefulness-promoting and sleep-promoting areas. Neuronal firing of the amygdala varies across the sleep–wake cycle, and stimulation of the amygdala during REM sleep increases PGO waves in REM and NREM sleep, whereas inactivation of the amygdala with tetrodotoxin decreases sleep latency and increases slow-wave activity during wakefulness, REM sleep, and NREM sleep. Conversely, ablation of the amygdala in rhesus monkeys is associated with increased sleep consolidation and total sleep time. These findings indicate that the amygdala is an important modulator of sleep and wakefulness regulation mechanisms.

Sleep neuroimaging studies conducted in healthy persons have reliably shown that REM sleep is a natural activator of the amygdala and anterior paralimbic areas and of the medial pons and thalamus. REM sleep is also associated with relative deactivation of lateral prefrontal parietal regions and primary sensory cortices. These selective activation and deactivation

patterns during REM sleep relative to wakefulness have yielded the hypothesis that dreams may reflect the mental representations of high limbic activations in conjunction with deactivation of high-order cortical regions. NREM sleep is a natural deactivator of arousal-promoting structures.

The functionally significant interconnections between the amygdala and wakefulness- and sleep-promoting areas, the unique limbic activation and cortical deactivation patterns observed during sleep in healthy persons, and the functional neuroanatomical findings in PTSD patients during wakefulness all support a role for a heightened amygdalar activity during sleep in PTSD, and provide preliminary guidance for the investigation of the neurobiology of PTSD during REM and NREM sleep. While the relationship between heightened amygdalar activity and dream content cannot yet be ascertained, the role of the amygdala in acquisition of the fear response and the emotional salience of stimuli raises the possibility that heightened amygdalar activity during REM sleep also contributes to salient, negative aspects of dreams and nightmares.

Treatments of PTSD-Related Nightmares

Nightmares are closely related to sleep disturbances, including increased sleep latency, decreased total sleep time, and increased number and duration of awakenings after sleep onset and restless or fitful sleep. Nightmares often produce an insomnia-like pattern of sleep disturbance, if not outright insomnia. Sleep avoidance and fear of darkness, frequent features associated with PTSD-related nightmares, can further reinforce the maintenance of both nightmares and insomnia.

Recommended (by the Expert Consensus Guideline Series on the treatment of PTSD) first-line treatments include Food and Drug Administration (FDA)-approved SSRIs such as sertraline and paroxetine, and cognitive-behavioral interventions such as prolonged exposure and cognitive therapy. However, nightmares are often resistant to such first-line PTSD treatments, and adjunctive treatments are often required to alleviate PTSD-related nightmares.

Several psychological and pharmacological nightmare-focused treatments have been shown to effectively reduce and eliminate nightmares in PTSD patients. Successfully treated nightmare patients often report improvements in sleep quality, feeling more rested upon awakening and having more daytime energy, and reduction in nightmares is a significant predictor of sleep improvement. In addition, nightmare reduction is associated with marked improvements in daytime PTSD symptoms, quality of life, depression and anxiety symptoms, and overall functioning. These findings suggest that at least in some cases, chronic nightmares may represent a primary sleep disorder rather than a symptom of a psychiatric disorder, and as such can benefit from targeted, adjunctive cognitive-behavioral or pharmacological treatments.

Imagery Rescripting and Rehearsal

Numerous techniques have been proposed to treat PTSD-related nightmares, including hypnosis, lucid dreaming, eye movement desensitization and reprocessing, desensitization, and imagery rescripting and rehearsal (IRR). However, only desensitization and IRR have been the objects of controlled studies. Only IRR has been shown to effectively reduce nightmare frequency and nightmare-related distress in patients suffering from idiopathic, recurrent, or PTSD-related nightmares.

IRR for nightmares is composed of two general elements, each of which utilizes several steps in the therapeutic process. The first component is an educational/cognitive restructuring element, focused on helping nightmare sufferers to consider their disturbing dreams as a learned behavior. The second component is an imagery education/training element, which teaches nightmare patients about the nature of human imagery and how to implement a specific set of imagery steps to decrease nightmares. Generally, patients are shown how a nightmare can be effectively treated as a problem in and of itself, without any discussion or emphasis on prior traumatic events or nonsleep-related PTSD symptoms. As such, IRR seeks to minimize the use of exposure therapy as an ingredient in its procedures.

When learning IRR, patients are instructed to modify an original nightmare in any manner of their preference, and to create a new dream scenario. The new dream scenario is then rehearsed in session, and practiced each day until the next session. The rationale is that the rescripting and rehearsal of new dream imagery during the day can replace or alter nightmare scenarios experienced during sleep. Generally, patients report reductions in nightmare frequency and intensity within 6–12 weeks, and improvements are maintained for as long as 30 months.

Several variations of IRR have now been described. The distinguishing features between variations of IRR generally revolve around the degree of exposure used during treatment sessions and/or the specific application of the technique during the sessions. IRR can be delivered in group or individual formats. The number of sessions required for IRR can vary from one to six sessions. Since IRR involves minimal exposure and abreaction, its effectiveness is most likely related to the patient's ability to increase mastery over distressing dream elements by generating new dreams. Research on the scripting of new dreams linked to IRR indicates that mastery is in fact a key

ingredient in this treatment. The observed increase in mastery is all the more remarkable given that IRR does not include instructions to increase mastery when the technique is described during treatment. Although these data are consistent with the view that a dysfunctional imagery system is involved in traumatic nightmares, more work is required to elucidate the relationship between variables related to patient characteristics (e.g., traumatized vs. nontraumatized, presence of psychiatric and sleep disorders, dispositional factors, degree of distress), nightmare content and type (e.g., replicative, recurrent, lifelong, idiopathic), and therapeutic effects (e.g., enhanced self-efficacy, perceived control, modes of emotion expression and representation).

Prazosin

Prazosin is a central α1 adrenoreceptor blocker that is FDA-approved for the treatment of hypertension. Prazosin is currently the most efficacious treatment for PTSD-related nightmares in military veterans and civilian populations with PTSD. Promising results for the use of prazosin to reduce PTSD-related nightmares became available after the Expert Consensus Guideline Series on the treatment of PTSD were established. Results from controlled trials indicate that prazosin effectively reduces chronic PTSD-related nightmares in military and civilian sample groups with PTSD. Reduction in nightmares with prazosin is associated with clinically meaningful improvements in sleep quality, overall PTSD severity, and daytime functioning in combat veterans with chronic PTSD. Most patients experience a recurrence of insomnia and nightmares upon prazosin discontinuation. The drug is well tolerated by patients, is associated with minimal side effects, and no adverse events have been reported with long-term use.

Serotonin-Potentiating Drugs

Randomized controlled trials on the efficacy of FDA-approved SSRIs for the treatment of PTSD (i.e., sertraline and paroxetine) either did not measure improvements in sleep using validated measures, or reported minimal improvements in nightmares or overall sleep quality. In fact, some SSRIs may increase the number of arousals during sleep and decrease total sleep time. Open-label trials with fluvoxamine suggest moderate improvements in PTSD-related nightmares, but randomized controlled trials have not been conducted and side effects may impede tolerability. Open-label trials and case reports suggest that serotonin-potentiating non-SSRIs, such as nefazodone and trazodone, can be associated with reductions in PTSD-related nightmares and sleep disruption. However, double-blind randomized controlled trials in PTSD samples are not available. The need for rigorous randomized controlled trials is highlighted by the example of cyproheptadine. Initial case series suggested that cyproheptadine was a potent agent for the alleviation of PTSD-related nightmares. However, a subsequent double-blind, randomized controlled trial in Vietnam veterans with PTSD found that cyproheptadine could in fact exacerbate nightmares and sleep disruption. A few randomized controlled trials have evaluated the efficacy of monoamine oxidase inhibitors and tricyclic antidepressants for PTSD, and slight to moderate improvements were reported in some, but not all, studies. Optimal doses, durability of therapeutic gains, side effect profiles, and tolerability have not been assessed specifically for PTSD-related nightmares and sleep disruption with non-SSRIs, monoamine oxidase inhibitors, or tricyclic antidepressants. It should be noted that very few trials targeting clinically meaningful reductions in PTSD-related nightmares and sleep disturbances have used specific nightmare measures (e.g., questionnaires, sleep or dream logs) as primary outcome measures. Such measures are necessary to determine the effects of targeted treatments on specific aspects of nightmares, such as frequency, intensity, nightmare-induced sleep disruption, and associated distress.

Other Pharmacological Agents

Several medications that have sedative properties have been used in PTSD patients. Antipsychotics such as olanzapine and quetiapine have been tested in PTSD and have been associated with mixed findings as to their potential for reducing PTSD-related nightmares and insomnia. Despite the lack of evidence for their efficacy in reducing both daytime and nighttime PTSD symptoms, benzodiazepines are often prescribed to patients with PTSD. An open trial with zolpidem, a nonbenzodiazepine hypnotic, reported improvements in sleep and some improvements in nightmares in military veterans with PTSD. Case series reports on other pharmacological agents, such as topiramate, respiridone, and gabapentin, among others, are also available. While most cases report some degree of improvement in nightmares and insomnia in PTSD patients, proper randomized controlled trials are necessary to fully assess the efficacy of these agents as adjunctive PTSD treatments for nightmares and insomnia, and to determine associated health risks in light of side effects such as tolerance, weight gain, and glucose dysregulation.

Nightmares Defined

Nightmares are currently defined in both the *Diagnostic and Statistical Manual of Psychiatric Disorders*, *Fourth Edition*, *Text Revision* (DSM-IV-TR) and the *International Classification of Sleep Disorders*, *Second Edition* (ICSD-2) (Table 1). These definitions are consistent in linking nightmares to abrupt rapid eye movement (REM) sleep awakenings with a clear recall of primarily fearful dream content. The more recent ICSD-2 criteria acknowledge that nightmares may involve dysphoric emotions other than fear and anxiety and distinguish idiopathic nightmares from the more severe and highly distressing nightmares associated with posttraumatic stress disorder (PTSD). However, the ICSD-2 does not subscribe to a criterion of subjective distress as does the DSM-IV-TR, even though converging evidence suggests that one's habitual manner of affective responding (nightmare distress) is an important determinant of nightmares as a clinical problem.

Nightmare Prevalence and Correlates

Large community-based epidemiological studies demonstrate a high prevalence of occasional nightmares: about 85% of adults report at least one within the past year, whereas 8–29% report at least one per month. These same studies indicate that 2–6% of respondents report weekly nightmares, a frequency widely considered to be of moderately severe pathology. The 2–6% range is robust cross-culturally, with similar rates reported in Canada, Europe, Japan, the Middle East, and America. This range may nonetheless underestimate the real prevalence of nightmares for a number of reasons, such as reliance on retrospective measures and undergraduate samples, inconsistent operational definitions, and failure to distinguish traumatic from nontraumatic nightmares.

Frequent nightmares are up to three to four times as prevalent in childhood and adolescence as in adulthood. According to the DSM-IV-TR, 10–50% of children aged 3–5 years of age have disturbing dreams, with a prevalence that increases through early adolescence. Nightmare 'problems' (duration >3 months) occur with prevalences in the same order of magnitude: 24%, 41%, and 22% for children between age ranges of 2–5, 6–10, and 11–12 years, respectively. Evidence from the Finnish Twin Cohort, a community-based sample of 1298 monozygotic and 2419 dizygotic twin pairs aged 33–60 years, suggests that nightmares are a common and stable trait from childhood to middle age and are substantially affected by genetic factors. In contrast, nightmare prevalence and frequency in elderly populations are considerably lower than rates found in younger adults.

Females at all ages consistently report nightmares at significantly higher rates than do males, although some portion of this difference may be attributed to trauma-induced nightmares. This consistent gender gap in nightmares appears to first emerge around early adolescence. Nightmares are more frequent and more prevalent in psychiatric populations and are associated with a diversity of symptoms: anxiety, neuroticism, and global symptom reporting, schizophrenia-spectrum symptoms; heightened risk for suicide; dissociative phenomena; health behavioral problems; and sleep disturbances. Nightmares are also linked to a diversity of psychopathological traits. They are particularly prevalent in PTSD, for which they are considered a hallmark symptom. A broad range of traumatic events may trigger nightmares: combat exposure, motor vehicle accidents, natural disasters, crime victimization, and rape.

Nightmares are also reactive to intense stress. More frequent nightmares are reported during increased life stress and are associated with specific stressors, such as anticipated surgery, experimental pain stimulation, menstruation, pregnancy, miscarriage, new motherhood, preparation for exams, sham intelligence testing, stock market downturns, and the viewing of disturbing movies. Their onset is often immediately preceded by stressful events, such as death of someone close, interpersonal conflict, news of a disaster (e.g., an earthquake), and major life events in general.

Nightmares also accompany several chronic health problems, including migraine, bronchitis/asthma, chronic obstructive airways disorder, cardiac disease, and substance abuse. In addition, individuals who report frequent nightmares are characterized by a number of personality variables strongly associated with waking emotional distress: heightened physical and emotional reactivity, imagery vividness, fantasy proneness, maladaptive coping, and thin boundaries.

The association of nightmares with this wide spectrum of pathological symptoms and conditions, all of which are marked by considerable waking emotional

Table 1 DSM-IV-TR and ICSD-2 diagnostic criteria for nightmare disorder[a]

Component	*DSM-IV-TR nightmare disorder (2000)*	*ICSD-2 nightmare disorder (2005)*
Nature of dream recall	A. Repeated awakenings from the major sleep period or naps with detailed recall of extended and extremely frightening dreams, usually involving threats to survival, security, or self-esteem	A. Recurrent episodes of awakenings from sleep with recall of intensely disturbing dream mentation, usually involving fear or anxiety but also anger, sadness, disgust, and other dysphoric emotions
Nature of awakening	B. On awakening from the frightening dreams, the person rapidly becomes oriented and alert (in contrast to sleep terror disorder and some epilepsies)	C. Alertness is full immediately on awakening, with little confusion or disorientation Recall of sleep mentation is immediate and clear
Nature of associated distress	C. The dream experience, or the sleep disturbance resulting from the awakening, causes clinically significant distress or impairment in social, occupational, or other important areas of function	D. Associated features may include: • Return to sleep after the episodes is typically delayed and not rapid
Timing of event	A. The awakenings generally occur during the second half of the sleep period	D. Associated features may include: • The episodes typically occur in the latter half of the habitual sleep period
Physiological criteria	None	None
Differential diagnosis	D. The nightmares do not occur exclusively during the course of another mental disorder (e.g., a delirium, posttraumatic stress disorder) and are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition	Nightmares are distinguished from: seizure disorder, arousal disorders (sleep terrors, confusional arousal), REM sleep behavior disorder, isolated sleep paralysis, nocturnal panic, posttraumatic stress disorder, acute stress disorder

[a]DSM-IV-TR, *Diagnostic and Statistical Manual of Mental Disorders*, *Fourth Edition, Text Revision*; ICSD-2, *International Classification of Sleep Disorders, Second Edition*. Items A–D refer to specific definitional criteria described in the manuals; REM, rapid eye movement. Data from American Psychiatric Association (2000) *DSM-IV-TR: Diagnostic and Statistical Manual of Mental Disorders*, 4th edn. Arlington, VA: American psychiatric association; and American Academy of Sleep Medicine (2005) *International Classification of Sleep Disorders: Diagnostic & Coding Manual*, 2nd edn. Westchester, IL: American Academy of Sleep Medicine.

distress, supports the contention that nightmare production is related to a personality style characterized by intense reactive emotional distress.

Models of Nightmare Production

Despite a literature that has proliferated over the past two decades, relatively little is known about the etiology and pathogenesis of nightmares. There is a surprising paucity of working models of nightmare production, with most existing attempts being based on clinical observation but little experimental verification. Many existing models address nightmares only indirectly within the broader context of theories about dream function or personality. Further, some models are concerned almost exclusively with elucidating a nightmare function but not how nightmares are formed.

Psychoanalytic and Neopsychoanalytic Models

It is widely accepted that Freud's dream theory failed to deal adequately with nightmares. To incorporate them into his theoretical framework, Freud resorted to the notion of masochistic wish-fulfillment dreams, within which anxiety feelings stemmed from the transformation of libido. Despite the unpopularity of this idea, twentieth-century theories of nightmare production were nonetheless largely informed by Freud's work. For example, various neo-Freudian models proposed that nightmares were expressions of repressed incestuous impulses, were residues of unresolved psychological conflicts, were attempts to transform shame into fear, and so forth. Some of these views (e.g., incestuous impulse theory) have held little currency in contemporary deliberations over processes of nightmare production, whereas others have continued to wield considerable influence. For example, one contemporary model embraces an explicitly psychoanalytic framework in describing a three-stage neurological mechanism responsible for normal dreaming and nonrecurring nightmares. Other, more recent, mastery and adaptation models of dream function (see later) are also broadly consistent with neopsychoanalytic orientations.

Personality and Evolutionary Models

Boundary permeability Based on extensive clinical work with frequent lifelong nightmare sufferers, Hartmann proposed the personality dimension of 'boundary permeability' to explain nightmare pathology. Nightmare sufferers fall to one extreme of this dimension ('thin' boundaries) by virtue of their striking openness, sensitivity, and vulnerability to cognitive and emotional intrusions – and possibly by biologically based differences as well. Hartmann reasoned that thin-boundary individuals were susceptible

to internal events not usually perceived by most others as threatening or traumatic, that they had difficulty discerning internal fantasy from external reality, and that they were prone to source monitoring disturbances across various states of consciousness. Their boundary 'thinness' thus consists in a vulnerability to spikes of heightened emotional distress; during dreaming this vulnerability leads to nightmares.

A modest body of empirical work supports the validity of the Boundary Questionnaire created to measure an individual's boundary thinness or thickness. As predicted by the model, thin-boundary persons have high levels of dream recall, dream bizarreness, and nightmare recall. Relationships have been found for adolescents as well as for adults, but not for healthy elderly individuals. However, failures to find relationships between boundary thinness and nightmare recall have also been reported. In general, despite the generally positive findings and the publication of a book on the boundary model, this approach has not been elaborated into a complete theory of nightmares and has not enjoyed widespread application as such by the research community.

Image contextualization Unlike most other models that consider nightmares to result from a breakdown in emotional regulation processes, Hartmann's contextualization model proposes that (with the exception of nonrepetitive PTSD nightmares) nightmares serve the function of contextualizing, or finding a picture context for an individual's predominant emotional concerns. Contextualization proceeds by establishing a wide swath of new associations to the emotion, the result of which is emotionally therapeutic. Contextualization is presumed to be a function of dreaming more generally, but the contextualizing processes in normal dreams are often difficult to discern when the underlying emotions are too weak or diffuse. However, after exposure to stressful or traumatic events that engender high levels of emotionality, the processes are more evident. Emotion is thus the central instigating force in the formation of dreaming and nightmares, and integration of this emotion, via the establishment of broad memory associations, is the ultimate goal of dreaming.

Contextualization occurs via contextualizing images, which are powerful central images of a dream whose emotions are consistent with a central concern but whose content may differ from this concern. For example, an image of being swept up in a tornado may contextualize an individual's feelings of helplessness, fear, and foreboding that stem from a prior assault. Hartmann's group has demonstrated that such images are, in fact, more frequent after trauma. Research has also revealed that the presence and intensity of contextualizing images are related to thinness on the Boundary Questionnaire, to a history of trauma, and to the impact of a dream on waking life. Independent validation of some features of this model was also recently reported.

Emphasis on a contextualizing mechanism likens this model to connectionist models of memory and emotional processing; both of which are thought to be central to REM sleep function. Recent evidence does support the notion that memory systems become hyperassociative and more flexible during REM sleep. Hartmann's focus on context formation during dreaming also presages recent theoretical trends in neuroscience – specifically, the view that sleep-related alterations in hippocampal context-building functions are key in determining how dreaming transmogrifies episodic memories into oniric worlds and relationships. Thus, the contextualization model anticipates both recent speculations that an REM sleep function is to create contextual memories and recent research demonstrating sleep-related facilitation of the consolidation of implicit, contextual (hippocampal-dependent) learning.

In sum, the contextualization model is a relatively new proposal which is still in the process of validation but which is consistent with several emerging trends in the neuroscience of memory.

Threat simulation The threat simulation model of nightmares is an evolutionary theory that considers nightmares to be virtual representations that enable the self to engage in behaviorally realistic responses to subjectively real threatening events. Active 'rehearsal' of responses during such simulations enhances threat-avoidance skills in the waking world and confers behavioral and survival advantages. Thus, Revonsuo suggests that nightmarish dreams are prime examples of dreams that fully realize this biological function. The suggestion that ancestral threats are more apparent in children's dreams than in those of adults underlines the importance of assessing the dreams of these two populations comparatively.

This model has generated substantial interest and empirical test in the scientific community but remains controversial. The evolutionary assumption of the model, that nightmares are heritable, has been supported to some extent. The only available study on this question used structural equation modeling of the responses of subjects from the Finnish Twin Cohort to reveal persistent genetic effects on the disposition to nightmares both in both childhood (44–45% of phenotypic variance) and adulthood (36–38%).

However, heritability *per se* is insufficient to establish function; many psychiatric disorders bear a genetic component. As described earlier, nightmares

are associated with increased vulnerability, psychopathology, and dysfunctional adaptation to the environment. A functional role for nightmares is not supported by the finding that sleep disturbances (including nightmares) increase the risk of developing PTSD upon subsequent trauma exposure and that nightmares following trauma are associated with more severe PTSD. PTSD is associated with a host of sleep and waking state abnormalities and does not appear to be an adaptive condition in any sense.

While this model has stimulated little research on the content of nightmares *per se*, assessment of dream content has provided several consistent findings. Revonsuo's group reported evidence that severely traumatized children living in environments of threat report dreams with more threatening events and dream threats that are more severe than do less traumatized or nontraumatized children. Similarly, the earliest dreams remembered by adults (i.e., dreamed when they were children) contain a very large proportion of threat themes, also as predicted by the model. Revonsuo also reported that the dreams of college students contained threats that were frequent (66% of reports), severe (39% nontrivial), realistic (aggression, failures, misfortunes, etc.), and directed toward the self (73%), and to which the self responded with relevant defensive behaviors (56%) – all findings consistent with the model. Mixed support comes from an independent study of recurrent dreams in which six of eight predictions from the model were judged to be supported. However, less than 15% of these dreams contained realistic and probable threats critical for physical survival or reproductive success. Further, less than 2% of the dreams supported all of the predictions. Similarly, only 8% of undergraduate students' most recent dreams contain realistic life-threatening events (and escape is depicted in only a third of these), whereas severe life-threatening events are experienced in real life by 45% of them. It bears noting, however, that the presence of threats *per se* in dream content does not necessarily prove that dreams are adaptive in an evolutionary sense; these threats may simply reflect daily reality, as stipulated by the continuity hypothesis of dreaming.

In sum, the threat simulation model remains a provocative but largely unproved explanation of nightmares. As an evolutionary theory, many of its tenets are difficult, if not impossible, to test empirically. However, it provides a context, which places nightmare studies within the broader field of evolutionary biology, and has generated many novel hypotheses for empirical testing.

Neurobiological Models

Neurotransmitter imbalance Hartmann and colleagues early proposed a model of nightmare etiology based upon the effects of pharmacological treatments for chronic nightmare sufferers. An imbalance in neurotransmitter systems, characterized by diminished levels of norepinephrine and/or serotonin and elevated levels of dopamine (or a combination of these), leads to repeated experiences of nightmares. Hartmann reviewed much of the evidence available at the time but appears to have abandoned this work in favor of the boundary and contextualization models. Evaluation of this complex model today would require an extensive review of the side effects and interactions of several classes of drugs and is not attempted here. Interested readers are directed to the 'Further reading' section for relevant reviews of this literature.

REM sleep desomatization Fisher and colleagues are among very few groups to have recorded polysomnographic variables during spontaneous nightmares. They found nightmares to be associated with smaller than expected levels of autonomic activation during REM sleep and, in some cases, stage 2 sleep. The extent of autonomic activation recorded with measures of heart (HR), respiratory rate (RR), and eye movement (EM) activity was low, was limited to the last few minutes of preawakening sleep, and was, in 60% (12 of 20) of the nightmares recorded, absent altogether. Even lower levels of activation were found in a more recent study. This apparent separation of subjective fear (fearful dream imagery) from its normal psychophysiological concomitants (low or no autonomic arousal) was referred to as 'desomatization,' that is, an REM sleep mechanism for modulating anxiety by abolishing or diminishing its physiological concomitants. Such a mechanism was thought to help preserve REM sleep, to prevent the self-perpetuation of anxiety, and to contribute to the mastery of traumatic experiences. Nightmares result when the anxiety exceeds a certain threshold and the REM desomatization mechanism breaks down, allowing autonomic activation to occur.

Findings from this study, though influential in clinical research, remain somewhat questionable because an indeterminate number of patients with borderline psychosis, prior trauma, and comorbid sleep terrors participated in the study sample. Nonetheless, some of the findings have been replicated with a sample of idiopathic nightmare cases. Little new empirical evidence has been brought to bear on this model, although some laboratory findings are consistent with the possibility that dream emotion is inhibited by REM sleep processes related to the orienting response. Fisher's findings and speculations, however, have had an impact. Several investigators have also suggested that components of REM sleep may be responsible for desomatization or desensitization – that

is, the eye movements of REM sleep desensitize affect in a way similar to what occurs in eye movement desensitization and reprocessing (EMDR) therapy.

In sum, the desomatization model is based upon a limited number of polysomnographic recordings and has not been tested systematically, but has generated much further speculation. The specificity of its proposed mechanism remains an intriguing explanation of nightmare function that is compatible with other theories of dream and nightmare function.

Mood regulation Kramer's mood regulatory theory of dreaming is premised on laboratory findings consistent with the claim that REM sleep is characterized by a 'surge' of affective arousal (e.g., a progressive increase and plateau in limbic system, eye movement, and heart and respiratory activity across the REM period). Dream content is proposed to serve the adaptive function of containing these surges by decreasing the intensity and variability of the associated emotion. This is achieved by a particular pattern of dream content that unfolds across the night and is referred to as 'progressive-sequential' (P-S) in nature. P-S dream series enable a form of emotional problem solving that ameliorates mood. P-S dreaming is distinguished from a repetitive-traumatic pattern, during which an emotional conflict is simply stated and restated without evidence of adaptive change. Nightmares presumably occur when the capacity of dreaming to assimilate the emotional surge in this fashion is exceeded.

While the physiological description of REM sleep as surgelike remains debatable, Kramer has marshaled some empirical support for the proposed function of dream content. In general, evidence that dreams are influenced by one's immediate presleep thoughts and emotional experiences, and that one's waking state mood is related to the previous night's dreams, is consistent with the notion that intervening dream activity regulates mood. More specific evidence that dreaming mediates this regulation is that pre- to post-decreases in mood scores, the 'unhappiness subscale' especially, are correlated with intervening dream content scores, scales involving the number of dream characters especially. While one study by Kramer's group failed to replicate this relationship, consistent findings have been reported by independent researchers. In this case, presleep depression scores were found to be correlated negatively with emotional tone in the dreams of the first REM period of the night (higher depression associated with more negative dreaming) but not with sleep physiology variables. There is also evidence for a mood regulatory function of dreaming in studies of persons undergoing marital separation, who report more negative dreams at the beginning and fewer at the end of the night and who prove more likely to be in remission a year later, compared to those with the opposite pattern. These findings may indicate that negative dreams early in sleep reflect a within-sleep mood regulation process, while negative dreams late in sleep reflect a failure of regulation.

The functional claims of the mood regulation model parallel those of several other nightmare models (e.g., image contextualization, REM sleep desomatization) which claim that dreaming functions to adaptively modify emotions. This claim is supported by a small but growing body of experimental evidence. However, there is as yet no convincing evidence that the P-S dream pattern *per se* is the active agent of mood regulation.

Affective network dysfunction Our neurocognitive model of nightmare formation is based upon a synthesis of findings in the areas of sleep physiology, PTSD, and anxiety disorders. It stipulates that nightmares reflect dysfunction in a network of processes that, during normal dreaming, serves the adaptive function of fear memory extinction. At the cognitive level, this extinction function depends upon three imagery processes that operate on the constituent elements of fear memories: (1) element activation, or the increased availability of isolated features of fear memories removed from their episodic (real-world) contexts, (2) element recombination, or the reorganization of these features into novel, virtual, 'here-and-now' simulations of reality, and (3) emotional expression in reaction to the recombined features, which allows new, fear extinction, memories to be formed and maintained.

At the neural level (see Figure 1), the fear extinction function is supported by a network of four limbic, paralimbic, and prefrontal regions that constitute the control center for a number of emotional processes, including the perception and representation of emotional stimuli and the expression and regulation of emotional responses. These four brain regions, which we refer to as the 'AMPHAC model,' include the amygdala (Am), the medial prefrontal cortex (mPFC), the hippocampal (Hip) complex, and the anterior cingulate cortex (ACC). The AMPHAC regions operate in a coordinated manner to influence other perceptual, cognitive, memorial, and affective brain events. However, general correspondences between each region and cognitive processes are also postulated (e.g., Am, emotional activation; Hip, control of memory context; mPFC, control of extinction memories; ACC, regulator of affect distress).

The cognitive and neural explanatory levels together define an affective network within which

Figure 1 Schematic representation of a network of brain regions hypothesized to be implicated in the production and extinction of fear during normal dreaming; dysfunction in this network is responsible for nightmares. (1) Context is relayed in realistic (virtual) form via anterior hippocampus (aHip) to basal nucleus (B) of the amygdala (Am) and is further processed by the central (Ce) nucleus. (2) Medial prefrontal cortex (mPFC) and dorsal and rostral anterior cingulate cortex (dACC, rACC) afferents to the amygdala regulate the output of Ce neurons to induce extinction and signal distress and maintain appropriate levels of fear. (3) Ce nucleus signals brain stem (Br) and hypothalamus (Hy) to produce (4) the autonomic and behavioral correlates of fear. Excitatory connections are shown in red, inhibitory connections in green. For readability, only connections judged most pertinent to the consolidation and extinction of fear are indicated. Reproduced from Levin R and Nielsen TA (2007) Disturbing dreams, posttraumatic stress disorder, and affect distress: A review and neurocognitive model. *Psychological Bulletin* 133(3): 482–528, with permission from APA.

perturbations may produce a variety of dysphoric dreaming types – from occasional bad dreams to nontraumatic nightmares to recurring posttraumatic nightmares. Further, network activity is 'cross-state,' meaning that it is active during both sleep and wakefulness, which means that its functions – and especially its dysfunctions – should be measurable with various psychophysiological instruments both during sleep and waking states.

Two cross-state factors are proposed for which substantial supporting evidence exists. One is a situational or state factor, affect load, and reflects the combined influence of stressful and emotional negative events (e.g., interpersonal conflicts, daily hassles) on an individual's capacity to effectively regulate emotions. Increases in affect load result in intensified dysphoric dreaming in general. A second factor is a dispositional or trait-like factor, affect distress, and is characterized as a long-standing tendency to experience heightened distress and negative affect in response to increases in affect load, and to react. Affect distress is influenced by events such as prior neglect and trauma, is akin to both the negative affect and negative emotions (personality dimensions), and is associated with a wide variety of psychopathological conditions (anxiety disorders, health behaviors, PTSD, etc.). Affect distress is related to early development and acts as a risk factor diathesis for emotional dysregulation in the face of subsequent stress.

Thus, during nightmares, high levels of affect load and/or affect distress interact with the neurophysiological state of REM sleep so as to favor the activation of fear memories that are coherent (i.e., that resist feature recombination). These memories are akin to those occurring in waking, fear-based pathological conditions such as phobias or social anxiety. Nightmare-related fear memories are highly resistant to extinction, overly weighted with response elements (usually involving escape or avoidance), and, in more severe instances, corrupted by elevated affect distress. A fuller delineation of this model can be found in recent work by Levin and Nielsen.

As a new model of nightmare formation, the affective network dysfunction model has not yet been tested empirically. However, its tenets are consistent with much literature; its neural propositions, especially, are consistent with recent neuroimaging studies of REM sleep, PTSD, anxiety disorders, and personality factors. To illustrate, several studies indicate that REM sleep is characterized by high levels of activation in Am, mPFC, ACC, and the hippocampal complex. Additionally, PET studies have found that glucose metabolic rates in mPFC during REM sleep are highly correlated with elevated anxiety in the content of dreams sampled during these REM periods. Neuropsychological evidence from brain-lesioned patients also supports the model, demonstrating a link between temporolimbic brain regions and frequent nightmares of both recurring and nonrecurring types. Eight of nine patients who reported recurring nightmares were found to have temporal or frontotemporal lesions, including, in some cases, the Hip or ACC. Nightmares and 'dream–reality confusions' (DRCs) were also habitually associated with limbic lesions (nine of ten patients); six of these patients had lesions affecting the mPFC or ACC or both.

Findings from PTSD patients also support this model. All four of the designated brain regions are affected in PTSD patients. Further, heightened affect distress may be expressed in the form of several sleep-related hyperarousal symptoms, including increased awakenings, wake after sleep onset (WASO), and insomnia, as well as nightmares in stages other than REM sleep and at times other than the habitual last third of the night (e.g., stage 2 nightmares occurring early in the sleep episode). Hyperarousal is also suggested by the expression of motor activity in sleep,

including REM-related twitches in leg muscles, more periodic leg movement during sleep in all stages, frequent large body movements, and more REM-related motor activity and vocalization. Explosive motor activity can be elicited from any stage of sleep in some patients with war-related PTSD.

In sum, the affective network dysfunction model is new and still untested but consistent with a large and recent empirical literature. The proposed fear extinction function, while novel, is nonetheless modeled after a well-established research literature on the nature, learning, and unlearning of fear memories. This function is compatible with adaptive emotional functions proposed by other dream and nightmare theorists and may serve as an integrative foundation for resolving these diverse theories.

Drosophila Apterous Neurons: From Stem Cell to Unique Neuron

S Thor, Linköping University, Linkoping, Sweden

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Animals contain large numbers of different cell types, and this cellular diversity is profound in the nervous system, where estimates in mammalians are as high as 10 000 unique cell types. Understanding how this remarkable cellular diversity is generated, and with such precision, remains one of the challenges of neurobiology. Although tremendous progress has been made during the past two decades with respect to our understanding of the molecular genetic mechanisms controlling nervous system development, due to the complexity of this system, in many cases research has not progressed beyond the descriptive level. For instance, in more complex tissues such as the mammalian, or even *Drosophila*, adult brains, we are far from even completing a survey of the cellular complexity, let alone understanding the genetic mechanisms involved in generating that diversity. Moreover, although one may argue that it is not necessary to understand the regulatory details underlying the specification and differentiation of each and every *Caenorhabditis elegans* and *Drosophila* neuron, this is obviously not true for the human nervous system. Here, the ultimate goal is to characterize such mechanisms for every one of the 10 000 different neuronal subtypes since they are all likely involved in some intriguing aspect of human biology and are likely linked to various human diseases. As exemplified here, by the regulatory complexity underlying specification of a few cell fates in the powerful *Drosophila* model system, decoding the molecular genetic mechanisms controlling the generation of the complete developing human nervous system remains a major challenge.

This article reviews studies on neuronal cell-type specification of a unique neuronal subset, the apterous (Ap) neurons in the *Drosophila* ventral nerve cord. The focus is on a subset of Ap neurons – the Ap cluster of four cells located in each thoracic hemisegment – and studies that address the origin, generation, specification, differentiation, and pupal remodeling of these neurons are reviewed.

The Apterous Neurons of the *Drosophila* Ventral Nerve Cord

The *Drosophila* central nervous system can be subdivided into the brain and the ventral nerve cord (VNC). These tissues are functionally equivalent to the mammalian brain and spinal cord, respectively. The VNC is segmentally organized into three thoracic and eight abdominal segments, and it contains approximately 10 000 cells, the majority of which are neurons. In the VNC, only 90 cells express the LIM-homeodomain gene *apterous* (*ap*), but these neurons, the Ap neurons, are remarkably diverse. They differ in axon pathfinding; most Ap neurons extend their axons in a common fascicle, whereas the Tv neuron innervates a peripheral secretory gland, the dorsal neurohemal organ (DNH), which is a specialized glial-derived structure present in the three thoracic VNC segments (Figure 1).

Ap neurons also differ in neurotransmitter expression and approximately half are peptidergic. In this peptidergic subclass, the Tv cell selectively expresses the neuropeptide gene *FMRFamide*, whereas dAp and Tvb cells selectively express the neuropeptide gene *Nplp1* as well as a dopamine type I receptor gene, *Dop-R*. Importantly, for these terminal differentiation genes, their expression within the VNC is confined to these subsets of Ap neurons; *FMRFa* is only expressed in 6 and *Nplp1/Dop-R* in 28 of the 10 000 cells present in the VNC, respectively. How is this remarkably specific gene expression controlled?

Genetic Mechanisms of Apterous Neuron Specification

Studies have identified a number of regulatory genes that act postmitotically in the specification and differentiation of the Ap neurons. These include the transcription factors *ap* (mammalian *Lhx2a-b*), the Col/Olf-1/EBF family member *collier/knot* (*col*) (mammalian *ebf1–3*), the zinc finger gene *squeeze* (*sqz*) (mammalian *CIZ*), and the basic helix–loop–helix gene *dimmed* (*dimm*) (mammalian *Mist1*) as well as the transcriptional cofactors *eyes absent* (*eya*) (mammalian *Eya1–4*) and *dachshund* (*dac*) (mammalian *Dach1–2*). In addition, FMRFa expression in the Tv neuron is critically dependent on a target-derived transforming growth factor-β (TGF-β)/bone morphogenetic protein (BMP) signal – the first identified case of a retrograde instructive signal. These regulatory genes act in a combinatorial manner such that a combinatorial code of *ap/sqz/dac/eya/dimm* and target-derived TGF-β/BMP signaling dictates Tv neuron identity and activates *FMRFa* expression, and *ap/eya/dimm/col* dictates Tvb/dAp identity and activates *Nplp1/Dop-R* expression (Figure 2).

As outlined previously, using the neuropeptides FMRFa and Nplp1 as terminal cell identity markers, as well as using independent axonal markers for these

Figure 1 (a) The *Drosophila* central nervous system is generated from a defined set of neuroblasts (gray circles) that delaminate from the ectoderm during embryonic stages 9–11. The six NB 5-6T neuroblasts are located laterally in the three thoracic hemisegments (red circles). NB 5-6T undergoes a series of divisions to generate an early lineage of neurons and glia, after which the four Ap cluster neurons are generated. A complex regulatory cascade, unique to the Tvb (Nplp1 neuropeptide expressing; green circles) and Tv (FMRFa expressing; blue circles) neurons, ensures that these two neurons acquire proper identity. (b) After completion of embryonic neurogenesis, the *Drosophila* VNC is segmentally organized into the three thoracic and eight abdominal segments. The VNC contains an estimated 10 000 cells, of which only 90 express the *ap* gene, with the prominent Ap cluster of four cells locates in each of the six thoracic hemisegments. All Ap cluster neurons have now extended their axons, and the Tv neurons (blue) have received the TGF-β/BMP ligand Glass bottom boat that finally triggers expression of the *FMRFa* neuropeptide gene, whereas the Tvb neurons (green) now express the *Nplp1* neuropeptide gene. (c) During metamorphosis, the Tv neurons undergo elaborate changes in their axonal projections, involving pruning, axon outgrowth, and branching. These events are under the control of the steroid hormone 20E that acts via the EcR-Usp nuclear receptor signaling system. The function of the 20E-EcR-Usp system during these events is rather complex, and a simplified version if depicted here.

neurons, a number of genes have been identified that are important for specification of Tv/FMRFa and/or Tvb/Nplp1 cell fate. However, how do these regulators act – in parallel or in a genetic cascade? Using a multitude of markers and experimental approaches, such as loss of function, rescue (gene A of mutant A), cross-rescue (gene A of mutant B), misexpression, co-misexpression, gene expression analysis, and temporal analysis of gene function using transgenic RNAi (*UAS-RNAi*), it has been determined that the identified regulators act in rather complex genetic cascades (Figure 1). It is noteworthy that not all regulators participate in all events during Ap cluster specification and differentiation. For instance, *ap* and *eya*, but not *sqz*, *dimm*, or *dac*, are involved in axon pathfinding of Ap neurons. Similarly, *sqz* plays a unique role in determining the proper composition of Ap cluster neurons, and *sqz* mutants display both ectopic Ap cluster neurons and ectopic Tvb neurons. Thus, there exists a clear division of labor, with most regulators participating in more than one, but not all, events during Ap cluster specification and differentiation.

The Apterous Cluster Is Generated by the Stem Cell Neuroblast 5-6T

Studies have led to the identification of the stem cell that generates the lateral four-cell clusters of Ap neurons located in the three thoracic segments that include the Tv and Tvb neurons (Figure 1(a)). A large body of work during the past 20 years has been dedicated to understanding the development of the *Drosophila* VNC, revealing how a specific region of the ectoderm acquires neurogenic potential; how this neuroectodermal sheet is patterned; and how precursor cells, central nervous system stem cells

Figure 2 (a, c) Expression of the neuropeptides Nplp1 and FMRFa is confined to 28 and 8 of 10 000 cells in the wild-type VNC, respectively. (b, d) Misexpression of specific combinatorial codes of regulators in all neurons, by crossing a transgenic *elav-Gal4* driver to transgenic lines carrying *UAS-cDNA* constructs, triggers widespread ectopic neuropeptide expression. (denoted neuroblasts in *Drosophila*), are determined within this sheet. These early patterning events result in the generation of a set of 30 neuroblasts in each developing hemisegment, each expressing a unique combinatorial code of regulatory genes – a code that will dictate a stereotyped number of asymmetric divisions that generate a unique set of neurons and glia. By taking advantage of this previously generated information, it has been determined that the four Ap cluster cells are generated from the thoracic neuroblast 5-6 (NB 5-6T) (Figures 1(a) and 1(b)). Having identified NB 5-6 as the stem cell generating the Ap cluster, now the goal is to decipher the mechanisms by which global regulatory mechanisms, acting along the anterior–posterior, dorsal–ventral, and segmental axes, integrate with temporal transitions in stem cells to generate the four Ap cluster neurons.

Remodeling of Apterous Tv Neurons during the Pupal-to-Adult Transition

After 3 or 4 days of life, *Drosophila* larvae leave the food, attach themselves to a rigid surface, and undergo a fascinating transformation – the metamorphosis of holometabolous insects. During this stage, many larval tissues undergo histolysis (tissue degradation) and many new, adult-specific structures are formed. At this stage, studies using live imaging time-lapse videos to follow the pruning and extension events in great detail have revealed that one of the Ap neurons, the Tv neuron, undergoes a dramatic remodeling of its axonal arbors, involving an initial retraction (pruning) followed by axon outgrowth and extensive branching onto the surface of the VNC (Figure 1(c)). Steroid hormones play a central role during insect metamorphosis and have been found to play an important role also in the Tv neuron. One of the key players in this regulatory system is the hormone ecdysone and its metabolite, 20-hydroxyecdysone (20E). 20E binds to a nuclear hormone receptor consisting of a heterodimer of two nuclear receptors, EcR and the RXR-ortholog Ultraspiracle (USP), and this heterodimer binds to target sites in the DNA to regulate gene expression. By analyzing EcR mutants, misexpressing dominant negative EcR forms, and by blocking EcR by transgenic RNA interference (*UAS-RNAi*), it has been demonstrated that EcR plays an important role, particularly during the pruning phase. For example, by driving expression of a dominant negative EcR construct from the FMRFa enhancer (*FMRFa-Gal4/UAS-EcRDN*), it was found that the pruning was severely impaired and axon branch extension delayed and reduced. Since 20E-EcR-Usp signaling likely affects a multitude of neurons in different ways, it would be interesting to learn how this system integrates with neuronal subtype-specific regulatory mechanisms. Moreover, whether other Ap neurons also undergo remodeling during metamorphosis has not been addressed.

Important Themes during Neuronal Subtype Specification

Studies of Ap neurons have revealed several interesting mechanisms of neuronal subtype specification, and the more pertinent ones are highlighted in this section.

Combinatorial Coding versus Master Regulators

In-depth genetic studies, particularly of the Tv and Tvb neurons, have revealed an intriguing division of labor between the identified regulators. Notably, whereas some features of both Tv/FMRFa and Tvb/Nplp1 neuron identity are under strict combinatorial control – expression of FMRFa requires the combined action of *ap/sqz/dac/eya/dimm* and target-derived TGF-β/BMP signaling and expression of *Nplp1* depends on *ap/eya/dimm/col* (Figure 2) – other features, such as neuropeptide processing capacity, are under discreet control of one regulator, namely *dimm*, which is necessary and sufficient to activate gene expression of the neuroamidase gene *PHM* in both Tv and Tvb. In fact, *dimm* can activate *PHM* expression in most, if not all, neurons and can thus be viewed as a 'master' regulatory gene, perhaps better termed a 'selector' gene, for one specific neuronal subtype property – neuropeptidergic identity.

Feed-Forward Loops

Genetic network studies in single cell systems such as *Escherichia coli* and yeast have identified a common regulatory loop denoted the 'feed-forward loop.' In this loop, gene A will activate gene B, and A/B then act together to activate C. Studies of the Ap neurons have revealed the existence of such feed-forward loops during both Tv and Tvb specification. This is clearly exemplified by the action of *col* in the early postmitotic Tvb neuron, in which it initially activates *ap* and *eya*, subsequently acts with *ap/eya* to activate *dimm*, and, finally, acts with all three regulators to activate *Nplp1* expression. In adjacent Ap cluster neurons, *col* plays only an early postmitotic role to activate *ap* and *eya*. Thus, the nature of *col* expression has an informative value: Transient *col* expression activates *ap/eya* and generates a 'generic' Ap cluster fate, whereas persistent *col* expression leads to subsequent activation also of *dimm* and, finally, *Nplp1*, and thus it has a Tvb-specific value.

Target-Derived Instructive Signals

The results of many studies of mammals during the past few decades have led to the development of the well-known neurotrophic model, in which mammalian neurons are strongly dependent on target-derived signals for their survival. These signals primarily revolve around two different receptor-tyrosine kinase signal transduction pathways – the neurotrophin and glial cell line-derived neurotrophic factor systems. Genetic studies in *Drosophila*, however, have revealed that the TGF-β/BMP signal transduction system is also used in a target-derived manner, specifically to modulate the arbor size of developing motor neurons. However, studies of the Tv neurons have revealed that the TGF-β/BMP system is also used in an instructive manner to dictate terminal identity of unique neurons, and they have found that expression of FMRFa is strictly dependent on a TGF-β/BMP signal from the DNH target gland. It is tempting to speculate that such instructive target-derived signals may indeed be quite common also in the mammalian nervous system, and that their identification may have been hindered by the prevailing target-derived survival signals – that is, malfunction of axon transport or axon misrouting may often lead to cell death, thus occluding any effects on neuronal cell fate determination.

Remodeling

When is a neuron terminally differentiated? The Tv neurons illustrate this issue: Their axons innervate the DNH target gland in the mid- to late embryo and begin expressing the FMRFa neuropeptide, only to go through a complete remodeling after 3 or 4 days of larval life. It is tempting to speculate that this morphological change may be accompanied by other changes in its function and neurotransmitter profile, and it will be interesting to relate the genetic mechanisms involved in generating the Tv neuron in the embryo to the mechanisms acting to remodel this cell in the pupae.

Conclusion

As revealed by the Ap neurons, there exists an amazing complexity of gene regulatory networks that act to specify unique neuronal cell identity. Similar highly complex networks have been identified that act to specify other well-studied neuronal subtypes, such as the ASER/L neurons of *C. elegans* and the spinal motor neurons of the chick and mouse spinal cord. The following are some of the more pressing questions that may now be addressed in this and other models: (1) How are the correct numbers of cells specified (i.e., only 6 Tv and 28 Tvb neurons per VNC)? (2) Are early specification genes used again during later remodeling and 'homeostasis' of mature neurons? (3) How is context specificity achieved – that is, most of the regulators identified that act to specify Ap neuron identity also act in other developmental events – how is their distinct role in each event determined? It is hoped that answering these questions will help us address neuronal subtype specification in humans.

Drug Addiction: Behavioral Neurophysiology

R M Carelli, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Drug addiction in humans is a chronic illness characterized by repeated cycles of compulsive drug intake, abstinence from drug taking, and resumption of drug consumption (relapse). In order to develop effective pharmacotherapies to treat drug addiction, it is critical to elucidate the underlying neurobiological mechanisms mediating this behavior. Research using a variety of techniques supports the view that the 'brain reward system,' most notably the nucleus accumbens (NAc) and associated regions, is crucially involved in the drug addiction process. Electrophysiological recording in behaving animals is one technique that has provided important insight into cellular mechanisms underlying drug-seeking behaviors. Some of the most informative studies have used electrophysiological recordings in conjunction with the drug self-administration procedure. In this case, extracellular neuronal activity is recorded in animals that are implanted with an in-dwelling catheter in the jugular vein, and trained to press a lever for intravenous infusion of a drug. Drug self-administration is considered one of the best animal models of human drug addiction since the drug is not given to the animals by the experimenter, but instead animals give the drug to themselves. In fact, virtually all drugs that are abused by humans are readily self-administered by animals including cocaine, heroin, nicotine, morphine, and alcohol. One advantage of this combined approach is that it allows for the characterization of cell firing within the brain reward circuit during specific stages of drug-seeking behavior (e.g., initiation of drug-seeking behavior including approach toward the lever vs. lever depression for drug infusion). Moreover, this experimental method allows for the investigation of other critical factors, such as the role of environmental stimuli or drug abstinence periods, in controlling and/or modulating cellular activity underlying drug addictive behaviors.

Anatomy of the Nucleus Accumbens: A Key Neural Substrate in Addiction

In order to appreciate the contribution of electrophysiological investigations in behaving animals to our understanding of the neurobiology of addiction, it is important to consider the anatomic organization of the NAc, a key neural substrate that has been extensively studied with respect to drug abuse. In the rodent, the NAc is composed of two primary subregions that differ with respect to their anatomic organization and functional properties: the core and shell. Extensive studies completed in rodents show that the subregions of the NAc receive afferent projections from a variety of cortical and subcortical structures including the basolateral amygdala (BLA), the prefrontal cortex (PFC), the subiculum of the hippocampus, and the ventral tegmental area (VTA). In turn, the major efferent projections of the NAc involve motor-related regions although some differences exist with respect to efferent projections of the core and shell. Specifically, the core parallels basal ganglia circuitry sending outputs through the ventral pallidum (dorsolateral district), subthalamic nucleus, and substantia nigra. These outputs in turn project via the motor thalamus to premotor cortical areas. In contrast, the shell projects preferentially to subcortical limbic regions including the lateral hypothalamus, ventral pallidum (ventromedial district), and VTA.

The vast majority of neurons in the NAc are of the medium-spiny type (MSN) that comprise the majority of the projection neurons from this region. Importantly, it has been shown that NAc afferents make 'convergent' synaptic contacts onto MSNs. For example, studies using immunocytochemistry in conjunction with electron microscopy showed that hippocampal and dopaminergic inputs converge onto the same NAc neuron. Similarly, a convergence of inputs from the medial PFC and the ventral subiculum on NAc neurons has been identified.

Virtually all drugs of abuse increase levels of the neurotransmitter dopamine in the NAc; dopamine is considered a key chemical substrate involved in drug addiction. In the NAc, it is believed that dopamine functions as a neuromodulator, influencing the activation of NAc cell firing by specific NAc afferents including the hippocampus, BLA, and PFC. As noted above, anatomic studies showing the convergence of synaptic input onto NAc neurons from various neural structures support the view that dopamine is in a unique position to modulate afferent inputs from cortical and subcortical areas onto specific NAc cells and ultimately influence behavior.

In summary, the NAc receives convergent afferent inputs from limbic structures involved in processing information related to memory (i.e., hippocampus), drive, and motivation (i.e., BLA), higher cortical processing (i.e., PFC), as well as a rich dopaminergic input from the VTA, and in turn sends efferent

projections to areas involved in movement (e.g., ventral pallidum and associated regions). Given this anatomic organization, it was proposed by Gordon Mogenson and elaborated upon by others that the NAc functions as a site for the integration of limbic information related to memory, drive, and motivation, and the generation of goal-directed motor behaviors (termed 'limbic-motor integration'). Within this model, dopamine plays a key role in this process by functioning to modulate or 'gate' the transfer of these neural signals and thereby influence goal-directed behaviors including those involved in drug addiction.

Neurophysiological Investigations of Drug Addiction: Overview

The majority of electrophysiological studies on drug addiction examined cell firing within the NAc and associated regions during cocaine self-administration, although heroin and ethanol self-administration have also been studied to a lesser degree. Investigations initially examined NAc activity relative to the operant response (typically a lever press) for intravenous cocaine. However, since drug addiction in humans is often characterized by periods of drug intake followed by abstinence and relapse, additional studies have sought to examine the characteristics of cell firing related to this cycle of addictive behavior. Moreover, animal studies show that the resumption of drug-taking behavior following removal of drug availability can be elicited by factors such as re-exposure to the drug, stress, and exposure to drug-associated cues (e.g., audiovisual cues previously paired with drug infusion). As such, the responsiveness of NAc neurons to cocaine-associated stimuli and the effects of drug abstinence on NAc activity have also been addressed. These later studies are important since it is well known that in human drug addicts, exposure to drug-associated cues (such as drug paraphernalia) following periods of drug abstinence often lead to intense craving for the drug and resumption of drug taking (relapse). These topics are considered in the following sections.

Nucleus Accumbens Cell Firing during Cocaine Self-Administration

Initial electrophysiology studies sought to determine the firing characteristics of NAc neurons during drug-seeking behavior, particularly involving cocaine. In rodents, the beginning of cocaine self-administration sessions typically involves an initial drug 'load-up' period during which time animals press the lever 2–5 times in rapid succession within the first 5 min of the session. This is followed by a more stable pattern of responding for the remainder of the session, in which rats press the lever once approximately every 5 min (depending on cocaine dose) to maintain optimal levels of drug in their system. Electrophysiology studies revealed that following the initial load-up phase, NAc neurons exhibit patterned discharges (increases and/or decreases in cell firing) time-locked to lever-press responding for intravenous cocaine during self-administration sessions within two distinct time domains. Specifically, NAc cells exhibit significant changes in activity within seconds of the reinforced response for intravenous cocaine (termed short-term patterned discharges) and/or cycle on the order of minutes within the entire inter-infusion interval (termed long-term cyclic alterations).

With respect to short-term patterned activity, NAc neurons increase firing within seconds before the lever-press response, or increase or decrease activity immediately after response completion. These findings indicate that distinct populations of NAc neurons encode information about the important features of drug-seeking behavior including response initiation and completion. Interestingly, similar types of neuronal firing patterns have been observed relative to lever-press responding for 'natural' rewards such as water, food, or a sweet sucrose solution. Given the anatomic difference between the core and shell subregions of the NAc, investigators examined whether short-duration patterned discharges were restricted to either subregion. Studies revealed that similar types of neuronal firing patterns are observed within the core and shell of the NAc. However, West and colleagues have shown that neurons in the core exhibit a greater change in firing rate within seconds preceding the lever-press response for cocaine. These findings indicate that the core may be more involved in processing information about the execution of drug-seeking behaviors.

In addition to the patterned discharges observed within seconds of the reinforced response for cocaine, other studies have shown that some NAc neurons exhibit patterned activity across a much longer time period. For neurons exhibiting long-term cyclic alterations, cell firing is time-locked to the reinforced response for the drug but cycles on the order of minutes within the entire inter-infusion interval. This type of activity has been described in detail in a series of reports by Peoples and West. The authors revealed that a subset of NAc cells exhibits changes (primarily decreases) in cell firing approximately 1–2 min after the reinforced response and then reverse activity

(i.e., increase firing) later in the inter-infusion interval. For the majority of neurons, this reversal is gradual and varies positively with the inter-infusion interval (termed 'progressive reversal') and is not related solely to locomotion.

Since dopamine is a key neurotransmitter linked to cocaine addiction, the relationship between this chemical signal and NAc cell firing has been considered. Microdialysis studies have shown that dopamine levels rise in the NAc at the start of cocaine self-administration sessions and fluctuate within a smaller range during the inter-infusion interval. It has been proposed that the decline in extracellular dopamine during the interval may trigger subsequent self-administration behavior in order to maintain optimal levels of dopamine in the NAc. Interestingly, the time course of the progressive reversal described by Peoples and West mirrored the interval in which dopamine levels were shown to decrease in microdialysis studies. As such, it was proposed that the progressive reversal of NAc cells may constitute a neurophysiological mechanism by which decreasing drug levels (and presumably decreasing NAc DA levels) results in subsequent self-administration behavior. This is an intriguing proposal because it suggests that particular subsets of NAc neurons may be involved in the maintenance of cocaine self-administration behavior.

Dopamine may also play an important role in modulating the activity of NAc neurons that exhibit changes in cell firing within seconds of the reinforced response for cocaine (short-term patterned discharges). As noted above, anatomy studies show that dopamine nerve terminals are in a unique position to modulate cortical and subcortical input onto NAc cells. Furthermore, studies employing an electrochemical technique termed fast-scan cyclic voltammetry revealed rapid dopamine release within seconds of the reinforced response for cocaine, and relative to presentation of cocaine-associated cues (i.e., a tone–houselight stimulus that was always paired with cocaine infusion). These findings show that dopamine release occurs within the same time domain as short-duration patterned discharges of NAc neurons and may thereby function to modulate NAc activity during drug-seeking behavior. In this regard, one possibility that has been proposed is that dopamine functions to decrease background firing rates of NAc cells, thereby increasing the signal-to-noise ratio of those neurons. The net result would be an increase in the patterned discharge of NAc neurons relative to the lever-press response for the drug, or stronger neural encoding of drug-seeking behavior.

Role of Drug Abstinence on Accumbens Cell Firing during Cocaine Seeking

Cocaine addiction in humans is characterized by cycles of drug taking followed by periods of abstinence and relapse. One factor that has been linked with relapse in humans is exposure to environmental cues associated with prior drug-taking behavior. These cues have the ability to elicit intense craving for the drug and resumption of drug use. In order to better model this aspect of addiction, researchers have begun to examine additional factors controlling NAc cell firing as it relates to drug-seeking behaviors. For example, electrophysiology studies have determined that distinct populations of NAc neurons are activated by a discrete audiovisual (tone–houselight) stimulus that was always paired with the intravenous infusion of cocaine during self-administration in rats. As noted above, rapid dopamine release has also been observed relative to presentation of these same cocaine cues.

Other studies have examined the activity of NAc cell firing following periods of experimenter-imposed cocaine abstinence. For example, West and colleagues established a behavioral task incorporating a tone that signaled cocaine availability during self-administration sessions (i.e., each lever press resulted in cocaine delivery only during tone presentation). Next, cocaine availability was removed for 3–4 weeks. Thereafter, presentation of the same tone resulted in cocaine-seeking behavior, and significantly activated neurons in the shell but not the core of the NAc. Importantly, NAc shell neurons were not activated during presentation of a neutral tone never associated with cocaine. These findings reveal a persistent processing in the shell region of the NAc regarding information about cocaine-associated cues lasting several weeks after the last drug exposure.

Likewise, research completed in our laboratory examined NAc neuronal firing properties during the resumption of cocaine self-administration following 1 month of drug abstinence. We showed that the percentage of neurons that exhibit patterned discharges dramatically increased (nearly twofold) following 1 month abstinence. These findings were specific to the core but not the shell of the NAc. Likewise, the strength of the neural correlates (determined via signal-to-baseline ratios) also increased as a function of abstinence. Collectively, the results show that removal of drug availability (abstinence) from cocaine self-administration results in a dramatic increase in the number and strength of NAc neurons that encode cocaine-related information. Thus, neurons in the NAc, a key neural substrate in addiction,

become much more active following drug removal and subsequent resumption of drug-taking behavior.

Distinct Populations of Nucleus Accumbens Neurons Selectively Encode Goal-Directed Behaviors for Drug versus 'Natural' Rewards

A long-held view is that the brain reward system evolved to process information about 'natural' reinforcers such as food, water, and sex and that abused substances exert their reinforcing properties by 'hijacking' this neural circuit. Importantly, electrophysiological studies have shown that NAc neurons exhibit patterned discharges relative to reinforced responding for natural rewards such as food and water, similar to that observed during cocaine self-administration sessions. However, those initial studies were completed in different sets of animals; a critical issue addressed in a subsequent series of studies in our laboratory is whether the same neural circuit (i.e., the same neurons in the NAc) similarly process information about goal-directed behaviors for cocaine versus natural rewards. To address this issue, experiments were conducted to determine if NAc neurons that encode information about drug-seeking behaviors are the same neurons that are responsive during goal-directed behaviors for 'natural' rewards. This was accomplished by recording NAc activity during a multiple schedule of reinforcement for a natural reinforcer (water or food) and cocaine. Animals were trained to press one lever for a natural reward, followed by responding on another lever for intravenous cocaine during the same behavioral session. It was observed that in well-trained animals, cocaine activated a population of neurons in the NAc that were generally not responsive during lever-press behaviors for water reinforcement (only 8% showed similar firing patterns). Interestingly, this finding was observed from the very first day of cocaine exposure indicating that separate neural circuits for the encoding of goal-seeking behaviors involving cocaine versus natural rewards are not related to chronic drug experience.

Additional studies support the notion that separate neural circuits (or microcircuits) differentially encode information about drug versus natural rewards, at least at the level of the NAc. Differential firing patterns have also been observed during a multiple schedule for food reinforcement and cocaine self-administration in both rodents and monkeys. Furthermore, presentation of cocaine-associated stimuli has the capacity to selectively activate the subset of NAc neurons that function to process information related to cocaine-seeking behaviors but not those cells that encode information about water reinforcement. Moreover, the selective encoding of goal-directed behaviors is not unique for cocaine versus natural rewards but has also been observed during behavioral sessions involving consecutive self-administration of cocaine and heroin. Future studies are needed to establish whether NAc neurons that encode information about drug reward (cocaine or heroin) are the same neurons that process information about other types of 'natural' reinforcers such as those involving sexual behaviors.

Insights into the Functional Organization of the Nucleus Accumbens

Electrophysiological examination of single-cell activity in behaving animals allows for the discovery of a level of cellular organization in the NAc not revealed by other experimental approaches. As noted above, electrophysiological studies employing multiple schedules of reinforcement revealed that distinct populations of NAc neurons differentially process information about goal-directed behaviors for cocaine versus 'natural' (e.g., water or food) reward. Likewise, different types of abused substances (heroin and cocaine) appear to activate different groups of cells within the NAc. These findings indicate that discrete microcircuits in the NAc selectively process information about drug versus 'natural' reward. One view consistent with these findings that was proposed by Pennartz and colleagues is that the NAc is comprised of a collection of neuronal 'ensembles' or groups of cells with different functional properties. A particular ensemble is temporarily and synchronously activated by a particular set of excitatory inputs from the PFC, hippocampus, and/or BLA that in turn activate distinct NAc outputs and ultimately influence behavior. The activation of specific ensembles is modifiable depending upon reward-related learning processes. Clearly, electrophysiological recordings of single NAc neurons in animals engaged in goal-directed behaviors for drug versus natural rewards support this view.

Neurophysiological Investigations during Self-Administration of Other Abused Substances

The activation of NAc neurons during drug-seeking behavior is not unique to cocaine, but has also been observed during behaviors directed toward other abused substances including heroin and ethanol. NAc neurons exhibit increases or decreases in cell

firing relative to lever press responding for intravenous heroin with the time course and types of neuronal firing patterns similar to the short-term changes observed during self-administration of cocaine. Interestingly, similar types of patterned discharges have been recorded even though the behavioral changes induced by heroin are dramatically different from psychomotor stimulant administration (i.e., cocaine). It is not clear from studies employing heroin whether long-term cyclic alterations in cell firing are evident during the entire inter-infusion interval, as reported during cocaine self-administration. Nevertheless, these findings are consistent with the notion that the NAc is involved in mediating goal-directed behaviors for drug rewards including both psychomotor stimulants and opiates.

NAc neurons also exhibit patterned activation during ethanol self-administration. In this case, animals typically consume the drug orally, as opposed to intravenous infusion. It has been reported that a subset of NAc neurons exhibit changes (increases or decreases) in cell firing within seconds before and/or following the reinforced response for ethanol. Reinforced responses for alcohol typically involve either lever-press responses or nose-poking behavior (in which rats have to break a photo beam with their snout within a specific slot in the chamber). In addition, neurons showed patterned discharges during presentation of a tone stimulus that signaled the availability of ethanol. Collectively, these findings show that NAc neurons encode information about goal-directed behaviors across different drug classes (cocaine, heroin, ethanol) independent of type of response requirement (i.e., lever press vs. nose poke).

Behavioral Electrophysiology of the PFC and BLA

As noted above, the NAc is one component of a larger brain reward circuit and additional studies have been completed that examined cell firing during drug self-administration in regions that give rise to NAc afferents. For example, the NAc receives projections from the PFC and studies have considered how this input may influence NAc cell firing during drug-seeking behavior. It has been shown that distinct subsets of neurons in the PFC exhibit patterned discharges relative to the operant response for cocaine or heroin, similar to NAc activity. Moreover, Woodward and colleagues applied cross-correlational analysis of simultaneously recorded PFC, and NAc cells during cocaine self-administration sessions show that NAc neurons discharge before medial PFC neurons in the majority of cases. This correlated firing suggests that the NAc and PFC may participate in the control of cocaine self-administration with the NAc playing a key role in the initiation of this behavior. We have also shown that neurons in the BLA exhibit similar types of patterned discharges during cocaine self-administration to that observed for NAc cells, and are also activated by cocaine-associated cues. Collectively, these studies suggest that the encoding of drug-directed behaviors in the brain extends beyond the NAc to a more distributed, interconnected neural network involving additional structures such as the PFC and BLA. Since these neural substrates send afferents to the NAc, it is likely that the activation of NAc neurons during drug-seeking behavior is influenced by particular cortical and subcortical inputs onto NAc neurons.

Concluding Remarks

In summary, electrophysiological recordings conducted in behaving animals reveal important information about how neurons in the brain reward circuit process information about drug-seeking behaviors. When used in combination with the drug self-administration procedure, studies revealed that distinct populations of neurons in the NAc and associated regions encode the key features of drug-seeking behaviors. Moreover, studies show that neurons process information about environmental cues associated with drug intake and are influenced by factors such as drug abstinence known to affect drug addiction in humans. Collectively, these studies set the foundation for future work that can provide additional insight into neural processes underlying drug addiction in humans, perhaps leading to new pharmacotherapies to treat this chronic illness.

Introduction

The enormous advances made possible by developments in molecular pharmacology, and the availability of refined preparations that provide exquisite control over many variables, make it very tempting to try and reduce the effects of psychoactive drugs to their direct actions on a receptor, following which a fixed series of intracellular reactions is initiated. The thesis of this article, however, is that the behavioral and psychological effects of psychoactive drugs cannot be reduced to the straightforward consequences of ligand–receptor binding, and attempts to do so neglect the complexity of drug actions. This is because, as put forward by Falk and Feingold, nearly two decades ago, "the behavioral action of a drug [is due to] a cluster of interactions among the pharmacological substance, the individual set of the organism, and the environmental setting"; that is, the effects of drugs on behavioral and psychological functions are not only a consequence of the pharmacological effects of the drug, but also on the context in which the drug is experienced.

Of course, it has long been known that the physical characteristics of the environment (e.g., in laboratory settings, the size and shape of cage, type of bedding, etc.) can have a large effect on the behavioral actions of drugs. However, of particular importance here is the notion that even when the physical characteristics of the environment are held constant, apparently subtle differences in the 'psychological context' powerfully modulate both the acute effects of psychoactive drugs on brain and behavior and, with repeated administration, the ability of these drugs to change the brain. This general theme is illustrated here by discussing a series of studies by Aldo Badiani, Terry Robinson, and colleagues concerning how the neurobehavioral effects of psychostimulant and opioid drugs are modulated by the circumstances surrounding their administration.

Environmental Modulation of the Behavioral Effects of Addictive Drugs

In most of the studies discussed here, doses of amphetamine, cocaine, or morphine were administered to rats in one of two conditions. Rats in one group were transported each day from distinct cages in which they lived to test cages, at which time they received drug treatments. Rats in another group lived in the test cages in which they received the drugs. Thus, rats in both groups received drug treatments in physically identical environments, but for one group this was a relatively 'novel' environment (so we call this the 'novel group') and for the other group it was 'home' (so we call this the 'home group'). This apparently minor difference in environmental context has a profound influence on the initial (acute) psychomotor-activating effects of amphetamine (Figures 1 and 4), morphine, and heroin, but relatively little influence on cocaine effects. The psychomotor-activating effects of these drugs are much greater when they are given in a novel environment than when they are given in the home cage.

Perhaps even more importantly, environmental context not only modulates the acute psychomotor-activating effects of drugs, but also alters the ability of repeated exposure to these drugs to produce behavioral sensitization, which may be crucial in the transition to addiction, as hypothesized by Terry Robinson and Kent Berridge. Behavioral sensitization refers to an increase in a drug effect with repeated drug administration and is thought to be due to drug-induced neuroplastic adaptations in brain systems that mediate drug sensitization effects, which include psychomotor-activating and incentive-motivational effects. When given in association with environmental novelty, repeated treatments with amphetamine, cocaine, morphine, or heroin produce much greater psychomotor sensitization than when these drugs are administered in the home cage. This effect is particularly striking when the treatments are administered via intravenous catheters activated by remote control, so that the animals in the home groups are almost completely deprived of any cue that could signal drug delivery. Under these conditions, repeated administration of low doses of amphetamine, cocaine, or morphine produced robust sensitization only in the novel group (Figure 1). At higher doses, however, these drugs produce psychomotor sensitization regardless of environmental context, indicating that the effect of environmental context is not to gate sensitization in an all-or-nothing way, but rather to modulate susceptibility to this particular form of drug-induced behavioral plasticity. It is not clear what accounts for this effect of environment on susceptibility to sensitization, but it does not appear to be due to group differences in associative learning.

Figure 1 Environmental modulation of the psychomotor response to an intravenous (i.v.) challenge with 1.0 mg kg^{-1} of amphetamine or saline in rats that had previously received repeated i.v. infusions of either saline or 1.0 mg kg^{-1} of amphetamine and were then withdrawn from treatment for 4 days. For the differences between home and novelty groups see text. Data from Crombag HS, Badiani A, and Robinson TE (1996) Signalled versus unsignalled intravenous amphetamine: Large differences in the acute psychomotor response and sensitization. *Brain Research* 722: 227–231.

Figure 2 Environmental modulation of the ability of rats to discriminate amphetamine (0.25 or 0.5 mg kg^{-1}, intraperitoneal (i.p.)) from saline in a water-reinforced operant procedure (FR30). For the differences between home and novelty groups see text. Data from Paolone G, Palopoli M, Marrone MC, et al. (2004) Environmental modulation of the interoceptive effects of amphetamine in the rat. *Behavioural Brain Research* 152: 149–155.

This environmental manipulation not only influences the psychomotor effects of drugs, but also modulates the discriminative effects of amphetamine (Figure 2). It is important, however, to point out that other drug effects do not appear to be modulated in the same way by environmental context. For example, environmental novelty has only a modest effect on morphine-induced eating, and virtually no effect on the ability of morphine to suppress phasic pain from radiant heat in the tail-flick test (Figure 3).

Environmental Modulation of Immediate-Early Gene Expression

A simple difference in environmental context presumably has a large effect on the acute psychomotor-activating effects of some drugs and on their ability to induce behavioral sensitization because environmental context alters in some way the neurobiological impact of drugs. The neuropharmacological effect of amphetamine, cocaine, and morphine that is thought to be responsible for their psychomotor-activating effects is their ability to increase dopamine neurotransmission in the dorsal and ventral striatum. However, despite the large effects of environmental context on behavior, it had no effect on the ability of amphetamine to increase dopamine release in the dorsal or ventral striatum, as indicated by microdialysis studies (Figure 4).

Addictive drugs, such as morphine, cocaine, and amphetamine, also induce the expression of the gene c-*fos* (encoding the Fos protein) and other immediate-early genes (IEGs) in a number of forebrain regions, including the caudate nucleus and the nucleus

Figure 3 Environmental modulation of morphine-induced hyperactivity, hyperphagia, and analgesia. Animals received repeated i.p. injections of either saline or morphine (4.0 mg kg^{-1}). Each bar indicates the average difference between the morphine and the saline group. The animals were tested under either home or novelty conditions (see text for details). Data from Paolone G, Palopoli M, Marrone MC, et al. (2004) Environmental modulation of the interoceptive effects of amphetamine in the rat. *Behavioural Brain Research* 152: 149–155.

accumbens. This is important because IEGs can serve as indicators of neuronal activity and are also thought to represent an initial step in initiating experience-dependent plasticity. Interestingly, studies on the influence of environmental context on drug-induced IEG expression using *in situ* hybridization have revealed that the ability of amphetamine, cocaine, or morphine to induce c-*fos* or *arc* mRNA expression varies greatly, depending on the environmental context (home vs. novel) in which the drugs are administered. Although a relationship between drugs and environmental novelty is detected in almost every cortical and subcortical structure that has been examined, the most interesting changes are noted to occur in the striatum and in the amygdala, two brain regions implicated in incentive motivation, reward, and learning.

Striatum

Environmental novelty enhances the ability of amphetamine and cocaine to induce c-*fos* or *arc* mRNA expression in the caudate-putamen, and the interaction is maximal in the caudal portions of the caudate, where c-*fos* mRNA levels are nearly two times greater than would be predicted by the simple addition of the effects of amphetamine and mere exposure to a novel environment (Figure 5). In the ventral striatum the effects of novelty and amphetamine (or cocaine) are infra-additive and there is no significant rostrocaudal gradient. Interestingly, in the nucleus accumbens the effect of mere exposure to a novel environment on Fos mRNA expression is greater than that produced by an injection of amphetamine or cocaine in the home setting, suggesting that the nucleus accumbens is especially responsive to environmental novelty.

Most importantly, in the striatum the effect of environmental context on drug-induced IEG expression does not simply represent a quantitative effect, but the context in which these drugs are administered determines which specific cells and circuits are engaged. In the striatum over 90% of the neurons are γ-aminobutyric acid (GABA)ergic medium spiny projection neurons. Approximately half of these neurons co-express mRNAs for pre-prodynorphin, substance P, and the dopamine D1 receptor and project directly to the output nuclei of basal ganglia (substantia nigra pars reticulata and the external globus pallidus), forming the so-called direct pathway. The other half of these projection neurons co-express pre-proenkephalin and D2 receptor mRNAs and modulate basal ganglia output nuclei via an 'indirect pathway' by providing an inhibitory input to the internal globus pallidus, which in turn inhibits the subthalamic nucleus (STN). When given at home, amphetamine, cocaine, or morphine induces robust Fos mRNA expression almost exclusively in dynorphin/D1-positive neurons. In contrast, when amphetamine (or cocaine) is given in association with environmental novelty it induces robust Fos mRNA expression in both dynorphin/D1 and enkephalin/D2 neurons, as well as in the STN (Figure 6). These findings indicate that which cells and circuits are engaged with psychostimulant drugs (and morphine) depends to a large extent on the environmental context in which the drugs are experienced.

The mechanism by which environmental novelty modulates the cells and circuits engaged by drugs is not known. It is known that mere exposure to a novel environment powerfully induces Fos mRNA expression in most cortical areas, and activation of corticostriatal projections induces c-*fos* expression

Figure 4 Environmental modulation of the psychomotor and neurochemical (dopamine release) response to an acute administration of amphetamine (0.5 mg kg^{-1}, i.v. for the left panels; 200 mg kg^{-1}, i.p. for the right panels). Three groups of rats were implanted with microdialysis probes aimed at one of the three regions of the striatal complex. Amphetamine was administered under either home (amphetamine group) or novelty (amphetamine + novelty group) conditions (see text for details). Some animals received saline in association with novelty (novelty group). Data from Badiani A, Oates MM, Day HEW, et al. (1998) Amphetamine-induced behavior, dopamine release and c-*fos* mRNA expression: Modulation by environmental novelty. *Journal of Neuroscience* 18: 10579–10593; and Badiani A, Oates MM, Fraioli S, et al. (2000) Environmental modulation of the response to amphetamine: Dissociation between changes in behavior and changes in dopamine and glutamate overflow in the rat striatal complex. *Psychopharmacology (Berlin)* 151: 166–174.

specifically in enkephalin/D2-positive neurons in the striatum. Thus, a working hypothesis is that novelty modulates drug-induced c-*fos* expression in the striatum via glutamatergic projections from the cortex to the caudate-putamen and to the STN. In support of this, *N*-methyl-D-aspartate (NMDA) receptor antagonists preferentially reduce amphetamine-induced Fos mRNA expression in enkephalin/D2-positive neurons, as does transection of corticostriatal fibers.

Amygdala

Other areas of brain regions where novelty and addictive drugs interact in a very complex manner are the amygdala and the bed nucleus of the stria terminalis (BST). Novelty, but not amphetamine or cocaine, induces Fos mRNA expression in the medial amygdala (MEA) and medial posterior nucleus of the BST (BSTmp). Induction of c-*fos* expression in these areas has been previously observed in response to some stressors but it is unlikely that the hypothalamic–pituitary–adrenal (HPA) axis is implicated in this effect of novelty, because amphetamine, at the same doses that fail to enhance c-*fos* expression in the MEA/BSTmp, produces plasma corticosterone levels comparable to those produced by novelty.

Both novelty and psychostimulants induce Fos mRNA expression in the basolateral amygdala, which has been implicated in the response to affective stimuli

Figure 5 Environmental modulation of saline- and amphetamine-induced (2.0 mg kg^{-1}, i.p.) Fos mRNA expression in the rat caudate and parietal cortex. The figure also shows representative densitograms. The animals were tested under either home (untreated, sal, and amph groups) or novelty (sal + novelty and amph + novelty groups) conditions (see text for details). Progressively greater intensity of the signal from the hybridized ^{35}S-riboprobe for Fos mRNA is indicated by the transition from blue to yellow to red. Data from Badiani A, Oates MM, Day HEW, et al. (1998) Amphetamine-induced behavior, dopamine release and c-*fos* mRNA expression: Modulation by environmental novelty. *Journal of Neuroscience* 18: 10579–10593.

and in conditioned reinforcement. When amphetamine or cocaine is given in association with novelty, Fos mRNA expression is further enhanced, a pattern similar to that observed in the caudate.

Amphetamine or cocaine administered in the home setting induces robust Fos mRNA expression in the central amygdala (CEA) and oval subnucleus of the BST (BSTov), whereas novelty produces only a modest effect. Quite surprisingly, when amphetamine (or cocaine) is given in association with novelty, the Fos response in these structures is much smaller than that produced by amphetamine (or cocaine) at home. This most unusual pattern is fundamentally different from what is observed in all other brain regions examined so far, and the reason for it is still unclear.

Neocortex

At least from a purely quantitative point of view the interaction between novelty and the effect of amphetamine in the neocortex and septum appears to be relatively simple. In these regions, as seen for the MEA and BSTmp, novelty produces much more robust c-*fos* expression than does exposure to amphetamine alone, and the effect of novelty is comparable in magnitude to that of amphetamine plus novelty (Figure 5). Double *in situ* hybridization studies are required to determine whether the lack of quantitative differences in c-*fos* expression between the novelty and amphetamine plus novelty groups masks a differential activation of distinct populations of neurons.

Environmental Modulation of Drug-Induced Structural Neuroplasticity

The influence of environmental context on the ability of drugs to induce psychomotor sensitization is not only interesting with respect to understanding how drug–environment interactions modulate drug effects, but it also provides a unique tool to explore whether any given drug-induced change in the nervous system is associated with drug-induced sensitization, or occurs as a function of mere drug history. Indeed, in the extensive literature on the neurobiology of sensitization there are almost no examples of attempts to dissociate the effects of mere drug history from the ability of drugs to induce sensitization. In sensitization experiments typically drugs are given

Figure 6 Effect of environment on amphetamine- and cocaine-induced Fos mRNA expression in the neurons of the direct vs. the indirect projection system of the rat caudate. These two subpopulations of striatal neurons were identified by examining the co-expression of markers for either D1 vs. D2 receptor mRNAs or prodynorphin vs. proenkephalin mRNAs. For the differences between home and novelty groups see text. Data from Badiani A, Oates MM, Day HEW, et al. (1999) Environmental modulation of amphetamine-induced c-*fos* expression in D1 versus D2 striatal neurons. *Behavioural Brain Research* 103: 203–209; and Uslaner JM, Badiani A, Norton CS, et al. (2001) Amphetamine and cocaine induce different patterns of c-fos mRNA expression in the striatum and subthalamic nucleus depending on environmental context. *European Journal of Neuroscience* 13: 1977–1983.

repeatedly in a manner that induces behavioral sensitization, and then brains are examined to determine if the drug treatment regimen altered the neurobiological measure of interest. However, such studies do not reveal whether drug treatment would have altered the molecule/measure of interest whether drug treatment induced sensitization or not.

However, the effect of environmental context as described herein provides an interesting way to hold drug history constant while varying drug treatment, to see whether drug treatment induces sensitization. The drug history of an animal in its home setting versus in a novel setting is constant, but within a given dose range only drug treatments in the novel setting induce the observed form of behavioral plasticity. If any given drug-induced neuroadaptation is related to the development of sensitization, it should be seen in the novel group but not the home group. This procedure has been used recently to determine whether one neural correlate of sensitization is specifically related to the development of sensitization or to mere drug history.

Terry Robinson, Bryan Kolb, and their colleagues have reported that repeated intermittent treatments with amphetamine or cocaine, treatments that induce behavioral sensitization, also alter synaptic organization in the nucleus accumbens and the prefrontal cortex, as indicated by changes in dendritic branching and in the number of dendritic spines on cells in these brain regions. It is not clear from these studies, however, whether psychostimulant drugs would produce this form of structural plasticity even if they failed to produce behavioral sensitization. This question was examined by treating animals with repeated injections of cocaine, either in the home environment or in a relatively novel test environment (as described

Figure 7 Effect of environment on the ability of repeated cocaine to induce structural plasticity in the shell of the nucleus accumbens. For the differences between home and novelty groups see text. Data from Li Y, Kolb B, and Robinson TE (2003) The location of persistent amphetamine-induced changes in the density of dendritic spines on medium spiny neurons in the nucleus accumbens and caudate-putamen. *Neuropsychopharmacology* 28: 1082–1085.

previously). Under the conditions of one experiment a cocaine treatment regimen (15 mg kg^{-1} daily for 8 days) was used that induced robust behavioral sensitization in the novel condition, but no significant sensitization in the home condition. Two weeks after the last injection the brains were examined for evidence of structural plasticity.

It was found that cocaine treatment increases spine density on medium spiny neurons in the 'core' of the nucleus accumbens only in the novel group (i.e., only in the group that was sensitized) (Figure 7). This is consistent with the hypothesis that drug-induced structural plasticity in the core of the accumbens is related to the development of psychomotor sensitization. In contrast, cocaine treatment increases spine density in the 'shell' of the accumbens in both the novel and the home groups (i.e., independent of whether drug treatment produced sensitization). Thus, in the shell this particular form of structural plasticity is associated with mere drug history, and does not require that drug treatments also induce sensitization. Finally, as indicated previously, the effect of environmental context is dose dependent, and as dose is increased amphetamine and cocaine induce sensitization even when given at home. It is important, therefore, that repeated treatments with a higher dose of cocaine (30 mg kg^{-1}), a dose that induces psychomotor sensitization even at home, produce structural plasticity in the core of the accumbens, even though treatments are given in the home cage.

Thus, the context in which cocaine is experienced not only modulates its ability to induce behavioral sensitization, but also its ability to induce structural plasticity in the core (but not shell) of the nucleus accumbens. Varying the context in which drugs are experienced provides a powerful way to dissociate those drug-induced neuroadaptations that are associated with the development of this form of behavioral plasticity from those that occur as a function of mere drug history.

Conclusions

Two important conclusions can be drawn from the findings on the environmental context of drug addiction. The first one is a cautionary note for neuroscientists who may be tempted to interpret behavioral data obtained under conditions similar to those of our 'novel' groups (as is customary in behavioral pharmacology) on the basis of molecular biology data obtained under conditions that are similar to those of our 'home' groups. The fact is, the behavioral and neurobiological effects of drugs vary qualitatively depending on the context in which they are experienced; therefore, to understand how drugs influence behavior and psychological function, they need to be studied 'in context.'

The second conclusion is that environmental context can exert a powerful modulatory influence on the ability of drugs to induce the neuroplastic adaptations implicated in drug addiction. Thus, an understanding of how repeated drug use sometimes leads to addiction will also require considering the environment in which drugs are experienced. Recent data from Aldo Badiani's laboratory indicating that environmental context has a powerful influence on the acquisition of cocaine self-administration behavior in the rat (Figure 8) further emphasize the importance of this issue for addiction research.

Figure 8 Environmental modulation of cocaine self-administration (0.2–0.4 mg kg^{-1} per infusion). The number of consecutive responses required to obtain, on a fixed ratio schedule, a single infusion was raised from 1 (sessions 1–2) to 2 (sessions 3–5) and then to 5 (sessions 6–7). The right panel illustrates the maximum number of responses emitted in a break-point procedure for the same doses of cocaine. The number of responses required to obtain a single infusion was increased within the session according to the following progression: 5, 10, 20, 30, 50, 70, 100, 150, 200, 300, 500, etc. Data from Caprioli D, Paolone g, Celentano M, Testa A, Nencini P, and Badiani A (2007) Environmental modulation of cocaine self-administration in the rat. *Psychopharmacology* 192: 397–406.

Addiction and Synaptic Plasticity

Glutamate Receptors as Targets for Addictive Drugs

There is abundant evidence that dopamine represents a key molecule for the development and expression of addictive behaviors. However, a growing body of evidence suggests that the excitatory neurotransmitter glutamate plays a central role during drug-dependent learning and other adaptive processes that ultimately lead to substance abuse, to modulate both ventral tegmental area (VTA) neurons and the limbic system. When glutamate is released from presynaptic terminals, it activates both ionotropic receptors – for example, receptors (Rs) for α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainate, and *N*-methyl-D-aspartate (NMDA) – and metabotropic glutamate receptors, and a variety of studies have shown that inhibition of any of these receptors interferes with both the development and the expression of addictive behaviors. For example, AMPAR antagonists or NMDAR antagonists impair lever pressing for cocaine. Further, morphine- and psychostimulant-induced place preference are disrupted as well. Similarly, AMPAR antagonists inhibit lever pressing for cocaine, amphetamine, and alcohol administration and impair amphetamine- and morphine-induced place preference. Along the same line, the development of behavioral sensitization (a behavioral index of craving) to cocaine, amphetamine, and morphine is blocked by NMDAR antagonists whereas AMPAR antagonists affect the maintenance of sensitization. These data support the hypothesis that all major drugs of abuse initiate abnormal learning mechanisms via activation of NMDARs and AMPARs, which ultimately leads to drug-dependent behaviors.

Long-Term Potentiation: A Cellular Substrate for Abnormal Learning and Memory Processes

Long-term potentiation (LTP) and long-term depression (LTD) were first described in the hippocampus many years ago. Unlike classical synaptic events that last from a few milliseconds to a few hundreds of milliseconds at most, LTP and LTD of AMPA receptors can last for hours, days, and perhaps longer, and represent the most studied forms of synaptic plasticity. The main reason LTP has received so much attention over the past 20 years is because it has been suggested as a key substrate of normal learning and memory processes. LTP and LTD typically have a rapid induction phase – which is in many cases, but not exclusively, NMDAR dependent – and a maintenance phase involving changes in glutamate release and/or AMPAR turnover and sensitivity. The temporal properties of LTP and LTD make them contenders for mediating rapid onset and persistent neural adaptations in the reward circuitry.

Both LTP and LTD have been identified in VTA dopaminergic cells. LTP is NMDAR dependent, whereas LTD is NMDAR independent, although LTD is blocked by activation of somatodendritic D_2 dopamine receptors present on VTA dopaminergic neurons. Subsequent studies have shown that amphetamine blocks LTD, whereas *in vivo* cocaine exposure as well as exposure to most other major drugs of abuse promotes LTP-like potentiation of AMPAR-mediated synaptic responses in VTA dopaminergic cells (Figure 1). Thus, the consequence of even a single exposure to an addictive drug is a persistent increase in the efficacy of glutamatergic synaptic transmission in VTA dopaminergic cells via potentiation of AMPARs. In the first study to provide evidence that *in vivo* exposure to an addictive drug (cocaine) leads to potentiation of AMPAR synaptic responses, the effect was observed for at least 5 days but less than 10 days following a single exposure. Importantly, the magnitude of cocaine-induced potentiation of AMPAR responses correlates with the magnitude of cocaine-induced locomotion, and, as with behavioral sensitization, cocaine-induced potentiation can be blocked by NMDAR antagonists. However, although these studies suggest that cocaine induces transient synaptic changes in VTA neurons, the results of the studies also imply that plasticity at excitatory synapses in the VTA perhaps plays a role in the initiation, but not the maintenance, of the addiction process, based on examination of synaptic plasticity in the VTA by using noncontingent, experimenter-administered cocaine procedures.

Because drug taking is a learned process, it is important to understand whether voluntary drug intake and passive drug exposure produce similar durations of synaptic plasticity. Further, since drugs of abuse are hypothesized to usurp learning processes in the motivational circuit, it is also important to determine whether voluntary intake of natural rewards produces changes in cellular functions similar to those produced by drugs of abuse. For this reason, our laboratory examined glutamatergic synaptic transmission in the VTA of animals trained to self-administer cocaine or food, as well as in the VTA of animals

Figure 1 Hypothetical α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPAR) modifications as a consequence of long-term potentiation (LTP). A ventral tegmental area excitatory synapse is expanded to indicate potential changes in glutamate receptor (GluR) subunit expression. (a) GluR1 subunits before LTP (NMDAR, *N*-methyl-D-aspartate receptor). (b) GluR subunit expression following LTP in response to addictive drugs. (c) Representation of typical dopaminergic cell firing pattern, both under control conditions of background firing (irregular tonic firing) and with a firing pattern in response to a reward or to a reward-associated (conditioned) stimulus (CS; phasic firing of high-frequency bursts). (d) Proposed changes in firing patterns following drug-induced LTP, when less tonic irregular firing and more burst firing might be observed, particularly in response to salient reward or reward-related (CS) stimuli. However, as mentioned in the text, it is possible that depolarization block might occur owing to increased AMPAR function. Depolarization block would lead to a temporary reduction of dopamine release. Adapted from Jones S and Bonci A (2005) Synaptic plasticity and drug addiction. *Current Opinion in Pharmacology* 5: 20–25.

administered noncontingent cocaine via a yoked design in which cocaine exposure is similar to that received by the animals self-administering cocaine. In this study, longer-lasting plasticity (3–4 weeks) at AMPARs was specifically observed during abstinence from cocaine, but not during food self-administration. Similarly, the excitatory synaptic inputs to the VTA are strengthened as well, but this only suggests that the learned association of the operant task with cocaine caused a long-lasting synaptic enhancement in the glutamatergic projections onto VTA dopamine (DA) neurons.

Plasticity at excitatory synapses has been demonstrated in brain regions receiving dopaminergic innervation, including prefrontal cortex, dorsal striatum, nucleus accumbens, hippocampus, and amygdala. The expression of LTP in these brain regions could contribute to acquisition of instrumental and Pavlovian learning under physiological conditions as well as being a consequence of chronic exposure to addictive drugs. Thus, it will be important to identify specific synaptic inputs that undergo plasticity under different learning conditions, since inputs to the VTA come from a variety of brain regions activated during reward-related learning. In addition, it will be interesting to examine the time course of onset and duration of synaptic plasticity in different parts of the reward circuit to ascertain the temporal role – and hence relative contribution – of each region.

In addition to evidence that LTP and LTD are expressed in the VTA, there is strong behavioral evidence that plasticity at glutamatergic synapses in the VTA is a possible key player in sustaining substance abuse. First, VTA dopaminergic cells are responsive to rewards and to cues learned by classical association to be predictors of reward. Second, place preference induced by cocaine shows dependence on VTA glutamate receptors. Third, inactivation of the VTA impairs cocaine-seeking behavior maintained by a drug-associated stimulus. Fourth, VTA glutamate receptor inhibition blocks stress and cue-induced relapse to cocaine seeking. Finally, repeated or even

a single administration of addictive drug (including cocaine, amphetamine, morphine, and nicotine) directly into the VTA initiates sensitization to systemic drug challenge, and NMDAR antagonists, delivered directly to the VTA, block the development of sensitization. Taken together, these findings strongly suggest that glutamatergic synapses in VTA dopaminergic cells constitute the sites of some of the earliest neural adaptations in response to addictive drugs. In summary, synaptic plasticity occurs at glutamatergic synapses in the VTA in response to several addictive drugs. Thus, potentiation of glutamatergic synapses might trigger persistent changes in dopaminergic cell signaling, thereby contributing to the persistence of pathological addictive behaviors.

Drug-Induced Synaptic Plasticity and VTA Dopaminergic Cell Activity

Thus far, we have discussed the evidence that drug-induced synaptic plasticity occurs in VTA dopaminergic cells, and that glutamate receptor activation onto VTA neurons is required for learning mechanisms in reward and addiction. However, a key question remains to be answered: What are the consequences of glutamatergic synaptic plasticity in the VTA for dopaminergic cell activity and dopamine release? VTA dopaminergic cells exhibit two main patterns of firing activity *in vivo*, single-spike firing and burst firing. Studies in rodents and primates have indicated that burst firing of VTA dopaminergic cells signals the occurrence of salient reward-associated stimuli. When spikes are clustered into bursts, the increase in extracellular dopamine in projection areas would likely produce a significantly larger amount of DA release than that observed for regularly spaced spike trains at the same mean spike frequency, as a consequence of nonlinear summation. Further, burst firing might promote co-release of a variety of peptides, as well as favor early gene expression. These results suggest that NMDAR activation might play two crucial roles in fine-tuning dopaminergic cell activity. First, NMDARs would promote induction of LTP of AMPAR responses. Second, NMDARs increase the efficiency of dopamine release by promoting burst firing of dopaminergic cells.

In vivo studies have shown that repeated cocaine or amphetamine administration causes an increase of VTA dopaminergic cell firing in response to AMPA exposure *in vivo*. Thus, it is plausible to hypothesize that LTP of AMPAR responses after a single or repeated drug exposure produces an increase in the incidence of burst firing, thus enhancing dopamine release. However, it is possible that excessive activation of AMPAR-mediated current might favor the occurrence of a depolarization block, thereby causing a reduction of action potential firing in VTA dopaminergic cells, and hence a reduction of dopamine release. It is very plausible that both phenomena might occur, ultimately causing an increase of the signal-to-noise ratio, where periods of depolarization blocks would be followed and/or preceded by periods of burst activity. Therefore, following drug exposure, plasticity at VTA excitatory synapses could be instrumental in determining a dramatic change of the firing pattern of VTA neurons, as reward-related stimuli are received and processed by VTA neurons. Such changes in the patterns of dopaminergic cell activity might represent an important mechanism by which dopamine signaling modulates the limbic circuit and sustains the formation of pathological drug-dependent learning that ultimately leads to substance abuse.

In conclusion, forms of synaptic plasticity sensitive to addictive drugs have been identified in the VTA. Addictive drugs administered either passively or voluntarily *in vivo* cause a rapid and persistent potentiation of AMPAR-mediated synaptic responses. Changes in AMPAR subunit expression are also reported to occur, but how such changes relate to the functional plasticity and behavioral effects of drugs is still a matter of debate. Ultimately, the questions are whether, and how, synaptic plasticity underlies specific forms of learning and long-lasting neural adaptations associated with addiction. These questions are fundamental in studies of the neurobiology of behavior and have yet to be answered.

Addiction and Ion Channels

Phasic alterations in action potential firing are a predominant mechanism through which neurons transmit information and drive behavioral expression. Firing changes are observed in several mesolimbic areas in association with many aspects of drug-related responding, including for operant responding and for stimuli that predict drug reward. Thus, any functional change that alters the firing properties of a neuron, either through glutamate receptor activation or ion channels, could significantly influence how the particular neuron and brain region contribute to behavioral expression.

Here we focus on investigations of ion channel modulation of acute drug effects, self-administration or reinstatement, and of modulation of ion channel function by chronic drug exposure. In this way, we hope to validate the potential *in vivo* role of a particular ion channel, and also identify consistencies or differences across different drugs of abuse. The contributions of intracellular signaling pathways to addiction have been addressed in recent reviews, and are not addressed here. In addition, acute effects of

drugs of abuse on ion channels through activation of G-protein-coupled receptors are extensive and varied, and are generally not addressed here.

We should note that there is much we do not yet know about regulation of addictive behaviors by particular ion channels; there are few channel types for which a broad range of drug-related behaviors has been investigated or for which the underlying brain regions have been identified. Furthermore, ion channel modulators could alter drug-related behavior by acting in brain regions different from those where a drug has its acute effects, thus altering the activity of the brain circuit underlying the behavior. This is a particularly important caveat when using transgenic animals or systemic channel modulators. Nonetheless, a channel modulator may actually be of great benefit for the treatment of addiction, even if therapeutic investigations outpace our understanding of its role at the cellular and regional level.

Calcium Channel Modulation of Addictive Behaviors

Perhaps the most widely studied example of ion channel regulation of an addictive behavior is the contribution of L-type voltage-gated calcium channels (LVGCCs), which can regulate firing, plasticity, and activation of intracellular regulatory molecules, to morphine tolerance and withdrawal (Figure 2). Concurrent administration of LVGCC antagonists with morphine significantly reduces the development of both tolerance and behavioral withdrawal symptoms, and also prevents the development of cellular changes thought to contribute to the expression of withdrawal (including upregulation of LVGCCs and reduced basal dopamine levels in many brain areas). Increased LVGCC levels after chronic morphine likely contribute causally to withdrawal, since acute inhibition of LVGCCs only, at the time of withdrawal, also significantly reduces signs of withdrawal.

A pattern of increased LVGCC density after chronic drug exposure, and reduction of the development of tolerance and withdrawal after treatment with LVGCC antagonists, are observed after chronic exposure to other drugs of abuse, including ethanol and nicotine. Chronic ethanol upregulates LVGCC levels, and acute LVGCC antagonists decrease ethanol withdrawal symptoms and the depression in DA levels associated with ethanol withdrawal. Reduced dopamine levels likely contribute to ethanol seeking, since self-administration of ethanol during withdrawal continues until nucleus accumbens (NAcb) dopamine levels are normalized. Thus, LVGCC dysregulation could represent a common mechanism underlying early withdrawal from abused drugs. However, not all drugs produce similar effects on LVGCCs; repeated amphetamine exposure upregulates VTA LVGCCs for at least 14 days.

The exact mechanism through which chronic exposure to LVGCC antagonists reduces withdrawal symptoms is uncertain. Opiate receptors can exert their cellular effects through calcium channels (e.g., for analgesia), and inhibition of LVGCCs might prevent these acute actions of opiate receptors and the development of compensatory neuroadaptations. LVGCC upregulation might also represent a more general homeostatic response to opiate-induced decreases in excitability – for example, through activation of G-protein-coupled inwardly rectifying potassium channels (GIRKs). Also, since low dopamine levels are associated with morphine withdrawal, it has been proposed that increased LVGCC levels reduce DA release in ventral tegmental area target regions, leading to some withdrawal symptoms; however, LVGCCs within the VTA enhance firing of DA neurons, so the cellular mechanism that could underlie this effect remains unclear.

In addition to regulation of withdrawal, LVGCC antagonists reduce the reinforcing effects of a number

Figure 2 A schematic demonstrating examples of ion channels reported to be altered after (a) chronic morphine administration (brain region not specified) or (b, c) chronic cocaine administration, with differential changes in the nucleus accumbens (b) and prefrontal cortex (c), indicating potassium channels and N-, R-, and L-type voltage-gated Ca^{2+} channels.

of abused drugs. LVGCC antagonists reduce self-administration of cocaine, ethanol, and opiates, and, in one study, LVGCC antagonists did not alter sucrose self-administration except at high doses. LVGCC antagonists also reduce conditioned place preference (CPP) for several drugs, as well as nicotine reinstatement and amphetamine sensitization. Intra-NAcb infusion of LVGCC antagonists reduces the development of behavioral sensitization to cocaine, although this enhances cocaine CPP. We should note that not all studies agree, and this could reflect the differential effectiveness of the various LVGCC antagonists examined or the differential action on particular VGCC subtypes.

Considerable human preclinical evidence suggests that LVGCC antagonists may ameliorate withdrawal, tolerance, and craving in human addicts. LVGCC antagonists decrease adverse symptoms during early withdrawal from ethanol, opiates, and amphetamine, although effects on cocaine maybe more moderate. LVGCC antagonists decrease the euphoric effect of opiates, while ethanol intoxication is not altered in humans, although LVGCC antagonists enhance the sedative and ataxic effects in rodents. LVGCC antagonists enhance the analgesic effect of opiates by reducing the development of tolerance, in agreement with studies showing decreased opiate tolerance in rodent models. Taken together, studies from humans and rodents generally concur regarding the antiaddictive properties of LVGCC antagonists. However, a study in monkeys found that LVGCC blockers did not alter cocaine self-administration or cocaine modulation of food self-administration. Thus, preliminary investigations have suggested, but have not fully established, the clinical utility of LVGCC antagonists in the treatment of some aspects of addiction.

In general, the cellular mechanisms and brain regions where LVGCCs modulate withdrawal or reinforcement are unknown. Calcium influx could contribute to memory formation, since LVGCCs are critical for some types of synaptic plasticity. In addition, LVGCCs enhance firing – in particular, burst firing – of a number of brain regions, including the nucleus accumbens and VTA. LVGCC can also enhance DA release from terminals. However, a recent study suggests that LVGCC antagonists can directly inhibit nicotinic acetylcholine receptors at more moderate doses, underscoring the need for caution when working to develop human therapies based on rodent models. In addition, some results regarding LVGCC and the cellular mechanisms seem paradoxical, since LVGCC antagonists can prevent memory impairments, in apparent opposition to any LVGCC contribution to memory formation through enhanced plasticity, firing, or gene expression. Thus, it will ultimately be critical to identify the particular brain regions where LVGCC antagonists modulate different addiction- and memory-related behaviors. Nonetheless, even if LVGCC antagonists are found to inhibit addictive responses through nonspecific or peripheral effects, this may not diminish their clinical utility for treatment of human addiction and alcoholism.

Modulation of Drug Reinforcement by Other Ion Channels

In addition to LVGCCs, a number of other channels have been investigated in relation to the reinforcing effects of drugs (see Table 1). Some studies also have observed changes in firing in which the underlying channel changes are unknown. Here we address G-protein-coupled inwardly rectifying potassium channels in detail, since GIRK agonists may represent a potential therapy for addiction.

Many receptors inhibit neuronal firing through activation of GIRKs, and GIRK2 knockout studies also support a role for GIRKs in some acute effects of ethanol. GIRK2 and GIRK3 knockout mice also exhibit reduced cocaine self-administration, perhaps suggesting enhanced cocaine reinforcement due to enhanced neuronal excitability. However, simultaneous knockout

Table 1 Examples of channels influencing drug-related behavior

Channel	*Behavior*
ATP-activated potassium channels	Forebrain levels decreased by chronic morphine; systemic agonist reduces morphine withdrawal symptoms
Kv1.1 A-type potassium channel	Kv1.1 antisense (intracerebroventricular administration) reduces amphetamine but not cocaine or basal locomotion, and also food intake
N-Type voltage-gated calcium channels	Transgenic knockout reduces ethanol self-administration and place preference as well as hypnotic effects
R-Type voltage-gated calcium channels	Reduces cocaine-induced locomotion without affecting cocaine sensitization or conditioned place preference
BK (large-conductance, calcium-dependent potassium channel)	BK overexpression increases ethanol tolerance in *Drosophila*, while ethanol tolerance in the hypothalamic–neurohypophysial system is associated with decreased BK activity

of GIRK2 and GIRK3 surprisingly increases cocaine self-administration, serving as an example of the caution required when addressing the cellular mechanisms underlying drug reinforcement after brain-wide changes in ion channel function.

Although removal of GIRK channels may prevent certain drug actions, GIRK activators, such as baclofen, which activates GIRK through $GABA_B$ receptors, may represent a powerful therapeutic intervention to counteract craving and drug seeking. In animals, baclofen prevents the expression of sensitization or reinstatement for several abused drugs, including morphine and psychostimulants. In preclinical human studies, baclofen reduced withdrawal symptoms and craving in cocaine, ethanol, and opiate addicts. Baclofen may reduce drug seeking by decreasing neuronal excitability in multiple brain regions, perhaps reducing neuronal hyperexcitability during withdrawal, and also decreasing cue-related firing and drug seeking.

Interesting as well is the increasing number of studies using DNA microarray or proteomic techniques to uncover proteins associated with differential preference for abused drugs, including ethanol. Some of these studies compare different ethanol-preferring and nonpreferring rodent strains, while others examine the consequence of ethanol exposure on gene expression. Of course, many different genes and gene products, including some channels, show differential expression and could contribute to ethanol preference.

Changes in Ion Channel Function after Chronic Drug Exposure

There is considerable interest in understanding the persisting changes in cellular function that may underlie craving and relapse, even after months or years of abstinence, following chronic self-administration of an abused drug. Changes in ion channel regulation of firing could dramatically alter sensitivity to relapse-inducing stimuli. However, with the exception of studies of psychostimulant alteration of ion channel function (Figure 2), relatively few studies have examined whether chronic drug exposure persistently alters ion channel function.

Repeated cocaine administration followed by 3 days of withdrawal reduces NAcb excitability due to increased potassium channel activity, decreased R- and N-type VGCC activity, and decreased sodium channel activity. Repeated cocaine administration has opposite effects in frontal cortical neurons, with enhanced excitability due to increased activity of LVGCCs and decreased activity of IRK and voltage-gated potassium channels. No changes are observed in the motor cortex, suggesting specific neuroadaptations in limbic areas. In contrast to cocaine, repeated amphetamine administration reduced sodium channel activity and excitability of subicular and frontal cortical neurons. Interestingly, some channel changes may be secondary to alterations in tonic activity of intracellular signaling molecules. For example, in the NAcb, increased tonic protein phosphatase activity and increased tonic protein kinase A (PKA) activity likely underlie the reduced calcium and sodium channel function, respectively. Also, importantly, enhanced excitability of frontal cortical neurons persists for 2–3 weeks after withdrawal from cocaine, suggesting that this activity may be long-lasting and thus may contribute to the expression of behavioral sensitization.

Chronic morphine also alters several ion channels other than LVGCCs, with different effects, depending on the brain region. The striatum shows reduced potassium channel (Kv1 and Kv2) mRNA, likely enhancing firing, while P/Q- and L-type VGCCs are reduced in trigeminal neurons but not in the locus coeruleus. Chronic morphine can also alter opiate channel coupling, with a change at the level of the receptor instead of the channel. Finally, after 10 months of ethanol exposure and 2–4 weeks of withdrawal, the only change in intrinsic excitability in hippocampal neurons was a decrease in the afterhyperpolarization, suggesting reduced K^+ channel function.

Conclusions and Future Directions

Although there are interesting and tantalizing clues pointing toward the effect of chronic drug exposure on channel function, many questions remain. Few studies have examined channel function beyond the period of early withdrawal, while changes persisting after weeks or months of abstinence may be critical in long-term susceptibility to craving and relapse. It is also clear that self-administration and passive administration can differentially alter gene expression and protein function, perhaps due to learned cues that come to be associated with the act of voluntary seeking or self-administration of drugs. Thus it is also critical to understand whether any changes in ion channel function are specific to active self-administration. A recent study has identified a change in glutamatergic function in animals that self-administered cocaine, but not in those that received cocaine passively, which perhaps represents a cellular correlate of learned associations, possibly between the drug experience and drug-associated cues, which can drive cocaine-seeking behavior.

Identifying the most critical cellular changes that may underlie the persisting neuroadaptations that drive relapse of drug seeking will likely require a number of different important techniques. Clearly, biochemical methods (such as Western blots and local knockdown or overexpression of particular signaling

molecules) provide tremendous power in identifying protein products altered by chronic drug exposure and prolonged abstinence, and which contribute to susceptibility to relapse. Similarly, large-scale screening for changes in protein levels (using proteomics) or mRNA levels (using DNA microarrays) hold great promise for indicating potential changes in channel function. In addition, we believe that brain slice experiments examining the electrophysiological consequences of chronic drug exposure and prolonged abstinence are critical, since there are many mechanisms that can alter receptor or channel function without changing total protein. Such experiments examining electrophysiological properties in brain slices from adult animals are laborious (due to the amount of time needed for training the animals) and technically challenging. However, the information gained is potentially of great value to the understanding of the mechanisms underlying drug self-administration and relapse.

Introduction

Many substances of abuse exist; they are classified according to their psychoactive effects on the individual's behavioral, psychological, and neurobiological functioning. For example, central nervous system depressants include ethanol, opiates, and sedative hypnotics. Stimulants include cocaine and methamphetamine. All substances of abuse are reinforcing. That is, they increase the probability of a subsequent response through increasing pleasure/reward or decreasing displeasure/pain processes. All drugs of abuse thus share a powerful psychoactive ('mind' altering) impact that enhances a learning process whereby the individual develops anticipatory responses to the drugs. These drug-induced effects are believed to contribute to the progression from drug abuse to drug addiction in susceptible individuals (see Table 1 for current definitions of drug abuse and addiction by the *Diagnostic and Statistical Manual for Mental Disorders*, fourth edition (*DSM-IV*)).

Addiction is a chronic disease characterized by repeated periods of drug craving, intoxication, bingeing, and withdrawal. This cycle culminates in the escalated preoccupation with the attainment and consumption of the substance. In particular, the compulsive consumption of the drug occurs at the expense of the attainment of other rewarding experiences and despite detrimental consequences to the individual's functioning (encompassing physical health and other personal, social, and occupational goals). This pattern continues despite attempts of the drug-addicted individual to stop or curtail drug use and even when the rewarding experiences from the drug are markedly reduced.

Note that not all individuals who consume or abuse psychoactive substances become addicted to them; it is estimated that approximately 10% of those who use drugs develop drug addiction/dependence. The precise statistic is uncertain; nevertheless, it depends on the drug of abuse, ranging from approximately 4% of marijuana users to approximately 32% of those who ever try tobacco (heroin, 23%; cocaine, 16–17%; and alcohol, 15%). This actual risk for developing drug addiction is determined by genetic (it is estimated that 50% of the vulnerability is genetically determined), developmental (the onset of progression to addiction is more likely to occur during adolescence and early adulthood), other individual (e.g., psychiatric comorbidity) and environmental factors (e.g., exposure to stress and availability of drugs), and their interactions. In this article, we concentrate on mapping drug addiction and the unique symptomatology of this chronic disease process to its underlying neurobiological mechanisms as revealed by neuroimaging studies.

Major Brain Circuits and Neurotransmitters Studied in Drug Addiction

Animal and human studies show that drugs of abuse exert their reinforcing and addictive effects by activating and ultimately co-opting the brain's reward system, a phylogenetically ancient circuitry normally involved in the reward sensations that are essential to learning and survival. This system was first discovered in the 1950s when it was observed that animals would work for electrical stimulation to specific brain regions, subsequently found to include myelinated fiber tracts in the medial forebrain bundle, which descend from the cortex and terminate at or near the cells bodies of dopamine (DA) neurons in the ventral tegmental area (VTA). The hub of the system consists of the mesolimbic and mesocortical DA fibers, which originate in the VTA and terminate in the nucleus accumbens (NAc), amygdala, hippocampus, and prefrontal cortex (PFC). This circuit's drug-induced stimulation occurs directly by triggering DA action or indirectly by modulating other neurotransmitters. The latter encompass, among others, glutamate (the main excitatory neurotransmitter in the brain, involved in the molecular changes that encompass long-term potentiation associated with learning), gamma aminobutyric acid (GABA; the main inhibitory neurotransmitter in the brain), endogenous opioids (involved in hedonic responses and pain regulation), acetylcholine (predominantly via its effects in nicotine receptors which reside in DA neurons in the VTA), cannabinoids (the cannabinoid CB1 receptor modulates DA cell firing), and serotonin (involved in impulsivity and mood).

The response of this DA mesolimbic circuit to drugs of abuse occurs in all organisms (it is not specific to addiction) and therefore cannot solely explain the progression to the complex phenomenology of drug addiction that occurs in susceptible individuals. Indeed, advances in our understanding of the neurobiology of drug addiction have expanded our current

Table 1 *DSM-IV* criteria for substance abuse and dependence

A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one or more (abuse) or at least three (dependence) of the following, occurring within a 12 month period:

Abuse

1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
2. Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
3. Recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)

These symptoms have never met the criteria for substance dependence for this class of substance.

Dependence

1. Tolerance, as defined by either of the following:
   (a) A need for markedly increased amounts of the substance to achieve intoxication or desired effect
   (b) Markedly diminished effect with continued use of the same amount of the substance
2. Withdrawal, as manifested by either of the following:
   (a) The characteristic withdrawal syndrome for the substance (refer to criteria A and B of the criteria sets for withdrawal from the specific substances)
   (b) The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
3. The substance is often taken in larger amounts or over a longer period than was intended
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use
5. A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain smoking), or recover from its effects
6. Important social, occupational, or recreational activities are given up or reduced because of substance use
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

view beyond the reward process and its underlying mesolimbic brain circuitry to include the cortical brain regions that are associated with higher order cognitive–behavioral functions such as attribution of emotional salience to stimuli in the environment and the adaptive control of behavior – two interrelated and core neuropsychological dimensions impaired in addiction (Figure 1). The first impairment refers to reward processing/reinforcement associative learning, whereby as addiction progresses the reinforcement value of drugs of abuse becomes more potent than most other non-drug-related/common stimuli in the environment (e.g., sex and food). The disruption of the following interconnected brain circuits is involved: (1) reward, mapped in the NAc and the ventral pallidum, involved in the processing of and sensitivity to drug and non-drug-related reward and possibly also negative reinforcers; (2) motivation/drive, represented in the orbitofrontal cortex (OFC) and the subcallosal cortex, involved in the behavioral drive to seek a reinforcer and in salience attribution; and (3) memory and learning, modulated by the hippocampus, amygdala, and dorsal striatum, involved in the formation and storage of drug-related memories, conditioned responses, and habits, respectively. Note the interaction between these circuits: attribution of salience to a given stimulus, which is a function of the OFC, depends on the relative value of a reinforcer compared to simultaneously available reinforcers, which requires knowledge of the strength of the stimulus as a reinforcer – a function of the hippocampus and amygdala. The second impairment refers to inhibitory control (e.g., impulsivity), which is suggested to be compromised, especially in a drug-related context, and is executed in the PFC, the anterior cingulate cortex (ACC), and the lateral OFC. Thus, as described later, these 'impairments in response inhibition and salience attribution' (I-RISA) and their neurobiological underpinnings are thought to provide a meaningful cutting-edge exploration of drug addiction.

Major Neuroimaging Findings in Human Drug Addiction

The imaging of DA *in vivo* is possible through the use of positron emission tomography (PET) and single photon emission computed tomography (SPECT). Specifically, through the use of radioactively labeled radiotracers such as C^{11}raclopride (for imaging DA D2/D3 receptors) and C^{11}cocaine, C^{11}altropane, or I^{123}B CIT (for imaging the DA transporters (DATs)), PET can be used to image DA function of the brain's subcortical basal ganglia (including the caudate and putamen). PET has also been used to evaluate the

Figure 1 Impaired response inhibition and salience attribution (I-RISA) model of drug addiction. Here, core clinical characteristics of the drug addiction cycle (encompassing intoxication, craving, bingeing, and withdrawal) are mapped vis-à-vis the functioning of the subcortical and cortical brain regions forming the mesolimbic and mesocortical dopamine circuit that is implicated in drug addiction and its underlying neuropsychological mechanisms. Reprinted from Goldstein RZ and Volkow ND (2002) Drug addiction and its underlying neurobiological basis: Neuroimaging evidence for the involvement of the frontal cortex. *American Journal of Psychiatry* 159: 1642–1652, with permission from the American Journal of Psychiatry, Copyright 2002. American Psychiatric Association.

pharmacokinetics of drugs at their site of action. For example, using C^{11}cocaine, studies showed a close correspondence between the fast uptake and clearance of cocaine in the human brain with the fast and short-lasting but intense 'high.' A parallel comparison with the pharmacokinetics of methylphenidate (a stimulant drug that, similar to cocaine, blocks DAT), measured with C^{11}methylphenidate, revealed that it was the fast uptake but not the presence of the drug in the brain that was linked to its rewarding effects as assessed by self-reports of 'high.' This study highlighted the relevance of the rate of drug delivery into the brain as one of the variables affecting the rewarding properties of drugs of abuse. This study also identified the importance of the rate of clearance of a drug from the brain in its reinforcing effects since the slower clearance of methylphenidate than that of cocaine would interfere with its frequent and fast administration, providing an explanation for the differential abuse rates of both drugs (low for methylphenidate and high for cocaine).

In addition to measures of neurochemistry, PET can also quantify regional brain function such as glucose metabolism (with ^{18}F-fluorodeoxyglucose (FDG)) and cerebral blood flow (with ^{15}oxygen). These measures can be assessed at a resting baseline and during a behavioral or pharmacological challenge. Functional magnetic resonance imaging (fMRI) provides temporally and spatially enhanced images of brain function. The fMRI signal is based on differences in the magnetic properties of oxygenated versus deoxygenated hemoglobin, producing a blood oxygen level-dependent (BOLD) contrast when brain tissue is stimulated. Because the neural and behavioral effects of acute drug administration tend to be of short duration, fMRI is especially well suited to identify the brain circuits activated during drug intoxication and their association with the drug's behavioral effects.

Both PET and fMRI have facilitated the study of the brain circuits underlying observable abnormalities in behavior, cognition, emotion, and personality in

psychopathology (including drug addiction). A particularly productive strategy has been the use of functional neuroimaging in conjunction with neuropsychological measures (including self-reports) during scanning and also outside of the restrictive imaging environment. The simultaneous recordings allow the mapping of the real-time drug effects (e.g., self-reported euphoria and craving) to their underlying neural basis; the assessment of neuropsychological functioning obtained outside of the imaging environment allows for a more in-depth analysis of trait measures, such as personality.

Association of Brain Imaging with the Core Clinical Drug Addiction Characteristics

Brain Imaging of Acute Pharmacological and Nonpharmacological Effects

Intoxication Intoxication occurs when a person consumes doses that are large enough to produce significant behavioral, physiological, or cognitive impairments. Early in the process of drug addiction, the initial drug-induced response is that of a sense of reward. Later, when drug addiction has developed, the impact of positive reinforcement decreases (e.g., feelings of 'high' or 'rush'), whereas that of negative reinforcement increases (e.g., alleviation of the stress of withdrawal). Preclinical (*in vivo* and *in vitro*) studies have consistently shown that the initial reinforcing drug effect is associated with increases in DA in the NAc. The precise mechanism of the drug-induced DA increases depends on the actual drug of abuse. Thus, cocaine increases DA by blocking the DAT, which is the main mechanism for recycling DA back into the nerve terminals. Indeed, PET studies have linked the level of DAT blockade by cocaine with the intensity of the self-reported 'high' (Figure 2). Depressant drugs such as benzodiazepines, barbiturates, and alcohol increase DA indirectly, in part via their effects on the GABA/benzodiazepine receptor complex. Opioid drugs such as heroin, oxycontin, and vicodin act by stimulating mu opiate receptors, some of which are located in DA cells and others in the GABA cells that regulate the DA cells and their terminals. Nicotine is believed to exert its reinforcing effects in part by activation of the $\alpha_4\beta_2$ nicotine receptors, which have also been identified in DA cells. Nicotine (similar to heroin and alcohol) also appears to release endogenous opioids, and this is also likely to contribute to its rewarding effects. Imaging studies have also documented that cigarette smoking results in inhibition of the monoamine oxidase (MAO) B and MAO A enzymes, which are involved in the metabolism of the catecholamines (including DA). This MAO inhibition is not due to nicotine but, rather, to some of the chemicals in the cigarette smoke; it is not limited to the brain but is observed throughout multiple organs in the body (Figure 3). Finally, marijuana exerts its

Figure 2 Correlation between dopamine transporter (DAT) occupancy by cocaine and subjective reports of 'high.' Ratings of 'high' significantly correlate with DAT occupancy in cocaine-addicted subjects: DAT occupancies >60% are consistently associated with significantly increased ratings of 'high' relative to baseline. Reproduced from Volkow ND, Wang GJ, Fischman MW, et al. (1997) Relationship between subjective effects of cocaine and dopamine transporter occupancy. *Nature* 386: 827–830, with permission.

Figure 3 Monoamine oxidase (MAO) B activity in cigarette smokers (right) showing dramatic reductions in the brain, kidneys, heart, and lungs. These data indicate that the MAO-inhibiting chemicals in smoke end up not only in the lungs but also throughout the entire body, providing an explanation as to why a wide variety of cancers (bladder, pancreas, and kidney) are much more frequently present in cigarette smokers than in nonsmokers. From Fowler JS, Logan J, Wang GJ, et al. (2003) Low monoamine oxidase B in peripheral organs in smokers. *Proceedings of the National Academy of Sciences of the United States of America* 100: 11600–11605.

effect by activating cannabinoid 1 receptors, which modulate DA cells as well as postsynaptic DA signals. Moreover, there is increasing evidence for the involvement of cannabinoids in the reinforcing effects of other drugs of abuse, including alcohol, nicotine, cocaine, and opioids.

Activation of the PFC, including the ACC (Figure 4), and the mesolimbic DA subcortical brain areas has been reported during drug intoxication in drug-addicted subjects – an effect that is proportional to the intensity of the subjective perception of intoxication, the reinforcing effects of the drug, or enhanced mood. It is also intriguing that in the case of marijuana or methylphenidate, activation of the PFC regions is predominantly observed in users but not in non-using subjects and in subjects in whom the drug induces intense craving or enhances mood. This suggests that PFC regions (including the OFC and ACC) are involved in the intoxication process, and that their response to drugs is in part related to previous drug experiences. Therefore, the intact functioning of memory circuits is crucial since these circuits set the expectations and prepare the drug-addicted individual for the drug's acute effects (indeed, these memory circuits are also activated during drug intoxication). This preparation is essential for activating homeostatic neurobiological and other physiological (e.g., cardiovascular) responses to counteract the acute effects of the drugs (note that overdosing is frequently reported in situations in which the drug-addicted individual consumes drugs in unfamiliar environments or circumstances).

Salience attribution/reward processing. Neuroimaging findings have provided the first evidence that the brain's threshold to responding to abstract rewards is modified in drug-addicted individuals and that it is directly linked to changes in the responsiveness of the PFC. In a fMRI study of the I-RISA model (Figure 1), cocaine-addicted individuals and matched healthy control subjects were given monetary reward for performance on an attention task. Results indicated that the OFC responded to different monetary amounts in a graded fashion (the higher the potential reward, the greater the response) and the dorsolateral PFC and

Figure 4 Functional magnetic resonance imaging and its application to measuring brain responses to intravenous cocaine (vs. saline) in addicted individuals. Intravenous administration of cocaine (but not saline) in ten cocaine-addicted individuals resulted in activations in a distributed brain network including the lateral prefrontal cortex and anterior cingulate cortex. Other activated regions were the insula, parahippocampal gyrus, nucleus accumbens, ventral tegmental area, and the amygdala. Reproduced from Breiter HC, Gollub RL, Weisskoff RM, et al. (1997) Acute effects of cocaine on human brain activity and emotion. *Neuron* 19: 591–611, with permission from Elsevier.

ACC responded to any money only in the healthy subjects but not in drug-addicted individuals. Instead, within the cocaine group, the higher the sensitivity to money in the dorsolateral PFC and ACC, the higher the self-reported motivation and ability to control behavior (Figure 5). Data further suggested that in the cocaine abusers, there was a 'disconnect' between subjective measures of motivation (how much they said they were engaged in the task) and the objective measures of motivation (how fast and accurately they performed on the task), implicating a disruption in the ability to perceive or translate into appropriate action inner motivational drives. Overall, this altered brain–behavior reward processing, which encompassed the role of the PFC in sensitivity to reward, awareness of inner motivation, and the ability to

Figure 5 Functional magnetic resonance imaging and its application to measuring brain responses to a secondary reward (money) in addicted individuals versus healthy control subjects. Whereas 12 control subjects had a complex neural response to monetary reward (e.g., monotonically positive in the orbitofrontal cortex and response to any money in the dorsolateral prefrontal cortex and anterior cingulate cortex), this complexity was compromised in 16 addicted subjects. Furthermore, sensitivity to monetary reward in the dorsolateral prefrontal cortex in the addicted subjects was associated with better self-reported ability to control behavior at a trait level. Reprinted from Goldstein RZ, Alia-Klein N, Tomasi D, et al. (2007) Is decreased prefrontal cortical sensitivity to monetary reward associated with impaired motivation and self-control in cocaine addiction? *American Journal of Psychiatry* 164: 43–51, with permission from American Journal of Psychiatry, Copyright 2007. American Psychiatric Association.

control behavior, may contribute to the chronically repeating pattern of impulsiveness and lack of control over drug use in addiction, as further described next.

Inhibitory control. Inhibitory control is a neuropsychological construct that refers to the capacity to control the inhibition of harmful and/or inappropriate emotion, cognition, or behavior. Critically, the disruption of self-controlled behavior is likely to be exacerbated during drug use and intoxication (culminating in bingeing, as further described later) as modulated by a compromise in an essential function of the PFC: its inhibitory effect on subcortical limbic regions (e.g., the NAc, basal ganglia, and the amygdala). This impairment in top–down control (a core function of the PFC) would release behaviors that are normally kept under close monitoring, simulating stresslike reactions in which control is suspended/inhibited and stimulus-driven behavior is facilitated. This PFC compromise is consistent with the accounts of drug-addicted individuals who claim that once they start taking the drug, they cannot stop, even when the drug is no longer pleasurable and clearly exposing the individual to physical or psychological risk. The use of psychoactive substances impairs mechanisms of inhibitory control not just during acute drug intoxication; this effect spreads to all stages of the addiction process, possibly contributing (together with the changed valuation system as described previously) to the initiation or escalation of undesirable or disadvantageous decisions and behaviors (e.g., trading a car for a couple of hits). Indeed, one of the most consistent findings from fMRI and PET studies is that of abnormalities (e.g., hypoactivations) in the PFC, including the ACC, and increased impulsivity on neuropsychological measures of behavior (including compromised detection and regulation of error responses on inhibitory control tasks such as the go/no-go task) in drug-addicted individuals who are current but also past users.

Craving It is well recognized that drug effects are modulated by nonpharmacological variables, including context and conditioned responses. These variables encompass learned responses that link the drug and its environment to a pleasurable or an intensely overpowering experience. This learning shapes an individual's expectations of the effects of a drug, which in turn modify the neural and behavioral responses to that drug, as mentioned previously. Thus, when addicted individuals are exposed to drug cues such as places, people, or paraphernalia associated with drug intake, an intense and urgent desire (drug wanting or craving) to consume the drug frequently develops, as documented by self-report and by concomitant DA increases in the dorsal striatum (caudate and putamen) (Figure 6). This DA activation of the dorsal striatum could result in the readiness to engage in the behaviors necessary to procure the desired object. Thus, variations in DA D2 receptor levels may be one of the neurobiological mechanisms that underlie the effect of environmental cues on the propensity to abuse drugs or even relapse; this possibility is supported by findings showing that other environmental factors, such as stress and social hierarchy, can affect baseline levels of DA D2 receptors.

In addition, craving by itself is sufficient in activating the PFC regions that are activated during intoxication in individuals previously exposed to the drug of abuse. Thus, higher levels of brain activation (measured by cerebral blood flow, FDG, or BOLD) in PFC areas, primarily in the OFC and ACC, have been demonstrated in cocaine users exposed to videotapes and other cues depicting drug-related stimuli (Figure 7), and these neural changes correlate with self-reports of craving. Similar cue-reactivity effects have been observed in other types of drug addiction (e.g., opiate and nicotine). The pathways between the PFC (including OFC and ACC but also the dorsolateral PFC) and mesolimbic subcortical (e.g., amygdala) regions may underlie the phenomenology of craving that encompasses recall of emotionally laden previous experiences and anticipation of a future drug reward. Moreover, the involvement of these pathways in drug craving suggests the intriguing hypothesis that drug addiction may engage the same neurobiological processes that underlie motivated behaviors required for survival (e.g., eating).

Bingeing Experience with a reinforcing substance (especially psychostimulants but also alcohol and heroin) could lead to bingeing, in which, for a discrete period of time, there is an extreme loss of control during which the individual engages in the repeated consumption of the substance. These bingeing episodes – or 'runs' in which the drug(s) is consumed for longer periods or in greater amounts than intended – can override survival actions (e.g., feeding, sleeping, and physical safety). Termination of these extreme periods usually occurs upon exhaustion or external circumstances such as lack of drug availability.

Bingeing is associated with DA, serotonergic, and glutamatergic circuits and probably involves the activation of the thalamo-OFC circuit and the ACC. Experimentally studying the neurobiology of bingeing in humans is not feasible for understandable reasons, although elegant laboratory designs can circumvent these difficulties. For example, studies of non-treatment-seeking drug-addicted individuals evaluated when and how often drug administration occurred within a medically supervised time-limited

Figure 6 Positron emission tomography with C^{11}raclopride to measure brain responses to cocaine cues in cocaine-addicted individuals. Image on the left and top right shows increased dopamine receptor availability in the caudate and putamen (but not in the ventral striatum) while the 18 subjects were watching a video of addicted individuals procuring and using cocaine versus a video of neutral scenes. This difference was positively associated with the abusers' reported cravings after the cocaine-cue video compared to the neutral video as shown in the bottom right image. From Volkow ND, Wang GJ, Telang F, et al. (2006) Cocaine cues and dopamine in dorsal striatum: Mechanism of craving in cocaine addiction. *Journal of Neuroscience* 26: 6583–6588.

Figure 7 Functional magnetic resonance imaging and its application to measuring brain responses to cocaine cues in cocaine-addicted individuals. Presented are the functional brain activations in the left medial frontal gyrus and the anterior and posterior cingulate cortices that were associated with cue-induced (by video depicting individuals smoking crack-cocaine) cocaine craving in 17 experienced cocaine users. Reprinted from Garavan H, Pankiewicz J, Bloom A, et al. (2000) Cue-induced cocaine craving: Neuroanatomical specificity for drug users and drug stimuli. *American Journal of Psychiatry* 157: 1789–1798, with permission from the American Journal of Psychiatry, Copyright 2000. American Psychiatric Association.

self-administration procedure. Such fMRI and behavioral studies in cocaine-addicted individuals have shown that repeated drug self-administration-induced 'high' correlated negatively with activity in limbic, paralimbic, and mesocortical regions including the OFC and ACC, whereas craving correlated positively with activity in these regions. To circumvent technical difficulties in such drug self-administration fMRI paradigms (e.g., the effect of motion), paradigms that simulate compulsive behavior (e.g., gambling when it is clearly no longer beneficial) or studies of other compulsive disorders (e.g., obsessive–compulsive disorder) might offer invaluable insight into the circuits underlying this extreme form of loss of control in addiction.

Withdrawal Withdrawal occurs upon terminating drug use and is accompanied by a variety of symptoms, including excessive fatigue, irritability, anxiety, and anhedonia. Withdrawal symptoms vary in intensity and quality depending on the type of the drug (more intense for heroin and alcohol than for cocaine) and the amount of time that has passed since last drug use. As such, they are typically characterized as 'early' versus 'protracted' withdrawal symptoms.

In general, results of PET studies in drug-addicted individuals show long-lasting changes (mostly reduced sensitivity) in regional neural responsiveness to pharmacological challenges that share common properties with the drug of abuse. However, during early withdrawal, activity in certain regions (e.g., the OFC and striatum) may be higher in the drug-addicted than in healthy comparison subjects, which has been linked with the subjective perception of craving. During protracted withdrawal (1–6 weeks since last use), brain activity in these regions is usually lower, an effect that is most accentuated in the PFC and that persists for at least several months of drug-free periods.

Chronic Effects and Other Issues

Chronic drug effects Whereas acute drug administration temporarily increases DA neurotransmission, chronic drug consumption results in a marked and sustained decrease in DA activity, which appears to be long-lasting and to persist months after protracted detoxification, and which is associated with dysregulation of frontal brain regions. Thus, PET and SPECT studies have revealed lower DA D2 receptor availability at baseline in the striatum (including ventral striatum, where the NAc is located) in cocaine-, heroin-, alcohol-, and methamphetamine-addicted individuals compared to control subjects (Figure 8). In animal studies, the drug-induced changes in the dorsal striatum are observed after longer drug exposures than those observed in the NAc and have been interpreted to reflect further progression into the addicted state. Studies have also shown changes in mu opioid receptors as well as endogenous opioids in cocaine abusers.

Relapse. Individuals who have developed drug addiction are prone to relapse even after prolonged periods of abstinence. For example, at 3 months post-treatment, 40–60% of individuals in treatment for alcohol problems relapse to a first drink, whereas by 12 months this rate increases to 70–80%. These rates are similar for heroin users. In stimulant (cocaine or methamphetamine)-dependent patients, rates of relapse over 6 months to 1 year following treatment have typically ranged from 21% to 33%. Among cigarette smokers, of the 70% who want to quit smoking, only 4.7% are able to quit for at least 3 months. The recovery rates for other types of drugs of abuse are also poor. Contributing factors to relapse include exposure to stress, drug cues, poor coping strategies, and disrupted cognitive and emotional functioning. Rates of relapse are also related to the availability of the drug and the availability of controlled environments, support systems, and medications.

Although most devastating, the neurobiology that underlies relapse in addiction is not well understood. A promising line of investigation uses fMRI to link cognitive or emotional activation of the striatal–PFC circuit with subsequent relapse in treatment-seeking

Figure 8 Positron emission tomography and its application to measuring dopamine receptor availability. This image shows lower striatal dopamine D2 receptor availability in drug users during withdrawal from cocaine, methamphetamine, heroin, and alcohol than in healthy comparison subjects. Reproduced from Volkow ND, Fowler JS, Wang GJ, and Swanson JM (2004) Dopamine in drug abuse and addiction: Results from imaging studies and treatment implications. *Molecular Psychiatry* 9: 557–569, with permission.

drug-addicted individuals; preliminary results suggest that stronger drug cue- or stress-induced activations in the putamen, ACC, and adjacent medial PFC in the early abstinence period are predictive of earlier (e.g., time to relapse) or more severe (e.g., consumption of the drug in greater amounts or for longer durations) relapse at follow-up in initially abstinent drug-addicted (cocaine, alcohol, and methamphetamine) subjects. These studies generally demonstrate that the regional fMRI activations are more sensitive in predicting relapse than task-related behavioral performance. This involvement of the PFC and ACC (and also the striatum and insula) in relapse prediction suggests that the neurobiological underpinnings of emotional and autonomic regulatory processes (e.g., suppression of craving, stress, or general negative affect) play a central role in the addicted individual's ability to remain abstinent.

Neurotoxicity *Brain structure*. Drugs of abuse have substantial neurotoxic effects as imaged in drug-addicted individuals. For example, studies using MRI have provided evidence of disruption in the OFC and ACC and in a broad network of related regions in addicted subjects compared to non-drug-using control subjects. Specifically, reductions in gray matter in frontal cortical regions (ACC and medial and lateral OFC) and limbic and paralimbic structures (including anteroventral insula and superior temporal cortex) were documented in abstinent cocaine-addicted individuals, methamphetamine users, alcoholics, and polysubstance users (Figure 9; see also Figure 10 for increases in striatal volumes in methamphetamine users). Studies using various MRI technologies have also provided evidence of white matter abnormalities in drug-addicted individuals, encompassing white matter hyperintensities, reduced white matter integrity, or overall increased volumes of white matter. In general, it appears that the frequency of white matter changes increases with age and with longer duration and amount of drug use. Studies have revealed changes specifically in frontal white matter integrity among stimulant-dependent subjects. Indeed, preclinical studies show that chronic administration of cocaine or amphetamine results in significant increases in dendritic branching and the density of dendritic spines in the PFC. Together, these changes in the synaptic connectivity and size of the PFC may underlie the changes in decision making, judgment, and cognitive control (e.g., increased impulsivity) that characterize drug addiction. Nevertheless, it is not clear whether these changes predate the development of addiction, are precipitated by the disease, or, probably, an interaction of the two.

Cerebrovascular events. The abuse of drugs such as cocaine, methamphetamine, and alcohol can lead to transient cerebral ischemia (through vasoconstriction but also through thrombosis formation), stroke, and hemorrhages. Indeed, imaging studies have provided evidence of marked regional decreases in cerebral blood flow present even in cocaine abusers who are neurologically asymptomatic. The vasoconstricting properties of these drugs are also likely to be implicated in their cardiotoxic effects that can result in myocardial infarction even in relatively young individuals.

The special case of methamphetamine. Of important mention here is methamphetamine, a highly addictive and potentially neurotoxic drug. In humans, imaging studies with PET have documented marked decreases in DAT, which were associated with psychomotor slowing and impaired learning and with incomplete recovery even after drug-free periods of 9 months. Furthermore, a hypermetabolic activity in the brain of the methamphetamine abusers was documented, which was interpreted to be consistent with inflammation/gliosis. Studies of methamphetamine abusers using magnetic resonance spectroscopy indeed have

Figure 9 Magnetic resonance imaging and its application to measuring brain structure/volume differences between drug-addicted individuals and control subjects. (Left) Regions of decreased gray matter density (including the ventromedial orbitofrontal cortex through the anterior cingulate cortex) in 13 cocaine-dependent subjects compared to 16 cocaine-naive individuals. (Right) The percentage (0–14%) of decreased gray matter density in the cocaine group relative to the control group. From Franklin TR, Acton PD, Maldjian JA, et al. (2002) Decreased gray matter concentration in the insular, orbitofrontal, cingulate, and temporal cortices of cocaine patients. *Biological Psychiatry* 51: 134–142.

Figure 10 Magnetic resonance imaging and quantitative morphometric analyses applied to measuring brain structure/volume differences between drug-addicted individuals and control subjects. Fifty methamphetamine users showed enlarged putamen (10%) and globus pallidus (7–9%) compared to 50 age- and sex-matched comparison subjects. Smaller striatal structures were associated with poorer cognitive performance and greater cumulative drug use in the methamphetamine users. From Chang L, Cloak C, Patterson K, et al. (2005) Enlarged striatum in abstinent methamphetamine abusers: A possible compensatory response. *Biological Psychiatry* 57: 967–974.

shown increases in the concentration of myoinositol, a glial marker. Of note is that the hypermetabolic activity was most prominent in the parietal cortex (association cortex), a brain region that is poorly innervated by DA terminals. Therefore, these results most likely reflect the effects of methamphetamine on neuronal types or circuits other than DA, including degeneration of myelinated processes, damage to serotonergic terminals, damage to pyramidal glutamatergic cells, and an impact on the glutamate receptors (including hypersensitivity to glutamate excitotoxicity).

Imaging alcohol neurotoxicity. Consumption of very large amounts of alcohol can lead directly to death by depressing the respiratory center in the medulla. Chronic alcohol-related neuropathology encompasses peripheral neuropathy which results from multiple vitamin B deficiencies and which is usually reversible with adequate nutrition. Other neurological complications include anterior lobe cerebellar degenerative disease and Wernicke–Korsakoff syndrome (resulting from thiamine deficiency and characterized by severe short-term memory loss). In addition to the gray and white matter changes as reviewed previously, evidence for global brain atrophy in alcohol-dependent subjects has also been accumulating.

Effects of exposure to drugs *in utero* Prenatal exposure to drugs can cause permanent changes in the brain, and these changes affect behavior. Fetal alcohol syndrome, for example, is associated with exposure to high doses of alcohol in the prenatal development period. Brain alterations seen in these individuals include reduced brain size; alterations in shape, tissue density, and symmetry; and volumetric reductions and abnormalities in the cerebellum, basal ganglia, and corpus callosum. These shape and tissue abnormalities highlight the regional nature of brain morphological differences and brain functional abnormalities in addiction and suggest that assessment of brain–behavior relationships should be regionally specific. In addition to alterations in brain structure, individuals with histories of heavy prenatal alcohol exposure face long-lasting deficits that affect many aspects of cognitive and behavioral functioning (e.g., visuospatial functioning, verbal and nonverbal learning, and memory, attention, and executive functioning). The mapping of the regional brain differences to the neuropsychological abnormalities remains to be established.

Studies of prenatal exposure to other substances provide evidence that they too may affect the developmental trajectory of the brain. For example, preliminary prospective studies suggest that prenatal exposure to active maternal cigarette smoking is associated with alterations in medial temporal lobe function and concomitant deficits in visuospatial memory; these are mostly observed in adolescent tobacco smokers and are further associated with early adolescence attention and conduct problems. Nevertheless, it is important to recognize that other factors, encompassing the parent's socioeconomic status and history of antisocial personality disorder, are more powerful predictors of these impairments in the offspring.

A novel approach emphasizes the combination of MRI and PET technologies to assess pharmacokinetics of drugs of abuse on the fetal brain *in vivo*. This approach has been applied in a nonhuman primate model. Measurement of radioisotope distribution in maternal and fetal organs demonstrated that although the uptake of radioactivity into the fetal brain after the injection of C^{11}cocaine is lower and slower than in the maternal brain, C^{11}cocaine (or its labeled metabolites) readily crosses the placenta; a measurable quantity of C^{11}cocaine (or its labeled metabolites) accumulates in the fetal brain early after injection, although the highest accumulation occurs in the fetal liver.

Imaging predisposition and vulnerability Differences in DA circuits may be one mechanism underlying the variability in responsiveness to drugs of abuse, which in turn could influence vulnerability to drug addiction. Baseline measures of striatal DA D2 receptors with PET in nonaddicted subjects have been shown to predict subjective responses to the reinforcing effects of intravenous stimulants. Thus, individuals with lower DA levels reported liking methylphenidate more than individuals with higher DA levels, and this lower baseline DA D2 level may predispose to drug abuse through the initial hedonic reactions to the drug. A PET study suggested that it is the higher than normal DA D2 receptor availability that may be driving the differential predisposition to drug addiction: Nonalcoholic members of alcoholic families may be protected from developing alcoholism by their higher DA D2 receptor availability (in caudate and ventral striatum), possibly through its effect on the ability to regulate emotion. It is important to note that although tempting, causality cannot be inferred from these neuroimaging studies. Nevertheless, preclinical studies showed that upregulation of DA D2 receptors in the NAc dramatically reduced alcohol intake in animals previously trained to self-administer alcohol.

Note that other neurotransmitters have also been implicated in the vulnerability for developing drug addiction. For example, the endogenous opioid and

serotonergic systems have been implicated not only in alcohol action (consumption and reinforcement) and dependence but also in the vulnerability to alcoholism. Similarly, genetic studies have linked the opioid system with alcoholism and heroin addiction. Abnormalities in these neurotransmitter systems are also related to anxiety and depression, which may further increase the risk for developing drug addiction.

Summary

Neuroimaging studies are beginning to highlight the role of neurobiology in the core characteristics of drug addiction, encompassing drug intoxication, craving, bingeing, withdrawal, and relapse. These studies point to alterations in drug-addicted individuals in their brain structure, encompassing cortical and subcortical brain regions, and brain neurochemistry, encompassing DA and other neurotransmitters such as GABA, glutamate, serotonin, and opioids. A promising line of functional neuroimaging research has focused on the role of the OFC and ACC in understanding how the value of the drug as a reinforcer progresses to become more important than other reinforcers, which over time can no longer compete with the enhanced saliency value of the drug for the drug-addicted individual. Together, the goal of brain imaging studies is to offer biomarkers for particular outcomes in susceptible and drug-addicted individuals. It would be helpful, for example, to be able to identify at early adolescence those individuals who could benefit from more intensive drug addiction prevention efforts. It would similarly be helpful to identify among treatment-seeking drug-addicted individuals who would benefit from more tailored interventions to prevent relapse. Beyond highlighting the role of specific brain regions and neurotransmitters in particular drug-related behaviors, these studies promise to highlight the neurobiology underlying complex human phenomenology, encompassing motivation and free-will, or the 'mind.'

Drugs Addiction: Actions

R A Wise, National Institute on Drug Abuse, Baltimore, MD, USA

Introduction

The immediate actions of most addictive drugs are at identified binding sites on various neurotransmitter receptors or transporters. These immediate actions are varied. The psychomotor stimulants amphetamine and cocaine act in circuitry involved in sleep–wakefulness, arousal, and attention, circuitry that is thought to be out of balance in depression, schizophrenia, and Parkinson's disease. The opiates heroin and morphine act in circuitry of thermoregulation, pain modulation, feeding, and control of intestinal contractions. Nicotine acts in circuitry at all levels of the nervous system, from the neuromuscular junction to the cerebral cortex. Alcohol destabilizes membranes and acts at receptors in multiple brain regions. Most of the actions of addictive drugs have little to do with the fact that the drugs are addictive. The addictive actions of addictive drugs, on the other hand, are a subset of each drug's actions, a subset presumed to result in activation of a common forebrain circuit that is involved in appetitive motivation.

The common denominator of addictive drugs is their ability to form compulsive response habits. The brain mechanisms through which addictive drugs come to establish response habits and dominate behavior are the brain mechanisms through which the natural pleasures of life – food, water, shelter, sexual interactions – have established response habits and dominated our behavior through most of our evolutionary history. Thus, it is within the brain circuitry of natural motivated behavior – circuitry dubbed 'reward circuitry' historically – that the brain mechanisms of addiction have been sought.

The concept of specialized reward circuitry in the brain arose from the discovery by Olds and Milner that direct electrical stimulation of certain portions of the brain could be more powerfully rewarding than food, sex, or the retrieval of a mother's pups. Brain stimulation was used to map anatomical sites contributing to this circuitry, and neurotransmitter antagonists and drug rewards – most notably a psychomotor stimulant and an opiate reward – were used to identify the chemical coding of this circuitry. Eventually, central microinjections of drugs and neurotransmitters were used to pinpoint synaptic junctions where addictive drugs and other substances – neurotransmitter agonists, antagonists, or enzymes – have rewarding actions. Most of our current knowledge of the actions of drugs of addiction comes from such studies. This line of investigation has implicated as core elements in the brain mechanisms of drug reward the mesolimbic and mesocortical dopamine systems, GABAergic neurons of the nucleus accumbens that are the efferent targets of the mesolimbic system, and GABAergic neurons of the midbrain that are both input neurons to the mesolimbic and mesocortical dopamine neurons and output neurons of the ventromedial subdivision of the extrapyramidal system. Various drugs of addiction act at each of these targets.

Psychomotor Stimulants

The psychomotor stimulants amphetamine and cocaine are habit-forming, largely because of actions at monoamine transporters causing elevations of extracellular dopamine. Blockade of either D1 type or D2 type dopamine receptors blocks the habit-forming effects of cocaine. Cocaine blocks the plasma membrane dopamine transporter, limiting the reuptake of extracellular dopamine and thus prolonging its actions at receptors on target neurons in a variety of forebrain structures. The olfactory tubercle, the medial prefrontal cortex, and the nucleus accumbens shell appear to be the most important dopamine terminal fields for cocaine reward. Rats can be trained to lever-press for cocaine injections restricted to each of these regions; the olfactory tubercle appears to be the most sensitive to the rewarding effects of cocaine. Cocaine blocks the noradrenergic and serotonergic transporters as well as the dopamine transporter, and each of these can take up dopamine under the right conditions. While blockade of the dopamine transporter appears to be most critical for cocaine reward in normal animals, cocaine remains habit-forming in mice lacking the dopamine transporter. In these animals, the blockade of the serotonin transporter appears critical for cocaine self-administration; cocaine is not rewarding in mice with both the dopamine and the serotonin transporters deleted. The mechanism for cocaine reward in these mice is not firmly established, but it is known that serotonin can inhibit γ-aminobutyric acid (GABA) release in the ventral tegmental area (VTA), which, in turn, should disinhibit the dopamine system. Cocaine is known to elevate nucleus accumbens dopamine levels in the nucleus accumbens of mice with the dopamine transporter deletion.

Whereas cocaine merely blocks dopamine uptake, amphetamine acts to reverse the dopamine transporter and cause release of cytosolic dopamine even in the

absence of nerve impulses. Amphetamine alters the subcellular localization of the vesicular monoamine transporter, apparently elevating cytosolic dopamine levels for release by reverse transport. Amphetamine also reverses the noradrenergic and serotonergic transporters. Amphetamine is self-administered directly into the nucleus accumbens, but not into the medial prefrontal cortex; self-administration into the olfactory tubercle has not yet been tested. Like amphetamine, a mixture of D1 type or D2 type dopamine agonists is rewarding when injected into the nucleus accumbens. Blockade of either D1 type or D2 type dopamine receptors blocks the habit-forming effects of amphetamine.

Opiates

The opiates morphine and heroin are habit-forming because of actions at receptors for the endogenous opioids enkephalin, β-endorphin, endomorphin, and dynorphin. Three classes of opioid receptors have been identified: μ opioid receptors activated by the endogenous opioids endomorphin, enkephalin, and β-endorphin; δ opioid receptors activated by enkephalin and β-endorphin; and κ opioid receptors activated by dynorphin. Of these the μ and δ opioid receptors appear to be most important for the rewarding actions of opiates; activation of κ opioid tends to antagonize reward function.

Morphine is rewarding when directly injected into two brain regions, the VTA and the nucleus accumbens. In the VTA morphine acts at μ opioid receptors on neurons containing the inhibitory neurotransmitter GABA. GABAergic neurons in this region normally hold their dopaminergic neighbors under inhibitory control; thus, morphine's action at μ receptors on these GABAergic neurons results in disinhibition of the dopamine system. These or adjacent GABAergic neurons also project to distal targets, and opiates have dopamine-independent as well as dopamine-dependent rewarding actions in the VTA. The selective μ opioid D-Ala^2,*N*-MePhe^4,Gly^5-ol enkephalin (DAMGO) is rewarding and activates the mesolimbic dopamine system when injected into this region, presumably acting on μ opioid receptors expressed by GABAergic neurons that normally inhibit their dopaminergic neighbors.

Morphine also acts at δ opioid receptors and the selective δ opioid D-Pen^2,D-Pen^5 enkephalin (DPDPE) is also rewarding. It also activates the mesolimbic dopamine system when injected into this region; as an activator of the dopamine system and also as a reward, it is approximately two orders of magnitude less effective than DAMGO. This may be due to the much more sparse expression of the δ opioid receptor in relation to that of the μ opioid receptor in this region.

The relative effectiveness of selective μ and δ opioid injections into the nucleus accumbens is not known, but again the presumed target is GABAergic neurons: in this case, the medium spiny output neurons of nucleus accumbens that receive dopaminergic input from the VTA. The κ opioids antagonize reward function, in part by inhibiting ventral tegmental dopamine neuron cell firing and in part by increasing dopamine uptake at dopaminergic axon terminals.

Nicotine

Nicotine acts at a subtype of acetylcholine receptor, the nicotinic acetylcholine receptor. This receptor is found widely distributed in the brain and also in the neuromuscular junction and the autonomic ganglion. Nicotine infused into either the VTA or the nucleus accumbens elevates nucleus accumbens dopamine levels, and nicotine injections directly into at least one of these regions – the VTA – are habit forming. Acetylcholine is the primary neurotransmitter in pedunculopontine and laterodorsal tegmental nuclei that provide input to the ventral tegmental dopamine neurons involved in reward function. Dopaminergic neurons in the VTA express both nicotinic and muscarinic acetylcholine receptors, the former is important for the rewarding effects of nicotine and the latter is important for the rewarding effects of direct electrical stimulation of reward sites in the lateral hypothalamus and adjacent portions of the medial forebrain bundle.

Alcohol

Ethyl alcohol (ethanol), like most other addictive drugs, elevates dopamine levels in the nucleus accumbens and other terminal fields of the mesocorticolimbic dopamine system. Unlike most other addictive drugs, the mechanism of action of ethanol does not seem to involve the binding of the drug to an identified neurotransmitter receptor or transporter. Ethanol disturbs lipid membranes, and while ethanol is not known to bind to a known receptor, it nonetheless alters ion movement through channels associated with known receptors. The neurotransmitter receptors most strongly implicated at present are $GABA_A$ and *N*-methyl-D-aspartate (NMDA) receptors; however, it is possible that $GABA_A$-associated effects are due to a presynaptic influence on GABA release rather than a postsynaptic effect on the receptor itself. Ethanol also appears to modulate ion flow through the purinergic P2X receptor and the serotonergic 5HT3 receptor.

Whatever the transduction mechanism, ethanol increases dopaminergic cell firing and nucleus accumbens dopamine levels, and is habit forming, at least in part, for that reason. Localized injections of ethanol

into the VTA are habit forming, and this is believed to be dopamine dependent.

Benzodiazepines and Barbiturates

Benzodiazepines and barbiturates act to enhance $GABA_A$ receptor function. Their sites of rewarding action are not known, but systemically administered benzodiazepines decrease dopamine levels in the nucleus accumbens. $GABA_A$ agonists and antagonists are rewarding or reward-inhibiting in the VTA, depending on the site of injection. The $GABA_A$ agonist muscimol is rewarding when administered into the posterior but not the anterior VTA; the $GABA_A$ antagonist picrotoxin is rewarding when administered into the anterior but not the posterior VTA. GABAergic neurons are ubiquitous in the brain, however, and the VTA may play a minor role relative to the nucleus accumbens in the habit-forming actions of benzodiazepines and barbiturates. Inasmuch as the mesolimbic dopamine system projects to GABAergic neurons in the nucleus accumbens, these drugs may well act more importantly at sites efferent to the dopamine system, within an anatomical cascade of GABAergic projections from the nucleus accumbens to the ventral pallidum, from the ventral pallidum and the nucleus accumbens to the VTA, and from the VTA to the medial thalamus, superior colliculus, and mesencephalic locomotor region.

Addictive Consequences

The mechanisms by which drugs become habit-forming are presumed to be mechanisms embedded in the circuitry the drugs activate and not in the immediate actions of the drugs at their receptors. The brain circuitry of reward function is not well understood, but the midbrain dopamine systems appear to play a major part. Injection of dopamine or dopamine agonists is habit-forming, and the psychomotor stimulants are not habit-forming when dopamine synaptic function is pharmacologically blocked or when forebrain dopamine is depleted. The fact that opiates, alcohol, nicotine, and cannabis elevate forebrain dopamine levels implicates dopamine in the rewarding effects of these drugs as well. The fact that blockade of dopamine receptors does not block all the habit-forming properties of morphine, nicotine, or phencyclidine indicates that dopamine does not play an exclusive, but merely a central, role in drug reward.

The ability of rewarding stimuli to establish response habits and to make otherwise neutral stimuli attractive is termed 'reinforcement.' Reinforcement is the process of 'stamping in' associations between stimuli and between stimuli and responses. The essential consequence of reinforcement is the enhanced consolidation of short-term memory for the rewarded response and the associated stimuli into a long-term memory that increases the probability that the response will recur and the associations remain established. Dopamine release appears to accomplish this. Thus the posttraining administration of the dopamine releaser amphetamine enhances the memory for whatever was learned in the training session, regardless of its relevance to amphetamine. For example, amphetamine given after an animal learns the location of a hidden underwater platform increases performance when the animal is subsequently required to find the platform. The mechanism by which dopamine enhances memory consolidation is not fully understood, but the effects of dopamine on intracellular guanine nucleotide binding proteins (G-proteins) are essential in most brain regions for two cellular models of synaptic plasticity: long-term potentiation and long-term depression. The role of dopamine in response reinforcement (habit-learning) appears to involve the metabotropic receptor-mediated action of dopamine on intracellular G-proteins in neurons receiving dopaminergic synapses or local nonsynaptic dopamine release.

A question of major recent interest is whether addictive drugs cause unique neuroadaptations in brain reward circuitry that are above and beyond the cellular correlates of learning and memory. Both cocaine and morphine cause a number of neuroadaptations, some of which result in tolerance to the drugs and some of which result in sensitization to the drugs. Some of the neuroadaptations are in dopamine neurons and others are in their GABAergic target neurons in the nucleus accumbens (and probably elsewhere). These neuroadaptations are common to the two drug classes, despite the fact that the drugs have opposite effects on the dopamine neurons while having common effects on the target neurons (morphine disinhibits the dopamine neurons while cocaine, by elevating dopamine levels at somatodendritic autoreceptors, inhibits them). It has been postulated that neuroadaptations caused by addictive drugs are responsible for the compulsive nature of drug self-administration and the fact that cravings for drug come to dominate cravings for more natural rewards such as food or sexual interaction. It remains to be determined whether addictive drugs are unique in the ability to cause these neuroadaptations; recent evidence suggests that some such neuroadaptations can be caused by intermittent exposure to concentrated sucrose solutions or to sex.

D-Serine: From Its Synthesis in Glial Cell to Its Action on Synaptic Transmission and Plasticity

S H R Oliet and J-P Mothet, Institut National de la santé et de la Recherche Médicale U862, Bordeaux, France

© 2009 Elsevier Ltd. All rights reserved.

Introduction

When thinking about brain signaling, neurophysiologists traditionally refer to the transfer of information from one neuron to another. Accordingly, the chemical synapse is viewed as the structure in which such communication occurs between the pre- and postsynaptic elements and where neurotransmitters are released from the presynaptic bouton to activate specific receptors localized on the postsynaptic neuron. This model, however, needs to be revised in view of the findings describing the role of glial cells as the third element of the chemical synapse. At the anatomical level, astrocytic processes enwrap up to 60% of the synaptic volume. Despite such an intimate structural relationship, astrocytes were believed to ensure only a housekeeping function at synapses. There is now accumulating evidence indicating that glial cells, and particularly astrocytes, contribute actively to synapse development, synaptic transmission, and neuronal excitability. These results fuel the emerging concept of the tripartite synapse, which considers astrocytes as an integral part of central and peripheral synapses. According to this model, glial cells first sense synaptic activity through a broad variety of ion channels, transporters, and receptors expressed at their surface. Synaptic activation of glial cells then triggers intracellular second-messenger pathways, including Ca^{2+} increases that vary according to the synaptic inputs solicited and the glial receptors involved. In turn, activation of these second-messenger pathways induces the release of active substances termed gliotransmitters (by analogy to neurotransmitters). These gliotransmitters mediating astrocyte-to-neuron signaling include glutamate, taurine, and adenosine triphosphate (ATP), which can be hydrolyzed in adenosine.

Another major gliotransmitter which could have a major role in brain signaling is D-serine. The discovery of this amino acid in the brain has forced us to reconsider the dogma that only L-isomers of amino acids occur in mammals. Organic molecules, and therefore biological molecules such as D-amino acids, are based on the chemistry of the carbon atom. Carbon atoms can have up to four bonded groups attached to them in three-dimensional space, forming a tetrahedron. Because of this structure, carbon-containing molecules can have the same four constituents, yet can differ in their structure by the location of the four groups in space. This property of carbon-based molecules is known as chirality. As an example, our hands are mirror images of one another, but they cannot be superimposed on one another. Similarly, carbon atoms with four different groups attached occur in two forms, known as enantiomers, that are not superimposable mirror images of one another (see Figure 1).

Although the chemical and physical properties of L-amino acids and D-amino acids are extremely similar, only L-amino acids seemed to have been selected from the origin of life on the primitive Earth. In this chemical evolutionary step, D-amino acids were eliminated, and it was thought that all living organisms were composed only of L-amino acids. This asymmetry in biology is assumed to be a feature of fundamental physics because it turns out that natural L-amino acids are more stable than their 'unnatural' mirror images, D-amino acids. Until the last 30 years, it was believed that D-amino acids were excluded from living systems except for D-amino acids in the cell walls of microorganisms. Now, biologists have discovered that nature can deal with at least two D-amino acids, D-serine and D-aspartic acid, in higher organisms. Of these two atypical amino acids, D-serine is potentially very important for the nervous system because it is likely be the major endogenous ligand for the strychnine-insensitive glycine-binding site of *N*-methyl-D-aspartate receptors (NMDARs), key receptors for excitatory transmission and cognitive functions. Since the late 1980s, it has been established that activation of NMDARs required glutamate and a co-agonist that was first identified as glycine. Yet significant levels of D-serine are present in rodent brain areas enriched in NMDARs, suggesting that D-serine might be an alternative to glycine for NMDAR activation. D-Serine and serine racemase (SR), an enzyme that synthesizes D-serine from L-serine, are mainly, if not exclusively, localized to astrocytes. That glial-derived D-serine is an endogenous ligand of NMDARs and was unambiguously demonstrated by the use of D-amino acid oxidase (DAAO), an enzyme that selectively degrades D-serine but not glycine. Under conditions in which D-serine levels are dramatically reduced with DAAO, NMDAR activity is markedly impaired in different brain regions. It is now obvious that glial cells, through the release of D-serine, contribute actively to NMDAR function in the mammalian brain.

Figure 1 The chirality in your hands. The term chiral (from the Greek word for hand) is used to describe an object which is not superimposable on its mirror image, for example, our two hands. This property is based on the fact that carbon atoms (C) bind four groups – COOH, NH_2, H, or any other radical (R) – in a three-dimensional space. Such a tetrahedral hybridized carbon with four different groups always forms a chiral center. Conversely, a substrate carbon atom is not chiral if two out of four of its groups are identical, as it is in the case of the amino acid glycine.

Localization of D-Serine

D-Serine is present in significant amounts in the brain of rodents and humans, where its levels (~500 μM) are up to one-third of the total free serine pool. Its distribution is heterogeneous with the highest concentrations in the telencephalon and the developing cerebellum. This pattern of distribution throughout the rat brain resembles that of NMDARs. In contrast, glycine immunoreactivity does not correspond to NMDAR distribution excepted for some regions where D-serine is also present. Detailed analysis of D-serine staining shows that it is mostly present in astrocytes that ensheath synapses. In the developing cerebellum, D-serine is localized to Bergmann glia, whereas in adults it declines to negligible levels. Recent investigations have found that microglia cells as well as Schwann cells contain significant amount of D-serine and SR, which are also found in Müller glial cells in the retina and in the supporting cell of the vestibular sensory epithelium. Whether D-serine and SR are also present in other types of glial cells, such as oligodendrocytes, pituicytes, tanycytes, or ependymal cells, remains unknown. Although at very low levels, neuronal immunoreactivity for D-serine has been still observed in the neurons of the cerebral cortex, the brain stem, and the olfactory bulb.

Synthesis and Degradation of D-Serine

The idea that D-amino acids and particularly D-serine serves specific roles in the brain was strengthened by the discovery of its metabolic pathway. High levels of D-serine in the mammalian brain are generated by the activity of a pyridoxal 5′-phosphate (vitamin B_6)-dependent enzyme, SR. This enzyme not only converts L- into D-serine, but also converts D- into L-serine, with a lower affinity. The enzymatic-catalyzed racemization of L-serine proceeds by removal of a proton from the asymmetric C–H bond of the amino acid to form a carbanion intermediate. The trigonal carbon atom of the carbanion, having lost the original asymmetry, then recombines with a proton to regenerate as an inverted tetrahedral structure corresponding to D-serine. The distribution of SR closely resembles that for D-serine, with the highest expression in the hippocampus and corpus callosum and very low levels in the amygdala, subthalamic nuclei, and the thalamus. Regarding cellular distribution, detailed analysis indicates that SR, like D-serine, is mostly confined to astrocytes, although substantial expression of SR is present in some neurons. However, due to the numeric preponderance of astroglia cells over neurons, glial cells remain the principal source of D-serine in the brain.

SR activity can be negatively regulated by a series of cellular compounds. Thus, glycine and a series of metabolites related to L-aspartic acid competitively inhibit the enzyme. Because glycine concentrations in astrocytes are approximately 3–6 mM, glycine would constitutively inhibit SR activity unless glycine and SR show different compartmentalizations within the astrocyte cytosol. The metabolic pathway for D-serine degradation remains more elusive. Mammalian D-serine can be metabolized by the peroxisomal flavoprotein DAAO, an enzyme highly present in astrocytes of the hindbrain and cerebellum. Adult DAAO-deficient mice display increased D-serine levels, especially in areas where it normally occurs at low levels. However, although DAAO protein is present in the forebrain, an area enriched in D-serine, levels of the D-amino acid appear relatively unchanged in this region in DAAO-deficient mice. This result suggests that other mechanisms are probably implicated in regulating D-serine concentrations in this brain area.

SR and DAAO may not work in isolation because SR and DAAO activities are controlled in opposite ways by nitric oxide (NO). Although NO enhances SR activity, it decreases that of DAAO, thus down-regulating the intracellular levels of D-serine. In turn, D-serine inhibits NO synthase in glial cells and stimulates the production of NO in neurons. Neuronal NO could thus represent an inhibitory feedback mechanism tightly regulating D-serine metabolism in astrocytes and thereby preventing its overproduction and excessive stimulation of NMDARs.

Release of D-Serine

Glial cells detect changes in their environment through a broad variety of ion channels, transporters, and receptors expressed at their surface. Specific activation of metabotropic and non-NMDA glutamate receptors on astrocytes induces the efflux of D-serine from these cells in culture (Figure 2).

Whether activating these glutamate receptors is the only stimulatory pathway for D-serine release remains to be determined. Similarly, the conditions during which the activation of glial glutamate receptors, and, consequently, D-serine release occur in response to afferent synaptic activity are unknown. Interestingly, release of glutamate from glial cells also occurs when metabotropic and non-NMDA glutamate receptors are stimulated. An important issue for D-serine release, and for gliotransmission in general, is the identification of the molecular pathway responsible for the efflux of active substances from cells that were long thought to be passive and/or unexcitable. Astrocytes, like all eukaryotic cells, use secretory lysosomes to transport new membrane and proteins to the plasma membrane during constitutive exocytosis. Most cell types also possess a pathway of regulated exocytosis in which secretory vesicles undergo Ca^{2+}-dependent fusion with the plasma membrane. Until recently, Ca^{2+}-regulated exocytosis was considered as a hallmark of neurons in the nervous system. Both constitutive and regulated secretory pathways require specialized proteins to bring together the membranes of the vesicles with the plasma membrane. The soluble *N*-ethylmaleimide-sensitive factor (NSF) attachment protein receptors (SNAREs) are leading candidates for mediating membrane fusion and most of them are present in glial cells. In addition, glial cells contain also synaptic-like microvesicles (SLMV) and large dense-core vesicles (LDCV), as revealed by electron microscopy and confocal microscopy analyses. Results obtained over the last decade using electrophysiological, biochemical, and imaging techniques suggest that astrocytes use a Ca^{2+}-regulated SNARE-dependent exocytosis to release glutamate from SLMVs but also ATP and peptides from LDCVs. In cultured astrocytes, activation of metabotropic and non-NMDA receptors effectively triggers a Ca^{2+}- and SNARE-dependent release of D-serine. In this experimental model, modifying extracellular or intracellular Ca^{2+} concentrations or depleting thapsigargin-sensitive Ca^{2+} stores, considerably impairs D-serine release. These results reveal that activation of non-NMDARs is the major source of extracellular Ca^{2+} and that mobilization of Ca^{2+} from internal stores is necessary for D-serine release. This is consistent with the observation that both inositol triphosphate (IP_3)- and caffeine/ryanodine-sensitive Ca^{2+} stores control the release from glial cells of glutamate, another gliotransmitter. Furthermore, inhibiting exocytosis with clostridial toxins or preventing amino acid uptake into vesicles with concanamycin or bafilomycin, impairs the release of D-serine from astrocytes. These results are thus consistent with a vesicular storage and release of the D-amino acid. Interestingly, astrocytic glutamate also appears to be stored in, and released from, vesicles. If glutamate and D-serine were co-stored in the same vesicles, this would be the perfect gliotransmitter cocktail to activate NMDARs. This hypothesis is indeed supported by the observation that some D-serine immunoreactivity is found in vesicles expressing the vesicular transporter for glutamate. The final proof that D-serine and glutamate are co-stored and co-released, however, awaits further investigations. The existence of a vesicular pathway does not exclude the possibility that other routes for D-serine release coexist in glial cells. Such nonvesicular pathways could involve processes that have been linked already to gliotransmitter release such as hemichannels, $P2X_7$ receptors, volume-sensitive channels, and reversal of transporters (Figure 3).

Figure 2 Induction of D-serine release at glutamatergic synapses. Synaptically released glutamate diffuses locally to neighboring glial processes and binds to AMPA (AMPAR), kainate (kainaiteR) and/or metabotropic (mGluR) receptors. This triggers the release of D-serine within the synaptic cleft, enabling NMDAR activation on the postsynaptic neuron. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; AMPAR, AMPA receptor; kainaiteR, kainaite receptor; mGluR, metabotropic glutamate receptor; NMDAR, *N*-methyl-D-aspartate receptor.

Figure 3 Concentration of D-serine in the synaptic cleft and the number of NMDARs available: (a) control, (b) with glial withdrawal in lactating rats. In (a), the concentration of D-serine is sufficient to make most NMDARs on magnocellular neurons available for activation by synaptically released glutamate. In (b), glial withdrawal causes a reduction of synaptic D-serine levels, thereby diminishing the number of NMDARs available. NMDAR, *N*-methyl-D-aspartate receptor.

Another important issue regarding D-serine release, and more generally gliotransmission, is to know whether specialized sites for its release exist in astrocytes. Regarding D-serine, it is not clear whether its release is restricted to the fine processes apposed to NMDARs or whether it can occur from any compartment of the glial cell. Interestingly, astroglial cells have functionally distinct compartments, known as microdomains, where localized high Ca^{2+} increases occur and which tightly enwrap synapses. Furthermore, electron microscopy analysis has revealed that glutamate-containing vesicles are found in glial processes that contact dentritic spines bearing NMDARs. It is thus tempting to speculate that D-serine release occurs from such localized glial microdomains in close vicinity to the synapses and to NMDARs. This hypothesis is supported by electrophysiological recordings obtained in the hippocampus and in the hypothalamus demonstrating that the level of occupancy of the NMDAR glycine site is higher at synaptic than at extrasynaptic receptors. Although this could simply reflect the proximity of synaptically released glutamate, which is the putative trigger for D-serine release, it could also indicate the existence of microdomains for gliotransmitter release localized at the synapses.

D-Serine Clearance

Like for most neurotransmitters, the signaling action of D-serine should be terminated by its clearance from the extracellular space. This could occur through metabolic breakdown, as it is the case with ATP and its hydrolysis by specific ectonucleotidases located in the extracellular compartment, and/or through cellular uptake as occurring for glutamate. Injection of D-serine into the lateral ventricle results in a preferential accumulation of the amino acid in glial cells, as expected if glial uptake is the main process involved in the clearance of the D-amino acid. Several putative candidates for D-serine transport have been identified on the membrane of glial cells but also on neurons. Glial cells express a Na^{+}-dependent transporter with low affinity for D- and L-serine and with characteristics similar to those of the alanine–serine–cysteine transporter (ASCT) system, which carries D-serine in cultured astrocytes as well as in isolated retina. Another neutral amino acid transporter, the ASC-1, has also been identified in neurons, and its cellular localization on axon terminals and dendrites suggests that it could contribute to the synaptic clearance of D-serine. Finally, a novel Na^{+}/Cl^{-} sensitive transporter has been described in rat brain synaptosomes which, in contrast to the ASCT system, has limited affinity for other neutral amino acids, including cysteine and alanine. It is thus conceivable that multiple transport systems, some of which may still be awaiting identification, contribute concomitantly to the regulation of D-serine concentrations in the extracellular space.

D-Serine Contribution to Synaptic Transmission and Plasticity

NMDARs are peculiar ionotropic receptors in the sense that they require not one but two different

agonists to be activated: glutamate and glycine. NMDARs are tetramers formed by the association of two NR1 and two NR2 subunits. On the NR1 subunits, there is a strychnine-insensitive binding site for glycine. This so-called glycine site can be activated not only by glycine but also by D-serine, with a higher potency according to the subunit composition of NMDARs. The discovery that D-serine occurs naturally in the mammal brain has thus completely changed our view regarding the identity of the endogenous ligand for NMDAR glycine-binding site in the brain. Although glycine was first identified as such, it is obvious today that in several brain areas the endogenous ligand of the NMDAR glycine site is D-serine and not glycine. And because D-serine is released from glial cells, these cells are likely to play an active, if not essential, role in regulating NMDAR-dependent processes, including synaptic transmission, synaptic plasticity, rhythmic activity, activation of second messenger pathways, gene expression, and pathophysiological phenomenon such as excitoxicity and neurodegeneration.

The first indication that D-serine could play a role in NMDAR function came from the observation that the D-amino acid was present in astrocytes ensheathing neurons bearing NMDARs. *In vitro* studies then revealed that D-serine was released from astrocytes on activation of their glutamatergic receptors. These findings strongly suggested that, in some regions of the brain, glutamate released from nerve terminals triggered D-serine release from glial cells, which, in turn, could modulate NMDARs localized on adjacent neurons. The functional role of D-serine was first studied in the hippocampus, where high densities of D-serine and NMDARs occur in the subiculum as well as in the CA1 and CA3 regions. In hippocampal neurons co-cultured with atrocytes, specific enzymatic degradation of D-serine with exogenous DAAO considerably reduces agonist-evoked and spontaneous NMDAR-mediated currents. Because DAAO does not affect glycine levels, this result unambiguously demonstrates that endogenous D-serine is required for NMDAR activity in this brain area. Similar results were obtained in the retina, where Müller glial cells appear to control NMDAR-mediated neurotransmission through the release of D-serine, as revealed by the inhibitory effect of DAAO on the NMDAR-mediated responses evoked by an agonist or light in retinal ganglia cells. The ability of D-serine to control NMDAR-dependent synaptic transmission has been confirmed through the use of a naturally occurring mouse strain lacking DAAO activity. In DAAO-deficient mice, the levels of D-serine are very high in the brain stem and spinal cord. As expected, NMDAR-mediated excitatory postsynaptic currents recorded from dorsal horn neurons in the spinal cord are significantly augmented in these animals. Knockout mice for the transporter ASC-1 provides another experimental model for studying the relevance of D-serine in glutamatergic neurotransmission; these mice display NMDAR-dependent hyperexcitability, presumably resulting from elevated extracellular D-serine associated with a deficient clearance of the amino acid.

Because in many brain areas NMDARs are responsible for the induction of long-term potentiation (LTP) and long-term depression (LTD), the cellular substrates for learning and memory in the mammalian brain, it is then important to know whether D-serine, and thus astrocytes, contributes to such forms of synaptic plasticity in the brain. The contribution of D-serine in LTP was shown in hippocampal cell cultures and brain slices where reducing D-serine levels with DAAO dramatically compromised the ability of high-frequency stimulation to induce LTP in CA1 pyramidal cells. This result confirms that D-serine, rather than glycine, is the endogenous ligand of NMDARs in this brain region, not only during basal transmission but also when synaptic inputs are stimulated intensively. Interestingly, it is commonly believed that senescence is associated with impaired NMDAR-dependent synaptic plasticity and notably LTP. In agreement with this hypothesis, a deficient LTP is observed in the hippocampus of a senescence-accelerated mouse strain. This senescent-related deficiency in synaptic plasticity appears to be due to an impaired D-serine metabolism, as indicated by the reduced production of the D-amino acid measured in the hippocampi of senescent rats. In agreement with this observation, the hippocampal LTP is completely rescued when the D-serine is supplied to the tissue. The key role of D-serine in governing NMDAR activity in the hippocampus is further supported by the demonstration that it is the major, if not the only, endogenous ligand involved in NMDAR-mediated neurotoxicity in this structure. Neuronal death is indeed prevented when slices are treated with serine deaminase, another enzyme that degrades D-serine, whereas supplying the slices with glycine oxidase (GO), an enzyme that degrades specifically glycine, does not affect NMDAR-dependent neurotoxicity.

Taken together, these findings suggest that astrocytic D-serine modulates NMDAR-dependent neurotransmission and synaptic plasticity in different brain regions. Because D-serine is synthesized and released from astrocytes, its action in these different regions depends on the astrocytic environment of neurons. Indeed, it is now accepted that glial coverage of neurons is not static and that it undergoes profound reversible anatomical remodeling in different

areas under different physiological and/or pathological conditions. The hypothalamo-neurohypophysial system (HNS) constitutes certainly the most striking example of such anatomical remodeling that can be observed physiologically because it occurs during lactation, parturition, and chronic dehydration. This system is made of magnocellular neurons, localized in the hypothalamic supraoptic and paraventricular nuclei, whose axons project to the neurohypophysis where their hormonal content, namely oxytocin and vasopressin, can be directly released in the bloodstream. The morphological plasticity of the HNS is characterized by a pronounced reduction in astrocytic coverage of oxytocin-secreting magnocellular neurons, which is entirely reversible on the cessation of the stimulation. Both SR and D-serine are found at high levels in this brain structure, and their expression is strictly restricted to astrocytes. The HNS thus provides a remarkable model for studying the physiological impact of glial-derived D-serine in the context of synaptic transmission and synaptic plasticity.

As reported for the hippocampus and the retina, treating hypothalamic slices with the highly specific enzyme DAAO dramatically reduced NMDAR-mediated synaptic responses recorded in magnocellular neurons, whereas degrading specifically glycine with GO has no effect, thereby indicating that D-serine is the endogenous co-agonist of NMDAR in the HNS. Accordingly, D-serine levels within the synaptic cleft, and thus the level of occupancy of the glycine site of synaptic NMDA receptors, is reduced under conditions in which the astrocytic coverage of neurons is diminished. This results in NMDAR-mediated synaptic responses of smaller amplitude in lactating than in control animals, a difference that disappears when saturating concentrations of D-serine are supplemented. Because the reduction of D-serine concentrations within the synaptic cleft caused by glial withdrawal lowers the number of synaptic NMDARs available for activation, the activity-dependence of phenomena such as LTP and LTD, whose induction depends on NMDAR activation, is modified. The neuron–glia remodeling causes a shift of the activity-dependence of long-term synaptic changes toward higher activity values, similar to what can be observed when NMDARs are partially blocked with pharmacological agents. Therefore, the glial environment of neurons, through its capacity to provide D-serine, has a profound impact not only on NMDAR-mediated synaptic transmission but also on the direction and magnitude of NMDAR-dependent long-term synaptic plasticity. Such astrocyte-mediated metaplasticity is likely to exist at all synapses where endogenous D-serine is involved in regulating NMDARs.

Conclusion

It is now clear that D-serine fulfils all criteria that identify it as the leader of a new class of brain messengers, the D-amino acids. Glial-derived D-serine plays essential roles in the mammalian brain. By modulating NMDARs, this amino acid contributes actively to the transfer and storage of information. Because of this role in governing NMDAR function, glial cells may become prime targets in pathological events that cause neurons to degenerate. It is well documented that over- or downstimulation of NMDARs are implicated in a large number of acute and chronic degenerative disorders, including stroke, epilepsy, peripheral neuropathies, Parkinson's disease, Alzheimer's disease, Huntington's disease, and in psychiatric disorders such as schizophrenia. Whereas previous therapeutic approaches centered directly on NMDARs have been associated with deleterious side effects, the discovery of D-serine as the predominant endogenous ligand of the NMDARs thus provides new strategies for the development of drugs that target NMDAR function indirectly through the modulation of D-serine metabolism, for example, by inhibiting SR or DAAO.

Introduction

Neurons communicate with one another via the release of neurotransmitters from synaptic vesicles (SVs) by exocytosis from presynaptic nerve terminals. Exocytosis is a fast membrane-fusion event. A typical nerve terminal in the brain contains approximately 200 SVs, yet individual exocytic events can occur with high frequency in the range of 5–50 Hz and for prolonged lengths of time (greater than 30 s). Therefore, SVs must be rapidly recycled to prevent the depletion of their finite number; otherwise, synaptic fatigue occurs. After exocytosis, synaptic vesicle endocytosis (SVE) retrieves them. Away from the synapse, a similar endocytic pathway, known as receptor-mediated endocytosis (RME) functions in many cellular processes, including receptor downregulation and intracellular signaling. Both SVE and RME involve plasma membrane budding (or invagination) and pinching off new SVs by membrane fission at the vesicle neck. As well as maintaining the SV supply, the process is responsible for the initial formation (or biogenesis) of mature SVs. The protein dynamin plays a crucial role at an early point in vesicle fission and at the final step.

Dynamin was originally identified as a nerve terminal phosphoprotein and later as a GTPase that can associate with microtubules *in vitro*. Sequencing of the *dynamin* gene revealed that it contained a GTP-binding site homologous to that of other GTPases (or G-proteins). Later, a superfamily emerged from large dynamin-like GTPases comprising proteins present across all eukaryotic species. The biological importance of dynamin was first discovered with the identification of temperature-sensitive mutants in *Drosophila* called *shibire* that give rise to a pleiotropic defect in endocytosis, leading to rapid paralysis at a nonpermissive temperature of 29 °C. When the *shibire* gene was cloned in 1991, it was found to be 70% identical to rat brain dynamin 1. To better understand endocytosis, research since then has focused on the molecular mechanisms underlying dynamin's ability to bind, manipulate, and fragment lipid.

Dynamin Superfamily

Dynamin is a 100 kDa GTPase enzyme belonging to a family of large GTP-binding proteins (Figure 1). Dynamins are also known as the large GTPases to distinguish them from four other families of G-proteins: the small Ras superfamily of small monomeric GTPases (20–25 kDa), the α-subunits of heterotrimeric G-proteins, the septins, and other regulatory GTPases. All these G-proteins have a conserved tripartite GTP-binding motif within their N-terminal domains. Based on their structural similarity, dynamin superfamily proteins can be grouped into three broad categories: the classical dynamins (dynamin 1, 2, and 3), the dynamin-related proteins (dynamin-like protein 1 (Dlp1), optic atrophy 1 (OPA1), mitofusins, Mx proteins), and the guanylate-binding proteins (GBPs)/atlastins. All dynamin superfamily members appear to share two extraordinarily unique properties of self-assembly, to which their mechanism of GTP hydrolysis is uniquely linked, and the ability to bind and tubulate lipids. This adapts them to membrane fission and fusion functionality. Members of the dynamin superfamily have diverse roles in multiple forms of vesicle fission from the plasma membrane (SVs, clathrin-coated vesicles, caveolae, and phagocytosis), as well as in membrane budding events within intracellular organelles (such as the mitochondria, Golgi, endoplasmic reticulum (ER), and peroxisomes).

Dynamin Domains

Dynamin superfamily members share three conserved domains in common: an N-terminal GTPase domain, middle domain (MD), and GTPase effector domain (GED) (Figure 1). The three domains distinguish them from other G-protein families and define the unusual enzymatic and self-assembly properties of these large GTPases. Most superfamily members contain additional domains tailored to their specific cellular function or subcellular location. For example, three groups have transmembrane domains and are integral membrane proteins: OPA1, mitofusins, and atlastins. Dynamin contains two additional functional domains: a pleckstrin-homology (PH) domain and a proline-rich domain (PRD) at the C-terminus.

GTPase domain The GTPase domain is the most highly conserved region. Compared with the Ras superfamily, dynamin has an unusually high GTPase activity and low affinity for GTP. Thus, it has a low basal GTPase activity which is controlled by self-assembly or lipid binding. Mutations in the GTPase domain such as K44A, K44E, and S45N are defective in GTP binding. These mutations are dominant-negative, and DNA constructs harboring them have

Figure 1 Domain structure of the human dynamin superfamily. All dynamin superfamily members contain a GTPase domain that binds and hydrolyses GTP, a middle domain (MD) and a GTPase effector domain (GED) that are involved in higher-order self-assembly and stimulation of GTPase activity. Classical dynamins also have a pleckstrin-homology (PH) domain that interacts with lipid membranes and a C-terminal proline-rich domain (PRD) that interacts with Src-homology 3 (SH3) domain-containing proteins. Other family members may have divergent sequences at their N-termini or between the MD and GED. Human dynamin superfamily members are grouped according to their domain structures, which are represented by color-coded symbols. GBP, guanylate-binding protein; GTP, guanosine triphosphate.

been widely used to inhibit endocytosis in cells by transfection. However, GTP binding alone is not sufficient to support endocytosis, and GTP hydrolysis is also required to complete fission. In particular, dynamin-dependent GTP hydrolysis is required for SVE at fast synapses in the nervous system.

Middle domain and GTPase effector domain Dynamin MD is involved in the formation of dynamin tetramers and then for the higher-order self-assembly of tetramers into rings and helices. It lacks sequence homology to any known protein structural motif. A synthetic peptide derived from the N-terminal half of the MD of dynamin 1 adopts an α-helical coiled-coil structure and forms stable tetramers in solution. It also makes extensive contacts with the self-assembling GED. The GED is also known as the assembly or coiled-coil domain. It binds to the GTPase domain, to the MD, and to itself to form homodimers. These interactions have been implicated in self-assembly of dynamin which leads to an increase of GTPase catalytic activity by up to 100-fold. Cryo-electron microscopy (EM) studies have suggested that the GED and the MD may form a stalk which mediates intermolecular interactions in self-assembled dynamin.

Pleckstrin-homology domain Among the dynamin family members, only the classic dynamins contain the PH domain. It mediates binding to lipid membranes via interaction with a family of phosphoinositide phospholipids. The PH domain of dynamin 1 has very low lipid specificity, but favors binding to phosphatidylinositol (4,5) bisphosphate ($PI(4,5)P_2$). Their interaction produces the highest stimulation of dynamin. A burst of $PI(4,5)P_2$ is generated at the plasma membrane early in endocytosis, which recruits dynamin to these sites of active endocytosis.

Proline-rich domain The PRD is present only in the classic dynamins and is a protein–protein interaction domain for a variety of signaling or cytoskeletal proteins. Dynamin 1 contains 13 PxxP motifs (where P is proline and x is any amino acid) which bind numerous SH3 domain-containing proteins that play important roles in endocytosis (Table 1). The PRD does not

appear to be important for dynamin assembly into rings because its deletion (Dyn1ΔPRD) has no effect. A major function of the PRD is to target dynamin to its site of action in the cell. Overexpression of Dyn1ΔPRD results in the failure of dynamin to accumulate at clathrin-coated pits. The PRD also allows dynamin to be recruited by key partners such as syndapin that may be involved in membrane tubulation. The dynamin 1 PRD is also the site for its phosphorylation and regulation of its activity in nerve terminals.

Dynamin Mediates Endocytosis

Dynamin in Flies

Drosophila has only a single *dynamin* gene, *shibire*, for multiple cellular functions of SVE, RME, and cytokinesis. The *shibire* temperature-sensitive mutant fly exhibits a rapid and reversible paralysis at a nonpermissive temperature, which was later identified as a block in endocytosis. Within a few minutes after exposure to the nonpermissive temperature, the nerve terminals of this fly are remarkably empty of SVs and show an accumulation of endocytic pits at the plasma membrane (**Figures 2(a)** and **2(b)**). At the base of these pits was one or two electron-dense rings; hence, they were called collared pits (**Figure 2(c)**). Tubular invaginations without collars accumulate in a number of other cell types in these flies, indicating a general defect in endocytosis (**Figure 2(d)**). Endocytosis is inhibited in all mammalian cells overexpressing a dynamin mutant (K44A or K44E) deficient in GTP binding (**Figure 2(e)**). As in *shibire*, large tubular invaginations are observed which are connected to the plasma membrane. Thus, mammalian dynamin has a similar role.

Mammalian Classic Dynamins

Unlike flies, mammals have three *dynamin* genes, *dynamin 1, 2,* and *3*. They are each approximately 100 kDa in size, and they appear to work together for endocytosis in the brain. Dynamin 1 is the most studied isoform and is essentially specific to the central nervous system (CNS), being highly enriched in presynaptic nerve terminals. Dynamin 2 is ubiquitously expressed in all tissues, including neurons. Dynamin 3 is predominantly expressed in the testis and in some regions of the brain, where it is found both presynaptically and postsynaptically. Within the brain, expression levels of dynamin 1 are approximately 100-fold greater than those of the others and at least five times higher than synapsin 1. In fact, dynamin 1 is among the most abundant neuronal proteins in the brain.

All three dynamins play a role in vesicle scission during the specialized neuronal function of rapid synaptic vesicle recycling. Dynamin 1 mediates the bulk of SVE, particularly all the endocytosis that occurs during a depolarization stimulus. A knockout of dynamin 1 in mice produces animals that are normal at birth but then die within the first week. Lack of dynamin 1 does not completely inhibit SVE, and at birth synapses from these mice are filled with SVs. Therefore, dynamin 1 is largely dispensable for the biogenesis and recycling of SVs during development. It is, however, essential for recycling during high or prolonged synaptic activity. SVE is severely impaired during nerve depolarization but resumes efficiently on stimulus termination. Overexpression of dynamin 3, but not dynamin 2, rescues the phenotype, suggesting that dynamin 3 has a homologous role to that of dynamin 1 but is much lower in abundance. Dynamin 3 is also found in dendritic spine tips, where it regulates their morphogenesis in developing neurons. Dynamin 2 is multifunctional. It plays a major role in SVE, but this appears to be mainly in the slow endocytosis that occurs after nerve stimulation has ceased. In neurons and nonneuronal cells, it mediates the conventional clathrin-mediated uptake of surface receptors or membrane. In addition, dynamin 2 mediates endocytosis of caveolae and is required for phagocytosis. It also plays a role in endocytosis-independent cellular functions, such as actin dynamics, cytokinesis, centrosome cohesion, apoptosis, and mitogen-activated protein kinase (MAPK) signaling.

Function of Other Superfamily Members

Dynamin-related proteins Dynamin-related proteins are large in size (70–100 kDa) and have a relatively low affinity for GTP and a high GTPase activity. However,

Figure 2 Endocytosis is structurally altered in the *Drosophila* mutant *shibire* and dynamin-K44A mutant: (a) electron micrograph of a typical coxal synapse of a *shibire* fly at the permissive temperature of 19 °C, which is full of synaptic vesicles (SVs) and two mitochondria; (b) a similar synapse at the nonpermissive temperature of 29 °C is characterized by the loss of SVs and the appearance of small invaginations of the plasma membrane, which possess an electron-dense ring or collar around their necks (arrowheads); (c) a higher magnification of a synapse containing collared pits at 29 °C, showing single (arrowheads) or double rings (arrow); (d) in contrast to neuronal cells, long labyrinthine tubules that lack collars are formed at the cortical region near the surface of a *shibire* garland cell at the nonpermissive temperature; cells were stained with tannic acid to show the structures of the tubules (arrows) and coated pits (arrowheads) that are continuous with the extracellular spaces; (e) an accumulation of long tubular structures (open arrows) are also apparent in the HeLa cell overexpressing dynamin 1-K44A mutant, reminiscent of the *shibire* phenotype; many of these tubular structures have coated ends (arrowheads). (a–c) Reproduced from Koenig JH and Ikeda K (1989) Disappearance and reformation of synaptic vesicle membrane upon transmitter release observed under reversible blockage of membrane retrieval. *Journal of Neuroscience* 9: 3844–3860. (d) Reproduced from Kosaka T and Ikeda K (1983) Reversible blockage of membrane retrieval and endocytosis in the garland cell of the temperature-sensitive mutant of *Drosophila melanogaster*, *shibire*^{ts}. *Journal of Cell Biology* 97: 499–507. (e) Reproduced from Damke H, Baba T, Warnock DE, et al. (1994) Induction of mutant dynamin specifically blocks endocytic coated vesicle formation. *Journal of Cell Biology* 127: 915–934.

they lack both the PH domain and the PRD. They share a common ability to self-assemble into oligomers and show elevated assembly-dependent GTPase activity. Most of the dynamin-related proteins are involved in the morphogenesis and maintenance of intracellular organelles such as the mitochondria (Dlp1, OPA1, and mitofusin) and ER (Mx, Dlp1, and atlastin) (Table 2). All members tested to date (Dlp1 and MxA) are able to self-assemble into rings and to tubulate lipids. Like classic dynamin, Dlp1 and Mx proteins appear to be involved in organelle fission events. For example, Dlp1 is responsible for the mitochondrial fission required for mitochondrial division. In contrast, OPA1 and mitofusin are integral membrane proteins responsible for the fusion of mitochondrial inner and outer membranes, respectively. The biological role of Mx proteins is less clear. Their expression is induced by interferon, and they provide cells with strong protection against viral infection.

Table 2 Functions of dynamin-related proteins

Protein	*Localization*	*Function*
Dlp1 (Drp1)	Cytoplasmic, mitochondrial outer membrane, peroxisome and endoplasmic reticulum	Organelle fission
OPA1	Mitochondria inner membrane	Mitochondrial fusion
Mitofusin 1 and 2	Mitochondrial outer membrane	Mitochondrial fusion
MxA and MxB	Smooth endoplasmic reticulum	Viral resistance

Dlp1, dynamin-like protein 1; OPA1, optic atrophy 1.

Guanylate-binding proteins/atlastins The crystal structure of human GBP1 (hGBP1) places the GBPs within the dynamin superfamily, despite low amino-acid sequence homology. hGBP1 has a low GTP-binding affinity and relatively fast GTP hydrolysis.

It is unique among the dynamin superfamily members in its ability to convert GTP to guanosine monophosphate (GMP), cleaving off phosphate from GTP in two successive steps. GBPs contain only the GTPase domain, MD and GED. Within cells, hGBP1 in its GTP-bound form appears to target the Golgi. Like Mx, GBPs are induced in response to interferons and play roles in protective immunity against microbial and viral pathogens.

Atlastins are the most recently described superfamily members. Like mitofusin and OPA1, atlastins are integral membrane proteins, with the same predicted membrane topology (N-terminal GTPase and short C-terminal sequences in the cytoplasm). This suggests a role in membrane fusion rather than fission. Atlastin 1 appears to be involved in vesicle budding and trafficking in the early secretory pathway between the ER and the Golgi. It is found at highest levels in the brain and is highly enriched in neurites and growth cones, where it plays a role in neurite outgrowth and axon formation.

Mechanisms of Dynamin-Mediated Membrane Fission

Role of Unassembled Dynamin Early in Endocytosis

Dynamin appears to act twice in the mechanism of endocytosis: early in the constriction of the invaginating vesicle and late in its scission. The first step involves a regulatory GTPase-like function of unassembled dynamin, and the second involves self-assembly and assembly-stimulated GTP hydrolysis. The two models are not mutually exclusive. It has been proposed that unassembled dynamin plays a role in the early, rate-limiting steps of endocytosis, prior to self-assembly. It has been suggested that dynamin in the GTP-bound state or in the course of steady-state GTP turnover serves as a kinetic timer that regulates and controls coated pit assembly and maturation. In this model, basal GTP hydrolysis of unassembled dynamin is controlled by an interaction of GED with the switch 2 region of the GTPase domain. One suggestion is that it acts as a molecular switch that recruits downstream effectors in a GTP-dependent fashion. For example, GTP-bound dynamin interacts with Hsc70 and auxilin, proteins that uncoat clathrin from vesicles, but no major partner has yet been found to interact with dynamin specifically in its GTP-bound state that accounts for its early role in endocytosis.

Ring Assembly on Lipid Templates

The second step of dynamin action in late stages of endocytosis involves assembly-stimulated GTP hydrolysis driving a twisting helix mechanism of action. Dynamin 1 exists as a tetramer that can self-assemble *in vitro* into two types of higher-order structures. In the absence of any factor, and on removal of salt, dynamin self-assembles into rings or stacks of rings (Figures 3(a) and 3(b)). In the presence of liposomes, microtubules, or other suitable template, dynamin forms spiral helices (Figure 3(c)). Such self-assembly results in an up to 1000-fold increase in GTPase activity. These higher-order structures resemble the collared pits seen at the base of endocytic pits in *shibire* (Figure 3(d)) and similar shaped helical spirals are seen in lysed nerve terminals treated with GTPγS, a nonhydrolyzable GTP analog (Figure 3(e)). Dynamin also has a membrane-deforming ability. When added to liposomes or lipid monolayers, purified dynamin 1 drives their transformation into tubules (Figure 3(f)). The addition of GTP to dynamin-coated lipid tubes *in vitro* causes their fragmentation into small vesicles (Figure 3(g)). The protein most likely mediates vesicle fission using the energy obtained from GTP hydrolysis.

Helical Tension and Twist Produce Fission

Two models were initially proposed to explain the mechanism of dynamin-mediated vesicle fission: the constriction model and the expansion model. A more recent model incorporates both concepts. In the constriction model, dynamin forms a collar around vesicle necks and constricts the lipid to induce fission (also called a pinchase activity; Figures 4(a) and 4(b)). This is supported by three-dimensional cryo-EM structures of dynamin in the constricted and nonconstricted states. Recombinant Dyn1ΔPRD forms a T-shaped dimer consisting of three prominent densities corresponding to the leg (GTPase domain), stalk (GED and MD), and head (PH domain). The addition of GTP causes the head and stalk to rearrange, potentially generating a force on the underlying lipid bilayer and resulting in rings of smaller diameter.

In the helical expansion model, GTP hydrolysis provides the energy for rapid expansion of the dynamin helix at the neck of the vesicle, which propels it from the presynaptic membrane into the cytosol (also called a poppase activity). This model is based on a dramatic increase in helical pitch of dynamin spirals formed on rigid lipid nanotubes following GTP hydrolysis (Figures 4(c)–4(e)).

A single twisting model consolidates both the previous models and is based on observations that dynamin-coated lipid tubules twist and supercoil on addition of GTP (Figures 4(f) and 4(g)). The twisting activity of assembled and activated dynamin produces a longitudinal tension that is released by tubule breakage. Hence, late-stage endocytosis may involve cooperation between mechanisms that generate membrane tension and those that mediate constriction (Figure 4(g)).

Figure 3 Dynamin forms rings and helices *in vitro* and *in vivo*: (a) purified dynamin self-assembles into a ring in the presence of GDP and γ-phosphate analogs; (b) purified dynamin self-assembles into and spirals in the presence of GDP and γ-phosphate analogs; (c) dynamin forms helices around lipid tubules when added to phosphatidylserine liposomes in the absence of any nucleotide; (d) the rings have an outside diameter of 50 nm and an inner diameter of 30 nm and resemble the collared structures seen in *shibire* mutant nerve terminals; (e) long invaginating tubules decorated with a helical pattern and a terminal clathrin-coated bud are observed in isolated nerve terminals (synaptosomes) treated with GTPγS; (f) dynamin also has the ability to deform liposomes into narrow tubules; (g) the addition of GTP to dynamin lipid tubules result in the fragmentation of the tubes. GDP, guanosine diphosphate; GTP, guanosine triphosphate; GTPγS, nonhydrolyzable GTP analog. Dynamin Recruitment to Sites of Endocytosis

The lipid-deforming property of dynamin is also shared with bin-amphiphysin-rvs (BAR) domain-containing proteins. BAR domain proteins have a binding preference for lipid curvature and are therefore proposed as shaping the neck of invaginating presynaptic plasma membrane during SVE. Syndapin 1, amphiphysin 1, and endophilin 1 are three such proteins that are abundant in the brain. These three also contain SH3 domains that bind dynamin 1 through its PRD, and these interactions are important for SVE. Similarly, formin-binding protein 17 (FBP17) is a BAR domain protein that binds dynamin 2 in the brain and testis. It is likely that these proteins function along with PI(4,5)P_2 in the recruitment of dynamin to endocytic sites. Some BAR-domain dynamin-binding proteins, and several others, also bind actin or actin assembly regulatory proteins (Table 1). It is thought that these interactions link the endocytosis machinery to the actin cytoskeleton.

Regulation of Dynamin 1 Function

The role of dynamin 1 in SVE is controlled by its phosphorylation. Dynamin 1 undergoes cycles of phosphorylation and dephosphorylation on nerve-terminal depolarization (Figure 5(a)). Stimulus-dependent dephosphorylation in synaptosomes (isolated nerve terminals) is very rapid (<1 s) and is mediated by the same Ca^{2+} influx through voltage-gated Ca^{2+} channels that initiates exocytosis and transmitter release. Dephosphorylation is mediated

Figure 4 Molecular mechanisms of vesicle fission by dynamin: (a) dynamin induces the tubulation of liposomes that are decorated with helical oligomers with a diameter of ~50 nm; (b) the addition of a nonhydrolysable GTP analog to the dynamin–lipid tubes caused the tubules to constrict to ~40 nm (these data gave rise to the constrictase or pinchase hypothesis); (c) dynamin binding to lipid nanotubes assembles to an oligomer in the form a helix with a pitch (interring spacing) of ~11 nm; (d, e) on GTP hydrolysis, the helix becomes much more uncoiled, with a dramatic increase in pitch to ~20 nm (these data gave rise to the poppase hypothesis); (f) biotinylated dynamin induces the tubulation of liposomes in the presence of a streptavidin-coated polystyrene bead; on addition of GTP, the bead rotates around the longitudinal axis of the tubule, suggesting the GTP-dependent twisting activity of dynamin; (g) current hypothesis of the mechanical action of dynamin in membrane fission. In (g), dynamin tubulates liposomes and forms a helical structure around the lipid tube. On the addition of GTP, the dynamin helix undergoes an increase in torsion, leading to straightening and twisting of the tubule to form supercoil structures (insets). The twisting activity contributes to the longitudinal contraction to establish membrane tension around the vesicle neck. In combination with the constricting activity of dynamin, vesicle fission is then achieved. GDP, guanosine diphosphate; GTP, guanosine triphosphate; GTPγS, nonhydrolyzable GTP analog. by the Ca^{2+}-dependent protein phosphatase, calcineurin, which can be blocked by calcineurin antagonists such as cyclosporin A (Figure 5(b)). After the stimulus is removed, dynamin 1 is slowly (~40 s) rephosphorylated by its endogenous protein kinase, cyclin-dependent kinase 5 (cdk5). Rephosphorylation can be blocked by a specific cdk5 antagonist, roscovitine. Synaptosomal dynamin 1 has seven phosphorylation sites, five of which reside in the PRD and two of which are in the MD (Figure 5(c)). Ser-774 and Ser-778 are the major cdk5 sites, representing 70% of the total dynamin 1 phosphorylation *in vivo*. Dynamin 3, but not dynamin 2, is also phosphorylated in nerve terminals at homologous sites. This supports the

Figure 5 Dynamin 1 phosphorylation in nerve terminals: (a) model for the regulation of dynamin 1 dephosphorylation by calcineurin on nerve terminal depolarization and rephosphorylation by cdk5 on repolarization; (b) phosphorylation, dephosphorylation, and rephosphorylation of dynamin 1; (c) domain structures of rat dynamin 1 (*a* and *b* are long and short splice variants) showing the location of all *in vivo* phosphorylation sites (the dominant sites are shown in bold); (d) a proposed model outlining how the dynamin 1 dephosphorylation and rephosphorylation cycle might regulate synaptic vesicle endocytosis. In (b), dynamin 1 isolated from ^{32}P-labeled synaptosomes is constitutively phosphorylated in resting nerve terminals (Ctrl), is dephosphorylated after stimulation for 5 s with 41 mM potassium chloride (S1), is rephosphorylated after potassium chloride removal (Repol), and is dephosphorylated on second depolarizing stimulus (S2, top panel). Dynamin 1 dephosphorylation is inhibited by specific calcineurin blocker, cyclosporin A (middle panel), whereas dynamin 1 rephosphorylation is inhibited by specific cdk5 antagonist, roscovitine (lower panel). As shown in (d), in resting nerve terminals dynamin 1 is constitutively phosphorylated in cytosol. During nerve stimulation, an influx of Ca^{2+} stimulates vesicle fusion (exocytosis) as well as calcineurin-dependent dephosphorylation of dynamin 1. This allows dynamin 1 to form a complex with the BAR domain-containing protein syndapin 1. The formation of dynamin 1–syndapin 1 complex may help localize dynamin 1 to the site of endocytosis, and it is essential for membrane retrieval. Other BAR domain proteins are also involved. After endocytosis, cdk5 rephosphorylates dynamin 1 and promotes the disassembly of the endocytic complex with syndapin 1. hypothesis that dynamin 1 and 3 share common control mechanisms and may have redundant functions in SVE.

Dynamin 1 phosphorylation and dephosphorylation have a number of effects in their functions that may explain their role in SVE; phosphorylation increases its GTPase activity *in vitro*, inhibits binding of the BAR domain containing protein syndapin 1, and localizes dynamin 1 to the cytosol of nerve terminals. Mutation of the main two dynamin 1 phosphorylation sites (Ser-774 and Ser-778) inhibits SV recycling in cultured neurons. A model has been proposed to explain the role of the phosphorylation cycle in the SVE cycle at the synapse (**Figure 5(d)**). On neuronal depolarization, Ca^{2+} influx stimulates SV fusion with the plasma membrane (exocytosis), followed by SVE to retrieve the empty SV. During the onset of SVE, Ca^{2+} activates calcineurin, which in turn dephosphorylates dynamin 1, along with seven other endocytic phosphoproteins (amphiphysin 1/2, synaptojanin 1, PIPKIγ, epsin 1, eps15, and AP180), collectively termed the dephosphins. Dephosphorylated dynamin 1 relocates to the plasma membrane, presumably through interaction with PI(4,5)P_2, which is enriched at sites of endocytosis, or through an interaction with syndapin 1, which is proposed to shape the neck of the budding vesicle. Dynamin 1 then assembles into helices around the neck of the budding vesicle. Via its twisting action and its assembly-dependent and lipid-stimulated GTPase activity, dynamin 1 releases the vesicle from the plasma membrane. At the completion of SVE, cdk5 rephosphorylates dynamin 1, which is dissociated from the plasma membrane and the syndapin 1 complex back into the cytosol. This process may reset dynamin 1 availability for the next cycle of endocytosis.

Dynamin and Synaptic Transmission

SV recycling in nerve terminals is a fundamental part of maintaining sustained synaptic transmission. It becomes rate limiting for neurotransmitter release under conditions of only moderate or prolonged stimulation. The role of dynamin in sustaining synaptic transmission was first evident from studies of *shibire* flies, which are paralyzed within 2 min at the nonpermissive temperature. The paralysis is brought about by SV depletion, resulting in synaptic transmission impairment. Targeted expression of the temperature-sensitive *shibire* mutant in different regions of the *Drosophila* CNS has been used to study the neural mechanisms of behavior. For example, its expression in the mushroom body revealed that synaptic transmission is required for retrieval of olfactory memory but not for memory acquisition.

In the mammalian CNS, presynaptic loading of GTPγS or a dynamin 1 PRD peptide abolishes endocytosis at the calyx of Held giant nerve terminal. These treatments have no immediate effect on exocytosis, but cause a use-dependent rundown of exocytosis at this fast CNS synapse. Similarly, when rat brain synaptosomes are incubated with a dynamin 1 phospho-mimetic peptide that specifically blocks binding of syndapin 1 (Figure 6(a)), endocytosis is inhibited. The peptide has no effect on exocytosis during the first 60 s of stimulation, but causes an activity-dependent rundown of glutamate release when the stimulation is maintained (Figure 6(b)). These observations establish a requirement of dynamin 1 and SVE in the overall control of synaptic transmission.

Dynamin Inhibitors

An activity-dependent rundown of exocytosis due to restricting dynamin 1 function might have clinical applications in treating neurological disorders such as epilepsy. Epilepsy is characterized by recurrent unprovoked seizures caused by excessive neuronal activity in the brain. Current pharmacological treatments target the ion channels and glutamate or γ-aminobutyric acid (GABA) receptors that control synaptic excitability. Targeting the GTPase activity of dynamin 1 is a more attractive candidate for an anti-epileptic drug because it would not affect synaptic transmission at lower frequency but would reduce synaptic transmission during excessive brain activity. The dynamin 1 phospho-mimetic peptide is a good candidate for such a dynamin 1 inhibitor.

A small number of dynamin inhibitors have been reported. The first was a small series of long-chain amines based on myristoyl trimethyl ammonium bromide (MiTMAB), and the second was a large series of bis-tyrphostin (Bis-T; Figure 6(c)) analogs. Both drugs inhibit lipid-stimulated dynamin 1 GTPase activity with a median inhibitory concentration (IC_{50}) in the low micromolar range, and MiTMAB inhibits endocytosis in exteriorized kidneys. A new small-molecule dynamin inhibitor, dynasore, also inhibits GTPase activity (Figure 6(c)). All these drugs reversibly inhibit both SVE and RME in cultured neurons or nonneuronal cells. Dynasore has no effect on SV exocytosis, but diminishes synaptic responses with repeated stimulation in hippocampal neurons expressing the fluorescent tracer synaptopHluorin (Figure 6(d)). This illustrates the potential for dynamin inhibitors to regulate synaptic transmission *in vivo*. Further development of these compounds may prove useful in the future treatment of synaptic transmission disorders.

Dynamin and Disease

There are several emerging links between the dynamin superfamily of proteins and human diseases, particularly neurodegeneration. Among the classic dynamins, only dynamin 2 has been directly implicated to date. Frame-shift and missense mutations affecting the PH domain lead to a dominant intermediate form of Charcot–Marie–Tooth disease (CMT) called DI-CMTB. CMT is a hereditary motor and sensory neuropathy, characterized by various progressive distal sensory maladies such as numbing of the extremities, deafness, skeletal deformities, and muscle weakness. Missense mutations in the MD cause autosomal dominant centronuclear myopathy, a slowly progressive congenital myopathy characterized by abnormal centrally located nuclei in muscle fibers and a slowly progressing muscle weakness. It remains unclear how dynamin 2 mutations cause these neurodegenerative diseases. Mutations in mitofusin 2, mostly in the region encoding the GTPase domain, also lead to CMT type 2A. Missense mutations in another mitochondrial dynamin-related protein, OPA1, cause dominant optic atrophy (DOA), the most commonly inherited optic atrophy, which presents in childhood as loss of visual acuity associated with optic nerve degeneration. Thus, mitochondrial fusion and fission are important for mitochondrial function and for the overall health of neurons. The observations underscore the importance of dynamin-related protein in maintaining organelle morphology and biogenesis.

At least 20 mutations in atlastin 1 (*SPG3A* gene) lead to dominant pure hereditary spastic paraplegia. Symptoms start in early childhood and can impair the function of the lower limbs. Atlastin 1 is enriched in the layer V pyramidal motor neurons in the

Figure 6 Dynamin controls endocytosis and synaptic transmission: (a) sequences of two penetratin-linked synthetic peptides made from the sequences in the dynamin 1 phospho-box; the $DynI_{769–784}AA$ peptide selectively inhibits syndapin 1 binding to dynamin 1, hence blocking synaptic vesicle endocytosis; (b) an activity-dependent rundown of synaptic transmission in the presence of $DynI_{769–784}AA$ peptide; (c) the chemical structure of two dynamin inhibitors, bis-T-23 and dynasore, which block the GTPase activity of dynamin; (d) rundown of synaptic responses in the presence of dynasore. In (b), synaptic vesicle exocytosis is monitored by the release of glutamate from synaptosomes stimulated with 4-aminopyridine (4-AP). The inset shows the subtracted value for the AA or EE peptides from the control exocytosis (Δ) and is zoomed on the first 3 min from 4-AP addition (which was at 60 s) to highlight the lack of effect during the first 45 s. In (d), synaptic vesicle exocytosis and endocytosis were measured in the synapses of hippocampal neurons expressing the reporter construct synaptopHluorin. An increase in fluorescence intensity indicates exocytosis, whereas a decrease indicates endocytosis. Note the lack of endocytosis in the presence of dynasore, which subsequently causes synaptic responses to diminish with repeated stimulation. In the control condition (DMSO), however, the responses remain stable. AA, $DynI_{769–784}AA$; Ctrl EE, $DynI_{769–784}EE$; DMSO, dimethyl sulfoxide; GTP, guanosine triphosphate. cerebral cortex, which have among the longest axons in the CNS. Mutations in an atlastin 1 binding partner, spastin (*SPG4* gene), also cause hereditary spastic paraplegia. Atlastin mutations affect vesicle trafficking from the ER to Golgi and impair Golgi morphogenesis, suggesting that this underlies the degeneration or dysfunction of the motor neurons. hGBP1 is the first GTPase known to be secreted from endothelial cells. Although no human mutations are known yet, increased hGBP1 concentrations are found in the cerebrospinal fluid of patients with bacterial meningitis. GeneChip arrays further suggest that the expression of the *GBP1* gene may play a role in the development of multidrug resistance.

Dysautonomia: Familial

G Gold-von Simson and F B Axelrod, New York University Medical Center, New York, NY, USA
S A Slaugenhaupt, Massachusetts General Hospital, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Clinical Phenotype

Familial dysautonomia (FD) was initially termed Riley–Day syndrome after the first two authors that originally described the disorder. It is now appreciated that FD is one example of a group of rare disorders termed hereditary sensory and autonomic neuropathies (HSANs). Within this classification, FD is HSAN type III. The HSANs are variable disorders in which normal migration and maturation of neural crest-derived cells has been impeded, especially those destined to evolve into the sensory and autonomic populations. The genetic defect affects prenatal neuronal development so that symptoms are present from birth, although individual expression varies widely. Because the entire autonomic nervous system is affected, there is a pervasive effect on the functioning of other systems.

The phenotypic expression of FD is extremely variable. Some manifestations of the disorder, such as hypotonia and poor suck, are apparent at birth, and others become more prominent and problematic as a function of age. In addition to decreased sensitivity to temperature and pain and consistent lack of overflow emotional tears, there are prominent gastrointestinal symptoms that include discoordinated swallows and gastroesophageal reflux resulting in aspiration and recurrent lung infections. The most prominent manifestation of abnormal gastrointestinal dysmotility in FD individuals is the propensity to vomit. Vomiting can occur intermittently as part of a systemic reaction to physical or emotional stress, or it can occur daily in response to the stress of arousal. Because vomiting is often associated with hypertension, tachycardia, diffuse sweating, and even personality change, this constellation of signs has been termed the dysautonomic crisis. Furthermore, FD patients have devastating cardiovascular perturbations that include postural hypotension without compensatory tachycardia, episodic hypertension, and arrhythmia with risk of sudden death. Insensitivity to hypoxia increases mortality, as it induces profound circulatory responses consistent with sympathetic denervation. In contrast to controls, when FD subjects are exposed to hypoxia during rebreathing, there is a marked decrease in heart rate and systemic blood pressure. Other frequent features of the disorder are delayed developmental milestones, short stature, dysarthria, and orthopedic problems such as kyphoscoliosis. Many symptoms worsen with advancing age, such as gait and vision due to spinocerebellar and optic atrophy, respectively. Fertility has been demonstrated in both sexes, and intelligence is generally within the normal range, although an increased incidence of learning disorders has been noted. With supportive care, morbidity and mortality have been reduced. Currently, approximately 54% of patients are over 15 years of age, and the probability of survival to age 40 is 50%.

Diagnosis

For more than 50 years, diagnosis was determined solely by clinical criteria, with confirmation in questionable cases supported by neuropathological data from sural nerve biopsy specimens. These clinical criteria consisted of absence of overflow emotional tearing, decreased deep tendon reflexes, absence of fungiform papillae on the tip of the tongue, and an absent axon flare following intradermal histamine in an individual of Ashkenazi Jewish or Eastern European Jewish extraction. However, with the recent identification of the genetic mutations causing the disorder, DNA diagnosis is now available. Screening programs for the Ashkenazi Jewish population are now globally available. The impact of these programs on the FD patient population is already appreciated as the number of new births has declined steadily. As a result, there is increasing attention on maximizing the function and improving the prognosis for the existing patient population.

Pathology

Although clinical manifestations suggest both central and peripheral nervous system involvement, consistent neuropathological lesions have only been described for the peripheral nervous system. Most of the symptoms in FD can be explained by the moderate to substantial lack of neurons in sensory, sympathetic, and some parasympathetic ganglia, as well as the continued attrition of these neurons throughout life. For example, superior cervical ganglia in FD patients have on average 12% of the number of neurons as ganglia from age-matched controls. Marked neuronal losses have also been documented in dorsal root ganglia and the parasympathetic sphenopalatine ganglia, while there is only a 20% mean loss of neurons in parasympathetic ciliary ganglia. The only consistent pathological change reported in the central

nervous system (CNS) is in the brain stem, where elevated levels of substance P are found. In addition, recent studies using functional neuroimaging provide new evidence for central dysfunction in FD, as there is hyperperfusion of temporal regions during the dysautonomic crisis.

Biochemical Abnormalities

Consistent with neuropathological descriptions of a decreased sympathetic neuronal population, FD patients have abnormal urinary catecholamine metabolite ratios. Homovanillic acid (HVA), the end product of dopamine, is increased and vanillyl mandelic acid (VMA) is decreased, resulting in elevated urinary HVA:VMA ratios. In addition, plasma levels of noradrenaline and dopamine β-hydroxylase (DBH) do not increase with standing. In fact, FD patients appear to have a distinctive pattern of plasma levels of catechols. Regardless of posture, plasma levels of dopa are disproportionately high and plasma levels of 3,4-dihydroxyphenylglycol (DHPG) are low, resulting in elevated plasma dopa:DHPG ratios, which are not seen in other disorders associated with neurogenic orthostatic hypotension. The high plasma dopa levels are consistent with FD subjects having an increased proportion of tyrosine hydroxylase in superior cervical ganglia. As a result of decreased sympathetic and parasympathetic innervation of peripheral tissues, there is hypersensitivity to adrenergic and cholinergic agents.

Genetics

FD is a recessive genetic defect with a remarkably high carrier frequency in the Ashkenazi Jewish population. The average carrier frequency is 1 in 30; however, it has been reported to be as high as 1 in 18 in Ashkenazi Jews of Polish descent. In 1993, the FD gene was mapped to an 11 cm region of human chromosome 9q31–33 using genetic linkage analysis in 26 families with more than two affected members. The closely linked markers showed strong evidence of allelic association with a single major haplotype present on >99.5% of FD chromosomes, suggesting that the overwhelming majority of FD patients shared a single founder mutation. Positional cloning strategies were used to identify mutations in a candidate gene known as *IKBKAP*. To date, three FD-causing mutations have been identified in *IKBKAP*: an intronic noncoding point mutation, IVS20 + 6T > C, which leads to variable skipping of exon 20, and two missense mutations, R696P (four patients) and P914L (one non-Jewish patient).

Importantly, all FD patients possess at least one copy of the major IVS20 + 6T > C mutation; 99.5% are homozygous, and five patients are compound heterozygotes for the missense mutations. The major mutation results in variable tissue-specific skipping of exon 20 in the *IKBKAP* transcript and thus weakens, but does not completely inactivate, the 5′ splice site of exon 20 (Figure 1). FD patient cell lines express both wild-type and mutant *IKBKAP* mRNA and are therefore capable of producing functional IKAP protein. This has also been shown in FD patients, making the disease quite unique in that patients have variable levels of IKAP protein in different tissues. The lowest levels of normal *IKBKAP* are produced in tissues from the central and peripheral nervous system (Figure 2). These observations suggest that the cellular level of IKAP protein in neurons falls below the threshold level required for normal development and maintenance.

IKAP Function

The *IKBKAP* gene encodes IKAP, which was originally identified as an IκB kinase complex-associated protein. However, this name is now a misnomer, as subsequent work has disproved the role of IKAP in this pathway. IKAP is a subunit of the highly conserved complex Elongator, which is involved in transcription elongation. Recently, RNA interference studies have shown that depletion of IKAP, and therefore Elongator, results in reduced transcriptional

Figure 1 Schematic showing the mRNA isoforms produced in familial dysautonomia (FD). The first six base pairs of the intron 20 sequence are shown, with the FD mutation (T > C) shown in red. WT indicates the normal *IKBKAP* mRNA containing exon 20. MU indicates the mutant message that lacks exon 20 and leads to a downstream stop codon in exon 21. The arrows indicate the locations of the PCR primers used to amplify the mRNA.

Figure 2 PCR amplification of wild-type and mutant *IKBKAP* mRNA in patient tissues showing tissue-specific variability in splicing. The top band is wild-type (contains exon 20), the bottom band is mutant (skips exon 20). Primers used are shown in Figure 1. Nervous system tissues show a marked reduction of normal mRNA.

elongation of several target genes via histone H3 hypoacetylation. A subset of these target genes is required for cell motility, and FD patient cells were shown to be defective in cell migration assays, suggesting that defective cellular motility may underlie the developmental neuropathology of FD. IKAP has also been implicated in a variety of cellular functions in addition to its proven role in transcription. Data in yeast suggest that the Elongator complex is involved in exocytosis and tRNA modification, while studies in mammalian cells implicate IKAP as a scaffold protein involved in cytoplasmic c-Jun N-terminal kinase (JNK) activation in response to extracellular stress. IKAP's role in these processes, and how they relate to the FD phenotype, is not yet understood.

Treatment of FD

At present, treatment of FD remains preventive, symptomatic, and supportive and must be directed toward specific problems. Dysphagia is initially treated by thickening feeds and feeding therapy. However, the insertion of a gastrostomy is frequently required. The gastrostomy ensures a route to maintain adequate hydration yet avoids aspiration. Esophageal dysmotility and gastroesophageal reflux are also common and increase the risk of aspiration. When medical management with prokinetic agents, thickening of feeds, and positioning are not successful, then surgical intervention (fundoplication) is performed. Failure of medical management is defined as radiographic evidence of lower respiratory disease, hematemesis, apnea, or failure to maintain adequate weight gain, growth, and hydration.

Treatment of the dysautonomic vomiting crisis is perhaps one of the most challenging aspects of care. In addition to treating the precipitating cause, for example, the stress of an infection, the crises are managed with a combination of intravenous or rectally administered diazepam and avoidance of dehydration and aspiration. The remarkable response to diazepam is consistent with the hypothesis that the crisis may be a type of autonomic seizure. If there is associated refractory hypertension, then clonidine via the gastrostomy or as a transdermal patch may be tried.

Postural hypotension can be treated with standard methods such as adequate hydration, lower extremity exercises, elastic stockings, fludrocortisone, and midodrine. Hypertension is usually transitory, so treatment should be directed to factors precipitating the hypertension such as anxiety or visceral pain. If the hypertension is persistent, diazepam and clonidine have been found to be particularly effective.

To compensate for alacrima, artificial tears are instilled on a regular basis. Corneal complications have been decreasing with regular use of artificial tear solutions and maintenance of normal body hydration. In addition, cautery of the tear duct puncta has been used in refractory situations. Tarsorrhaphy has been reserved for unresponsive and chronic situations. Corneal transplants have had limited success.

The nature of the major FD mutation suggests an alternative route toward the development of therapies for FD. It has been speculated that by raising the amount of the normal protein product, IKAP, the progression of FD will be slowed and the clinical symptoms reduced. RNA splicing mutations are

sometimes referred to as 'leaky' since they produce both mutant and wild-type transcripts from the same allele, as in FD. There are several examples in both murine and human disease which demonstrate that subtle differences in the level of normal protein produced can lead to striking differences in disease phenotype and severity. Therefore, splicing defects have become attractive candidates for the development of therapeutics since small shifts in splicing efficiency may lead to drastic phenotypic improvement. Targeting splicing defects as a means of treating genetic disease is a young field that has shown some initial promise. A variety of strategies have been used to alter splicing, including oligonucleotide-based technologies, RNA-mediated mechanisms, and pharmacologic agents. Screening strategies using FD patient cells have identified three compounds that alter the expression or splicing of the *IKBKAP* gene. Tocotrienols have been shown to increase the expression of *IKBKAP* in cultured cells. Two compounds, epigallocatechin gallate (EGCG) and kinetin, have been reported to alter splicing of *IKBKAP* and enhance inclusion of exon 20, thereby increasing the amount of normal *IKBKAP* mRNA. The bioactivity of kinetin is significantly higher than that of EGCG, and kinetin has been shown to increase the amount of IKAP protein. To date, efficacy of these compounds in patients has not been shown and clinical trials are necessary.

Summary

Although FD is genetically and pathologically homogenous, there is great variability in clinical expression resulting in protean manifestations. Thus, FD serves as a model to enhance our knowledge of the autonomic nervous system and the various ways it can influence other systems. Furthermore, the most important piece of information to result from the discovery of the FD gene is that, despite the presence of a homozygous mutation, cells from individuals with FD can produce wild-type *IKBKAP* message and IKAP protein. This offers the hope that protein expression and primary and secondary gene functions may be manipulated by potential therapeutic agents.

Dyslexia: Neurodevelopmental Basis

G F Eden, Georgetown University Medical Center, Washington, DC, USA

Introduction

Developmental dyslexia, also referred to as reading disability, is an unexpected reading problem that cannot be attributed to poor intellectual ability or educational shortcomings. Unlike acquired reading disorders such as alexia (acquired dyslexia), this reading disability is developmental in nature and accounts for about 80% of all learning disabilities. The 5–12% of the population affected with developmental dyslexia struggles to attain proficient levels of reading accuracy and fluency, without which they are prevented from deriving meaning from text. The identification of individuals with dyslexia and research into its etiology have been complicated by variations among researchers and educators in placing boundaries between dyslexic and typical readers. Further, although individuals with dyslexia have traditionally been distinguished from those poor readers with lower cognitive capacities or those lacking appropriate reading instruction, avenues for improving reading in these populations may follow similar paths. The most popular approach to counter dyslexia entails explicit instruction in phonological representation (i.e., phonological code). This approach has been reinforced by the positive relationship observed between phonological skills and reading proficiency in the majority of children during the early school grades. Further, functional brain imaging studies have revealed lower brain activity in dyslexic people during the performance of skills invoking phonological representations, and more recently, brain imaging techniques have been employed to study the functional anatomy of reading interventions. Linkage studies continue to reveal candidate genes, pointing to the multigenetic nature of dyslexia and its heterogeneous phenotype. The behavioral manifestations of dyslexia also include deficits in sensorimotor performance which, much like the language-based deficits, have been tied to perturbations in brain function. Together, this information about the behavioral manifestations and biological markers of dyslexia is being used to ensure better identification of dyslexia and more effective treatment strategies.

Behavioral Profile of Developmental Dyslexia

Definition of Developmental Dyslexia

There are numerous definitions of dyslexia. One formulated in 2002 by a working group commissioned by the National Institutes of Health and the International Dyslexia Association specifies the following:

> Dyslexia is a specific learning disability that is neurological in origin. It is characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede growth of vocabulary and background knowledge.

This definition serves researchers and practitioners. It reflects four decades of behavioral research indicating that the word-decoding and reading-fluency deficiencies observed in dyslexia are the symptoms of an underlying deficit in phonological processes. The definition is therefore now more specific than earlier definitions were in identifying one of the cognitive deficits and less specific about the role of IQ. Previous versions of the definition operated using a discrepancy definition. Under that model, IQ measures provided a benchmark of expected achievement against which to measure actual reading achievement. Typically in the United States, a discrepancy of least one standard deviation (15 standard score points) defines dyslexia for inclusion of a student in research studies or allocation of resources by school systems. However, the existence of a strong correlation between IQ and reading achievement biases against identifying individuals with dyslexia, in part because responses to verbal portions of the IQ test are influenced by reading experience. In addition, some of the core deficits exhibited by individuals with dyslexia are shared by poor readers with lower IQ (known as garden-variety poor readers), and these deficits are typically the focus of applied interventions (e.g., phonological coding). Hence IQ is no longer included in the above definition. From an educational perspective, these interventions are now administered in the school systems under a 'response to intervention' model, which in itself selects for those children who fail to benefit from standard instruction, with the next stage being implemented for those students

who fail to show sufficient gains at the previous level. Finally, the more recently derived data from neuroscience research indicating anatomical differences in the brains of individuals with dyslexia has motivated the inclusion of the now widely accepted notion that developmental dyslexia has a neurobiological origin. However, measures of brain function are not currently used to diagnose dyslexia. Hence the current definition of developmental dyslexia has been shaped by a convergence of research findings and the practical aspects of educational reality.

Cognitive Characteristics of Developmental Dyslexia

For the majority of children, early phonological coding skills predict the course of their later reading development. These skills encompass sound manipulation at the phoneme level (phonemic awareness), rapid naming of letters and numbers (phonological retrieval), and short-term verbal memory (phonological recoding). Children who fail to show awareness of the phonemic structure of spoken words at the kindergarten level are more likely to struggle in acquiring grapheme–phoneme correspondence rules, and this affects their long-term ability to decode words. These observations have led to ways by which to identify children with dyslexia early, as those children with poor phonological representation are considered to be at higher risk for reading disability, even prior to the advent of formal schooling. This longitudinal research, together with the fact that treatments aimed at promoting the phonological code are fairly successful in helping children with reading disabilities, has given rise to the notion that a phonological core-deficit hypothesis represents the best explanation for dyslexia.

However, while phonological processes are impaired in many poor readers, these children may also exhibit deficits in other language-related processes, including vocabulary, morphology and syntax, and text comprehension. Likewise, measures of vocabulary and grammar attained at kindergarten are strongly associated with reading outcome in second grade. Finally, skills in the domain of orthography, such as the ability to name words based on visual information or appreciating letter patterns that are legitimate, affect reading fluency and reading comprehension in the later grades.

In sum, the most prominent cognitive deficit associated with dyslexia is that pertaining to phonological coding. However, it should not go unnoticed that other language skills make strong predictions for later reading development and that the process of reading itself promotes phonological representation. Hence it would be fair to say that dyslexia is associated with a number of language-based deficits, with poor decoding serving as the identifying feature. However, because the definition of dyslexia is largely exclusionary, it is not surprising that the result is the identification of heterogeneous populations of dyslexics. This in turn results in variability in the description of the dyslexic phenotype. Although the phonological and other language deficits are prominent and most are directly related to the process of reading acquisition, other behavioral manifestations have been observed and will be described next.

Sensorimotor Characteristics of Developmental Dyslexia

While the behavioral measures of phonological coding described above have provided a strong theoretical framework at the cognitive level, this approach has not been able to address other diverse symptoms observed in dyslexia outside the domain of language. Psychophysical studies in the domain of vision and audition have suggested aberrations within lower-level, perceptual systems, and impaired motor performance in individuals with dyslexia also suggest the possibility of motor system involvement. The hypotheses put forward in this area of research are sometimes based on systems, such as the magnocellular-based visual perceptual hypothesis, or on concepts (such as temporal integration) or are directly linked to locations in the brain (e.g., parietal and cerebellar deficits).

It was first demonstrated by Lovegrove and colleagues using psychophysical experimental techniques that magnocellular visual system function is altered in individuals with dyslexia. These studies were largely confirmed by data acquired using neuroanatomical (altered magnocellular layers in the lateral geniculate nucleus at postmortem), electrophysiological, and functional neuroimaging techniques comparing dyslexics with nondyslexics. For example, the perception of visual motion, which relies on magnocellular function, usually induces a robust activation response in the dorsal visual stream, including parietal cortex and area MT/V5. However, in individuals with dyslexia, this activity is reduced or absent (see **Figure 1**). These results raise the question of the nature of the relationship between dorsal stream function, which is highly developed for visuospatial perception in human and nonhuman primates, and reading, a skill that is uniquely human and has come into use very recently. The dual symptomatology of impaired visual motion perception and phonological processing could be due to the close proximity of brain regions functionally specialized for these divergent tasks, resulting in equal susceptibility under circumstances of brain perturbation. Another possibility is that visual perception that requires tracking of rapidly changing information is impaired because of systematic differences in sensory systems that handle rapidly changing

Figure 1 Horizontal sections of the brain reveal that typical adult readers (left) display activity in visual cortex, including area MT/V5, during the perception of visual motion. Adults with dyslexia (right) lack this activity. From Eden GF, VanMeter JW, Rumsey JW, Maisog J, and Zeffiro TA (1996) Abnormal processing of visual motion in dyslexia revealed by functional brain imaging. *Nature* 348: 66–69.

information. While neither of these hypotheses has been confirmed, this latter idea has some parallels with a hypothesis that has emerged from the study of auditory perception in children with reading problems.

In this case, the poor readers were children with a primary diagnosis of specific language impairment (SLI; see the section titled 'Comorbid disorders') and were found to require longer intervals in order to accurately perceive the sequence of rapid successive auditory inputs. This work by Tallal and colleagues also suggested a link between early sensory processing of nonverbal sounds and phonological processing. This led to an intervention strategy in which children completed exercises devised to improve processing of rapidly presented successive acoustic stimuli and to improve speech perception. However, while initial laboratory work showed promise for improving language function in children with SLI, independent, randomized controlled studies have not yet demonstrated any long-term benefits to reading. Nevertheless, the temporal-deficit hypothesis continues to be actively investigated and provides an interesting model by which to examine whether the remediation of behavioral deficits observed in dyslexia generalize to improvements in other domains, specifically reading.

On the other hand, a locus-specific theoretical framework for understanding the behavioral manifestations of dyslexia has been built around the cerebellum. Nicolson and Fawcett, for example, have argued that reading and phonological deficits arise in parallel with poor skill automaticity, the latter being dependant on cerebellar integrity. While this work is supported by behavioral and functional brain imaging results, the claims that reading gains can be brought about via regimens that target functions carried out by the cerebellum have been controversial.

The appeal of most brain-based research is that it ties into well-characterized neural functions and frequently offers an explanation for the numerous deficits noted in dyslexia. However, a common weakness of this research is that the causal relationship between sensorimotor deficits and reading has not been demonstrated. To do so would require the examination of behavioral deficits over a wide age range or longitudinally, in large participant groups. Only in this way can it be established whether a perceptual deficit plays a causal role in disrupting phonological coding abilities. Research of this type is ongoing and will undoubtedly provide a clearer picture of the direction of causality among these factors.

Biological Basis of Developmental Dyslexia

Brain-Based Evidence

A landmark study by Galaburda and colleagues in 1985 revealed microscopic anomalies in the brains of individuals with dyslexia examined at postmortem (see Figure 2). As the appropriate brain imaging tools became available, this finding provided the impetus for a large number of investigations into the anatomical and physiological integrity of reading-impaired participants *in vivo*. Since then, an abundance of investigations using functional neuroimaging (positron emission tomography and functional magnetic resonance imagery) have reported anomalous patterns of activation associated with reading and phonological representation in adults with persistent and compensated developmental dyslexia. Although these studies have varied in their use of tasks (e.g., the detection or judgment of rhymes, nonword reading, and implicit reading) and in terms of the languages spoken by the participants, their respective observations have largely been consistent. The most common finding for differential brain activity between dyslexic and nondyslexic participants falls into left-hemisphere perisylvian regions. Differences in task-related signal change in the left parietal cortex are commonly reported in children and adults with dyslexia. It is important that these differences are not the result of lower task performance by the dyslexic participants or simply the consequence of impoverished reading experience. In addition, there are reports of altered involvement of the left inferior frontal gyrus in dyslexia (some report hypo- and others hyperactivation) and underactivity in the left occipitotemporal junction (BA 37), the latter being a common finding. For example, during the performance of reading

tasks, dyslexic adults from different countries showed common underactivity in this region despite their differences in language experience (see Figure 3).

Considering the number of brain regions identified in these studies, it is conceivable that dyslexia may arise in a number of different ways. Further, the loci at which functional differences are observed do not necessarily represent the original site of perturbation. However, recent MRI studies measuring fractional anisotropy (estimating white matter integrity) do concur with the physiological differences observed in left temporal parietal in dyslexia. Therefore, not only do functional and anatomical findings converge, but also data emerging from genetic research are beginning to offer a gene-based explanation for the neuronal migrations that may lie behind these neuroanatomical and neurophysiological differences observed in dyslexia.

Figure 2 An example of a brain examined at postmortem. The individual was diagnosed as having had dyslexia. Developmental anomalies consist of neuronal ectopias and architectonic dysplasias. Adapted from Galaburda AM, Sherman GF, Rosen GD, Aboitiz F, and Geschwind N (1985) Developmental dyslexia: Four consecutive patients with cortical anomalies. *Annals of Neurology* 18: 222–233.

Figure 3 During word processing, dyslexics in French-, Italian-, and English-speaking countries, despite their inherent differences in language systems, all exhibit less activity than controls at the occipitotemporal junction of the left hemisphere. From Paulesu E, Demonet J-F, Fazio F, et al. (2001) Dyslexia: Cultural diversity and biological unity. *Science* 291(5511): 2165–2167.

Genetic Evidence

There is abundant evidence that component reading skills which influence reading acquisition are strongly influenced by genes; however, it is already clear that the elusive 'dyslexia gene' is a myth. That is, at least seven regions of susceptibility have been identified by linkage studies (on chromosomes 1, 2, 3, 6, 15, 18, and X), and four candidate genes (on chromosomes 3, 6, and 15) have been associated with dyslexia phenotypes. This complexity may help explain the co-occurrence of dyslexia with other learning and developmental disorders. In any case, there is hope that genetic screening, together with other information, will help to identify individuals at risk for dyslexia well before reading problems emerge in the classroom.

Consistent with human postmortem reports of migration anomalies as well as with animal models, the candidate genes implicate abnormalities in the coding of axonal guidance and neuronal migration. In the present case, they are believed to be involved in the abnormal organization of cortical networks that contribute to the component skills of reading acquisition. As a caveat, however, it must be noted that the known functions of the candidate genes might be expected to lead to a general rather than to a specific disorder. Furthermore, it seems likely at this stage of research that the culprits are mutations in regions that regulate the candidate genes.

Dyslexia in Different Languages and Orthographies

How many of the reading problems encountered by individuals with dyslexia are unique to the English language? Although most of the language-based deficits described above have been reported for dyslexia in a variety of different countries and the neurobiological basis for these problems is shared in large part among users of the alphabet (see Figure 3), there are differences in the rate of reading acquisition that can be attributed to variations in language characteristics. For example, it has been argued by Ziegler and Goswami that the differences in syllable structure and the consistency by which phonology is mapped to orthography will affect the rate at which children reach reading proficiency (e.g., faster in German than in English). It is interesting that skills such as phonological coding also play a role in logographic writing

systems, such as Chinese, although in this case the role of orthography clearly is more dominant. Not surprisingly, Chinese reading, compared with English reading, evokes greater responses in the visual system and less activity in the superior temporal lobe regions that are associated with phonological processing in the alphabetic languages. Struggling Chinese readers show less activity in frontal systems thought to be responsible for the mapping of orthography to phonology and orthography to semantics (see Figure 4). In other words, dyslexia is omnipresent, and while there are common elements that support reading across languages and writing systems, there are also unique differences in the brain signatures for reading, each of which is most likely susceptible to changes that could result in reading disability.

Comorbid Disorders

Developmental Dyslexia and Attention-Deficit/Hyperactivity Disorder

It has been suggested that as many as 40% of children with dyslexia also have attention-deficit/hyperactivity disorder (ADHD). Because these disorders have been seen both alone and together, there has been some debate as to whether they were entirely independent. More recently, a common etiology to their co-occurrence has been supported by genetic evidence of susceptibility regions on chromosomes 2, 8, 14, and 15. Separately, either disorder can affect learning or either can affect focus of attention, thus making their independent and collective contributions particularly difficult to identify. Obviously, the importance of correct diagnosing has obvious treatment implications, whether academic, behavioral, or pharmacological. Few neuroimaging studies have focused on the question of a common etiology, as opposed to independent etiologies, of ADHD and dyslexia, with the former focusing on frontal and subcortical function and the latter on language substrates.

Developmental Dyslexia and SLI

Approximately 50% of children diagnosed with SLI in early childhood will develop learning difficulties, particularly in reading, especially if the language impairment is severe and is still present on school entry. Dyslexia is not the inevitable outcome of SLI, however, and dyslexic individuals do not necessarily have a history of SLI – evidence that the two disorders are independent. Brain imaging studies support the proposition that phonological deficits and language comprehension are served by different neural networks, further support for independent etiologies. Like ADHD, SLI has been studied alone and in combination with dyslexia. Although phonological-awareness problems might be expected to be associated with SLI, studies have found only mild deficits in that group on measures of phonological-coding skills. In contrast, dyslexic participants with or without comorbid SLI have poorer phonological skills. The separate and combined aspects of these often coexisting disorders make it prudent to adopt specific intervention strategies to address their respective deficits, highlighting phonological processes on one hand and listening comprehension on the other.

Therapeutic Approaches to Developmental Dyslexia

Given the plurality of weaknesses in addition to reading problems that are observed in individuals

Figure 4 During a homophone judgment task, Chinese normal (blue) and impaired readers (red) differ in brain activity in left-middle frontal gyrus (top panel) and inferior frontal gyrus. From Siok WT, Perfetti CA, Jin Z, and Tan LH (2004) Biological abnormality of impaired reading is constrained by culture. *Nature* 431(7004): 71–76.

with dyslexia, the necessity for multiple treatment strategies may seem pressing. As discussed above, programs that emphasize phonological coding are known to facilitate reading acquisition. However, targeting just this one domain is not sufficient. Although gains in phonological representation can bring about growth in multiple aspects of reading, they do not generalize to all aspects of reading. For example, promoting reading fluency and reading comprehension in addition to phonology requires other types of intervention approaches. Studies targeting domains of reading other than phonological coding, such as orthography, are less numerous. Increasingly, successful treatment methods represent a combination of training approaches (combining phonics, phonemic awareness, fluency, vocabulary, and reading comprehension), which, although logical from an educational perspective, complicates any experimental approach to identify independent contributors of reading recovery. It is interesting that the methods by which these instructions are delivered in clinics or classrooms often involve 'multisensory' enhancing techniques, whereby the same principles are taught by reliance on several sensory systems, through speaking (audition), visual imagery or visual representation touch, and motor system involvement (writing, air writing, or body movements that correspond to the number of syllables or phonemes in a given word). These observations from the classroom are ripe for neuroscientific inquiry, based on our understanding of neural responses under conditions of single versus multiple sensory stimulation in the auditory and visual systems.

Evaluating the benefits of various remediation strategies for dyslexia is beyond the scope of this article; a thorough review of representative therapies has been published by Alexander and colleagues. From the neuroscientific perspective, it is of value to establish the neural correlates of successful reading interventions as these provide important insight not only into brain mechanisms of dyslexia but also into behavioral plasticity. Based on a rich animal and human literature of training-induced brain plasticity and functional reorganization following rehabilitation from cerebral injury, one can consider several paths that would lead to changes following successful reading intervention in developmental dyslexia. One is a mechanism by which brain regions with known anomalies in dyslexia are shown to establish a more typical response. An alternative brain response could involve the manifestation of brain activity in brain regions not typically associated with the reading process. Such compensatory strategies have been described for stroke patients in brain regions contralateral to the injury (and which encompassed the site typically activated by the now relearned skill). Functional brain imaging technology has allowed these models to be subjected to the test. For example, in a study comparing dyslexic adults with persistent reading problems following 120 h of intensive reading intervention to a matched group of dyslexics receiving no intervention at all, the intervention group was found to have increased activity in bilateral parietal and right perisylvian cortex following the intervention (see Figure 5). These results suggest that the significant gains in reading enjoyed by the intervention group could be attributed to right hemisphere compensation combined with increases in a more typically reading-related left hemisphere brain region. Several functional brain imaging studies have also been conducted in children receiving reading interventions, and a review of this small literature suggests a role for age (or brain maturation) in directing the pattern of treatment-induced brain plasticity. This, however, does not mean that changes in brain activity necessarily guarantee behavioral gains, and results from these studies are meaningful only if the studies follow rigorous research practices, such as the use of controlled, randomized experimental designs.

Summary

Developmental dyslexia has been studied in the context of learning, development, experiential factors, genetic influences, and brain function. For all children, a mastery of reading requires the integration and coordination of sensorimotor and cognitive processes. How these fail to operate at an optimal level to bring about accurate and fluent reading in the context of normal cognitive function and appropriate teaching methods continues to be questioned from the viewpoint of behavior and brain function. Avenues of remediation within both cognitive and sensorimotor

Figure 5 Functional anatomy of phonological manipulation following reading remediation (Group X Session interaction) revealed increases during phonological manipulation in left parietal cortex and fusiform gyrus. Right hemisphere increases included posterior superior temporal sulcus/gyrus and parietal cortex. Reprinted from Eden GF, Jones KM, Cappell K, et al. (2004) Neural changes following remediation in adult developmental dyslexia. *Neuron* 44(3): 411–422.

domains are under active investigation to establish the efficacy of these approaches as well as to discover their neuronal targets. Investigations into the hereditary mechanisms of reading deficits hold the promise of strengthening the understanding of the neural mechanisms of dyslexia. Together, behavioral and physiological studies continue to aid in the early identification of dyslexia and best avenues for its treatment.

Introduction

Dystonia is a neurological syndrome characterized by involuntary muscle contractions, which may cause twisting and repetitive movements or abnormal postures. Dystonia can affect any part of the body, including the arms and legs, trunk, neck, eyelids, face, or vocal cords. Dystonia can involve any voluntary muscle or muscle groups. In 1911, Oppenheim was the first to use the term dystonia to describe a childhood-onset syndrome, characterized by twisted postures, muscle spasms, abnormal walking with bending, twisting of the torso, and development of sustained fixed postural defects also known as dystonia musculorum deformans. This is one of the most severe forms of dystonia affecting most regions of the body. Because the movements and resulting postures are often unusual, and the condition is rare, it is one of the most frequently misdiagnosed neurological conditions.

Dystonia is the third most common movement disorder after Parkinson's disease and tremor, affecting more than 300 000 people in North America. The prevalence estimates for primary dystonia range from 2 to 50 cases per million for early onset dystonia and from 30 to 7320 cases per million for late-onset dystonia. From an analysis of methodological information from 14 selected studies, it was concluded that all of the studies based on treatment settings or record-linkage systems, and two population-based surveys, were probably flawed by incomplete ascertainment; a third population-based study provided the largest prevalence for late-onset dystonia but probably overestimated the prevalence of the disorder. Age and ethnic differences among study populations further biased comparisons of the estimates. On the basis of methodologically more robust service-based studies and the likely percentage of underdiagnosis in a given area, more accurate prevalence estimates may be 111 per million for early onset dystonia in Ashkenazi Jews from the New York area, 600 per million for late-onset dystonia in northern England, and 3000 per million for late-onset dystonia among Italians older than 50 years of age.

Classification of Dystonia

Dystonia is classified into three categories based on the cause of dystonia, the location of symptoms in the body, and the age of onset (see Figure 1).

Classification Based on Cause

Based on the cause, dystonia is classified as either primary, if the sole symptom is dystonia, or secondary, if the dystonia is not the sole feature observed. Primary dystonias (PTDs) are largely genetic in origin, and the dystonia is the sole symptom of the patient. On the other hand, secondary dystonias result from the effects of medications, trauma, toxins, infections, or other disorders. Spinal cord, head, and peripheral injuries are also believed to be contributors to secondary dystonia. Other examples of secondary dystonias include levodopa-induced dystonia in the treatment of parkinsonism; acute and tardive dyskinesia due to antipsychotic agents; and dystonias associated with cerebral palsy, cerebral hypoxia, cerebrovascular disease, cerebral infections and postinfectious states, stroke, encephalitis, brain tumor, and toxicants such as manganese, cyanide, and 3-nitropropionic acid.

Tardive dystonia and tardive dyskinesia are caused by exposure to antipsychotic drugs. The term tardive means 'late,' indicating that the condition occurs after drug exposure, and the terms dyskinesia and dystonia describe the types of movements involved. Tardive dystonias and dyskinesias may also develop as a symptom after prolonged treatment with levodopa in some Parkinson's patients. These symptoms may develop after weeks or years of drug exposure.

Classification Based on Affected Body Regions

Dystonias that are localized to a certain body part are referred to as focal dystonias. When more than one muscle group is affected, the dystonia is called multifocal, and when adjacent body parts are involved it is referred to as segmental dystonia. When many regions are affected, it is referred to as generalized dystonia.

Focal dystonias

- *Blepharospasm*. Increased blinking and involuntary closing of the eyes characterize this disorder. Blepharospasm affects the eye muscles and usually begins gradually with excessive blinking and/or eye irritation. In the early stages, it may only occur with specific precipitating stressors, such as bright lights, fatigue, and emotional tension. It is almost always present in both eyes. Blepharospasm can occur with dystonia affecting the mouth and/or jaw and is referred to as Meige's syndrome. In such cases, spasms of the eyelids are accompanied by jaw clenching or mouth opening, grimacing, and tongue protrusion.
- *Cervical dystonia*. Cervical dystonia is also known as spasmodic torticollis, characterized by the

Figure 1 General classification of dystonia.

neck muscles contracting involuntarily, causing abnormal movements and posture of the head and neck. Cervical dystonia characterized by forward tilting of the head is referred to as anterocollis, backward tilting is called retrocollis, and sideways tilting is called torticollis. The contractions in the neck muscles may be sustained or jerky. Spasms in the muscles or pinching of nerves in the neck can result in considerable pain and discomfort, causing the abnormal posture of the head and neck.

- *Oromandibular dystonia*. Oromandibular dystonia is characterized by forceful contractions of the jaw and tongue causing difficulty in opening and closing of the mouth and often affecting chewing and speech. This syndrome is often associated with torticollis, blepharospasm, or spasmodic dysphonia. When oromandibular dystonia is combined with blepharospasm, the condition is referred to as Meige's syndrome. The symptoms usually begin between ages 40 and 70 years and appear to be more common in women than men. Difficulty swallowing is a frequent clinical feature of oromandibular dystonia.
- *Spasmodic dysphonia*. Spasmodic dysphonia is characterized by involuntary spasms of the vocal cords causing interruptions of speech and affecting the quality of voice. Two types of spasmodic dysphonia are generally observed. In the adductor type of dysphonia, speaking causes abnormal involuntary excessive contraction of the muscles that bring the vocal cords together. This causes a tight voice pattern,

often with abrupt initiation and termination of the voice, resulting in a broken speech pattern. In the abductor type of dysphonia, increased contraction of the muscles that separate the vocal cords results in a breathy, whispering voice pattern. In addition, three other subtypes of spasmodic dysphonia have been identified. One is a combination of adductor and abductor symptoms in which an individual may demonstrate both types of spasms when speaking. In a second subtype, spasmodic dysphonia symptoms are accompanied by a tremor in the voice. A third subtype involves a primary voice tremor that is so severe the patient experiences adductor voice interruption during the tremor. Although it can begin at any time during life, spasmodic dysphonia seems to occur frequently in 40- to 50-year-olds.

- *Writer's cramp*. This is a task-specific focal dystonia of the hand and the symptoms usually appear when a person is attempting a task that requires fine motor movements. The symptoms may appear only during a particular type of movement, such as writing or playing the piano, but the dystonia may spread to affect many tasks. Two types of writer's cramp have been described: simple and dystonic. People with simple writer's cramp have difficulty with only one specific task. In dystonic writer's cramp, symptoms will be present not only when the person is writing but also when the person is performing other task-specific activities, such as shaving, using eating utensils, and applying makeup. The symptoms usually begin between the ages of 30 and 50 years and affect both men and women.
- *Paroxysmal dystonia*. Paroxysmal dystonia is characterized by brief attacks of dystonic movements and postures and a return to normal posture between the attacks. The paroxysmal dyskinesias are classified as action-induced (kinesigenic) or non-action-induced (nonkinesigenic). The most common paroxysmal dyskinesias are paroxysmal kinesigenic choreoathetosis (PKC) and paroxysmal dystonic nonkinesigenic choreoathetosis (PDC), also known as paroxysmal dystonia. The majority of cases of PKC and PDC are idiopathic or familial (either autosomal dominant or occasionally sporadic).
- *Myoclonic dystonia*. Myoclonic dystonia is characterized by rapid jerklike movements alone or in combination with the sustained muscular contractions and postures of dystonia. Myoclonic movements are the most prominent clinical feature in the majority of people affected. The distribution of these rapid 'jerks' is variable, but most frequently the central part of the body is affected, including the shoulders, arms, neck, and trunk. Rarely are the face and legs affected. The jerks may occur synchronously or asynchronously in different muscle groups. The dystonic symptoms of prolonged muscle spasms or abnormal posture may also be present. The distribution of symptoms of myoclonic dystonia is different from that of typical childhood-onset dystonia; myoclonic dystonia more often affects the upper body, whereas typical childhood-onset dystonia usually affects the legs. The age of onset is in the first or second decade of life, although some cases of adult onset have been reported.
- *Musicians with dystonia*. It has been observed that musicians are prone to task-specific focal dystonia or musician's dystonia. The vigorous practice and constant repetition of precise movements over the course of many years that are required for performing at an expert level can cause task-specific focal dystonia.

Dystonia-plus syndrome To describe dystonias manifesting with other neurological disorders, the classification of dystonia-plus was coined to distinguish some dystonic syndromes from both PTD and secondary disorders. The dystonia-plus group includes dystonic syndromes with neurological features in addition to dystonia, in which clinical and laboratory findings suggest neurochemical disorders but with no evidence of neurodegeneration. Included in this category are disorders characterized by dystonia with parkinsonism (i.e., DYT5 and DYT12) as well as myoclonus–dystonia (DYT11).

- *Rapid-onset dystonia parkinsonism*. Rapid-onset dystonia parkinsonism (RDP), a rare hereditary form of dystonia, is characterized by the abrupt onset of slowness of movement (parkinsonism) and dystonic symptoms. The classic features of RDP include involuntary dystonic spasms in the limbs, prominent involvement of the speech and swallowing muscles, slowness of movement, and poor balance. Onset of the combined dystonic and parkinsonian symptoms can be sudden, occurring over hours to days. Symptoms usually stabilize in less than 4 weeks, after which there is reported to be little progression. RDP usually occurs in adolescence or young adulthood (age range, 15–45 years), but the onset of mild dystonia–parkinsonism has been reported in individuals up to the age of 58 years.
- *X-linked dystonia parkinsonism*. X-linked recessive dystonia parkinsonism (XDP) was first described in 1976 by Lee and colleagues as endemic in Panay, Philippines, affecting predominantly the male population. It is an adult-onset disorder characterized by progressive and severe dystonia often affecting other body regions and progressing to generalized dystonia. Pathology of the XDP corpus striatum demonstrated that the neurons of the matrix compartment are

relatively spared, whereas the striosomes are severely depleted during the dystonic phase of the disorder. However, the matrix compartment also loses neurons as the disease progresses into parkinsonism.

Classification Based on Age of Onset

Based on the age at which the symptoms of dystonia develop, it is classified as early onset and late onset. Early onset dystonia occurs between the ages of 2 and 28 years (median age, 14.5) and the symptoms usually develop mostly in the limbs and spread to the rest of the body and become stabilized within 5 years. Late-onset dystonia usually begins after age 28 years, and the symptoms generally remain focal.

Early onset generalized dystonia Early onset generalized dystonia is a PTD and the most common hereditary form of dystonia; it is characterized by twisting of the limbs, specifically the foot/leg or hand/arm. Early onset generalized dystonia has also been referred to as dystonia musculorum deformans. The following are symptoms of early onset generalized dystonia: twisted postures; turning in of the foot or arm; muscle spasms; unusual walking with bending and twisting of the torso; rapid, sometimes rhythmic, jerking movements; and progression of the symptoms to sustained or fixed postures. The spasms may spread to involve twisting contractions of other parts of the body. Because the legs and trunk are commonly affected in early onset generalized dystonia, abnormal gait is generally noticed in patients. The age of onset varies from 2 to 28 years, but the peak period is between the ages of 7 and 10 years, with symptoms progressing and stabilizing within a 5-year period.

Early onset dystonia is caused by a mutation in the DYT1 gene, which codes for a protein called torsinA. The mutation involves deletion of a single glutamic acid residue at position 302/303 in the amino acid sequence of torsinA. The precise function of torsinA is not known; however, it belongs to the family of AAA+ proteins involved in a variety of cellular functions. Several invertebrate and vertebrate animal models have been developed to better understand the impact of mutation in torsinA on these model animals.

Dopa-responsive dystonia Dopa-responsive dystonia (DRD) is a hereditary form of dystonia characterized by progressive difficulty in walking. The symptoms resemble those of early onset generalized dystonia (DYT1). However, DRD differs from DYT1 in that patients with DRD respond very well to L-DOPA therapy. Although the symptoms of DRD usually present at approximately the age of 7 years, the disorder may appear at any age. Symptoms may appear minor (e.g., muscle cramps after exercise) or present later in life in a form that more closely resembles Parkinson's disease.

Pathophysiology of Dystonia

There is no distinct pathology in dystonia. Studies of DYT1 dystonia demonstrated that the overall immunostaining pattern of torsinA was not different in dystonia and normal brains in the midbrain and neostriatal regions. However, a later study demonstrated the nigral dopaminergic neurons to be larger in both DYT1 and non-DYT1 dystonic brains compared to normal, and they may be more closely spaced in DYT1 brains. Other than these changes in neuronal size and spacing in dystonic brains, there was no indication of neuronal loss, inflammation, or altered distribution of torsin-like immunoreactivity. One study demonstrated brain stem pathology and showed the presence of perinuclear inclusion bodies in the midbrain reticular formation and periaqueductal gray in four clinically documented and genetically confirmed DYT1 patients but not in controls. The inclusions were located within cholinergic and other neurons in the pedunculopontine nucleus, cuneiform nucleus, and griseum centrale mesencephali and stained positively for ubiquitin, torsinA, and the nuclear envelope protein lamin A/C. Similar results were demonstrated in transgenic and knockin models of DYT1 dystonia. Studies of X-linked dystonia parkinsonism have revealed a loss of cells in the striasome compartment of the striatum at the dystonic phase of the disorder, and upon progression to parkinsonism, a loss of cells in the matrix was also observed.

Imaging Studies in Dystonia

No structural abnormalities of the brain have been demonstrated by performing magnetic resonance imaging (MRI) on patients with primary focal dystonia. However, functional neuroimaging with positron emission tomography (PET) revealed differences in DYT1 carriers versus affected individuals. PET, single-photon emission computer tomography, MRI, and magnetoencephalography are powerful tools to elucidate anatomical and functional impairment underlying movement disorders, including dystonia. They have revealed that presymptomatic cerebral abnormalities may be a common feature in dystonia no matter the clinical status. In addition, techniques using specific markers have focused on the type of receptors that may be disinhibited and/or on the kind of neurotransmitters that may be dysregulated in dystonia.

Genetics of Dystonia

In the past two decades, genetic studies of families of affected individuals have led to the identification of several chromosomal loci linked to dystonia. A genetic basis has been implicated in 15 dystonias. However, the gene mutations responsible are known for only a few of them. Table 1 presents the different types of dystonias known so far to have a genetic basis:

- *DYT1*. This designation refers to the gene responsible for most cases of early onset and limb-onset primary dystonia. Also known as Oppenheim dystonia, DYT1 dystonia is an autosomal dominant disorder with reduced penetrance and variable expressivity. The DYT1 gene, which has been mapped to chromosome 9q34.1, encodes for a protein called torsinA. Mutation in torsinA results in the loss of a single glutamic acid residue at position 302/303 in the amino acid sequence of the protein.
- *DYT2*. This genetic designation was reserved for a possible autosomal recessive primary dystonia. However, no such form has been confirmed.
- *DYT3*. This refers to the gene for a neurodegenerative, X-linked recessive disorder that is characterized by dystonia and parkinsonism. Known as X-linked dystonia–parkinsonism or Lubag, the disorder has been reported primarily in young adult Filipino men. The DYT3 gene has been mapped to chromosome Xq13.1.
- *DYT4*. This genetic designation is for an autosomal dominant primary dystonia in a multigenerational Australian family. DYT4 dystonia is primarily characterized by abductor ('whispering') spasmodic dysphonia (laryngeal dystonia).
- *DYT5a,-b*. DYT5a refers to the gene known as GTP cyclohydrolase I (GCH1), which has been mapped to chromosome 14q22.1. Mutations of the GCH1 gene may result in the dystonia-plus syndrome called dopa-responsive dystonia (Segawa syndrome), which is transmitted as an autosomal dominant trait. DYT5b is inherited in an autosomal recessive mode and is due to mutation in the TH gene localized to chromosome 11p15.5. The gene encodes for tyrosine hydroxylase, the enzyme that synthesizes the neurotransmitter dopamine.
- *DYT6*. This is for an autosomal dominant primary dystonia mapped to chromosome 8 (8p21–q22). Described in two Mennonite families (kindreds), this form of dystonia may be of childhood or adult onset; initially it affects limb, cranial, or neck muscles and typically extends to involve multiple body regions.
- *DYT7*. This genetic designation is for an autosomal dominant, adult-onset primary dystonia of the neck region (familial torticollis) that has been mapped to chromosome 18p in a German kindred.
- *DYT8*. This designation is for paroxysmal nonkinesigenic dyskinesia (PNKD) that may be inherited as an autosomal dominant trait. PNKD is characterized by sudden, transient episodes of excessive or disorganized (hyperkinetic or dyskinetic) movements that may occur spontaneously or be triggered or worsened by stress, fatigue, or other factors. Abnormal movements may include any combination of

Table 1 Genetically defined forms of dystonia

Dystonia locus	*Dystonia type*	*Mode of inheritance*	*Chromosomal location*	*Gene product*
DYT1	Early onset generalized dystonia	AD	9q34	TorsinA
DYT2	Generalized dystonia	AR	UNK	UNK

AD, autosomal dominant; AR, autosomal recessive; DRD2, dopamine receptor 2; GCH1, GTP cyclohydrolase 1; TH, tyrosine hydroxylase; UNK, unknown; XR, X-linked recessive.

dystonia, chorea, athetosis, and/or ballismus. DYT8 has been mapped to chromosome 2q33–q35.

- *DYT9*. This genetic designation is for a family affected by an autosomal dominant disorder known as 'choreoathetosis spasticity, episodic.' It is characterized by sudden, transient (paroxysmal) attacks of dyskinesia – such as chorea, athetosis, limb dystonia, imbalance, and difficulty speaking (dysarthria) – that, in some cases, may be associated with constant weakness and stiffness of the legs (spastic paraplegia). Paroxysmal episodes may be precipitated by physical exercise, lack of sleep, alcohol consumption, stress, or other factors. DYT9 has been mapped to chromosome 1p.
- *DYT10*. This designation is for paroxysmal kinesigenic dyskinesia (PKD), a neurologic movement disorder that may be transmitted as an autosomal dominant trait. In patients with PKD, sudden episodes of dyskinesia, including dystonic movements, may be triggered by sudden voluntary movement or unexpected stimuli (startle). DYT10 has been mapped to chromosome 16p11.2–q12.1.
- *DYT11*. This is an autosomal dominant disorder known as myoclonus–dystonia. Genetic analysis demonstrated mutations of the DRD2 (dopamine receptor 2) gene, which has been mapped to chromosome 11q23. Mutations in the gene for ε-sarcoglycan may also give rise to this disorder.
- *DYT12*. This is characterized by abrupt onset of slow, dystonic movements and prominent bulbar features. The gene responsible for rapid-onset dystonia–parkinsonism, an autosomal dominant disorder, has been mapped to chromosome 19q13. Mutations in the ATP1A3 gene are the cause of this disorder.
- *DYT13*. This is an autosomal dominant disorder with incomplete penetrance (58%). Clinical presentation and age at onset are more variable than in DYT1, and the neck is involved in many affected individuals. The chromosome locus for this condition has been mapped to 1p36.11–p36.32.
- *DYT14*. This is an autosomal dopa-responsive dystonia linked to chromosome 14q13. The substantia nigra and locus ceruleus showed a normal abundance of severely hypomelanized dopaminergic neurons and no Lewy body, similar to that observed in DYT5a.
- *DYT15*. This is associated with a large Canadian kindred in which 12 members over four generations had alcohol-responsive myoclonic dystonia characterized mainly by jerky movements of the upper limbs, hands, and axial muscles. Four members also had dystonia of the upper limbs, and 1 had dystonia of the leg. The chromosomal locus was mapped to 18p11; however, the gene responsible for this syndrome has not been identified.

Therapy

There are no adequate treatments for dystonia. Current treatments are palliative only, guided by the age of onset, cause, and medication history. Early onset dystonia is usually treated with L-DOPA, which helps in the differential diagnosis of DRD versus DYT1; DRD responds very well to L-DOPA, whereas DYT1 does not. However, because of the identification of a causative mutation in DYT1, L-DOPA treatment can be avoided if the patient is first subjected to genetic testing.

Medications

Dopaminergics Primary dystonias respond to drugs such as levodopa that increase dopamine levels; however, some patients respond to agents that block or deplete dopamine, although caution must be taken because the medications may evoke tardive dystonia.

Anticholinergics Drugs that block acetylcholine, thereby deactivating muscle contractions, are among the most commonly used medications for the treatment of dystonia. The dosage is limited by central side effects, such as confusion, drowsiness, hallucination, personality change, and memory loss, and by peripheral side effects, such as dry mouth, blurred vision, urinary retention, and constipation.

Benzodiazepines Benzodiazepines block $GABA_A$ receptors in the central nervous system and may relax muscles and ease symptoms associated with dystonia. The primary side effect is sedation, but others include depression, personality change, and drug addiction. Rapid discontinuation can result in a withdrawal syndrome.

Baclofen Baclofen is used for the treatment of spasticity. It is a GABA agonist that activates the $GABA_B$ receptor. The primary site of action of this drug is the spinal cord, where it reduces the release of neurotransmitters that stimulate muscular activity. Baclofen can be administered orally or via a surgically implanted (intrathecal) pump that delivers the drug directly to the spinal cord.

Botox Treatment

For focal dystonias, intramuscular injection of botulinum toxin substantially reduces the involuntary movements of the muscles, thereby providing substantial relief from dystonic symptoms. Botox is injected into specific muscles to weaken muscle activity sufficiently and reduce spasm but not enough to cause paralysis. Botox prevents the release of acetylcholine, a neurotransmitter that causes muscle contractions. However,

treatment with Botox is not permanent; it needs to be repeated every few months.

Surgical Treatment

Only patients with intractable dystonias that do not respond to any therapies are considered for surgical procedures. Ablation of parts of the thalamus and pallidum was originally done for Parkinson's disease, the rationale being that abnormal firing in these brain regions was considered to result in either Parkinson's disease or dystonia. Therefore, surgical removal of this malfunctioning brain region is believed to correct this abnormal firing. Primary early onset generalized dystonias have been treated successfully with surgical removal of either the pallidum or parts of the thalamus. This is highly invasive surgery and the process cannot be reversed. This procedure is being replaced with deep brain stimulation that is comparatively less invasive than surgical removal of brain regions.

Deep Brain Stimulation

Early onset generalized dystonias that are not treatable using any other available treatments are considered for deep brain stimulation. In this procedure, electrodes are implanted in the globus pallidus using stereotaxic methods. The deep brain stimulation electrodes are connected by wires to a type of pacemaker device (called an impulse generator) implanted under the skin of the chest, below the collarbone. The electrodes are then stimulated at a certain frequency and send electrical pulses into the brain region. Although the mechanism by which deep brain stimulation works is not clear, the procedure has successfully treated many primary generalized dystonias.

Other Therapies

Physiotherapy, yoga, and stretching exercises have been found to be beneficial to dystonic patients. In some patients, the use of sensory tricks has provided temporary relief from their dystonic symptoms. These sensory tricks frequently involve touching or stroking a particular spot on the skin. The exact mechanism of relief obtained by these sensory tricks is not understood. It is believed that stimulation of the skin may interrupt abnormal nerve impulses that cause involuntary contraction of muscles.

Molecular Approaches

In DYT1 dystonia for which the gene defect is known, intervention with siRNA technology has been successful in selectively silencing the production of mutant torsinA message in cell culture models. It is hoped that the development of such technology can lead to prevention or a cure for DYT1 dystonia. However, this technology is not developed enough to be applied to human patients.

Definition, Terminology, and Diagnostic Criteria of Myoclonus–Dystonia

Definition

Myoclonus is a rapid, brief contraction ('fast lightning jerk') of one muscle or a group of muscles which may or may not result in observable movement at a joint. The movements can involve any muscle group but most commonly occur in proximal muscles of the limbs and in the neck and trunk musculature. Dystonia, on the other hand, is characterized by sustained twisting and repetitive movements, resulting in abnormal postures. Myoclonus and dystonia may occur together in several diseases. Some patients with primary torsion dystonia display fast dystonic movements which may resemble myoclonus, and occasional myoclonic jerks may occur superimposed on dystonic movements. Conversely, myoclonus may be associated with dystonic features.

Terminology

A large variety of different terms has been used in the past to describe familial myoclonus or myoclonus in combination with dystonia, including 'paramyoclonus multiplex,' 'hereditary essential myoclonus,' 'familial essential myoclonus,' 'essential familial myoclonus,' 'dominantly inherited myoclonic dystonia with dramatic response to alcohol,' 'hereditary myoclonic dystonia,' 'myoclonus–dystonia (M-D),' and 'inherited myoclonus–dystonia syndrome.' Lang proposed to use a hyphenated combination of the two terms 'myoclonus' and 'dystonia.' The order of presentation was used to emphasize the more constant of the two features – 'dystonia–myoclonus' describes dystonia with some myoclonic jerks, while 'M-D' was suggested as the appropriate term for a predominantly myoclonic syndrome associated with dystonia. Accordingly, the term 'M-D' shall be used herein for all cases of myoclonus associated with dystonia. However, it has to be noted that in several M-D families, affected individuals may display myoclonus or, rarely, dystonia as the sole symptom of the disease. A patient with clinically typical M-D is shown in Figure 1.

Myoclonus or dystonia is considered primary if either is the only neurological feature, and the etiology is unknown or genetic. M-D is often referred to as a 'dystonia-plus' syndrome. Owing to the advances in the molecular genetics of the dystonias in the past 10 years, a genetically based categorization has been introduced. Currently, at least 15 different types of dystonias can be distinguished on a genetic basis, designated dystonia *DYT1–DYT15*. M-D linked to chromosome 7q is synonymous with dystonia 11 (or *DYT11*, OMIM 159900 – now *epsilon-sarcoglycan*, or *SCGE*, OMIM 604149), and a second M-D locus has been described on chromosome 18p (*DYT15*, OMIM 607488). Finally, based on the identification of the *epsilon-sarcoglycan* gene as the major M-D gene, M-D may be grouped under the sarcoglycanopathies. (Note: The Online Mendelian Inheritance in Man (OMIM) database is a catalog of human genes and genetic disorders from the National Center for Biotechnology Information (NCBI).)

Diagnostic Criteria

Although several similar descriptions had appeared in the literature before 1967, Mahloudji and Pikielny were the first to define diagnostic criteria for M-D, which they referred to as 'hereditary essential myoclonus.' Original diagnostic criteria were (1) onset of myoclonus in the first or second decade, (2) males and females equally affected, (3) a benign course, often variable but compatible with an active life of normal span, (4) dominant mode of inheritance with variable severity, (5) absence of seizures, dementia, gross ataxia, and other neurological deficits, and (6) normal electroencephalogram (EEG). These criteria have been modified by Gasser and more recently by Klein based on findings in genetically proved (*DYT11*) M-D and are subdivided into cardinal and optional diagnostic criteria for M-D. Since members from at least three mutation-positive families have been found to have epileptic seizures and/or EEG changes, absence of seizures and an abnormal EEG are no longer considered exclusion criteria for M-D. Adapted diagnostic criteria are as follows.

- Cardinal criteria
  1. Onset of myoclonus usually in the first or second decade of life; dystonic features are observed in more than half of the affected patients in addition to myoclonus and may rarely be the only manifestation of the disorder.
  2. Males and females about equally affected.
  3. A relatively benign course, often variable, but compatible with an active life of normal span in most cases.

Figure 1 Four-year-old girl with clinically typical M-D and a proved *SGCE* mutation. (Left) Dystonic posturing of the right hand when attempting to lift a cup with the left hand. (Right) Both hands are needed to hold a pen when drawing, which provokes writer's cramp and myoclonus of the upper body half.

4. Autosomal dominant mode of inheritance with variable severity, and incomplete penetrance which is dependent on the parental origin of the disease allele; affected individuals usually inherit the disease from their father.
5. Absence of dementia, gross ataxia, and other neurological deficits.
6. Normal somatosensory evoked potential (SSEP); normal results of computed tomography (CT) or magnetic resonance imaging (MRI) neuroimaging studies.

- Optional criteria
  1. Response of symptoms (particularly of the myoclonus and to a lesser degree of the dystonia) to alcohol.
  2. Various personality disorders and psychiatric disturbances.

Clinical Features of M-D

The myoclonic jerks typical of M-D are brief, lightninglike movements, usually beginning in and most often affecting the neck, trunk, and upper limbs, with legs involved less prominently. Less common distributions of myoclonus include laryngeal, distal upper limb, and truncal. Approximately half of the affected individuals have focal or segmental dystonia that presents as cervical dystonia and/or writer's cramp. In contrast to primary torsion dystonia, involvement of lower limbs is rare and usually does not occur at onset. In addition, the dystonia does not tend to generalize in the course of the disease. Rarely, dystonia is the only manifestation and sometimes develops years after the onset of myoclonus. Age of onset is usually in childhood or adolescence. In many cases, myoclonus is the presenting symptom. For example, in a study of 23 mutation carriers, the average age of onset for myoclonus was 5.4 years, whereas the mean age of onset of dystonia was 8.8 years.

The involuntary movements are frequently precipitated or worsened by active movements of the affected body part. Other factors eliciting or enhancing the hyperkinetic movements include certain postures, emotional stress, anxiety, nervousness, fright, excitement, fatigue, sound, startle, touch, and caffeine. In female patients, the involuntary movements have been described to worsen premenstrually. The myoclonus and dystonia disappear during sleep. However, single violent jerks may occur at night and may be severe enough to wake up the patient, a phenomenon previously described by Friedreich. Response of the myoclonus and, to a lesser extent, of the dystonia to alcohol is a very frequent finding but not invariably present. Some patients experience a rebound phenomenon after alcohol withdrawal. By contrast, M-D is relatively unresponsive to medical treatment.

The course of the disease is often relatively benign. An initial worsening of symptoms is almost always followed by stabilization of the condition in adulthood, with most patients remaining completely independent in the activities of daily living. The disease is usually compatible with an active life and normal life span in most patients and even spontaneous remission of M-D has been reported in selected cases. In some patients, however, M-D may be gradually progressive and may lead to considerable functional disability and result in early retirement.

Psychiatric disorders are a frequent finding in M-D patients. Many reports can be found of alcohol abuse and addiction to alcohol, as well as of personality disorders and psychiatric abnormalities. Psychiatric disorders include obsessive–compulsive disorder, major affective and anxiety disorder, and panic attacks.

Although psychiatric problems are probably part of the M-D phenotypic spectrum, they are not invariably present (and often not specifically assessed).

Unusual features have been described in selected M-D families with identified mutations in the *SGCE* gene and include postural and other forms of tremor and mild mental retardation. Epileptic seizures have been documented in some patients or may occur due to alcohol withdrawal.

Clinical Features of M-D Patients with Documented *SGCE* Mutations

Most descriptions of patients with proved *SGCE* mutations include details on the mean age of onset, the presence and distribution of myoclonus and dystonia, and the response to alcohol (Table 1). Although most cases are familial, information on affected family members is not systematically given. Conversely, some reports describing larger families do not include details on individual family members but rather summarize mean ages of onset, and percentages of certain M-D signs or clinical features cannot be unequivocally linked to the pedigrees and mutations. Therefore, the data presented here are from mutation-positive index patients, based on data published between 2002 and 2006, with detailed clinical information.

A total of 44 patients had an average age of onset of 6.9 ± 6.5 years with a range of 0.3–30 years. Information on gender was provided for 42 of the 44 index patients, 14 (33.3%) of whom were male and 28 (66.7%) female. All 44 index patients (100%) had myoclonus, whereas dystonia was present in only 36 (81.8%). Both myoclonus and dystonia affected mainly, and sometimes exclusively, the upper body half, with predominant involvement of the neck and upper limbs. Additional lower limb involvement was described in almost half of the index patients on whom information was available (20/42; 47.6%). A response to alcohol was positive in 21 of the 44 index patients (47.7%), negative in three of 44 (6.8%), and unknown in the remaining 20 patients (45.5%). It should be kept in mind, however, that these frequencies are probably biased by the fact that only index patients have been included here, resulting in likely oversampling of clinically typical cases.

A previous review (in 2003) by the authors included available information on relatives and revealed that 84 of 92 (91.3%) affected had myoclonus, and only 52 of 92 (56.5%) showed dystonia. Thus, in 40 of the 92 (43.5%) affected individuals, myoclonus was the only movement disorder, while in eight of 92 (8.7%), dystonia was the sole sign of M-D.

Differential Diagnosis

The clinical picture with myoclonus, dystonia, or both, which often occurs in a familial fashion, along with the absence of any other neurological signs or symptoms, is quite distinct. In most cases, the diagnosis of M-D can be established on clinical grounds with a relatively high degree of diagnostic certainty.

Most other conditions in which myoclonus is a prominent feature are characterized by a variety of

n.r., not reported.

other neurologic signs and symptoms not compatible with a diagnosis of M-D (e.g., ataxia). Genetically defined conditions with myoclonus as a major component include progressive myoclonus epilepsy, also known as Baltic myoclonus, caused by mutations in the *cystatin B* gene (formerly *EPM1*; now *CSTB*); myoclonus epilepsy of the Lafora type, associated with mutations in the *EPM2A* gene; and myoclonus epilepsy associated with ragged-red fibers (MERRF), due to mutations in mitochondrial genes. Finally, patients with the trinucleotide repeat disorder dentato rubro pallido luyisian atrophy (DRPLA) may also present with myoclonus.

Genetic Findings in M-D

M-D is inherited in an autosomal dominant fashion. However, it should be noted that, for two main reasons, 'pseudo'-sporadic cases may occur despite the presence of a mutation in the *SGCE* gene. First, *de novo* mutations have been described, and second, *SGCE* mutations show reduced penetrance, meaning that some family members do not develop the disease although they are mutation carriers. M-D due to *SGCE* mutations is one of the rare examples in which a molecular mechanism has been discovered that explains the majority of reduced penetrance.

Reduced Penetrance Due to Imprinting of the *SGCE* Gene

Zimprich et al. were the first to point out that reduced penetrance was found particularly in the offspring of affected females, suggestive of possible maternal imprinting (Figure 2). Parental imprinting is defined as the epigenetic marking of certain subregions of the parental genome in mammals – that is, imprinted genes are expressed from one allele only, according to their parent of origin. Analysis of the distribution of parental alleles in eight informative families revealed that almost 90% inherited the mutated allele from their father, whereas about 90% of the unaffected carrier family members inherited the mutated allele from their mother. Interestingly, an imprinting mechanism has also been described for the orthologous *SGCE* mouse gene, which is predominantly expressed from its paternal allele in all adult mouse tissues, with the exception of weak expression from the maternal allele in mouse brain. Subsequently, paternal transmission of the human *SGCE* mutant allele was demonstrated in affected individuals, as well as DNA methylation differences, supporting maternal imprinting. However, the reasons for reversal of the maternal imprint in a minority (about 10%) of cases remain unknown.

Figure 2 Pedigree demonstrating reduced penetrance of *SGCE* mutations due to paternal transmission of the mutations. This may result in transmission of the mutation through several generations of unaffected individuals (generations III–V in this example). Of note, there is one case of maternal inheritance of the disease (Patient IV:9), as occurs in about 10% of the described M-D patients with *SGCE* mutations. The reason for these exceptions from paternal transmission remains unclear. Squares represent males, circles female, and diamonds individuals of unspecified sex.

Mutational Screening of the *SGCE* Gene

Testing to date has identified mutations in the *epsilon-sarcoglycan* gene at the *DYT11* locus in many individuals with familial M-D.

Frequency of *SGCE* mutations in tested patient samples A comprehensive review of 22 articles on results of screening for *SGCE* mutations reveals a total of 558 index patients and 233 affected family members with a diagnosis of M-D, other forms of dystonia, or other movement disorders. Fourteen of the 22 publications were case reports describing 30 M-D index patients and their affected family members ($n = 113$). These index cases were all mutation-positive, and 25 of them had a positive family history (83%). Therefore, the majority of these cases were preselected for positive family history and/or had previously been used in linkage studies to the *DYT11* locus on chromosome 7 and, thus, were biased toward finding *SGCE* mutations. Three out of 15 available pedigrees showed exceptions from paternal transmission (Table 2). In the eight remaining studies, 528 index patients with various

movement disorders were genetically investigated. This included 149 patients with diagnosed M-D (28.2%), 335 with different forms of dystonia (63.5%), 32 with Tourette's syndrome (6.1%), eight with Ramsay–Hunt syndrome (1.5%), and four with benign hereditary chorea (0.8%). Among these were 34 apparently unrelated mutation carriers, 23 of whom had a positive family history (67.6%). An *SGCE* mutation was found in 22.8% (34/149) of the M-D index patients. In contrast, no mutations were detected in patients affected with other forms of dystonia or other movement disorders (Table 3). For the nonmutation carriers, a positive family history was reported in 25.3% (117/462) of the cases. Exceptions from an inheritance pattern characteristic of maternal imprinting appeared in 11.8% (2/17) of the described mutation-positive families and in 36.1% (22/61) of the mutation-negative families.

Types and localization of *SGCE* mutations More than 40 different *SGCE* mutations have been reported to date (Table 4 and Figure 3; http://www.dmd.nl). Thirty-two of these are exonic, including three exon rearrangements (c.exon5del, c.exon6del, and c.exon1_exon12del), 14 single base pair substitutions, and 15 small deletions or insertions of one or several base pairs. Additionally, nine splice-site mutations were found. Nine of all known mutations are recurrent. A majority of mutations result in premature protein truncation before or within the *SGCE* transmembrane domain. Of note, the recent identification of exonic deletions in four families with M-D but without otherwise identifiable *SGCE* mutations suggests that some percentage of individuals with M-D and as yet undetected mutations may have this type of mutation.

Sarcoglycan Genes and SGCE Protein

SGCE, the fifth sarcoglycan gene to be identified, consists of 12 exons and is highly homologous to the gene encoding α-sarcoglycan. Both gene sequences predict a hydrophobic signal sequence followed by an extracellular domain with a conserved consensus site for asparagine-linked glycosylation, and four highly conserved cysteine residues. The overall gene structure is conserved, which implies that both genes may have arisen through a gene duplication event. However, the introns in the gene encoding α-sarcoglycan are smaller than those in *SGCE*, which is estimated to span 70.9 kb. *SGCE* has a hydrophobic transmembrane domain and a short cytoplasmic domain. An alternative cytoplasmic domain, which was seen in only one of four isolated cDNAs, resulted from the inclusion of exon 10. Exon 10 is of particular note, as it is homologous to the Alu class of repetitive DNA sequences. The murine gene for ε-sarcoglycan maps to the syntenic region on mouse chromosome 6. Other alternative splice variants in mouse brain that affect the C-terminal end of the encoded protein have been identified and at least one of these (exon 11a) is conserved in the human sequence. Finally, a processed pseudogene, *pseudo-ε-sarcoglycan*, is located on human chromosome 2. *SGCE* is widely expressed in both embryonic and adult tissues, including smooth muscle, Schwann cell membranes of peripheral nerves, and brain, and is widely expressed in various brain regions both during development and adulthood.

The SGCE protein consists of 405 amino acids and has a predicted molecular mass of 47 kDa (without exon 10 and posttranslational modifications). The function of the SGCE protein is still largely elusive. The other members of the sarcoglycan family, α-, β-, γ-, and δ-sarcoglycan, compose the heterotetrameric sarcoglycan complex which is an important component of the dystrophin-associated glycoprotein assembly in striated muscles. This complex and its associated components are thought to link the cytoskeleton with the extracellular basement membrane, thus stabilizing the muscle and protecting it from contraction-induced damage. SGCE appears to be functionally similar to α-sarcoglycan in skeletal muscle; however, its function in the brain is presently unknown. It has been speculated that, because *SGCE* is maternally imprinted and because the vast majority of affected individuals inherit their disease gene from their fathers, the disease is caused by loss of function of SGCE protein. However, up to 5% of cases inherit their mutated allele from their mothers and presumably also express the wild-type allele from their fathers. Further, co-expression of both alleles has been documented in one patient. Therefore, the mechanism of disease is not entirely clear.

Genetic Heterogeneity of M-D

Mutations in two other genes have been associated with M-D: it remains unclear if a missense mutation in the *dopamine receptor D2* (*DRD2*) gene found in a single family (in combination with an *SGCE* mutation) is disease-causing or a rare polymorphism. An 18 bp deletion in the *DYT1* gene that is usually associated with early-onset primary torsion dystonia was found in another single family. However, mutations in *SGCE* were subsequently identified also in this family and the significance of this combination of mutations is unknown.

Many simplex and familial cases without identifiable *SGCE* mutations have been reported, suggesting locus heterogeneity. A large Canadian family with clinically similar M-D does not have a mutation in the *SGCE* gene but rather shows linkage to markers

on chromosome 18p (locus *DYT15*). Two other families also show possible linkage to this chromosomal region. However, the overall contribution of this locus to M-D cannot be determined until the gene is identified.

Phenotype–Genotype Correlations

An association between the localization or type of the reported mutations and the described phenotype of the patients is not obvious. This is not surprising since almost all *SGCE* mutations are nonsense mutations causing premature protein truncation upstream of the transmembrane domain. Therefore, the mutated proteins – regardless of the exact location of the mutation – will not be able to localize to the membrane and it is thus unable to execute its function. Since only the paternal *SGCE* allele is transcribed due to maternal imprinting, SGCE mutations likely act through a loss-of-function mechanism, though, as described earlier, this is not entirely clear-cut.

Rare evidence for an association of genotype and phenotype has been reported in a patient with a complex clinical picture comprising M-D and other features. Due to a large deletion on chromosome 7 (q21.2-q21.3), this patient was affected with microcephaly, short stature, dysmorphic face, and language delay in addition to the myoclonus and dystonia. We recently observed a similar patient with a 7q21.3-q22.1 deletion, encompassing the entire *SGCE* gene as well as the adjacent *COL1A2* (*collagen, type I, alpha 2*) gene. Interestingly, several mutation carriers reported skin and joint problems that were likely explained by haploinsufficiency of the COL1A2 protein. Although such patients are probably rare, these findings stress the importance of a careful and comprehensive clinical examination with special emphasis on potential additional (nonmotor) signs. This will facilitate genetic testing and, in turn, help in providing the optimal counseling and treatment to patients.

Animal Models

Animal models of myoclonus (but not of M-D) have long been available but studies have mostly focused on posthypoxic myoclonus and other secondary forms of myoclonus. Recently an *sgce* knockout mouse model was created and heterozygous mice with a paternally inherited knockout allele were examined for behavioral and neurochemical abnormalities. These mice exhibited myoclonus, deficits in motor coordination, hyperactivity, and psychiatric alterations, including anxiety. In addition, significantly higher levels of striatal dopamine and its metabolites, as well as an inverse correlation between the dopamine and serotonin metabolites, were found. These results suggest that a single *SGCE* mutation can lead to alterations of dopaminergic and serotonergic systems resulting in the phenotypic spectrum seen in M-D patients.

Figure 3 Schematic representation of the *SGCE* gene and identified mutations (for detailed references, see http://www.dmd.nl). Point mutations are indicated above the gene, and small deletions and exon rearrangements are shown below the gene. Mutations detected in the current study are emphasized by bold characters; frequency of the mutation is given in parentheses; respective references are indicated on the right. Numbering of the mutation according to the transcription start as +1. The sequence encoding the transmembrane domain of SGCE is highlighted in gray; *, mutation also includes 82 bp of adjacent intron 3.

Diagnostic and Ancillary Tests

The diagnosis of M-D is established on clinical grounds and can be confirmed by genetic analysis.

DNA Tests

Genetic testing for M-D – that is, a screen for mutations in the *SGCE* gene – is currently available commercially or on a research basis in selected laboratories specializing in the molecular analysis of movement disorders, but does not usually include a screen for exon rearrangements. A listing of laboratories offering clinical genetic testing can be found at http://www.geneclinics.org.

Other Laboratory Tests

By definition, all laboratory tests are normal in primary M-D. However, routine laboratory testing should be performed to exclude secondary causes of the movement disorder. Liver function tests may be abnormal in patients who regularly consume alcohol.

Neuroimaging

Likewise, neuroimaging studies, including CT and MRI, are entirely unrevealing in M-D, with the possible exception of degenerative changes due to chronic alcohol intake.

Treatment

In general, medical treatment of M-D has proved to be rather ineffective. Uniformly, the best 'treatment' results are achieved with alcohol. However, the risk of addiction to alcohol and the unacceptable side effects of this 'medication' render it an unacceptable treatment option. Initial promising results with γ-hydroxybutyric acid, as well as its cousin sodium oxybate, have been reported, but potential for abuse exists for both of these drugs.

Selected patients have been reported to respond to various benzodiazepines or antiepileptic drugs such as valproate. However, most patients with a good treatment response have been described on a case report basis only. Drugs reported to have a beneficial effect include baclofen, and L-5-hydroxytryptophan. Finally, Korten et al. successfully applied very large doses of levodopa ($5\,\mathrm{g\,day^{-1}}$), which, however, cannot be recommended at such high doses and has otherwise been shown to be ineffective. The following drugs have been tested without any good effect on the involuntary movements: amphetamine, heroin, carbamazepine, propranolol, chlorazepate, and haloperidol.

Stereotactic thalamotomy has improved myoclonus, but caused dysarthria in one patient and mild hemiparesis in another. In two other M-D patients, myoclonus responded to thalamotomy but did not result in any significant gain in function. Deep brain stimulation of the medial globus pallidus was shown to ameliorate both myoclonus and dystonia. Finally, neurostimulation of the ventral intermediate thalamic nucleus has been demonstrated to be a safe and efficacious treatment in several patients with medically intractable and progressing M-D.

Duchenne Muscular Dystrophy: Clinical Features, Pathology

Duchenne muscular dystrophy (DMD) is the most common myopathy, muscular dystrophy, and lethal X-linked disease in humans. Elucidation of the molecular genetics and pathobiology of this disease is the cornerstone of our understanding of all muscular dystrophies and congenital myopathies, and it is therefore the appropriate starting point for an overview of the muscular dystrophies.

Duchenne dystrophy presents in males as progressive proximal weakness, usually noted at about the age of 2 years, when the onset of walking is delayed. Affected boys may rise from sitting on the floor by 'climbing' up their legs, in what is called Gower's maneuver. This consists of first raising the hips high, with hands and feet on the floor, then using the arms to compensate for the weakness of proximal hip muscles by pressing hands successively upward against the feet, shins, and thighs, thus bringing the torso and head to an upright position. The typical course of Duchenne dystrophy is relentless loss of muscle strength, losing ambulation (wheelchair bound) by the age of 8–10 years, developing musculoskeletal deformity, scoliosis, and respiratory compromise, and usually succumbing to the accumulated effects of weakness by the second to third decades of life. Cardiomyopathy is also a feature and fatal arrhythmias may occur. The pseudohypertrophy in the calves and, less prominently, shoulders is due to fibrosis and not to true muscular hypertrophy. Steroids and respiratory and physical therapy may ameliorate some of these effects, although no effective long-term therapy is available.

The disease affects one in 3000 boys (boys carry only a single copy of the X chromosome, so X-linked disorders are usually only seen in males). Nevertheless, extremely rare abnormalities in the X chromosome may manifest as DMD in girls. A significant finding is markedly elevated serum creatinine phosphokinase (CPK), a muscle enzyme that is released in the systemic circulation by the breakdown of myocytes. Although an elevation in CPK is only indicative of myocyte destruction from many possible causes, the elevations in DMD, in the range of 2000–20 000 IU, is rarely seen except in muscular dystrophies. After initial examination and laboratory studies, most patients suspected of having a myopathy undergo a skeletal muscle biopsy, which in DMD has diagnostic features. The features do, however, vary with the clinical stage of disease at the time of the biopsy. In young boys at the age of ~2 years, when the diagnosis of DMD may first be entertained, the muscle biopsy shows excessive variation in fiber size, and occasional degenerating or regenerating muscle fibers and very subtle fibrosis. The biopsy has remarkably few pathological changes. By the age of 8 years, when the patient is likely severely clinically affected, possibly nonambulatory, the biopsy shows marked variation in fiber diameter, with both tiny atrophic fibers and some enlarged hypertrophic fibers, and a dramatic increase in degenerating and regenerating myocytes. There may be scattered chronic inflammatory cells and macrophages. Fibrosis is present, and there will be variable amounts of infiltration by adipose tissue (fatty replacement). Biopsies in the second decade of life, or seen at autopsy, will show 'end-stage' muscle, typically with only a few atrophic fibers remaining, and muscle fibers largely replaced by fibroadipose tissue. At this stage the muscle will appear to the eye fibrous and yellow, hardly recognizable and without the normal pink appearance of muscle (Figure 1).

The diagnostic test that can be performed with clear result at any of these stages is immunocytochemical staining for dystrophin (see later). In current medical practice it is now frequently possible to unequivocally diagnose DMD based on clinical features and molecular genetic studies performed on patient genomic DNA from several sources, such as a blood sample or buccal swab. In a small percentage of patients these tests are not diagnostic and further testing on a muscle biopsy is necessary.

Dystrophin: Identification, Features of Gene and Protein

DMD was described clinically in the late nineteenth century, and efforts to identify a pathogenetic process were repeatedly made in the twentieth century, using histological and biochemical techniques of ever-increasing sophistication and sensitivity. Nevertheless, no abnormality that would explain the relentless death of myocytes could be found. Starting in the mid-1980s a purely genetic approach was harnessed to study the genomic DNA of an unfortunate boy with a relatively large deletion on the X chromosome; he had three diseases, McLeod's anemia, chronic granulomatous disease, and DMD, suspected to reflect three contiguous genes lost in the single deletion.

Figure 1 Muscle biopsies, stained with hematoxylin and eosin, from patients with Duchenne muscular dystrophy at three ages. Note the progressive fibrosis, noticeable at the age of 5 years, and the profound loss of myocytes and replacement by adipose tissue at 15 years.

Based on this, Kunkel and co-workers successively localized the deleted DMD gene, cloned the complete cDNA, and developed antibodies based on the predicted amino acid sequence. The last effort facilitated characterization of the protein product of the deleted DMD gene. This protein, which is absent in DMD, was named dystrophin. The 'reverse genetic' approach, a term that refers to locating the disease-causing protein by working 'backward' from the mutation in an affected individual, rather than forward from an abnormal protein, was groundbreaking and a forerunner of what is now the commonly used method of positional cloning.

The dystrophin gene is 2.4 megabases (Mb; million base pairs) long and in terms of genomic span is the largest in the human genome. It has been speculated that this may contribute to the high frequency of mutations, since a random process might be expected to affect a large target with a proportionately high frequency. The precise genetic locus is Xp21.2. The cDNA is 14 kilobases (kb; thousand base pairs) and is composed of 74 exons. Whereas the gene spans a uniquely large region of genomic DNA, the cDNA, like the protein which it encodes, is large, but by no means the largest cDNA or protein (the great size of the dystrophin gene reflecting the large stretches of intronic DNA).

Certain predictions about dystrophin can be made from study of the cDNA and recognition of homologies with other well-studied proteins. Dystrophin is composed of 3684 amino acids and has a high degree of homology with the spectrin family of actin-binding cytoskeletal proteins. The N-terminal nucleic acid sequence predicts a canonic actin-binding domain. The central portion of the protein contains 24 approximately repeated sequences, characteristic of spectrin family members. This portion of spectrin, like cytoskeletal proteins, has the biophysical properties of a stiff rod, and in the case of dystrophin is interrupted by two proline-rich regions which predict a hinge. There are two additional proline-rich hinge regions at each end of the rod domain. The C-terminal region is unique and bears no homology to any known protein. Its structure suggests a calcium-binding domain, although further study has indicated that there is no functional calcium binding. The C-terminal region was initially speculated to be associated with unspecified integral membrane proteins, and further work has confirmed that it is the moiety which is involved in protein–protein interactions with a variety of other proteins. The C-terminal domain is also subject to a complicated assortment of tissue-specific alternative splice variations, and these in turn affect the possible repertoire of protein–protein interactions.

A milder phenotypic variant of DMD is Becker muscular dystrophy (BMD), which is also X linked and about one-tenth as common. The pattern of weakness is similar, but the clinical features are considerably more variable in age of onset, progression, and severity. It was initially predicted on purely genetic grounds that this was not a distinct disorder, but was an allelic variant at the DMD locus. Molecular genetic studies have confirmed this. In essence, DMD is marked by the nearly complete absence of dystrophin, whereas BMD reflects the presence of dystrophin which is abnormal in molecular weight (either decreased or increased, reflecting deletions or duplications) or is reduced in amount. An arbitrary threshold that has been used is a reduction to 5% or less of normal for DMD.

As a general rule, frame-shifting mutations in any part of the dystrophin cDNA will produce DMD, while mutations which preserve the reading frame

will produce BMD. There are exceptions: massive deletions will produce DMD, and deletions in the C-terminal region tend to produce DMD irrespective of reading frame.

With the identification of dystrophin, the development of polyclonal and monoclonal antibodies to dystrophin became possible and this in turn created a powerful tool for both the exploration of normal biology and pathologic diagnosis. Dystrophin is normally found precisely associated with the sarcolemma of the myocyte, but not with any sarcoplasmic or internal structures (Figure 2). In the standard transverse plane this appears as a uniform circumferential line, but confocal or other imaging techniques show that this is in fact a reticulated network, with a spacing that roughly corresponds to the sarcomeric or Z-line spacing. Immunoelectron microscopy has demonstrated that the localization is more precisely subsarcolemmal. The density of dystrophin appears to be increased at the two areas of sarcolemmal specialization, the neuromuscular junction (NMJ) and the myotendinous junction. Although the context is different, dystrophin maintains this sarcolemmal distribution in smooth muscle, cardiac muscle, and extraocular muscle.

Standard immunohistochemistry techniques using a dystrophin antibody applied to frozen tissue sections of a muscle biopsy show an essentially complete absence of dystrophin reactivity, diagnostic of DMD (Figure 3). The term 'essentially' is used because, by a variety of not completely understood processes, some mutations can be circumvented by alternative splicing or perhaps second mutations, with the result that a vary rare minority of fibers are seen by immunocytochemistry to express normally localized dystrophin, so-called revertant fibers. The amount is minute, undetectable by Western blot, and of no physiologic significance. Nevertheless, augmentation of these fibers is considered as a therapeutic approach.

Less commonly, patterns of uniform weak and or irregular, but still sarcoplasmic, dystrophin immunoreactivity are seen, and these are characteristic of BMD. It is prudent to confirm the diagnosis with Western blot or molecular genetic analysis.

In women who carry one defective copy of the dystrophin gene, a mosaic pattern may be seen. In such 'carrier females' rare fibers – and it should be noted, only in some regions ('nuclear domains') in the multinucleate syncytial myocyte – are negative for dystrophin. In most cases this is a small proportion of fibers and there is no clinical myopathy, although serum CPK may be elevated. In rare female carriers there will be a skewed X inactivation, for reasons that remain speculative, and a larger proportion, possibly even a majority, of fibers will be dystrophin negative, because there has been inactivation of the X chromosome carrying the wild-type dystrophin gene. These unfortunate women will manifest varying degrees of myopathy and, of particular concern, cardiomyopathy.

Figure 2 Hematoxylin and eosin (H&E) stain of normal skeletal muscle (upper left) and immunocytochemical labeling of muscle for dystrophin, β-dystroglycan, γ-sarcoglycan, and merosin (α2-laminin subunit). Note that labeling for each of the dystrophin and dystrophin-associated proteins is restricted to the sarcolemma.

Figure 3 A muscle biopsy from a boy with presymptomatic Duchenne muscular dystrophy. Hematoxylin and eosin-stained section (a) shows abnormal variation in fiber diameter, and small rounded basophilic fibers which are regenerating (b). Dystrophin immunostaining is absent. β-Dystroglycan (c) and α-sarcoglycan (d) immunolabeling is uneven, but present and normally localized to the sarcolemma.

Autosomal Limb-Girdle Muscular Dystrophies

Although DMD constitutes the large majority of progressive proximal myopathic syndromes with dystrophic features based on muscle biopsy, clinical neurologists have long recognized that there were phenotypically similar diseases which were most distinctive for not being sex linked (i.e., occurring in females), and in families that were ascertained to show autosomal recessive or, less commonly, dominant inheritance. The clinical courses of these diseases were quite variable or heterogeneous, although in some instances as severe as DMD. These diseases were referred to as types of limb-girdle muscular dystrophy (LGMD). One geographic region in which an autosomal recessive LGMD is particularly prominent is North Africa; the disease there was initially called severe childhood autosomal recessive muscular dystrophy (SCARMD), or muscular dystrophy of the Magrebian type (LGMD2C).

Genetic linkage studies have been the backbone of defining or rationalizing the now three dominant and 12 recessive forms of this disease. Linkage studies which establish a chromosomal localization (or at least exclude all of the known localizations) are now the standard for establishing a new member of this class (Table 1).

Congenital Muscular Dystrophy

In addition to DMD and the autosomal variants which present in childhood, there are patients identified in infancy who are typically hypotonic and whose biopsies show a dystrophic myopathy. Rather than being characterized by markedly elevated serum CPK, the CPK is usually normal to moderately elevated (<1000 IU). Disease progression is usually slow, with survival into adulthood. Within this group of diseases some patients have additional features. Some showed an associated rigidity or contractures, sometimes at birth and sometimes developing over time. Others showed associated, often severe, central nervous system (CNS) and ocular malformations, referred to as Walker–Warburg syndrome, muscle–eye–brain (MEB) disease, and Fukuyama congenital muscular dystrophy. All are relatively rare, autosomal recessive diseases and show some geographic predilection. MEB is found in Finland, and Fukuyama muscular dystrophy is most commonly found in Japan.

The Dystrophin-Associated Complex

Following the identification of dystrophin there was rapid progress in biochemical, genetic, and molecular biological unraveling of the LGMDs. Sarcolemmal membrane preparations were subjected to isolation, solubilization, and separation of proteins in elution fractions enriched in dystrophin (i.e., dystrophin-associated proteins). The precise number of proteins was initially not clear, but consensus has settled on a canonic seven proteins: α- and β-dystroglycans (43 and 156 kDa); α-, β-, γ-, and δ-sarcoglycans (50, 43, 32, and 35 kDa, respectively); and sarcospan (25 kDa). The four sarcoglycans and α-dystroglycan are glycoproteins. Posttranslational cleavage of a

[a]Conflicting reports unresolved.

The genetic linkage, and proteins harboring causative mutations where known, are listed. AD, autosomal dominant; AR, autosomal recessive; BMD, Becker muscular dystrophy; DMD, Duchenne muscular dystrophy; FKRP, fukutin-related protein; LGMD, limb-girdle muscular dystrophy; MDC, merosin-deficient congenital muscular dystrophy; POMGnT1, protein *O*-mannose β-1,2-*N*-acetylglucosaminyltransferase 1; POMT, protein *O*-mannosyltransferase; XL, X linked.

single peptide produces α- and β-dystroglycans, and the α component is glycosylated. Refinement of the solubilization conditions suggested that although the group as a whole formed a complex – the dystrophin-associated glycoprotein complex (DAG complex) – the dystroglycans and sarcoglycans were each more tightly associated into two subcomplexes.

Each of these proteins has been shown to have complicated but selective and specific patterns of association with other muscle proteins, with some but not all other members of the DAG complex, and with other cytosolic muscle proteins. Of particular importance, a dystroglycan is found to bind to merosin, the α_2 subunit of laminin, a component of the muscle extracellular matrix.

The DAG Complex: A Functional Model

Based on the initial details, a working functional model of the DAG complex evolved; this model has been refined, with major aspects supported by considerable further experimental testing. At its simplest functional core, it appears that there is a bridge from cytoskeletal actin, through dystrophin, to β-dystroglycan, to α-dystroglycan, and ending in merosin (Figure 4). This bridge is presumed to provide mechanical support for the sarcolemma, which must withstand a lifetime of cycles of contraction and relaxation. The complex of sarcoglycans is tightly attached to β-dystroglycan and, based on its potential for causing LGMD, appears to contribute critically to the function of this bridge, though a precise role has been elusive. The most common speculation is that the sarcoglycan subcomplex plays a facilitating signal transduction role, but experimentally tested details are wanting.

Two lines of research, the genetic characterization of the LGMD and the molecular genetic characterization of proteins closely interacting with dystrophin, rapidly converged. Simply, the proposed mechanistic model suggested that mutations rendering elements other than dystrophin in the bridge connecting the actin cytoskeleton to the extracellular matrix ought to produce diseases phenotypically similar to DMD/BMD. It was quickly recognized that the North African

Figure 4 Diagram of dystrophin and the dystrophin-associated complex. C term, C-terminal end; N term, N-terminal end; NOS, nitric oxide synthetase.

SCARMD reflected mutations in α-sarcoglycan or, somewhat more frequently, γ-sarcoglycan. Shortly thereafter, families with type 2E LGMD (LGMD-2E) were recognized to have mutations in β-sarcoglycan, and somewhat later the very uncommon LGMD-2F was found to reflect a δ-sarcoglycan mutation. Each of these mutated proteins could be reliably identified by immunohistochemistry with specific antibodies performed on muscle biopsies. The attractive suggestion – that the presence of a null mutation in any one of the sarcoglycans destabilized the whole complex and as a result there was an essentially complete secondary loss of all sarcoglycans – does not appear to be true. The levels are reduced, but the secondary reduction is variable and not absolute.

Certain other predictions of this model present apparent or real paradoxes. The model suggests that dystroglycan mutations should manifest as an LGMD, yet no dystroglycan-null patients have been identified. Since α and β forms are produced by the cleavage of a single peptide, they might not be lost independently. The surprising absence of pathogenic dystroglycan mutations was explained when a targeted deletion in the mouse was created and shown to be an early embryonic lethal event. A tissue-specific conditional mutant and fortuitous mosaics do confirm that loss of dystroglycan in muscle does produce a severe dystrophic myopathy. This highlights the further consideration that although mutations of each of the components of dystrophin-associated proteins may produce a myopathy, these proteins may be expressed in nonmuscle tissues, and thus mutations produce a phenotype of 'myopathy plus,' depending on expression in other tissues. In the case of dystroglycan, Reichert's membrane is such an additional critical site. In contrast, sarcospan is a 25 kDa tetraspan

integral membrane protein which is a component of the dystrophin-associated complex. This is lost secondary to the loss of sarcoglycans, but so far it is not itself associated with any recognized disease phenotype; naturally occurring mutations have not been identified but a targeted null mutation in mouse has no apparent pathology.

Microscopic analyses have shown that a large number of proteins have the same sarcolemmal localization as do dystrophin and the core dystrophin-associated proteins, or, based on biochemical analyses, are present in sarcolemmal membrane fractions enriched in dystrophin or associate with one or more of the DAG proteins *in vitro*. Some of these other proteins, but not all, when mutated, cause forms of LGMD. Whether these should be regarded as part of the dystrophin-associated complex is unclear. Viewed in this more expansive fashion, the complex consists of ten or more proteins, some of which have predominant localizations elsewhere in the myocyte. The following proteins are some of the better studied examples.

Calpain 3 is a calcium-activated neutral protease which is mutated in patients with LGMD-2A. Although it is tempting to speculate that its substrate is a component of the DAG complex (DAGC), or a protein that interacts with the DAGC, the substrate or substrates are not know. Caveolin 3 is the muscle-specific member of the family of proteins, caveolins, which coat caveolae, the 50–100 μm vesicles and invaginations that lie below the plasma membrane of myocytes, the sarcolemma. Caveolins have been suggested to have a variety of functions, and it seems likely that they are involved in membrane trafficking or recycling. Mutations in caveolin 3 cause LGMD-1C.

α-Dystrobrevin is the 94 kDa mammalian homolog of an 87 kDa phosphoprotein, originally isolated as a component of the *Torpedo* electric organ, and localized to the NMJ. A homolog, β-dystrobrevin, is encoded by a separate gene and is found in several tissues (kidney and brain, but not skeletal muscle). α-Dystrobrevin is highly alternatively spliced, giving rise to at least five variants. This protein proved to be one of the components of the dystrophin-enriched muscle membrane fraction, and associates with the C-terminal end of dystrophin as well as with syntrophin. Mice with a deletion in the dystrobrevin gene have a mild skeletal and cardiac myopathy (albeit much less dramatic than when there is dystrophin or sarcoglycan deficiency) and structural changes at the NMJ. One family with cardiomyopathy has been found to have a missense mutation in the dystrobrevin gene.

Syntrophins comprise a family of three distinct but highly homologous and conserved 53 kDa intracellular proteins. They have a postsynaptic density/disc/zonula occludens-1 (PDZ) domain which facilitates interacting with a variety of signaling and membrane proteins, including nitric oxide synthetase (NOS), aquaporin-4, and potassium channels, among others. They also bind to the C-terminal domain of dystrophin, exon 74, so they may couple dystrophin to a variety of functionally different molecules. In muscle, β_2-syntrophin is found predominantly at the NMJ, while the α_1 form is found at the extrajunctional sarcolemma. It addition to the range of proteins interacting with syntrophin, syntrophin binds to an alternatively spliced exon in dystrophin, possibly the mechanism for further precise control of the location and type of protein–protein interaction. Thus far no myopathy or other disease has been associated with syntrophin mutations. Mice with a target null mutation of a syntrophin do not have a dystrophic phenotype and only show structural alterations of the NMJ.

The spatially specific distribution of syntrophins raises a more general distinction. There may be two independent systems involving dystrophin and several of the dystrophin-associated proteins: one at the sarcolemma, primarily supporting mechanical stability, and an independent role at the NMJ, involved in organization of the NMJ postsynaptic apparatus. Only the former has a clearly established causal role in a group of diseases, the muscular dystrophies. There is no recognized pathology or pathophysiology of the NMJ in Duchenne dystrophy.

Filamin C is a striated muscle-specific member of a family of actin-binding proteins. It is localized to the sarcolemma, as well as to cytosol and sarcomeric Z-lines, is associated with γ- and δ-sarcoglycan, as well as multiple Z-line proteins, and its distribution seems to be altered in some patients with muscular dystrophy. There are no recognized diseases with filamin C mutations and it has not been identified in dystrophy patients, but mice with a targeted deletion have lethally hypomorphic skeletal muscle and die at birth due to respiratory failure. Filamin C seems a good candidate to play an intracytoplasmic signaling role, one element of which is the dystrophin–DAG complex.

A remarkable finding is that neuronal nitric oxide synthetase (nNOS) is associated with the dystrophin–DAG complex. This association appears to be mediated through syntrophin, which in turn is associated with dystrophin. The cellular localization is sarcolemmal. nNOS is lost in the *mdx* mouse model of dystrophin deficiency, as well as in DMD biopsies. Clearly a host of possible cytotoxic and cytoprotective roles might be mediated through nNOS, although a specific role in dystrophic muscle remains speculative.

Glycosylation-Dependent Muscular Dystrophies; Muscular Dystrophies with CNS Involvement

Although CNS abnormalities are not found with most muscular dystrophies, there is a distinct group of diseases with dystrophic myopathy and typically neuronal migration defects. In this group are Fukuyama muscular dystrophy, muscle–eye–brain disease, Walker–Warburg syndrome, LGMD-2K, and MDC-1C. These are associated with various constellations of structural ocular abnormalities and cerebral malformations, including lissencephaly, cerebellar and pontine hypoplasia, and agenesis of the corpus callosum. Seizures and mental retardation are common.

The explanation of this conjunction of muscular dystrophy and CNS malformation is found in the answer to a molecular genetic paradox. It is apparent in the list of genetically distinct LGMDs that although there is a group of dystrophies that are caused by mutations in dystrophin-associated proteins which function consistent with the proposed mechanistic model, this group consists of only six of 20 dystrophies. Others do not easily fit this model. Some of these mutated dystrophin-associated proteins, including fukutin, fukutin-related protein (FKRP), LARGE, POMT1, and POMGnT1, have the feature in common of facilitating the glycosylation of other proteins, specifically a dystroglycan. All of the disorders associated with the genes encoding these proteins are characterized by hypoglycosylation of a dystroglycan, and the hypoglycosylated form has been shown to be unable to bind normally to laminin (and possibly also to other interacting proteins such as neurexin, perlican, and agrin).

POMT1, POMT2, and POMGnT1 have demonstrated *O*-mannosyltransferase activity. LARGE is predicted to be a glycosyltransferase based on sequence homology, although activity has not been demonstrated; however, LARGE does appear to be able to bypass the absence of POMT in glycosylating α-dystroglycan. Fukutin is localized to the Golgi apparatus, and but it is unclear that it has enzymatic activity; it may exert its effect by associating with or regulating a glycosyltransferase. FKRP similarly may function as a chaperone rather than having autonomous enzymatic activity. Substrate specificities for these proteins are poorly understood, and their effects may be exerted by glycosylating proteins other than or in addition to dystroglycan.

The glycosylation of sarcoglycans remains to be studied. In the absence of a clear understanding of the role of the sarcoglycans it is difficult to say what effect failure of normal glycosylation might have. Nevertheless, it seems reasonable to speculate that hypoglycosylated sarcoglycans may not be able to play their normal role, and like the absence of sarcoglycans, hypoglycosylation may disrupt the function of the structural bridge from actin through dystrophin and dystroglycan to the extracellular matrix, leading to a dystrophic myopathy.

A striking feature of the muscular dystrophies, which appear to be mediated through the failure to glycosylate components of the DAG complex, is their propensity to also affect the CNS. This reflects a role for dystroglycan at the blood–brain barrier (BBB), and in targeted deletions of dystroglycan, using tissue-specific conditional deletion (to circumvent the embryonic lethal phenotype of the nonconditional deletion), the dystroglycan mutations produce cerebral malformations. This effect is certainly independent of dystrophin, since the localization is totally different from the localization of dystrophin in the CNS. It is also independent of α-, γ-, and δ-sarcoglycans, since these do not occur in the CNS. It does, however, parallel the distribution of utrophin, so this may be the cytoplasmic component of a transmembrane complex, and might also involve the CNS-specific short dystrophin gene products, Dp71 and Dp140 (see later).

Dysferlin: Sarcolemmal Repair Mechanism

Dysferlin presents a novel but paradigmatic extension of thinking about sarcolemmal proteins and LGMD. Dysferlin is a 230 kDa protein with a high degree of homology to the fer-1 family of proteins, initially found in *Caenorhabditis elegans*. It was identified by positional cloning as the gene responsible for LGMD-2B as well as Miyoshi (distal) myopathy. Initially it was supposed, given the series of sarcolemmal proteins which were causal for LGMD, that dysferlin, also sarcolemmal, and causative of LGMD-2B, should also be associated with the DAG complex. Indeed, a small amount of early data suggested an association with caveolin 3. However, further studies showed that dysferlin-deficient myocytes were slow to seal calcium leaks after membrane damage. The membrane 'patching' process involves recruitment of membrane vesicles, possibly associated with caveolin 3, to a region of damage, and involves an association of dysferlin with annexin A1 and annexin A2, a connection first suggested by relevance network analysis of expression array data, and then confirmed by standard biochemical methods. The process is calcium dependent. Dysferlin therefore is the mirror of the dystrophin-associated proteins; whereas the latter appear to function by protecting the sarcolemma from mechanical stress damage, dysferlin functions independently to repair such damage.

Figure 5 Dystrophin in murine (a) neurons of frontal cortex (arror indicates neuronal cell body) and (b) cerebellar Purkinje cells (mol, molecular; pcl, Purkinje cell layer; gcl, granule cell layer), arrows indicates Purkinje cell body, and (c, d) in peripheral nerve (c: longitudinal section – arrow indicates a node of Ranvier; d: double-labeled cross section – neurofilament-labeled axons are green, Dp116 is red). In neurons, the dystrophin labeling is a punctate distribution along perikaryon and dendrites. In peripheral nerve, the short dystrophin isoform Dp116 is localized to the Schwann cell membrane.

Dystrophin and Dystrophin-Associated Proteins in the Central and Peripheral Nervous Systems

Although the vast majority of detailed understanding of dystrophin and the dystrophin-associated proteins is derived from study of skeletal muscle, and patently this is the locus of the pathologic process that results in muscular dystrophy, these proteins are expressed in nonmuscle tissue. This is the basis for some nonmyopathic features of muscular dystrophies, raising many novel possibilities about the functions of these proteins.

Dystrophin is present predominantly in skeletal, cardiac, and smooth muscle, but is also found at about 100-fold lower levels in CNS tissue. This is still greater than the low background level of transcript and protein found in most other tissues, and is presumed to reflect the endogenous vascular smooth muscle. Tissue culture and neuroanatomical studies have shown that CNS dystrophin is localized to neurons, and further to specific classes of neurons, such as those of the cerebral cortex, the hippocampus, and the Purkinje cells of the cerebellum. Furthermore, the distribution is in a punctuate pattern along dendrites and neuronal perikarya, a pattern that would be consistent with a localization to synaptic junctions (Figures 5(a) and 5(b)). Immunogold ultrastructural studies suggest localization to synaptic junctions, and fractionation of synaptosomes and postsynaptic densities show that these are progressively more enriched in dystrophin. This enrichment also parallels the development of synapses in the early postnatal period. Studies of the retina show similar punctuate distribution of dystrophin in the outer plexiform layer, which is predominantly synaptic neuropil, and some studies report localization at synaptic junctions.

A functional presence of dystrophin at synapses in the CNS, and particularly in the neocortex, would fit well with the early observation of a mild static cognitive impairment that is a well-documented feature of DMD and BMD. Repeated studies have shown that the IQ in cohorts of boys with DMD is normally distributed (arguing against the co-deletion of a second contiguous gene) and the mean is depressed by about 1 standard deviation. It follows that about one-third of boys with DMD will have an IQ that falls below the arbitrarily chosen threshold for 'mental retardation' of 70, but it is important to recognize that this does not imply a distinct cognitively affected population, but rather that there is some effect on cognitive function in all affected individuals. In contrast to the musculoskeletal impairment, the mild cognitive effect is nonprogressive and does not correlate with the degree of musculoskeletal disease.

Dystrophin Isoforms

Following the identification of full-length, 427 kDa dystrophin, it was recognized that there were several transcripts, as well as a very homologous autosomal protein, utrophin, and a series of small homologous utrophin-related transcripts. The function of these proteins remains unclear, although their tissue-specific distribution suggests or constrains their possible roles. The smaller dystrophin transcripts are derived from additional tissue-specific promoters located in introns of the dystrophin gene. Each of the smaller transcripts, like dystrophin, may have some additional variation as the result of alternative splicing. Some but not all of the small transcripts have short, novel first exons, although the majority of the coding sequence, and thus the composition of the protein, is identical to the cognate region of dystrophin. In terms of domains, all of the small transcripts are composed of varying amounts of the dystrophin rod domain, and all preserve the novel C-terminal domain. Apparently this precludes that any of the short forms are actin-binding proteins, but all are involved in protein–protein interactions, likely with integral membrane proteins, either dystroglycan, or other unidentified ligands. The specific shorter transcripts are as follows:

- Dp71 (71 kDa), found in many tissues.
- Dp116 (116 kDa), found in Schwann cells.
- Dp140 (140 kDa), found in CNS, possibly glia, and the epithelium of the ascending loops in the kidney.
- Dp260 (260 kDa), found in the retina.

In addition, full-length dystrophin transcription is driven by three relatively tissue-specific promoters, the skeletal muscle promoter, a cerebral promoter (brain promoter), and a Purkinje cell promoter. The transcripts and protein products are identical, and at least in the case of the muscle and brain promoter the brain promoter will drive some, albeit a lower than normal, level of transcription in muscle, in the absence of a functional muscle promoter.

It follows that in the CNS the situation in regard to dystrophin transcripts is considerably more complicated than in skeletal muscle. There are three promoters driving the expression of full length dystrophin in neurons, as well as Dp260, predominantly in retinal tissue; Dp140, possibly in astrocytes or ependymal cells; and Dp71, in greater abundance than any of the foregoing, although the localization is unclear, but likely to be glial. Although a strict genotype–phenotype correlation between cognitive impairment and dystrophin mutations has not been established, there is a suggestion that deletions toward the C-terminal region may be overrepresented in the more cognitively impaired DMD patients. Consistent with this, the more C-terminal mutations would disrupt more of the different dystrophin transcripts, and hence perhaps produce greater perturbations in CNS function. Nevertheless, loss of 427 kDa dystrophin alone is sufficient to produce cognitive impairment. Although no correlated physiologic abnormality has been identified in the neurons of the CNS, a distinctive retinal physiologic abnormality, decreased amplitude of the electroretinographic scotopic b-wave, has been correlated with loss of dystrophin and Dp260.

The question of a neuronal equivalent of the DAG complex is also complicated and very incompletely understood. Dystroglycan is present in the CNS, but appears to have a completely different and nonoverlapping distribution compared to dystrophin. Dystroglycan is found at the pia limitans along the Virchow–Robin perivascular boundary. This most closely approximates the distribution of utrophin, the autosomal homolog of dystrophin. The localization of the short dystrophin isoforms (Dp140 and Dp71) is too poorly demonstrated to say if there is a better correlation with either of these. The α-, γ-, and δ-sarcoglycans are not expressed in the CNS; the β-sarcoglycan transcript is present, although the protein has not been localized. A gene encoding the fifth sarcoglycan, epsilon, a protein which does replace α-sarcoglycan in some sarcoglycan complexes in cardiac and smooth muscle, has been identified by positional cloning as the gene responsible for familial myoclonus-dystonia, but the localization or function of the protein in the CNS remains unknown.

Nevertheless, targeted disruptions of dystroglycan in mice, or abnormalities of its glycosylation in mice or humans, produce migrational abnormalities, particularly adjacent to the pia limitans. CNS abnormalities, in addition to the dystrophic myopathy, are a feature of just those LGMD which appear to result from mutations of putative glycosyltransferases and reduction or loss of their function. However, this effect is independent of dystrophin, and these malformations are not a part of the DMD phenotype. Conversely, the cognitive impairment associated with DMD is not a feature of LGMD-2C–LGMD-2F. It seems clear that dystroglycan is involved in a complex in the CNS that does not involve dystrophin, but possibly substitutes for utrophin, and that dystrophin is likely associated with one or more integral membrane proteins or complexes, but is different (and at present unknown) from those in muscle. One of these associations may be known; a growing body of evidence suggests an association of Dp71 with aquaporin-4, which mediates a role in blood–brain barrier function and water homeostasis.

Exploration of the functional roles of proteins first identified in skeletal muscle in association with dystrophin, as they occur in the CNS, promises many more such unexpected findings.

The DAG Complex in Peripheral Nerve

As mentioned, Schwann cells which ensheathe peripheral nerve axons express Dp116, localized to the outer wrap of the Schwann cell (abaxonal Schwann cell membrane) and at the node of Ranvier (Figures 5(c) and 5(d)). There is a parallel localization of dys troglycan, the ε-, β-, δ-, and ζ-sarcoglycans, and the α_2 subunit of laminin (merosin). These appear to form a membrane-spanning structural complex with considerable similarity to that present in skeletal muscle. Loss of the most peripheral component, the α_2 subunit of laminin (merosin-deficient congenital muscular dystrophy; MDC-1A), is characterized by slowing of the peripheral motor nerve conduction, both in humans and in mice with the similar mutation. The murine model, the *dy/dy* mouse, has marked pathology, including bundles of unmyelinated axons in the spinal roots, hypomyelination, abnormalities at the node of Ranvier, and abnormal ion channel distribution; descriptions of the equivalent human nerve biopsies are lacking. Nerve conduction abnormalities are not reported in association with C-terminal dystrophin mutations, which would affect Dp116 and β-sarcoglycan or δ-sarcoglycan mutations (LGMD-2D, LGMD-2F), but since nerve conductions studies are not routinely part of the diagnostic evaluation of suspected muscular dystrophy this may be simply an absence of evidence.

Dystrophin and Animal Models of Muscular Dystrophy

Dystrophin is remarkably conserved across the evolutionary spectrum. Dystrophin homologs have been identified in metazoans (*Drosophila* and *C. elegans*), zebra fish, shark, fugu, *Torpedo*, *Xenopus*, rodents (mice and rats), dogs, cats, horses, and primates. There is an actin-binding protein or gelation factor with high homology to dystrophy in *Dictyostelium*. Components of the dystrophin complex are also found in *C. elegans*, Annelida (leech), *Drosophila*, *Xenopus*, *Torpedo*, and zebra fish, as well as in more complex organisms. Homologs of the LARGE glycosyltransferase have been reported in several vertebrates, including mouse, dog, chicken, zebra fish, and fugu. Nonetheless these homologs do have alterations at the nucleic acid and amino acid levels (and these increase with evolutionary distance), and as a practical matter specific reagents may or may not recognize a specific homolog across species boundaries.

It follows that naturally occurring or targeted mutations in each of these species will provide potentially useful models of the dystrophic myopathies. However the histologic dystrophic myopathy may be difficult to recognize, or may not occur in species more remote evolutionarily from vertebrates. Additionally, some models, notably the murine models, precisely model the genetics and molecular biology of human dystrophy but are limited in modeling the histologic or pathologic sequelae. This is in itself informative, but indicates that careful consideration must be given to choosing an appropriate model system for a particular question or study. Certain models, such as *Torpedo*, are particularly apt for study of the role of the NMJ, but only the canine model provides a realistic equivalent of human disease for testing functional reconstitution or compensation in a potential therapy, and zebra fish, *C. elegans*, or *Drosophila* may be most useful for screening approaches.

Mouse Models

Far and away the most important series of animal models of dystrophin loss, or loss of the DAG complex, have been the mouse models. Of these, the first and most important is the *mdx* mouse, a naturally occurring mutant which was identified as a model of Duchenne dystrophy based on genetics and histology, well before the identification of dystrophin. The *mdx* mouse shows a maximum of necrosis and regeneration before 3 months of age and active damage declines thereafter, although internalized nuclei remain increased. The mice have normal appearance, size, and life span and they are susceptible to increased damage with exercise. There is damage to the diaphragm that is comparable to that seen in human DMD, although respiratory function is apparently uncompromised; CPK is elevated. In addition to findings directly related to skeletal muscle organization and degeneration, the synaptic folds at NMJs were found to be flattened.

Soon after the identification of dystrophin, it was recognized that the *mdx* mouse is a dystrophin-null mutant with a stop codon in exon 23. Among other results, an upstream stop codon is quite amenable to exon-skipping mechanisms, and the *mdx* mouse has a high rate of rare, immunocytochemically detected 'revertant' (normally localized dystrophin-positive) fibers. This phenomenon increases with age, or with exposure of the muscle to high levels of ionizing radiation.

In short, the *mdx* mouse is an excellent genetic and molecular biological model of DMD, a poor

physiological model (although biophysical measures of sarcolemmal parameters are probably valid), and a very inadequate model of the pathology of human DMD. Some improvements in the *mdx* model have been made by the 'mdx^{cv}' series of dystrophin mutants. These strains are the product of a mutagenesis screen, and represent a series of mutations spread down the length of the dystrophin molecule. Some, such as mdx^{4cv} and mdx^{5cv}, have deletions that are less prone to revertant fibers, a technical advantage in monitoring an intentional restoration of dystrophin expression. Another mutation, mdx^{3cv}, is a leaky splice mutation, but due to its location at exon 66 it lowers the level of all seven of the dystrophin gene transcripts. Researchers have used other technologies to generate additional target mutations of the dystrophin gene. Series of such mutants have been useful for attempting to establish genotype–phenotype correlations between specific dystrophin mutations and particular molecular genetic or physiologic abnormalities.

Mouse models of DAG complex mutations All of the components of the human DAG complex and the full repertoire of associated proteins and short dystrophin isoforms, utrophin, and the utrophin isoforms are found in the mouse. The corollary targeted mouse null mutants of many of these molecules have been made and are frequently available for research.

Targeted mutations of all four core sarcoglycans, as well as ε-sarcoglycan, have been created. The mutant mice show a range of phenotypes, including cardiomyopathy (δ-sarcoglycan). The attempt to produce a mouse deficient in dystroglycan led to the first insight that this was a very early embryonic lethal mutation, but subsequent strategies, primarily Cre–*lox* technology, have permitted the tissue-specific deletion of dystroglycan. The *myd* mouse has a mutation of the LARGE gene, a glycosyltransferase gene that recapitulates many of the biochemical and histologic features of POMT1 mutations. A naturally occurring murine model, the *dy/dy* mouse, has a defect in merosin, with severe pathology similar to merosin-negative congenital muscular dystrophy (MDC1A). At least four (two naturally occurring, two engineered) dysferlin-null mouse strains have been reported. Like the dystrophin-null mice, the dysferlin-null mice have considerably less pathology than is seen in the human equivalent, Miyoshi distal myopathy and LGMD2B, but are important molecular biological surrogates.

Dystrophin-Deficient Feline; Lethal Muscle Hypertrophy

Several strains of domestic cat are dystrophin deficient and exhibit lethal muscular hypertrophy; these cats have decreased activity and stiff gait and run abnormally. Histologically they have a dystrophic appearance, with hypertrophy and dystrophic calcification. The cats succumb (they are euthanized for humane reasons) at 18 months to 2 years due to complications of hypertrophy of the pharyngeal muscles and diaphragm. At this stage fibrosis is not prominent. This defect has been termed 'hypertrophic feline muscular dystrophy' (HFMD).

Utrophin, α-sarcoglycan, and β-dystroglycan are present in feline muscle. Merosin (laminin $\alpha 2$) deficiency has been reported in several strains of American and European cats and is manifest as muscular dystrophy and neuropathy similar to that seen in human MDC1A.

Dystrophin and Muscular Dystrophy in Dogs

A golden retriever and a beagle with X-linked dystrophin deficiency have been identified and maintained as breeding colonies. The offspring exhibit elevated CPK from birth. Diaphragmatic weakness is present at birth and is more severe than limb muscle involvement. As they grow, the dogs exhibit gait disturbance, limb and temporal muscle weakness, and eventually macroglossia, dysphagia, drooling, and contracture of the mandibular joint. There is hypertrophy of the sublingual muscles by 1 year of age, similar to the cat model. The dystroglycan gene has been characterized in these dogs.

Dystrophin and DAG in Zebra Fish

The zebra fish, a vertebrate with many desirable features for genetic manipulation and molecular biological analysis, has been shown to have homologs of dystrophin, as well as the components of the DAG complex. Strains have been identified with mutations that have been mapped to the dystrophin gene, and these fish have abnormal skeletal muscles with progressive degeneration and short survival. Phenotypically similar strains will likely prove to have mutations in components of the DAG complex. In addition, it is possible to reduce expression of these proteins using morpholino technology. The zebra fish may be the simplest organism which has a muscle phenotype that is reasonably comparable to that seen in tetrapods.

Dystrophin and DAG in *Drosophila*

Drosophila melanogaster has been shown to have homologs of dystrophin, several of the smaller dystrophin isoforms, and the core components of the dystrophin-associated complex: four sarcoglycans, dystroglycan, and sarcospan. Disruptions of either the dystrophin homolog or the dystroglycan homolog

produce decreased mobility and progressive degeneration of muscle. In addition, there are abnormalities of cell polarity and defective photoreceptor development.

Dystrophin and Muscular Dystrophy in *C. elegans*

Caenorhabditis elegans has a dystrophin Dys-1 like protein, expressed in muscle. It also has homologs of the entire DAG complex, and dystrobrevin. Mutant strains have been identified with truncated Dys-1 protein. The mutants are hyperactive, but muscle appears to be structurally normal. The physiologic abnormality is thought to reflect alterations in cholinergic transmission. A mutation in a homolog of the dystrophin-associated protein dystrobrevin, called dyb-1, produces a similar phenotype.

Several interesting observations have come out of the phylogenetic perspective on dystrophin, in addition to the practical experimental aspects. As might be expected, the onset of manifestations of dystrophin deficiency increases in proportion to the longer development and life span of species. Perhaps of more significance, the severity of dystrophic pathology in skeletal muscle appears to increase with species size. Only the canine model fully recapitulates the later stages of histologic myofiber degeneration and musculoskeletal disease seen in humans. Mice, in contrast, have normal life span, and unless stressed essentially are free of overt musculoskeletal disease. It seems likely that fiber length and biomechanical factors are paramount, but the precise relationship has not been defined.

It is also apparent that dystrophic myopathy and indeed muscular manifestations change dramatically in the simpler organisms. The predominant phenotype is abnormality at the NMJ, synaptic vesicle trafficking, and cell polarity at an embryonic stage. Nonetheless, the underlying biochemical process may be informative and the facility of genetic manipulations may make these apt models for specific studies.

Conclusion

Insight into the severe progressive myopathies known as muscular dystrophies, of which the archetype is DMD, has evolved from two convergent lines of study. The underlying classification has been put on a precise rational basis by progress from subjective phenotypic (clinical) characterization to classification based on the Mendelian inheritance of mutations at specific chromosomal loci. This has been complemented by the molecular genetic identification first of dystrophin, and then of a series of interacting dystrophin-associated proteins. In several instances these have matched the genetic loci identified in affected families. Positional cloning in affected families has identified other proteins. Out of this a model has emerged of a cytoskeletal framework which extends from the actin cytoskeleton, through dystrophin, to the integral membrane protein β-dystroglycan and the peripheral membrane protein α-dystroglycan, and which is anchored to the basement membrane component merosin, the α_2 chain of laminin. The complex of four sarcoglycans (glycosylated integral membrane proteins) is an intrinsic component of this complex and is critical for its function, although the precise mechanism is unclear. Further study of this core complex has identified several more proteins which, when mutated, are responsible for additional forms of muscular dystrophy, several because they have a critical role in glycosylating dystroglycan, without which dystroglycan is not functional. Yet the proteins responsible for several forms of muscular dystrophy remain to be identified, and the pathogenetic mechanism for several of the identified proteins remain to be understood.

A host of questions remain to be answered about the role of 'muscular dystrophy' proteins in the non-muscle tissue in which they occur, and the additional phenotypic features when they are lost or nonfunctional. A wide range of organisms have homologs of dystrophin and the dystrophin-associated proteins, and provide to varying degrees genetic, molecular biological, and pathological models of the muscular dystrophies. These provide a wide array of situations in which to explore normal and abnormal function and to test potentially therapeutic strategies.

Eating Disorders

W Kaye, University of California at San Diego, La Jolla, CA, USA

Introduction

Anorexia nervosa (AN) and bulimia nervosa (BN) are disorders that tend to occur in women and typically have an onset during adolescence but can occur in males as well as at other ages. Both AN and BN are often chronic, disabling conditions characterized by aberrant patterns of feeding behavior and weight regulation, and deviant attitudes toward and perceptions of body weight and shape. The etiology of AN and BN is presumed to be influenced by developmental, social, and biological processes; however, understanding of its etiology and pathophysiology remains incomplete. AN and BN are often considered to be a consequence of cultural attitudes toward standards of ideal body shape. However, although dieting behavior and the drive toward thinness are common in industrialized countries, AN and BN affect only an estimated 0.3–0.7% and 1.7–2.5%, respectively, of females in the general population. Moreover, numerous descriptions of a syndrome reminiscent of AN date from the late seventeenth century or earlier, suggesting that factors other than current culture play an etiologic role. In addition, these syndromes, particularly AN, have a relatively stereotypic clinical presentation, sex distribution, and age of onset, underscoring the role of intrinsic biologic vulnerability and diagnostic validity of the syndrome.

Description

AN is divided into two subtypes. In the restricting subtype, subnormal body weight and an ongoing malnourished state are maintained by unremitting food avoidance. In the bulimic subtype of AN, there is comparable weight loss and malnutrition, yet the course of illness is marked by supervening episodes of binge eating, usually followed by some type of compensatory action such as self-induced vomiting or laxative abuse. Individuals with BN remain at normal body weight, although many aspire to ideal weights far below the range of normalcy for their age, gender, and height. The core features of BN include repeated episodes of binge eating followed by compensatory self-induced vomiting, laxative abuse, or pathologically extreme exercise or fasting, as well as excessive concern with weight and shape. Although abnormally low body weight is an exclusion for the diagnosis of BN, 25–30% of bulimics have a prior history of AN. In addition, some individuals with AN convert to BN. Finally, persons afflicted with AN and BN, despite differences in the topography of their feeding behavior, share equivalent concerns with weight and shape. Likewise, common to individuals with AN and BN are low self-esteem, depression, anxiety, obsessionality, and perfectionism.

Core Symptoms

AN and BN are syndromes consisting of disturbances of a range of behaviors, including feeding, mood, impulse control, body image perception, as well as other domains. The most striking features are related to eating and body image. In AN, an inexplicable fear of weight gain and unrelenting obsession with fatness, even in the face of increasing cachexia, accounts for a protracted course, extreme medical and psychological morbidity, and standardized mortality rates exceeding those of all other psychiatric disorders. People with AN have stereotypic patterns of food choices. They severely restrict food intake, particularly fats and carbohydrates, but rarely stop eating completely; rather, they restrict their caloric intake to a few hundred calories per day. They tend to be vegetarians, have monotonous choices in food intake, select unusual combinations of foods and flavors, and have ritualized eating behaviors. BN usually emerges after a period of food restriction, which may or may not have been associated with weight loss. Binge eating is followed by either self-induced vomiting or some other means of compensation for the excess of food ingested. The majority of people with BN have irregular feeding patterns, and satiety may be impaired.

It has long been debated whether symptoms in individuals with AN and BN are cause or consequence of malnutrition. Confounding this understanding is the reality that most studies of symptoms have been done when individuals are ill. Particularly common in individuals with AN are personality traits of marked perfectionism, conformity, obsessionality, constriction of affect and emotional expressiveness, and reduced social spontaneity. Studies have shown that the majority of individuals with AN and BN exhibit childhood perfectionism, obsessive–compulsive personality patterns, and anxiety (particularly obsessive–compulsive disorder and social phobia), and these symptoms predate the onset of AN and BN. Because

these characteristics typically are present in childhood, prior to the onset of the eating disorder, and persist even after long-term weight recovery, they may be traits and not merely epiphenomena of acute malnutrition and disordered eating behavior. Individuals with BN are also more likely to exhibit histories of behavioral dyscontrol, substance abuse, and overt family conflict in comparison to those with the restricting subtype of AN.

It is important to note that other 'core' symptoms are common in AN and BN. One of the most puzzling symptoms of AN is the severe and intense body image distortion in which emaciated individuals perceive themselves as fat. Individuals ill with AN in particular have stereotyped hyperactive motor behavior, anhedonic and restrictive personalities, reduced novelty seeking, and a lower incidence of alcohol and drug use. Neuropsychological findings, using a broad range of assessments, have been somewhat inconsistent. A more focused, hypothesis-driven approach, pioneered by Tchanturia, Treasure, and others, has been based on the observation that people with AN show, as core features, high harm avoidance, inflexibility of thinking, rigid behaviors around eating, and high perfectionism. In addition, there is inflexibility on cognitive tasks and an inability to change past patterns of thinking, which can be conceptualized as difficulties in set shifting. These symptoms are evident in individuals with AN both during the acute phase of the illness and after weight restoration. In addition, such difficulties in set shifting are shared by the healthy sisters of those with AN, raising the intriguing possibility that set shifting represents a potential endophenotype for genetic studies of AN. Individuals with AN show a rigid pattern of responding and an inability to change a pattern of response once a behavior has been initiated. They also seem to have difficulty accessing and using conventional strategies for problem solving, such as learning from making mistakes. Rather, they obsessively repeat the same strategies despite the fact that such strategies are maladaptive and are not productive. Moreover, they often fail to accurately recognize and incorporate affective and social stimuli in the environment. Most strikingly, denial of emaciation or being ill, lack of insight, and resistance to treatment are often present. These characteristic styles raise the question of whether there is some physiologic disturbance of executive brain mechanisms that detect errors or plan and verify actions.

Familial/Genetic

Findings from case–control studies suggest a 7- to 12-fold increase in the prevalence of AN and BN in female relatives of eating-disordered probands compared to relatives of never ill controls. Despite the phenotypic differences between AN and BN, the two disorders appear to share at least some liability features in common. Convergent findings from family and twin studies indicating an increased coaggregation of AN and BN among relatives of AN and BN probands argue that a confluence of shared and unique liability features characterize the broader spectrum of eating disorder phenotypes. This significant familial occurrence of AN and BN provides impressive evidence of the heritability of both phenotypes.

Twin studies can differentiate genetic from environmental effects by comparing concordance for a trait, or disorder, between identical (monozygotic; MZ) and fraternal (dizygotic; DZ) twins. Although relatively few twin studies of AN and BN have been performed, they consistently show that approximately 50–80% of the liability to eating disorders is genetic. The transmitted liability to eating disorders may possibly be underpinned by a more diffuse phenotype of continuous traits. Specifically, evidence from population-based twin studies indicates heritability of disordered eating attitudes, weight preoccupation, dissatisfaction with weight and shape, dietary restraint, binge eating, and self-induced vomiting, with 32–72% of the variance in these behavioral features potentially accounted for by genetic factors. In addition, subthreshold forms of eating disorders have also been shown to coaggregate in families with full syndrome AN and BN, consistent with the possibility of a continuum of transmitted liability in at-risk families manifesting a broad spectrum of eating disorder phenotypes.

Identification of specific genes that play a role in AN and BN is in its infancy. Still, several studies of AN have replicated findings of a region on the short arm of chromosome 1 and potential involvement of the serotonin (5-HT) 1D (HTR1D) and opioid delta 1 (OPRD1) receptor genes in this region. In addition, traits thought to be related to liability to eating disorders, such as drive for thinness, obsessionality, anxiety, and concern over mistakes, have been associated with a number of linkage signals in BN and AN. A growing number of studies using a case–control design have examined the potential association of various candidate genes with AN and BN. Evidence linking AN and BN to monoamine functioning has led researchers to target 5-HT and dopamine (DA)-related genes, but findings have tended to be inconsistent or negative. In addition, the primary role of feeding, energy expenditure, or gender in the pathology of AN and BN has led researchers to examine genes related to these processes. In summary, no consistent evidence for association of a candidate gene

with either AN or BN has accrued to date, although inadequate sample sizes severely constrain these efforts. Additional research is necessary to clarify conflicting findings and replicate initial results.

Pathophysiology

There is growing acknowledgment that neurobiological vulnerabilities make a substantial contribution to the pathogenesis of AN and BN. Still, we have little understanding of how such vulnerabilities result in disturbances of brain pathways or what systems are primarily involved. For example, are there disturbances of pathways related to the modulation of feeding behaviors, mood, temperament, obsessionality, or impulse control? Are there primary disturbances of pathways that may modulate some factors related to body proprioception and thus result in body image distortions? The past decade has seen the introduction of tools, such as brain imaging, which hold the promise of being able to characterize complex neurocircuits and their relationship to behavior in living humans. In fact, these tools have rapidly advanced knowledge to the point where we can begin to make educated guesses about the pathophysiology of AN and BN and start to model mechanisms that may be used to test hypotheses.

In general, imaging studies have been relatively consistent in that many studies have findings in frontal, cingulate, temporal, and/or parietal regions. Thus, it can be stated that individuals with eating disorder, when ill and after recovery, have alterations in brain activity compared to matched controls. However, it should be noted that these studies have not consistently identified regions, pathways, or behavioral correlates. Sample sizes have been small, and imaging technologies and methods vary widely. Moreover, investigations have tended to assess relatively large regions of brain that vary widely between studies. Moreover, articles to date indicate alterations of brain function. Because brain pathways are highly complex, the neuroanatomy of AN and BN has only begun to be characterized.

When ill, people with AN, and to a somewhat lesser extent BN, commonly have neuroendocrine, autonomic, and metabolic disturbances and an exaggeration of comorbid psychiatric symptoms. Neuropeptides have been of interested because they could play a role in disturbances of appetite regulation, mood, impulse control, endocrine function, and many of the other physiological disturbances. Determining whether such symptoms are a consequence or a potential cause of pathological feeding and other altered behavior is a major methodological issue in the field. It is difficult to study AN prospectively due to the young age of onset and difficulty in premorbid identification of people who will develop AN. An alternative strategy is to identify behavioral phenotypes that are independent of the confounding effects of malnutrition by studying women who have recovered from AN and BN. The majority of neuroendocrine and neuropeptide alterations present during symptomatic episodes of AN and BN tend to normalize after recovery. These neuropeptides include corticotropin-releasing hormone, opioid activity, neuropeptide Y, and leptin. This observation suggests that most of the disturbances are consequences rather than causes of malnutrition, weight loss, and/or altered meal patterns.

In contrast, considerable studies have reported disturbances of brain 5-HT and DA function during the ill state and persisting after recovery. Studies using positron emission tomography (PET) brain imaging with [^{18}F]altanserin binding potential (BP) have characterize the 5-HT2A receptor. This receptor is of interest because it has been implicated in the regulation of feeding, mood, and anxiety and in antidepressant action. Ill and recovered AN and BN patients have reduced [^{18}F]altanserin BP in limbic regions. Several groups have assessed the 5-HT1A receptor in AN because this receptor may play a role in anxiety, mood and impulse control, feeding behavior, as well as in selective serotonin reuptake inhibitor (SSRI) response. PET imaging with the radioligand [^{11}C]WAY100635 found increased 5-HT1A binding in individuals who were ill and recovered from BN, whether or not they ever had AN. Finally, several lines of evidence support the possibility that disturbances of DA function could contribute to alterations of weight, feeding, motor activity, and reward in AN. PET imaging with [^{11}C]raclopride to assess DA D2/D3 receptor binding showed recovered AN patients had significantly higher [^{11}C]raclopride BP in the anteroventral striatum. Importantly, these studies have consistently found relationships between receptor binding and harm avoidance, a construct which is highly elevated in recovered eating-disorder individuals and characterizes overconcern about future events. Together these studies support earlier findings of persistent 5-HT and DA function in AN and BN.

Studies have used functional magnetic resonance imaging (fMRI) to assess symptoms. Studies have used either pictures of food or tastes of sugar and other substances, and they have found persistent alterations of brain pathways in individuals recovered from AN. These studies have implicated frontal as well as the insular cortex and related regions, pathways known to modulate feeding behavior. Brain imaging studies done in the past decade in human and nonhuman primates show that a primary taste cortex resides in

the rostral insula and adjoining frontal operculum. Some studies argue that these regions provide a representation of food in the mouth that is independent of hunger and, thus, of reward value. The responsiveness of taste neurons in secondary regions, such as the orbitofrontal cortex, may compute the hedonic value of food. These studies raise the provocative possibility of disturbances of higher order modulation of feeding in AN. Other fMRI studies have addressed body image distortions and have found altered response in left parietal regions, which have also been seen in PET studies. Theoretically, body image distortion might be related to the syndrome of neglect which may be coded in parietal, frontal, and cingulate regions that assign motivational relevance to sensory events. It is well-known that lesions in the right parietal cortex may not only result in denial of illness or anosognosia, and the numerous misidentification syndromes but also produce experiences of disorientation of body parts and body image distortion. Several brain imaging studies have reported altered left parietal cortex function. It is intriguing to raise the possibility of whether left hemisphere disturbances of this pathway contribute to body image distortion.

Treatment

A number of consensus publications have reviewed treatment options for AN and BN. These include the American Psychiatric Association guidelines and the National Collaborating Centre for Mental Health guidelines. These publications should be consulted for more specific details about therapy. In addition, websites such as that of the National Eating Disorders Association can be accessed for more information and referrals for treatment.

Bulimia Nervosa

Controlled outpatient trials have provided convincing evidence for the efficacy of both psychological and pharmacological treatments for BN. The largest number of controlled trials have focused on manual-based cognitive behavioral treatment (CBT). These studies have shown a decrease in the frequency of binge eating and purging episodes of approximately 60–70%, with complete abstinence from these behaviors in 30–50% of cases. There is also evidence that CBT results in improvements in other psychological symptoms of the disorder, including preoccupation with body shape and weight, and that CBT is more effective than more narrow behavioral approaches in addressing bulimic symptoms. Other data suggest that manual-based interpersonal therapy may achieve reduction in symptoms similar to results achieved with CBT, although the rate of response may be somewhat slower. Preliminary reports indicate that structured self-help approaches may be of assistance to some individuals, consistent with suggestions regarding the potential usefulness of 'stepped-care' algorithms in treatment planning.

The efficacy of a wide variety of antidepressant medications in the treatment of BN has been demonstrated in a number of double-blind, placebo-controlled trials. The average decrease in binge frequency for patients receiving the antidepressant medication was approximately 55%, approximately twice the widely variable rate of response for patients randomized to placebo administration. Only a minority of patients in the medication treatment trials actually achieved full abstinence from binge eating and purging behaviors. Whereas antidepressant administration may contribute to reduction in symptoms of depression, the reduction in bulimic symptoms does not appear to be correlated with the magnitude of the antidepressant response. With similar response rates seen across different classes of antidepressants, initial choice of medication is often based on a range of clinical considerations including typical side effect profile.

Several studies have compared response to psychotherapy and pharmacotherapy or to combination treatment. In general, these trials have demonstrated a greater decrease in frequency of bulimic episodes for psychotherapy (usually CBT) in comparison to pharmacotherapy. Although combined treatment was not notably superior to either treatment alone, this approach may be helpful in decreasing symptoms of depression, anxiety, and eating-related symptoms in some individuals. Currently, there are no established predictors of which patients might respond preferentially to psychotherapy or pharmacotherapy, although it has been suggested that individuals who show little response during the early sessions of CBT may be candidates for alternate treatment interventions.

Anorexia Nervosa

Progress in developing new and more effective treatment interventions for patients with AN has been slower than for BN. Individuals with AN are often resistant to treatment because they tend to have ego syntonic symptoms or may frankly deny being underweight or in need of treatment. Few control trials of any therapy have been performed, in part because it has been difficult to enlist cooperation of individuals with AN and in part because psychological and pharmacological strategies that have been successful in other disorders appear to be less effective in this

illness. For severely emaciated patients, hospitalization for supportive medical care and weight restoration may be useful or necessary. Still, relapse is common after discharge. Controlled trials suggest that the Maudsley family therapy techniques appear to be particularly helpful in younger patients with AN. Follow-up studies suggest that these interventions may also help prevent relapse in patients who achieve weight restoration. Studies have begun more systematic evaluation of the potential benefits of manualized cognitive behavioral and family therapies for this disorder. A range of medications, including SSRIs and neuroleptics, have been tried in AN, but there are few controlled trials in ill, malnourished patients. Some data have raised the possibility that fluoxetine may be useful in reducing relapse after weight restoration particularly in those with restricting-type AN compared to bulimic-type AN.

Summary

The etiology of AN and BN remains unknown. It may be that individuals with AN and BN may have a genetically transmitted alteration of neurotransmitter function that contributes to anxiety and obsessional symptoms in childhood. Perhaps brain changes caused by pubertal female gonadal steroids contribute to triggering the onset of an eating disorder. It is possible that people who develop eating disorders may respond in an overanxious manner to stimuli or have exaggerated overconcerns about the future. Because of these temperament traits, and perhaps traits related to disturbed body image, people with eating disorders may be more vulnerable to focusing on and incorporating certain societal messages, or they may be particularly susceptible to stress. It may be that people with AN and BN find that extremes of food intake produce neurochemical changes that temporarily reduce dysphoric moods, and thus they are prone to restrictive eating for AN and overeating for BN.

Echolocation I: Behavior

A D Grinnell, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Echolocation is the active detection, localization, identification, tracking, and interception or avoidance of targets, based on information obtained from the echoes of emitted sounds. Several groups of animals have independently evolved this adaptation, but the behavior was first demonstrated and is most highly developed in bats of the suborder Microchiroptera. One genus of Megachiroptera (*Rousettus*), toothed whales, two genera of birds (*Steatornis*, the South American oil bird, and *Collocalia*, the cave swifts), and shrews are known to echolocate. Echolocating animals other than Microchiropterans usually have excellent night vision and use echolocation facultatively.

Study of echolocation began in the late 1700s. Spallanzani, in Italy, and his Swiss counterpart, Jurine, showed that blinded bats could orient, avoid obstacles, and feed while flying, and that hearing was necessary for these capabilities. Not until 1938, however, did Donald Griffin, then an undergraduate at Harvard, establish that flying bats emit trains of brief, high-frequency sounds and use their echoes to detect and avoid obstacles. The study of echolocation has since become one of the most challenging and fascinating areas of neuroethology.

With their remarkable adaptations for flight and echolocation, bats are among the most diverse and successful orders of mammals. They evolved echolocation more than 50 Ma and have since differentiated widely. Echolocating bats inhabit all climatic zones in all continents except Antarctica. They range in weight from <2 to >100 g and in wing span from <15 cm to almost 1 m. About 70% are insectivorous, catching flying insects in their tail or wing membranes at rates up to 2 s^{-1}. Prey range in size from mosquitoes to large moths and beetles. Some species eat small birds or other bats: others lap blood from roosting birds and large mammals. Some use both prey-generated sounds and echolocation to glean vegetation or the ground for prey like cicadas, walking sticks, crickets, katydids, and scorpions. At least one genus of bats eats frogs and several catch fish or floating insects by skimming the water surface where they have detected movement. Many bats feed on fruits. Others are specialized for nectar feeding, with elongated snouts, long tongues, and the ability to hover (Figure 1).

All bats must also detect and avoid obstacles such as tree branches, leaves, wires, and buildings; drink by flying low over a body of water, dipping in just the lower jaw; land by flipping around at the last moment to grip a surface irregularity with their hind claws; and find their way (probably with the aid of vision and olfaction) throughout a home territory that may encompass many square miles. To accomplish these feats, bats must simultaneously localize many echo sources in three-dimensional space and discriminate the shapes, dimensions, and surface textures of each. In short, bats transform the cacophony of echoes they encounter when flying in their nocturnal environments into a series of acoustic three-dimensional 'snapshots' of the environment approaching the detail obtained visually by day-flying insectivorous birds.

Echolocation Sounds and Foraging Niches

Within any given habitat, different bat species exploit different niches. Independent of their often quite distant phylogenetic relationships, bats hunting in similar acoustic environments use similar repertoires of sounds that differ depending on the demands of each environment. A major determining factor is the amount of echo 'clutter' interference the bat faces while foraging. Although all bats must be able to fly and orient in cluttered space, most tend to hunt selectively (1) in open air (no clutter), (2) near borders between open space and foliage, water surface, or the ground (background clutter), or (3) in dense vegetation (highly cluttered space). Each niche is further refined by the size of prey; the minimum distance from clutter a bat can capture flying insects; whether prey can be gleaned from vegetation, water surface, or ground; and whether prey-generated sounds are required for detection. Bats exploiting these niches, or combinations thereof, apportion the resources of an environment and are said to form different guilds (Figure 2).

Search Phase Sounds and Detection

Bats use relatively simple, stereotyped signals, but there is considerable facultative flexibility in duration, frequency structure, intensity, and repetition rate, all of which vary in ways that optimize information retrieval in a given environment and stage of echolocation. The sounds, produced in the larynx, are mostly ultrasonic (>20 kHz) and only a few milliseconds long. Their intensity, measured 10 cm in front of the bat, ranges from <60 dB sound pressure level (SPL) ('whispering bats') to >130 dB SPL. Broadband signals, mainly downward frequency

Figure 1 Representative bats. (a) *Myotis velifer* (family Vespertilionidae), a bat that hunts in open air; (b) *Antrozous pallidus*, a gleaning bat, with prey; (c) *Rhinolophus ferrumequinum*, a long CF/FM-emitting bat that hunts in highly cluttered environments and often echolocates for prey from a perch; and (d) *Rousettus*, the only Megachiropteran that echolocates. Photographs by Merlin Tuttle, Bat Conservation International, Inc.

modulation (FM) sweeps through an octave or more, often with multiple harmonics to further broaden the bandwidth, can be used in any of the three clutter-defined niches. However, bats that hunt in open space have little concern about obstacles in their flight path so tend to optimize the range of detection by using loud, long (5–25 ms) sounds that concentrate the energy into a relatively narrow band of frequencies to which the bat is highly sensitive. These may have almost constant frequency (CF) or shallow FM sweeps (quasi-CF) (Figure 2, *Nyctalus noctula* and *Pipestrellus kuhlii*; see also Figure 1(a)). Search calls are typically emitted at rates of 2–10 s^{-1}, often in phase with wing beats.

In open air, insectivorous bats can detect medium-sized moths at 5–10 m. They dart at ~1 cm diameter artificial targets tossed into the air when they are within about 2 m (but almost invariably stop pursuit before intercepting the target). Echoes from small targets may be attenuated by 90 dB or more. This attenuation reflects the spherical spreading loss from the point of emission and again from the reflecting target (echo intensity falls with the third to fourth power of distance). For small targets echo intensity varies inversely with the fourth power of sound wavelength; hence, some bats that forage on small insects emit dominant frequencies as high as 150 kHz. However, atmospheric attenuation also

Figure 2 Schematic design showing different echolocation foraging niches and the flight silhouettes and signal designs used during search flight by representative species hunting in each niche. The niches are defined by the amount of acoustic clutter interference. In open air (no stippling), bats tend to be fast fliers and search with CF or quasi-CF signals, which are good for long-distance detection but not for localization. After detection, emitted sounds become broadband. Bats that hunt within about 5 m of the edge of the ground or vegetation or that trawl the water surface (light stipple) tend to use sounds with both CF and FM components, emphasizing FM as they face greater echo clutter. Finally, those that hunt amid vegetation, facing severe echo clutter, either use very short broadband signals or long CF/FM signals. The latter are specialized for 'flutter detection.' From Schnitzler H-U and Kalko EKV (2001) Echolocation by insect-eating bats. *BioScience* 51: 557–569, copyright, American Institute of Biological Sciences.

increases with frequency (5.6 dB m^{-1} at 150 kHz), restricting the range of echolocation in very high frequency bats.

Bats that hunt within about 5 m of vegetation or over water, where targets must be detected against background echo clutter, search with pulses that contain a prominent FM component, either alone or with a CF component (CF/FM or FM/CF) (e.g., Figure 2, *Pteronotus quadridens*, *Noctilio leporinus*). Bats that move from open air to background-cluttered space shift from CF or CF/FM to largely FM signals, and the reverse (Figure 2, *Pi. kuhli*). The CF component facilitates detection and the FM component allows localization of background obstacles.

Within each guild, further ecological distinctions are correlated with subtle differences in emitted pulses. For example, five sympatric European species of *Myotis* all use brief FM sweeps to hunt for insects in the presence of background clutter. The greater the bandwidth of the FM signals used by a given species, the closer to a cluttered background it can recognize and capture stationary tethered insects (from 2–3 cm with a 120 kHz bandwidth to 14 cm with a 40 kHz

Figure 3 Correlation between the 'minimal capture distance' and the bandwidth of the FM search calls used by five sympatric *Myotis* species. Minimal capture distance was defined as the distance from a background 'clutter screen' at which 50% of tethered targets (mealworms) were captured within 1 min of searching flight. Mean ±SD for each species is indicated. From Siemers BM and Schnitzler H-U (2004) Echolocation signals reflect niche differentiation in five sympatric congeneric bat species. *Nature* 429: 657–661.

bandwidth, Figure 3). Gleaning bats typically use faint broadband signals. Often they use prey-generated sounds to detect and localize prey, but some bats can detect and capture quiescent insects on vegetation by echolocation alone.

In highly cluttered space, many bats that hunt on the wing use steep FM sweeps (e.g., Figure 2; *Myotis myotis* and *Artibeus jamaicensis*). However, others use long CF signals terminating in a brief FM sweep (Figure 2; *Rhinolophus ferrumequinum*). Long CF/FM bats are of particular interest because their auditory systems are highly specialized to utilize information in the CF component of echoes (see below).

Pursuit and Capture

After detection, bats must determine the distance, direction, and nature of the echo source(s). Obtaining this information requires broadband sounds. Almost universally, after detection, the rate and extent of the FM sweep increase, the repetition rate increases, and pulse duration decreases (Figure 4). Use of broadband FM sweeps allows redundant measurement of pulse–echo delay by many parallel frequency-tuned channels, thereby providing accurate information about distance. At the same time, binaural comparison of echo intensity at different frequencies yields

Figure 4 Sound spectrographic records of the emitted sounds of representative species as they search for, detect, pursue, and capture an insect in flight (a–e), and glean an insect from a surface after detection during flight (f) and after detection from a perch (g). *T. brasiliensis* and *N. noctula* are typical open-air foraging bats. *P. pipistrellus* and *S. bilineata* hunt close to the edge of foliage, and *R. ferrumequinum* hunt, often from perches, in a highly cluttered environment. Note the changes in signal structure and repetition rate associated with insect pursuit and capture in flight. From Schnitzler H-U and Kalko EKV (2001) Echolocation by insect-eating bats. *BioScience* 51: 557–569, copyright, American Institute of Biological Sciences.

information about direction, and the relative intensity of different frequencies in the echo and the location of spectral notches provide information about target shape. The decrease in emitted pulse duration appears intended to avoid overlap of outgoing and returning echo: a severe form of forward masking. Echoes from multiple objects in the environment do overlap, however, and each must be independently localized and identified.

Finally, as bats close in on a target, especially a flying insect, the repetition rate reaches 100–200 s^{-1} (the 'terminal buzz'). Pulse duration decreases to a fraction of a millisecond, and any remaining CF component tends to disappear. Intensity is reduced, and the starting frequency of the FM sweep often decreases (Figure 4(e)). The high pulse repetition rate during insect pursuit probably maximizes information acquisition for tracking and capturing moving targets. Such 'buzzes' are seldom observed during avoidance (or capture) of stationary targets (Figures 4(f) and 4(g)).

Long CF/FM Bats and Doppler-Shift Compensation

These bats, which hunt in cluttered environments, include members of the Old World families Rhinolophidae and Hipposideridae and one New World representative, *Pt. parnellii* (family Mormoopidae). The best-studied Rhinolophid, *R. ferrumequinum*, can hunt on the wing but often perches and hunts by acoustically scanning the environment (Figure 1(c)). Its search sounds have a CF component of about 83 kHz that can last 100 ms, ending in a brief FM sweep to ~70 kHz. *Pt. parnellii*, which always hunt in flight, emit a dominant CF component of ~61 kHz that lasts about 30 ms and terminates in an FM sweep to ~45 kHz. In both species, the CF is regulated to within ~50 Hz, or 0.06%. After the bats detect a target, the CF duration first increases to maximize the duration of the CF component of the echo. It then decreases as the repetition rate increases and the depth of the FM sweep increases (Figure 2(e)). Although the duty cycle (percentage of time sounds are emitted) may be close to 100%, only the CF component of echoes overlaps with outgoing sounds. This long CF is critical to their echolocation strategy.

Echoes returning from objects in front of a bat are Doppler-shifted upward in frequency in proportion to the bat's flight speed. Moving targets return echoes at a slightly different CF frequency than surrounding stationary objects. As echoes return upward-shifted in frequency, long CF/FM bats exhibit 'Doppler-shift compensation.' They lower their emitted CF just enough to maintain the returning echo at a constant 'reference' frequency (Figure 5). In both *Rhinolophus*

Figure 5 Doppler-shift compensation in *Rhinolophus ferrumequinum*. A stationary bat, trained to track a phantom target, emitted a constant stream of orientation sounds. A microphone picked up the emitted sounds and played them back at a frequency that ranged sinusoidally from the same as the emitted frequency (CF approximately 83 kHz) to a frequency upward shifted by 3 kHz (simulating a target moving toward the bat at 12 m s^{-1}). The bat reacted by lowering the emitted CF of each emitted sound by just enough to compensate for the upward Doppler-shift of the preceding echo. As a result the echo returned at an almost CF. The bat compensates very little to downward Doppler-shift, representing a target moving away from the bat. Kindly provided by Dr. Walter Metzner, UCLA.

and *Pteronotus*, the cochlea and nervous system are highly specialized – relatively insensitive to the downward-shifted emitted CF, but exquisitively sensitive to the reference frequency of the echo CF and to small fluctuations around it. The long CF appears to be used mainly for detection and discrimination of flying insects based on wing beat-specific modulations in the frequency and amplitude of the echo CF. Perching *Rhinolophus* hunt with sounds in which the CF is in the range of insensitivity and echoes of approaching insects are shifted upward into the range of high sensitivity.

The similar use of Doppler-shift compensation by *Rhinolophus* and *Pteronotus* is a remarkable example of convergent evolution. However, details of cochlear mechanisms and the neural circuitry for analysis of echoes are different in the two species. *Rhinolophus* does not use multiple harmonics in various pulse–echo combinations to obtain information, a central feature of the *Pteronotus* nervous system. Moreover, *Rhinolophus* emits sounds through the nostrils and *Pteronotus* by mouth.

In bats that emit short (<10 ms) CF/FM signals, Doppler-shift compensation is less accurate than in long CF/FM bats, and their auditory systems are less sharply tuned around the CF. A short CF component is less useful than a long CF for obtaining Doppler-shift information, especially about target wing beats.

The short CF component probably serves primarily to improve target detection, while the FM sweep provides most of the information about distance, direction, and the nature of targets. *Noctilio*, a pisciverous New World bat, often emits pulses in pairs or triplets, one of which is an 8–10 ms pure CF; the others are CF/FM.

Laboratory Studies of the Limits of Echolocation Skills

Detection

Early experiments using changes in pulse emission rate as a criterion of detection showed that the FM bat *M. lucifugus* reacted to an array of 1 mm diameter wires at about 2 m and to 0.18 mm wires at almost 1 m. In a major advance in the methodology for studying echolocation, Simmons used a food reward to train bats to sit on a platform, emit orientation pulses, and choose between alternative targets by crawling to the left or right of a Y-shaped platform. The threshold distance for *Eptesicus fuscus* to detect a 19.1 mm-diameter sphere was 5.1 m, while a 4.8-mm-diameter sphere was detected at 2.9 m. In these and similar experiments with other bats, the absolute echo intensities at threshold ranged from 8 to 40 dB SPL, that is, 50–85 dB fainter than the emitted sounds. Thresholds are lowest in long-eared 'whispering bats,' such as *Plecotus*.

These threshold values are comparable to those of most mammals at their best frequencies. However, bats must detect and analyze these sounds within milliseconds of emitting much louder sounds and in the presence of interfering echoes from other objects. In most mammals, responsiveness to echoes is actively suppressed. Bats, on the other hand, suppress responsiveness to outgoing sounds – by synchronized middle-ear muscle contraction and efferent neural inhibition coupled to pulse emission – and they have neural mechanisms for exaggerating responsiveness to returning echoes.

Range (Distance) Discrimination

To catch an insect, a bat must localize its prey within 1–2 cm in three-dimensional space. Sound travels 34.4 cm ms^{-1} in air. Hence, the delay between emission of a pulse and return of an echo is an accurate measure of distance. Simmons showed that several species of bats using broadband FM signals could determine which of two targets was closer if the difference was 8–15 mm or greater (45–85 μs, about 3% of the overall delay). The same bats seamlessly made the same discrimination when real targets were replaced by 'phantom' targets – playbacks of the bat's emitted sounds picked up by a microphone and broadcast from two equidistant loudspeakers at the angle of the original targets but at different delays corresponding to the different distances tested with real targets (Figure 6). This confirmed that pulse–echo delay is the criterion used for distance discrimination. In similar range discrimination tests, the long CF/FM bat, *Rhinolophus*, was less accurate (30–41 mm). The CF component is comparatively useless for distance discrimination, and their FM component is less broadband than the sweeps used by FM bats. The emitted sound appears to open a 'ranging window' of 20–30 ms duration during which echoes arriving at different delays excite different populations of 'delay-tuned' neurons.

Figure 6 Range-difference discrimination by two *Eptesicus fuscus* in a two-alternative forced-choice behavioral test, where each bat was asked to distinguish which of two real targets was the closer. The correct choice was a target at 30 cm distance, the wrong choice was at a greater distance as shown in the upper abscissa. The targets were 20° to each side of midline. The real targets were then replaced by 'phantom targets', simulated by playing back the bat's emitted sounds from loudspeakers in the directions and at delays corresponding to the distances tested with real targets. The behavior was the same for both real and phantom targets. The dashed line indicates 75% correct choices, the usual criterion for successful discrimination. From Simmons JA (1973) The resolution of target range by echolocating bats. *Journal of the Acoustical Society of America* 54: 157–173.

Time-Intensity Trading, Middle-Ear Muscles, and Echo 'Gain Control'

In general, the latency of a neural response decreases as stimulus intensity increases. In behavioral experiments, bats consistently perform as if they interpret a 1 dB increase in echo intensity as a 15–17 μs decrease

in delay. When a bat approaches a target, the increase in echo intensity (12 dB per each halving of distance) would be expected to introduce a systematic error in distance perception.

This problem may be minimized by changes in sensitivity imposed by the middle-ear muscles, which contract during each pulse emission, sharply decreasing sensitivity. As the muscles relax during the few milliseconds after pulse emission, sensitivity recovers. The closer the target is, the louder the echo, but also the greater the attenuation due to middle-ear contraction. This modulation of sensitivity after each emission, combined with a decrease in emitted sound intensity as a bat nears its target, may compensate almost completely for the increase in echo intensity due to the decrease in distance. If so, echoes would return at almost constant intensity during the last 1–2 m of pursuit. This echo 'gain control' would reduce errors otherwise resulting from the intensity-latency trade-off.

Fine Temporal Resolution/Range Jitter Discrimination

Early behavioral measurements unexpectedly suggested that the threshold for distance discrimination was about the same over a wide range of absolute distances (30–240 cm). One would expect the discernible difference to increase in proportion to absolute distance. The behavioral measurements might instead have tested the uniformity with which a bat held its head at a constant distance from the microphone as it moved on its Y-shaped platform emitting pulses in the direction of each target.

In order to minimize this potential possibility, Simmons trained *Eptesicus* to discriminate between two phantom targets. One target always returned echoes at the same delay; the other returned echoes that alternated ('jittered') between slightly shorter and slightly longer delays (Figure 7). Only one phantom target returned an echo to any given pulse, determined by which of two microphones received the louder emitted sound. The 'jitter' was reduced until the bat could no longer distinguish which target appeared to be jittering in space. The results indicated that *Eptesicus* could easily detect 1–2 μs jitter and even as little as 10–100 ns if the signal-to-noise level was high! Although this astonishing 'hyperacuity' is highly controversial, it has been confirmed in part by others who found that *Eptesicus* resolved jitter almost perfectly down to 400 ns – the smallest difference tested. This is for jitter between successive echoes separated by ~100 ms! Subsequent research indicates that reduction in signal bandwidth, especially by high-pass filtering (excluding lower frequencies in the echo), degrades performance. With full bandwidth, the jitter thresholds approach those expected for an ideal receiver performing coherent cross-correlation between pulse and echo (Figure 7).

Additional experiments support the idea that bats can resolve temporal differences in the microseconds range. Taking advantage of the time–intensity trade-off, Simmons showed that reducing the amplitude of the earlier of two sounds by 1 dB or increasing the intensity of the later sound by 1 dB eliminated the perception of jitter when the interval between echo delays was 15–17 μs. This result coincides with the prediction that the bat interprets the louder sound as arriving 15–17 μs earlier. Spectral cues would not yield this result. If instead of alternating the delay between pairs of sounds in a jitter experiment the phase of one sound was changed by 90° or 180° compared to the other, bats clearly detected the difference.

'Glints,' Multiple–Wave Front Resolution, and Target Discrimination

To extract the information encoded in multiple overlapping echoes, bats must be able to identify which objects produce which echoes. This identification likely involves recognition of target dimensions based on wing beat detection, on spectral transformations due to differential reflection of different frequencies in the pulse, and on analysis of multiple 'glints' returning from different features of the target, overlapping in time.

The ability of bats to resolve multiple wave fronts in echoes has been tested with both real and phantom targets. When presented with two Plexiglas plates having arrays of holes drilled to a different depth, bats discriminated differences in depth of <1 mm. *Rhinolophus* can discriminate between pairs of phantom targets that differed from the positively reinforced reference separation of 7.7 μs (1.3 mm) by only 1 μs (equivalent to a spatial difference 0.17 mm). Such overlapping wave fronts create spectral notches in the compound echo. The position of the notches depends on the extent of overlap of echoes from the two surfaces and how individual frequency components reinforce and cancel each other. Consequently, two-wave front discrimination is thought to be based on subtle spectral cues. Mathematically, however, the cues could equally well be two separate but overlapping echoes slightly displaced in time. When bats are asked to distinguish a two-wave front echo from a single-wave front echo, their performance deteriorates when one of the two wave fronts is at the same delay as the single wave front.

Figure 7 Range 'jitter' discrimination by *Eptesicus fuscus*. (Top) Experimental design. Microphones (m) picked up emitted sounds and played them back from one or the other loudspeaker (s) at delays corresponding to a constant distance for one target (c and d) and a distance that alternated back and forth by Δt (between a and b) in successive echoes from the other target (Bottom) (A–D): Performance of two bats to jitter between 0 and 100 ns, when the echoes (playback of the bats' own cries) were high-pass (HP, red) or low-pass (LP, blue) filtered (–24 dB per octave) to reduce the FM bandwidth. *Eptesicus* sounds contain nearly equal sound levels between 90 and 25 kHz. Symbols in panels A and D indicate cutoff filter settings. Note that removal of low-frequency components of the echoes degraded jitter discrimination more severely than removal of high-frequency components. (E) Plot of bats' jitter acuity thresholds at 75% correct response levels for different HP and LP filter settings (horizontal axis). Dashed red and blue lines show linear regression and solid lines show 99% confidence limits. Predicted thresholds for optimal receivers with coherent (open squares, brown line) and semicoherent (green) processing FM echoes are shown for each filter condition. (2004) Delay accuracy in bat sonar is related to the reciprocal of normalized echo bandwidth, or *Q. Proceedings of the National Academy of Sciences* 101: 3638–3643.

Angular Resolution in the Horizontal and Vertical Dimensions

To intercept and catch an insect, a bat must know where the insect is in three-dimensional space within ±2–5°. Laboratory experiments have confirmed that bats can discriminate between two targets separated by as little as 1.5° in the horizontal plane (azimuth) and about 3° in the vertical plane. The cues for horizontal and vertical angular discrimination are less obvious than for distance (pulse–echo delay). Unlike vision, the auditory input from either ear does not provide a map of space. The map must be computed in the brain by comparing inputs at the two ears.

Pulse emission is somewhat beamed. Sound intensity falls off by ~10 dB within 30–45° off-axis in both horizontal and vertical planes. High frequencies are more narrowly beamed than low frequencies. Auditory sensitivity tends to be more directional than emitted intensity, again especially at the higher frequencies in each bat's range. The large and complex pinnae and the prominent tragus are essential to establishing directionality. In long CF/FM bats, and to a lesser degree in some short CF/FM bats, the distal portion of one pinna flicks forward and the other backward in synchrony with each pulse emission. During the next pulse the movements are reversed.

These ear movements probably are important for processing the CF component, determining target direction, or both.

Cues for horizontal localization of targets are interaural time (ITD) and intensity (IID) differences. For most echolocating bats, ITD is a maximum of 25–30 μs. IIDs, which depend on ear structure and sound shadows cast by the head, vary with frequency and can be as great as 40 dB at high frequencies in the echo (Figure 8). Typically, at 40 kHz and higher, sensitivity changes by an average 0.5–1 dB per degree over the ±30° on either side of midline. Thus a target 5° on one side of midline generates an echo that arrives at one ear about 2.5 μs earlier than at the other and is perceived as being 5–10 dB louder on the side that hears the echo first. Since a 1 dB difference in intensity translates into a difference of 15–17 μs in response latency, bats most likely use IIDs to discriminate direction in the horizontal plane.

Vertical displacement above or below the horizontal plane does not affect the phase or arrival time of echoes at the two ears. However, spectral peaks and notches in the echo result from interference between multiple wave fronts of an echo bouncing off different parts of the elaborate structures of the pinna and tragus. Thus, changes in vertical angle can dramatically

Figure 8 Directionality of hearing in a representative little brown bat, *Myotis lucifugus* (family Vespertilionidae). Diagrams showing the sensitivity of the evoked response from one posterior colliculus at 20, 40, 60, and 80 kHz to sounds coming from different positions in the hemisphere in front of the bat. Numbers are decibel SPL at threshold. Contour lines are drawn at every 5 dB. Sensitivity was greatest to sounds coming from the contralateral side. The colliculus on the other side would respond in mirror-image fashion, so binaural comparison would approximately double the perception of change in intensity with change in direction in the horizontal plane. Single units in the auditory pathway show much sharper directionality than this. From Grinnell AD and Grinnell VS (1965) Neural correlates of vertical localization by echo-locating bats. *Journal of Physiology* 181: 830–851.

alter sensitivity at different frequencies (Figure 8). It is thought that vertical localization can be done monaurally based on multiple-wave front interference patterns. However, it is questionable whether these spectral cues can be separated from the large intensity differences that result from changing horizontal direction. Therefore, bats may learn to interpret IIDs at different frequencies for both horizontal and vertical directionality. Even slight distortion of the configuration of the pinnae in the long-eared bat *Plecotus* seriously degrades wire avoidance skills.

Echolocation by Other Animals

The Megachiropteran *Rousettus* and the birds that echolocate do so facultatively, with broadband tongue clicks. They have been little studied. However, *Rousettus* avoid mist nets and appear to be quite skilled at echolocating. In contrast to other Megachiropterans, which orient entirely visually, *Rousettus* are maximally sensitive to ultrasonic frequencies and show the temporal resolution needed for echo detection and analysis (Figure 1(d)).

Dolphins and other toothed whales also have good vision but have developed echolocation to a level rivaling that of Microchiropteran bats. Broadband clicks are generated by forced movements of air through nasal passages and focused by the waxy melon of the forehead. A low searching rate is punctuated by foraging 'buzzes' of up to 600 clicks per second. Both the frequency spectrum (much of the energy >100 kHz) and intensity can be regulated depending on the echolocation task. Hearing is mediated through a fat body inside the lower jaw that extends to the temporal bone of the ear. Despite the animals' overall size, sensitivity is maximal in the ultrasonic frequency range. The bottle-nosed dolphin *Tursiops* can detect a water-filled 7.6 cm-diameter steel sphere at >100 m; discriminate a 3 mm difference in wall thickness of equal-sized aluminum spheres; distinguish targets composed of bronze, glass, and stainless steel; and distinguish spherical from cylindrical targets, independent of echo strength. They can visually recognize targets in air that they have learned to discriminate using echolocation when blindfolded underwater.

Introduction

The order *Chiroptera* (bats) comprises one-fifth of mammalian species and consists of two suborders: Megachiroptera (173 species) and Microchiroptera (813 species). All microchiropterans thus far studied echolocate, but only one megachiropteran (genus *Rousettus*) does. The morphology and ecology of bats are so diverse that echolocation behavior and orientation sounds (biosonar pulses or, simply, pulses) are quite different among different species of bats. Bats that emit biosonar pulses which always consist of a constant frequency (CF) component followed by a frequency-modulated (FM) component are called 'CF–FM' bats, whereas bats that emit biosonar pulses which always consist of an FM component only are called 'FM' bats. Accordingly, the auditory system differs among species. As is well known, toothed whales (about 70 species), such as dolphins, echolocate. In addition, two species of birds, *Steatornis* (oilbird) and *Collocalia* (swiftlet), have been known to echolocate. The biosonar pulses of the whales, birds, and *Rousettus* are clicks. Microchiropterans are not blind; their eyes are suited for scene analysis at night and function for long-range navigation, whereas echolocation is suited for short-range scene analysis in the dark and functions for object avoidance, hunting insect, etc.

Studies in the neuroscience of echolocation have been mainly performed with five different species of microchiropterans: *Pteronotus parnellii* (mustached bat), *Rhinolophus ferrumequinum* (horseshoe bat), *Myotis lucifugus* (little brown bat), *Eptesicus fuscus* (big brown bat), and *Antrozous pallidus* (pallid bat). The first two species are CF–FM bats and the last three are FM bats, all being insectivorous. Among them, the parallel and hierarchical processing of biosonar information was first and best explored in *Pteronotus*. Thus, the neurophysiology of the auditory system of *Pteronotus* is mainly described in this article.

Properties of Biosonar Signals

The biosonar pulses of *Pteronotus* always consist of a long CF component followed by a short FM component. Since each biosonar pulse contains four harmonics ($H_{1–4}$ in Figure 1(a)), there are potentially eight major components ($CF_{1–4}$, $FM_{1–4}$). The second harmonic (H_2) is always predominant, with CF_2 at ~61 kHz and FM_2 sweeping from 61 to ~49 kHz. The CF_2 frequency slightly differs among individual bats and is sexually dimorphic: CF_2 in males is ~1.04 kHz lower than in females. In target-directed flight, a CF–FM pulse varies in duration and emission rate (Figure 1(b)), but its spectrum changes little. *Rhinolophus* also emits CF–FM sounds with CF_2 at ~83 kHz. In comparison, *Myotis* and *Eptesicus* emit FM pulses that sweep downward about one octave within a range between 100 and 15 kHz. The properties of FM pulses vary depending on the species and echolocation situation (Figures 1(c) and 1(d)). Such species-specific biosonar pulses can be elicited by electrical stimulation of the cingulate cortex, periaqueductal gray, or the midbrain reticular formation.

The middle ear muscles start to contract a few milliseconds prior to sound emission, then maximally contract during, and relax within, a few milliseconds after a sound emission, in order to attenuate vocal self-stimulation by ~20 dB. Such a muscle contraction is well synchronized with a sound emission even at the emission rate of 200 s^{-1}. The stapedius muscle plays the essential role in this attenuation of vocal self-stimulation. Its tetanus-fusion frequency is ~320 s^{-1}. When the bat emits a sound, its vocal system sends signals (efferent copy) to the auditory system and attenuates vocal self-stimulation by ~15 dB, perhaps at the nucleus of the lateral lemniscus. These muscular and neural attenuations of vocal self-stimulation facilitate the detection of echoes returning after the emission of the strong biosonar pulses. *Rhinolophus* moves its pinnae synchronously with the emission of biosonar pulses, which go up to ~100 s^{-1}, to scan the auditory field in front of the animal. A nose-leaf bat such as *Rhinolophus* radiates biosonar pulses through the nostrils. The radiation pattern of the pulses is modulated by the nose leaf (leaflike attachment at the nose), which moves synchronously with pulse emissions.

Echoes that elicit behavioral responses in *Pteronotus* usually overlap with the emitted pulse, so that biosonar information is extracted from a complex sound potentially containing up to 16 components. Different components or parameters of echoes carry different types of target information (Table 1). The long CF component is an ideal signal for target detection and velocity measurements (relative velocity and velocity of insect wing-beat), while the short FM component is more appropriate for ranging, localization, and characterization of a target. *Pteronotus* and *Rhinolophus* optimize the acquisition of target information by an acoustic behavior called 'Doppler-shift

Figure 1 Biosonar pulses of the mustached bat, *Pteronotus parnellii* (a, b) and the little brown bat, *Myotis lucifugus* (c, d). (a) The four harmonics (H_{1-4}) of a *Pteronotus* biosonar pulse (P) each consist of a long CF and a short FM component, so that there are eight components: CF_{1-4} and FM_{1-4}. Most of the sound-energy is in the second harmonic (H_2), with CF_2 at about 61 kHz and FM_2 sweeping from 61 to about 49 kHz. As the bat approaches a target, a reflected echo (E) is Doppler-shifted (DS) in frequency, and its delay from the pulse becomes shorter. (b) During target-directed flight, *Pteronotus* increases the rate of its pulse emissions. The bat initially lengthens the duration of the pulse and then systematically shortens it. Pulse–echo overlap is maximal when the pulses emitted are longest in duration. (c) *Myotis* emits short downward-sweeping FM pulses. The duration and frequency sweep range of the pulse change during target-directed flight. (d) During target-directed flight, *Myotis* increases the rate of pulse emissions and shortens pulse duration so as to avoid pulse–echo overlap. Circled numbers 1–4 correspond to those in (c). CF, constant frequency; FM, frequency modulation. (b) Adapted from Novick and Vaisnys (1964). (d) Adapted from Friend, Suga, and Suthers (1966).

Table 1 Different parameters of an echo relative to the biosonar pulse at the ear carry different types of target information. Bats detect small objects and discriminate small differences between objects

Echo	*Target*	*Just noticeable difference*
Detection	Long wire	80 μm diameter (Rf)
	Long wire	100 μm diameter (Ml)
	Disk	4.2 mm diameter at 127 cm (Ml)
	Disk	10 mm diameter at 200 cm (Ef)
Doppler shift	Velocity	
Steady shift	Relative velocity	0.06–0.36% (Rf)
Periodic shift	Insect wing-beat	0.01–0.07% (Rf)
Periodic shift	Wing-beat rate	30% (Ef)
Amplitude	Subtended angle	16% (Ef)
Delay	Range	14 mm (81 μs) (Ef)
Jittered delay	Jittered range	10 ns (1.7 μm) (Ef)
Amplitude + delay	Size	16% (Ef)
Amplitude spectrum	Fine characteristics	87 μm in texture (Ef)
Binaural cues	Azimuth	1.5° (Ef)
Pinna-tragus cue (spectral notch)	Elevation	3° (Ef)

compensation,' by which the frequency of the Doppler-shifted echo CF_2 is stabilized by changing the pulse CF_2 frequency at about 61 and 83 kHz, respectively, the frequency to which peripheral neurons are extremely sharply tuned. Echoes from flying insects are periodically Doppler-shifted, that is, frequency modulated, by beating wings. Such periodic Doppler shifts evoke hunting behavior of hungry bats. They also show an acoustic behavior called 'intensity compensation,' by which the echo intensity is stabilized at their preferred intensities.

The Auditory System of CF–FM Bats

Subcortical Specialization

The structure of the auditory system of a bat is basically the same as that of other mammals, but it shows a specialization in a species-specific way, reflecting the properties of its biosonar pulse and echolocation behavior. In particular, *Pteronotus* shows a unique functional organization for processing biosonar information. The width and thickness of the basilar membrane in the cochlea vary along its longitudinal axis, differently from those in primates. An innervation density of auditory neurons to hair cells also varies along the basilar membrane (Figure 2). One of the most striking features is the extremely sharp tuning of the auditory periphery for fine frequency analysis of the CF_2 component at about 61 kHz (about 83 kHz in *Rhinolophus*). Accordingly, auditory nerve fibers are also very sharply tuned to 61 kHz. They can code a 6-Hz frequency shift from 61 kHz, so that they can easily code the small FM of echoes that would be evoked by the wings of flying insects. The CF_2 processing channel is disproportionately large from the cochlea through the auditory cortex.

The other striking feature of the auditory system of *Pteronotus* is the parallel and hierarchical organization to extract certain types of biosonar information by 'combination-sensitive' neurons. All the CF and FM components of the biosonar pulse differ in frequency (Figure 1(a)), so that they are separately analyzed in the cochlea and are sent in parallel into the brain by different auditory nerve fibers. In the CF_{1-3} processing channels, many neurons at higher levels show 'level-tolerant' sharp frequency tuning for further analysis of the CF signals. A level-tolerant tuning curve has a very narrow bandwidth regardless of stimulus level and plays a role in level-tolerant fine frequency analysis. Inhibition in the central auditory system plays many different roles in auditory signal processing. Lateral inhibition, which occurs at different levels of the central auditory system, creates the level-tolerant sharp frequency tuning and amplitude tuning (Figures 3(A)–3(D)). Therefore, some neurons are tuned to a specific combination of frequency and amplitude. Sharpening of frequency-tuning curves by lateral inhibition is most dramatic in the CF_2 processing channel, which mostly projects to the Doppler-shifted constant frequency (DSCF) processing area of the primary auditory cortex (Figure 3(f)).

The parts of the CF_{1-3} processing channels are first integrated in the inferior colliculus for the extraction of velocity information from biosonar pulse–echo pairs. As a result, 'CF/CF combination-sensitive neurons' are produced. They are tuned to a specific combination of pulse CF_1 and echo CF_2 or CF_3, showing strong facilitation when pulse CF_1 is combined with echo CF_2 or CF_3. Their frequency-tuning curves for facilitation are very sharp and level-tolerant (Figure 4(c)). CF_1 is ~36 dB weaker than CF_2 and ~24 dB weaker than CF_3. According to an interpretation, CF/CF neurons extract velocity information from Doppler-shifted CF_2 or CF_3 referring to an emitted CF_1. The CF/CF neurons project to the CF/CF and dorsal intrafossa (DIF) areas in the auditory cortex via the medial geniculate body (Figure 4(d)).

In the FM_{1-4} processing channels, some neurons respond preferentially or selectively to FM sounds. FM sensitivity or selectivity is explained by the sequence of stimulation of excitatory and inhibitory tuning curves by an FM sweep or a neural circuit incorporating 'disinhibition' and/or 'facilitation.' The inferior colliculus has frequency versus latency coordinates. Part of the latency axis is used as delay lines. The parts of the FM_{1-4} processing channels are integrated into the inferior colliculus to create 'FM–FM combination-sensitive neurons' which are tuned to specific echo delays for the extraction of target-distance information from biosonar pulse–echo pairs. The neural mechanisms for creating FM–FM neurons consist of at least four physiological components: phasic/constant latency neurons, delay lines, coincidence detectors, and amplifiers. An FM sound sequentially stimulates an array of neurons tuned to different frequencies by sweeping across their frequency-tuning curves. Phasic/constant latency neurons are suited for coding that moment of the stimulus, that is, for coding the exact timing of the pulse and its echo (i.e., the echo delay). They are mostly created in the subcollicular nuclei, whereas the other three components are created in the inferior colliculus. Delay lines shift the response to the pulse FM_1 in time. A coincidence detector (FM–FM neuron) has two inputs: one input carries nerve impulses evoked by the pulse FM_1 through a delay line, and the other input carries nerve impulses evoked by the echo FM_n ($n = 2$, 3, or 4) without delay lines (Figure 5(b)). An echo always delays acoustically from the pulse

Figure 2 Nerve fiber innervation densities as illustrated by whole-mount preparations of basal and second turns of the cochlea of the mustached bat (A) and a graphic display of neuron density as a function of basilar membrane length (B). (A) The large basal turn (left) and the small second turn (right). Three prominent densely innervated regions (a, c, e) are identified on the basis of the size and density of myelinated nerve trunks. Each of these regions is bounded by sparsely innervated regions (b, d, f). (B) The distribution of the neural density along the cochlea shows peaks which closely correspond to the nerve densities shown in (A). The densities are shown from base (0%) to apex (100%). (A) Reproduced from Henson MM and Henson OW Jr. (1991) Specilizations for sharp tuning in the mustached bat: The rectorial membrane and spiral limbus. *Hearing Research* 56: 122–132, with permission. (B) Reproduced from Zook JM and Leake PA (1989) Connections and frequency representation in the auditory brainstem of the mustache bat, *Pteronotus pamelli. Journal of Comparative Neurology* 290: 243–261, with permission.

emitted by the bat, and the amount of echo delay is linearly related to a distance between the bat and an echo source, for example, a target. At a coincidence detector whose neural delay is equal to an echo delay, the excitatory response to the echo FM_n arrives at the same time as the delayed excitatory response evoked by the pulse FM_1. Then, the facilitation of the auditory response of the coincidence detector (i.e., FM–FM neuron) occurs. FM–FM neurons produced in this way are thus tuned to specific echo delays, that is, specific target distances. They project to thalamic FM–FM neurons, which show stronger facilitative responses to pulse–echo pairs and sharper delay tuning than the collicular FM–FM neurons. These thalamic FM–FM neurons project to the FM–FM, dorsal fringe (DF) and ventral fringe (VF) areas in the auditory cortex (Figure 5(c)). As a consequence of such parallel and hierarchical processing of complex sounds, there are many functional divisions in the auditory cortex (Figure 6).

Figure 3 Sharpening of frequency-tuning curves (A and B) and creation of amplitude tuning (C and D) by lateral inhibition (E) in the Doppler-shifted constant frequency (DSCF) processing channel. (A and C) Frequency-tuning curves (A) and amplitude (intensity)–response (number of impulses) functions (C) of three peripheral neurons (a, b, and c in (E)). The amplitude–response functions are measured with a tone burst at a best frequency of neuron b. The double-headed arrow in (A) indicates that the neurons respond to upward- and downward-sweeping FM sounds with a sweep range shown by the length of the arrow shaft and that the threshold of the response is slightly higher than that to a CF tone at a neuron's best frequency. The horizontal bar in A indicates that these neurons respond to a noise burst with a specific bandwidth shown by the bar length and that the threshold of the response is slightly higher than those to the FM sounds. (B) A subcortical neuron (d in (E)) has a level-tolerant sharp frequency-tuning curve sandwiched between inhibitory-tuning curves (shaded) as a result of lateral inhibition from neurons a and c in (E). Neuron d is tuned to a specific combination of a best frequency (BF) and a best amplitude (BA) because of the overlapping inhibitory areas. (D) The amplitude–response function measured with a tone burst at the BF of neuron d is highly nonmonotonic. The double-headed arrow and horizontal bar in (B) indicate that neuron d shows very high thresholds to FM sounds and noise bursts and does not respond to them. (E) Neural circuit for lateral inhibition. The arrow- and bar-heads represent excitatory and inhibitory synapses, respectively. (F) In the DSCF area of the auditory cortex, each cortical column is characterized by a specific combination of BF and BA for the excitation of neurons (vertical arrows). With an oblique electrode penetration, both BF and BA systematically vary (oblique arrow). It has the frequency-versus-amplitude coordinates. (D) Based on Suga (1965a, 1965b, 1969, 1973). (E, F) Based on Suga (1965b, 1977) and Suga and Manabe (1982).

Cortical Specialization

In the primary auditory cortex of *Pteronotus*, high-frequency-sensitive neurons are located anteriorly and low-frequency-sensitive neurons are located posteriorly. Part of the auditory cortex has binaural bands which consist of either excitatory–excitatory neurons (EE; excitatory inputs from both ears) or excitatory–inhibitory neurons (EI; an excitatory input from one ear and an inhibitory input from the other ear). The EE band is callosally connected, but the EI band is not. Therefore, the auditory cortex of *Pteronotus* shares its functional organization with that of the cat and ferret. However, the auditory cortex of the mustached bat shows at least four unique aspects: (1) About 30% of the auditory cortex (called the DSCF area) is devoted to the representation of 60.6–62.3 kHz sound, although the total range of frequency representation in the auditory cortex is from 7 to 120 kHz (Figure 6(b)). Neurons in the DSCF area are combination-sensitive. (2) Another 30% of the auditory cortex (called the CF/CF and FM–FM areas) is primarily devoted to extract target velocity and range information from a biosonar pulse–echo pair by comparing the two signal elements. (3) The auditory cortex shows multiple representations of information-bearing elements such as velocity and range. (4) The auditory cortex shows no hemispheric asymmetry for biosonar signal processing, but appears to show asymmetry for processing communication calls. The DSCF, CF/CF, and FM–FM areas are highly specialized for

Figure 4 Neural mechanisms for creating Doppler-shift (velocity) axis in the CF/CF velocity-processing channel. Triangular frequency-tuning curves at the periphery (a) are changed into level-tolerant sharp frequency-tuning curves in the subthalamic auditory nuclei by lateral inhibition (b). Then, the CF_1 and CF_2 or CF_3 channels are integrated in the inferior colliculus to create two types of velocity-tuned CF/CF combination-sensitive neurons: CF_1/CF_2 and CF_1/CF_3 (c). The CF/CF neurons show a strong facilitative response to a specific combination of CF_1 and CF_n in the frequency domain. These neurons project to the CF/CF area in the auditory cortex and form the CF_1/CF_2 and CF_1/CF_3 subdivisions (d). In each subdivision, a cortical column is characterized by a specific combination of two frequencies (vertical arrows). Each subdivision has frequency-versus-frequency coordinates, in which relative target-velocities from –2 to 9 ms are systematically mapped (oblique arrow) (Suga et al., 1983a). See **Figure 3(B)** for the horizontal bars and double-headed arrows (Suga, 1965b).

the processing of biosonar information. The functional organization of these areas is described in the following paragraphs.

Neurons in the DSCF area are tuned to specific frequencies and amplitudes and form 'frequency-versus-amplitude coordinates' (i.e., tonotopic vs. ampliotopic representations). The frequency-tuning curves of the great majority of DSCF neurons are extremely sharp and level tolerant, that is, the widths of the tuning curves are narrow, even at high stimulus levels. Therefore, they are suited for level-tolerant frequency (velocity) discrimination. Both level-tolerant frequency tuning and amplitude selectivity result from lateral inhibition that occurs in the subcortical auditory nuclei. The frequency representation in the DSCF area is extremely fine. Inactivation of this area reversibly impairs the bat's ability to detect fine frequency differences (0.08–0.8%), but not its ability to detect differences larger than 3%. The DSCF area represents the frequency and amplitude modulations of echoes from a flying insect by the spatiotemporal pattern of neural activity occurring in its frequency-versus-amplitude coordinates. DSCF neurons are FM_1–CF_2 combination sensitive and, perhaps, provide information to the bat for maintaining appropriate distances from background objects for optimal hunting.

Neurons in the CF/CF area respond poorly to biosonar pulses and Doppler-shifted echoes when presented alone, but show a remarkable facilitative response to a pulse–echo pair. The essential elements in the pair are the CF_1 of the pulse and the CF_2 or CF_3 of the echo. For maximum facilitation, a specific frequency relationship between the two CF signals is required regardless of stimulus levels, because the majority of CF/CF neurons show level-tolerant sharp frequency tuning for facilitation. They are tuned to specific amounts of Doppler shifts, that is, relative target velocities. CF_1/CF_2 neurons are clustered dorsally and CF_1/CF_3 neurons are clustered ventrally (**Figure 6(b)**). The CF_1/CF_2 and CF_1/CF_3 subdivisions each have frequency-versus-frequency coordinates for the systematic representation of target velocities from 9 to –2 m s^{-1}. About one-third of CF/CF

Figure 5 Neural mechanisms for creating delay-tuned neurons and a delay (range) axis in the FM–FM range-processing channel. Delay-tuned neurons utilize delay lines (0.4–18 ms long) that are mostly created at inferior collicular neurons tuned to frequencies swept by FM_1 (top portion of (b)). The delay-tuned neurons do not use delay lines created at neurons tuned to frequencies swept by FM_n ($n = 2$, 3, or 4) (bottom portion of (b)). The filled triangles in (a) and (b) are neural responses. An array of delay-tuned neurons in the inferior colliculus receives signals from the neurons responding to either FM_1 or FM_n channels (right portion of (b)). In a delay-tuned neuron (circle with the X) where an echo (EFM_n) delay from the pulse (PFM_1) is equal to the delay line associated with it, the signals from FM_1 and FM_n arrive at the same time. Then, the neuron shows a strong facilitative response. The neuron acts as a coincidence detector and multiplier. Three types of collicular delay-tuned neurons separately project to the FM–FM area of the auditory cortex through the thalamus, forming three subdivisions within the FM–FM area (c). Each subdivision of the FM–FM area shows columnar organization characterized with a specific echo delay, that is, best delay (BDe) for the excitation of neurons (vertical arrows). It has an echo delay axis from 0.4 to 18 ms (i.e., range axis). For simplicity, phasic-on response (onset detector), amplitude tuning, and FM sensitivity are not included in this model. Adapted from Suga (1990).

neurons show phase-locked responses to the periodic frequency modulations of the echo CF component that would be evoked by the wings of a flying insect when the biosonar pulse is paired with a Doppler-shifted echo. As for DSCF neurons, CF/CF neurons are tuned in amplitude as well as in frequency. However, amplitotopic representation is not known in the CF/CF area. CF_1/CF_2 and CF_1/CF_3 neurons are also clustered in the DIF area (Figure 6(b)). These CF/CF neurons are tuned to unusually high speed, if the interpretation is correct.

Neurons in the FM–FM area respond poorly or not at all to either a biosonar pulse or echo alone, but show a strong facilitative response to a pulse–echo pair with a specific echo delay, the essential elements being the FM_1 of the pulse and one of the $FM_{2–4}$ components of the echo. FM–FM neurons are tuned to specific echo delays, that is, target ranges. FM_1–FM_2, FM_1–FM_3, and FM_1–FM_4 neurons are separately clustered, so that the FM–FM area consists of three subdivisions (Figure 6(b)). Each subdivision has an echo-delay axis from 0.4 to 18 ms for the systematic representation of 7- to 310-cm target ranges (range axis). About 25% of FM–FM neurons are tuned to echo delays shorter than 4 ms (69-cm target range) and respond vigorously to each pulse–echo pair delivered, even at a rate of 100 s^{-1}. Therefore, the FM–FM area is involved in information processing even during the terminal phase of echolocation. Reversible inactivation of the FM–FM area temporarily impairs the bat's ability to detect a small difference in echo delay.

FM–FM neurons are tuned not only to specific echo delays but also to specific echo amplitudes. Therefore, they would respond best to targets of specific cross-sectional areas at specific distances. FM_1–FM_4 neurons are theoretically better suited for fine characterization of small targets than FM_1–FM_2 neurons, because FM_4 has a much shorter wavelength and broader bandwidth than FM_2. Therefore, the distribution of neural activity perpendicular to the range axis on the cortical plane represents the amplitude spectra of all FM components of an echo, which are directly related to target characteristics such as shape and size.

The three types of FM–FM neurons (FM_1–FM_2, FM_1–FM_3, and FM_1–FM_4) are also clustered in the DF and VF areas (Figure 6(b)). The DF area is smaller than the FM–FM area and consists of three clusters of

Figure 6 The functional organization of the auditory cortex of the mustached bat. (a) Dorsolateral view of the left cerebral hemisphere and the branches of the median cerebral artery (mca). The long branch is on the fossa. The ascending and descending auditory pathways are indicated by the arrows. The auditory cortex consists of several electrophysiologically distinct areas. (b) The frequency (tonotopic) representation of the primary auditory cortex (AIa, DSCF, and AIp) and the functional organization of the other areas are indicated by lines and arrows. The DSCF area has axes representing target-velocity information (echo frequency: 60.6–62.3 kHz) and subtended target-angle information (echo amplitude: 13–98 dB SPL). It consists of two subdivisions suited for either target detection (shaded) or target localization (unshaded) which are occupied mainly by EE or EI neurons. Neurons in the DSCF area are sensitive to an FM_1–CF_2 combination. The FM–FM area consists of three major types of FM–FM neurons (FM_1–FM_2, FM_1–FM_3, and FM_1–FM_4), which form separate clusters. Each cluster has an axis representing target ranges from 7 to 310 cm (echo delay: 0.4–18 ms). The CF/CF area consists of two major types of CF/CF neurons (CF_1/CF_2 and CF_1/CF_3), which are also found in separate clusters. Each cluster has two frequency axes and represents a target velocity from –2 to $+9\,m\,s^{-1}$ (echo Doppler-shift: –0.7 to +3.2 kHz for CF_2, and –1.1 to +4.8 kHz for CF_3). The DIF area also contains two types of CF/CF neurons. The DF area also consists of the three clusters of FM–FM neurons, and has an axis representing target ranges from 7 to 140 cm. The VF area also contains FM–FM neurons, and represents target ranges up to 80 cm. The DM area has an axis representing the azimuthal location of the target on the contralateral side in front of the animal. This azimuthal representation is incorporated with frequency representation. The functional organization of the DP, VA, VM, and VP areas remains to be studied further. AC, auditory cortex; CBL, cerebellum; CER, cerebrum; CN, cochlear nucleus; DM, dorsomedial area; IC, inferior colliculus; MGB, medial geniculate body; NLL, nucleus of lateral lemniscus; P.p.p, *Pteronotus parnellii parnelli*; SOC, superior olivary complex; sti., stimulation; VA, ventroanterior; VM, ventromedial area; VP, ventroposterior. Adapted from Suga N (1984) The extent to which biosonar information is represented in the bat auditory cortex. In: Edelman GM, Gall WE, and Cowan WM (eds.) *Dynamic Aspects of Neocortical Function*, pp. 315–373. New York: Wiley.

Figure 7 Parallel and hierarchical processing of different types of biosonar information carried by complex biosonar signals. The eight components (CF_{1-4} and FM_{1-4}) of the biosonar pulse and its echo are analyzed at different locations on the basilar membrane in the cochlea (bottom). These signal elements coded by auditory nerve fibers are sent up to the auditory cortex (AC) through a number of auditory nuclei (left margin): cochlear nucleus (CN), superior olivary complex (SOC), nucleus of lateral lemniscus (NLL), inferior colliculus (IC), and medial geniculate body (MGB). During the ascent of the signals, frequency selectivity is increased in some neurons, and amplitude, constant-frequency (CF), and frequency-modulation (FM) selectivities are added to some neurons (arrows with a star). Each star indicates that the addition of selectivity takes place in the auditory nuclei and cortex as well as in the nucleus where the arrow starts. The CF_2 channel is associated with a sharply tuned local resonator and is disproportionately large. It projects to the DSCF area of the AC. In certain portions of the IC, two channels processing different signal elements (e.g., CF_1 and CF_n or FM_1 and FM_n; $n = 2$, 3, or 4) converge to produce two major types of combination-sensitive neurons: velocity-tuned CF/CF neurons and delay-tuned FM–FM neurons. Velocity-tuned neurons project to the CF/CF area of the AC, where target-velocity information is systematically represented (left top). Velocity-tuned neurons also cluster in the DIF area. Delay-tuned neurons project to the FM–FM, DF, and VF areas of the cortex where target-range information is systematically represented (center top). The delay lines utilized by them are mostly created in the inferior colliculus. The DSCF area has frequency-versus-amplitude coordinates for systematic representation of the properties of an echo CF_2 and consists of two subdivisions, mainly containing excitatory–inhibitory (EI) or excitatory–excitatory (EE) binaural neurons (right column). Intraural intensity difference- or intraural time difference-tuned neurons (ITD, IID) are created in the SOC. The superior colliculus (SC) has a cluster of 3D-tuned neurons. Revised from Suga (1988).

FM–FM neurons as in the FM–FM area. Each cluster has an echo delay axis up to 9 ms for systematic representation of target ranges up to 155 cm. The VF area is much smaller than the DF area and has an echo delay axis up to 5 ms for systematic representation of target ranges up to 86 cm.

The parallel and hierarchical processing of biosonar information has been best explored in *Pteronotus* (Figure 7). DSCF, CF/CF, and FM–FM neurons are undoubtedly specialized for the feature extraction from biosonar signals. However, they also respond to certain types of communication sounds which are comparable to biosonar signals, but contain a first harmonic much stronger than that of the biosonar pulses.

The Auditory System of FM Bats

Eptesicus and *Myotis* are so-called FM bats. Their auditory cortices have no areas comparable to the DSCF, CF/CF, and FM–FM areas of *Pteronotus*. Their auditory systems, however, also create neurons tuned to behaviorally relevant values of parameters characterizing biosonar signals through excitatory (facilitatory)–inhibitory interactions taking place at different

subcortical levels of the auditory system. All of the neurons discussed in the following list are frequently found in the inferior colliculus and above.

1. *Latency-constant, phasic on-responding neurons*. Clustered in the 'columnar' region of the ventral nucleus of the lateral lemniscus, they can mark the onset time of the emitted pulse and may be used for the processing of target-distance information carried by echo delays.
2. *Paradoxical latency-shift neurons*. Their response latency is long for a strong sound, but shifts short for a weak sound. When the strong sound (e.g., emitted biosonar pulse) is followed by the weak sound (e.g., echo) with a time delay equal to the latency shift, the excitation evoked by the weak sound superimposes on that evoked by the strong sound and evokes a strong facilitative response. Therefore, the paradoxical latency-shift neurons are suited for processing target-distance information carried by an echo delay.
3. *Duration-tuned neurons*. They are mostly tuned to short durations like biosonar pulses. In the auditory cortex, neurons with short best durations are ventrally located to those with long best durations.
4. *FM-sensitive or-specialized neurons* (*simply, FM neurons*). For the excitation of FM neurons, the direction, sweep rate, and duration of FM sounds are important. Short FM sounds similar to the biosonar pulses are best for exciting them.
5. *Delay-tuned neurons*. They are different from the delay-tuned neurons of the CF–FM bats, because they are sensitive to the combination of FM_1–FM_1. An echo-delay map has not yet been found in the FM bats.
6. *Level-tolerant, sharply frequency-tuned neurons*. They are tuned not only in frequency but also in amplitude. During the search phase of echolocation, *Eptesicus* lengthens its biosonar pulse by adding a quasi-CF component to the end of the FM pulse to optimize target detection. The analysis of the quasi-CF component by level-tolerant, sharply frequency-tuned neurons is suited for enhanced target detection.
7. *FM or AM rate-tuned neurons*. They may be suited to respond to the repetitive biosonar signals during target-directed flight and/or FM or AM sounds which are commonly found in the communication calls of some bats.

Signal Processing for Sound Localization

As with other mammals, bats can use interaural intensity differences (IIDs) and interaural time differences (ITDs) for the localization of a sound (echo) source in azimuth, and the 'pinna–tragus' (or simply 'pinna') cue for the localization of the sound source in elevation. The pinna cue is a spectral notch (or notches) created by interference between sound waves directly incidenting on the eardrum and indirectly incidenting on it through the reflection by the pinna and tragus. The large pinna of the bat amplifies sound waves and facilitates sound localization. The pinna cue perhaps starts to be processed in the cochlear nucleus, whereas the binaural cues start to be processed in the lateral and medial superior olivary nuclei. IID is the primary cue to localize high-frequency sounds. It is encoded by 'EI' neurons that are excited by one ear stimulation and inhibited by the other ear stimulation. This binaural interaction makes the EI neurons sensitive to IIDs: their response magnitude drastically changes as a function of IID, that is, of azimuthal location of a sound source. They are not tuned to a specific azimuth degree. Instead they quickly increase their response, reaching a plateau, when a sound source is moved laterally from front 0°. The cut-off azimuth degree at which the response reaches the plateau differs from neuron to neuron. The EI neurons are first created in the lateral superior olivary nucleus and project to the inferior colliculus. Neurons in the dorsal nucleus of the lateral lemniscus (DNLL) are inhibitory and are EI. They bilaterally project to the inferior colliculus. DNLL neurons either modify collicular EI neurons or create EI neurons in the inferior colliculus. In the inferior colliculus, EI, EE (binaurally excited), and EO (monaural) neurons are separately clustered. EE neurons are most sensitive to a sound source at front 0°.

The inferior colliculus projects to the superior colliculus where visual, auditory, and somatosensory signals are integrated and where sensory–motor interface occurs. The superior colliculus plays an important role in head and pinna orientation. It contains neurons tuned to a specific combination of azimuth and elevation ('2D neurons') and those tuned to a specific combination of echo delay, azimuth, and elevation ('3D neurons'). The 2D neurons are located throughout the superior colliculus, whereas the 3D neurons are located in the anterior half and near the midline. EI, EE, and 2D neurons exist in all mammalian brains and are not unique to bats; however, 3D neurons are found only in the bat brain.

In the auditory cortex of the *Eptesicus* and *Pteronotus*, low-frequency-tuned neurons are sensitive to more laterally located sound sources, whereas high-frequency-tuned neurons are sensitive to more medially located ones. Therefore, the frequency (tonotopic) axis is also the azimuthal axis. EI and EE neurons are separately clustered in the DSCF area of the auditory cortex.

Protection of Biosonar Information Processing from Jamming by Biosonar Pulses of Conspecifics

Bats, such as the mustached bat, live in large colonies. Consequently, one important problem faced by individual bats is how to protect their echolocation system from the jamming effect of biosonar pulses emitted by conspecifics. Bats' echolocation is hardly ever jammed by sounds delivered from multiple loudspeakers. There are several possible mechanisms that could work in combination to reduce jamming: (1) the sharp directionality of biosonar pulses, (2) the sharp directional sensitivity of the ear and binaural hearing, (3) the signature of biosonar pulses and the personalized auditory system, (4) an auditory time gate for processing echoes, (5) heteroharmonic sensitivity, (6) variation in emitted signals and the sequential processing of echoes, and (7) efferent copy originating from the vocal system. Items (4) and (5) are unique and are related to the response properties of FM–FM and CF/CF neurons (Figures 4 and 5). These mechanisms are explained in the following paragraphs.

CF/CF and FM–FM neurons do not respond or poorly respond to echoes which delay by more than 20 ms from the emitted pulse. That is, they have an auditory time gate for processing velocity or distance information by comparing the higher harmonics of the Doppler-shifted echo with the first harmonic of an emitted pulse. The first harmonic (CF_1 and FM_1) is the weakest component (Figure 1(a)). It has less than 1% of the total energy of the emitted pulse. However, it is used as the reference to measure relative velocity and distance of a target.

Why does the auditory system create such heteroharmonic-sensitive neurons instead of homoharmonic-sensitive neurons such as CF_2/CF_2 and FM_2–FM_2? Let us consider the situation in which hundreds of bats are flying in a cave and the first harmonic of their pulses is completely suppressed by the antiresonance of the vocal tract. Then, in the air, there are many second, third, and fourth harmonics produced by conspecifics. The combinations of these harmonics cannot excite the heteroharmonic-sensitive FM–FM and CF/CF neurons because the first harmonic is absent. When the animal itself emits pulses, however, the first harmonic is present at the larynx and stimulates both of the ears by bone conduction. The FM–FM and CF/CF neurons are then turned on by the first harmonic to process target-distance and velocity information, respectively. In this way, the neural computation of biosonar information in the auditory system is protected from the jamming that would otherwise be caused by the sounds emitted by many conspecifics flying nearby.

Corticofugal Feedback for Auditory Signal Processing

The parallel and hierarchical processing of auditory signals in the ascending auditory system greatly depends on the descending (corticofugal) auditory system, which forms multiple feedback loops (Figure 7). The corticofugal system modulates subcortical neurons for sharpening and shifting of neural tuning curves in the frequency, amplitude, time, and spatial domains and plays a key role in reorganization (plasticity) and, therefore, organization of the auditory system. In the DSCF and FM–FM processing channels of the mustached bat, inhibition is strong so that corticofugal modulation is different from that in the big brown bat, rodents, and cats.

Electrical Perception and Communication

Introduction

Electric Fishes

This article concerns electrical communication in fish, an unusual modality of communication found only in fishes that are capable of both generating and receiving weak electric signals in water. Electrogenesis in fish arose independently in six groups of marine or freshwater fishes (Table 1). Electric organs are derived from modified muscle or nerve cells. Some of these fish are strongly electric and have been known since antiquity; others are weakly electric and went unnoticed until the 1950s. Communication is most highly developed among weakly electric fishes.

Occurrence of Electroreceptors

For electric communication to occur, an electric fish must have the ability to sense electric signals in water. The electric sense was discovered in only 1961 but has since been found among most primitive orders of fishes, even those that do not possess electric organs. There is good evidence for electroreception in lampreys, sharks, rays, sawfishes, chimeras, lobe-finned fishes, and primitive ray-finned fishes including the bichirs, polypteriformes, sturgeons, and paddlefishes. It may have been present in many extinct groups of fishes. However, this special 'sixth sense' does not occur in most species of modern ray-finned fishes (bowfins, gars, and teleosts) except for two separate phylogenetic lineages or clades of teleosts: the catfishes worldwide plus gymnotiforms of South America and the notopterid plus mormyriform fishes from Africa. In the gymnotiforms and mormyriforms, a novel submodality of tuberous electroreceptors evolved independently. Tuberous sensors are physiologically adapted for detecting high-frequency components of electric organ discharges (EODs). One strongly electric teleost group, the Uranoscopidae, lacks electroreceptors altogether.

The Signaling Environment and Signal Transmission

Electric communication is restricted to aquatic environments where the conductivity of the medium is sufficient to transmit electric signals. When the signaler discharges its electric organ, a dipole-shaped electric field causes current to flow through the water parallel to the electrostatic field lines. Currents are strongest near the source and diminish rapidly with distance. Electric signals are detected by distant receivers as current passes through the electroreceptors embedded in the skin (Figure 1).

Advantages of Electric Communication

Electric communication in fish is used for a variety of behavioral functions, including advertisement of species, gender, and individual identity; courtship; aggression; threat; alarm; and appeasement. Although these are the same functions as acoustic, vibratory, visual, or chemical signals, the special physical constraints on the electric modality have resulted in the evolution of unique design features which have shaped the form of signals, the mechanisms for their reception, and their function.

Little is known of electric communication among the Torpedo rays, the electric skates, the malapterurid catfishes of Africa, or the several groups of catfishes with weak electric discharges (Mochokidae, Clariidae). Although fish in these taxa emit both weak and strong discharges in social contexts, they also do so in isolation, during prey capture and defense. The signals are irregular and difficult to study. Little is known about the social context and behavioral consequences of signals. Most of the information about electric communication comes from studies of gymnotiform and mormyriform fishes (Figures 2 and 3), in which the communication modality is highly complex and well developed.

Dual Functions

Fishes that communicate electrically also use electroreception for detecting objects in the environment, sensed as distortions in the self-generated fields from their own organs. The dual functions of 'electrolocation' and communication help explain the adaptive significance of weak electric organs, which must have been intermediate stages in the evolution of more-powerful electric organs used for prey capture and defense.

Electric Signal Production and Signal Transmission

Electric Organs

Electric organs (Table 1 and Figure 2) are specialized for generating electric currents outside the animal's body. They are usually located in the fish's tail, which prevents current shunting by the body tissues and maximizes signal range. Electric organs are composed

Table 1 The six known groups of electric fishes, arranged taxonomically

Electric fishes	*Picture*
Rajiformes (electric skates): marine, worldwide Rajidae (weak, pulse discharges, ampullary receptors) (14 genera, 200 species) including *Raja*, all with electric organs	Torpediniformes (electric rays): marine, worldwide Narcinidae (strong, pulse discharges, ampullary receptors) (9 genera, 24 species) including *Narcine* Torpedinidae (strong, pulse discharges, ampullary receptors) (2 genera, 22 species) *Hypnos, Torpedo*	Mormyriformes (African electric fishes): sub-Saharan Africa and Nile River Gymnarchidae (weak, wave discharges, ampullary ND tuberous electroreceptors) (1 genus, 1 species) *Gymnarchus*	
Mormyridae (weak, pulse discharges, ampullary and tuberous electroreceptors) Petrocephalinae (1 genus, 30 species) *Petrocephalus*	Mormyrinae (16 genera, 177 species) *Boulengeromyrus*, *Brienomyrus*, *Campylomormyrus*, *Genyomyrus*, *Gnathonemus*, *Heteromormyrus*, *Hippopotamyrus*, *Hyperopisus*, *Isichthys*, *Ivindomyrus*, *Marcusenius*, *Mormyrops*, *Mormyrus*, *Paramormyrops*, *Pollimyrus*, *Stomatorhinus*	Gymnotiformes (neotropical electric fishes): South and Central America Apteronotidae (weak, wave discharges, ampullary and tuberous electroreceptors) (15 genera, 54 species): *Adontosternarchus*, *Apteronotus*, *Compsaraia*, *Magosternarchus*, *Megadontognathus*, *Orthosternarchus*, *Parapteronotus*, *Pariosternarchus*, *Platyurosternarchus*, *Porotergus*, *Sternarchella*, *Sternarchogiton*, *Sternarchorhamphus*, *Sternarchorhynchus*, *Tembeassu*	
Gymnotidae (strong, weak, pulse discharges, ampullary and tuberous electroreceptors) (2 genera, 33 species): *Electrophorus*, *Gymnotus*	
Hypopomidae (weak, pulse discharges, ampullary and tuberous electroreceptors) (7 genera, 16 species): *Brachyhypopomus*, *Hypopomus*, *Hypopygus*, *Microsternarchus*, *Steatogenys*, *Stegostenopos*	
Rhamphichthyidae (weak, pulse discharges, ampullary and tuberous electroreceptors) (3 genera, 15 species): *Iracema*, *Gymnorhamphichthys*, *Rhamphichthys*	
Sternopygidae (weak, wave discharges, ampullary and tuberous electroreceptors) (5 genera, 30 species): *Archolaemus*, *Distocyclus*, *Eigenmannia*, *Rhabdolichops*, *Sternopygus*

Table 1 Continued

Electric fishes	*Picture*
Siluriformes (catfishes): Africa Malapteruridae (strong, pulse discharges, ampullary receptors) (two genera, 18 species) *Malapterurus*, *Paradoxoglanis*	Mochokidae (weak, pulse discharges, ampullary receptors; one genus known to be weakly electric, at least three species with weak electric discharges) *Synodontis*	Clariidae (weak, pulse discharges, ampullary receptors; one genus known to be weakly electric, at least one species) *Clarias*	
Perciformes (Stargazers)marine Uranoscopidae (strong, pulse discharges, electroreception absent; two genera, unknown number of species) Astroscopus (three species), *Uranoscopus*	

Each of the species in this list is capable of either weak or strong electrogenesis using specialized electric organs (indicated in red). Some of the electrogenic species have weak electric discharges, and others have strong electric discharges, as indicated. Weak, weak electric organ discharge (EOD); strong, strong EOD; wave, wave-discharging species; pulse, pulse-discharging species.

of cells called electrocytes, derived from nerve or muscle. Weak or strong discharges are produced by the synchronized action potentials from hundreds or thousands of cells acting in series and in parallel. The discharge is initiated in the command nucleus in the medulla and transmitted via a medullary relay nucleus to the electromotor nucleus in the spinal cord. Electromotor neurons innervate the individual electrocytes in the electric organ. For Apteronotid fishes, the electric organ is neural in origin and is simply composed of the spinal electromotor neurons which are anatomically specialized. The discharges of individual electrocytes summate when they are arranged in series, and the currents from individual cells summate when they are arranged in parallel. The voltage of the electric eel, *Electrophorus electricus*, can be an astonishing 500–600 V at the peak of the pulse discharge because of the linear summation of thousands of electrocytes in series. Most of the gymnotiforms and mormyriforms generate only weak discharges of about 10 V – sufficient for short-range communication and active electrolocation but not for prey capture or defense. The discharges of a few notable large mormyrids such as *Mormyrus* and *Mormyrops* can be felt by humans, but most cannot. The discharges were unknown until 1951, when Hans Lissmann from Cambridge University, using electronic amplifiers, discovered continuous 300–500 Hz wavelike discharges emanating from the tail of *Gymnarchus niloticus*, a mormyriform (Figure 2). Several years later, Lissmann demonstrated that this fish could electrolocate objects in its environment if the objects differed in conductivity from the surrounding water. By the 1960s, MVL Bennett, H Grundfest, C Coates, A Fessard, and others had documented EOD diversity in fishes, and T Szabo and TH Bullock and colleagues had made the first electrophysiological recordings from electroreceptors in weakly electric fish. By the 1970s, P Black-Cleworth, P Moller, B Kramer, W Harder, C Hopkins, M Westby, J Bastian, C Bell, TH Bullock, W Heiligenberg, and others had provided strong evidence for the existence of electric communication in weakly electric fishes. Today, researchers working in Africa and South America and in laboratories continue to search for new species, novel signals, and distinctive patterns and functions for electric communication. Neurobiologists have discovered novel mechanisms for electrogenesis and its control, as well as important general mechanisms of information processing and sensory–motor

Figure 1 In electric communication, one individual, the signaler, S, generates an electric organ discharge by firing its electric organ, usually located in the tail. This generates a nonpropagating electrostatic field around the fish in three dimensions, approximating the electric field from a dipole. Electric current is sensed by the receiver, R, at a distance, using electroreceptors embedded in its skin. Signalers use pulse waveforms to advertise their gender, age class, and species, and they use patterns of discharges to threaten, show submission, approach, or court other fish.

Figure 2 Electric fish, electric organs, and electric organ discharges (EODs) of a mormyrid fish, *Brienomyrus* sp. (top); a mormyriform, *Gymnarchus niloticus* (middle); and a gymnotiform, *Brachyhypopomus pinnicaudatus* (bottom). *Brienomyrus* and *Brachyhypopomus* are both pulse-discharging species whereas *Gymnarchus* is a wave-discharging species. The center column shows histological sections of the electric organ for *Brienomyrus* and *Gymnarchus* and cleared and stained whole mount of Sudan black-stained electrocytes of *Brachyhypopomus*. The EODs are recorded head positive upward in each case. Photo of *Gymnarchus* by Masashi Kawasaki; photo of *Brachyhypopomus* electric organ by JP Sullivan.

integration. Although unusual, electric fish have become an important model system in neuroethology.

The Nature of Electric Signals

There are two components of the electric discharge signals of fish (Figure 4). The first is the stereotyped waveform of the electric organ discharge (EOD), which is fixed for an individual but varies between individuals, genders, and species. The second is the sequence of pulse intervals (SPI), which is generated by the pacemaker or command nucleus in the medulla. Complex neural networks in the midbrain and thalamus modulate activity in the command nucleus, producing the patterns used for communication displays. Both EODs and SPIs are important for this function. EODs are especially important for tonic advertisement of identity, and SPIs are key elements of threats, alarm signals, courtship patterns, and signals of submission. Some patterns and processes that generate them are summarized below.

Figure 3 Electric organ discharge (EOD) waveform diversity of mormyrid fishes from the Ogooué and Ivindo River basins of Gabon, West Central Africa. A single EOD waveform typical of the species is shown for each of 21 species. From Sullivan JP and Hopkins CD (2001) Quand les poissons apportent leur pierre et leurs signaux électriques. *Canopée Bulletin sur l'Environment en Afrique Centrale* 19: 17–20.

Signal Transmission: The Geometry of Electric Fields in a Volume Conductor

EODs are transient pulses with durations ranging from 100 μs to 20 ms. They produce nonpropagating electrostatic fields, not propagating electromagnetic waves. This feature contrasts with acoustic communication, in which signals propagate as waves with a finite velocity, generating echoes and reverberations. Electric signals are transmitted instantaneously, with no echoes. Geometric spreading in electrogenesis also differs from sound. Acoustic signal intensity decreases according to the inverse square of distance from the source; electric field magnitude decreases according to the inverse cube of distance.

Figure 5 shows isopotential contours surrounding the gymnotiform *Eigenmannia* at one phase of its EOD cycle. The potential reverses sign at the midplane between the two poles of the electric organ. The electric field, which is computed as the vector derivative of potential, follows a circular arc from positive to negative pole, declining in magnitude in proportion to the inverse cube of distance from the dipole center.

With movable mutielectrode arrays, EOD fields can now be digitally mapped in both time and space. *Eigenmannia* produces a very simple electric field which closely approximates an oscillating dipole with one pole located at the midpoint of the body, the other at the tip of the tail (Figure 6). The location of the

Figure 4 There are two components to electric signals from fish: the fixed electric organ discharge (EOD) waveform and the variable sequence of pulse intervals (SPI). (a) The EOD of *Brienomyrus brachyisitus*, a mormyrid, is an invariant three-phase waveform shown with head-positivity upward. Calibration is in milliseconds. (b) The EOD is generated in the electric organ, which consists of four parallel columns of approximately 100 electrocytes located in the caudal peduncle. (c) The SPI is shown both as a sequence of pulses (upper trace) and as a plot of interpulse interval versus time (lower). (d) The SPI is generated in a command nucleus (CN) in the medulla and sent to the electric organ via the medullary relay nucleus (MRN), and then to the spinal electromotor nucleus. SPIs are highly variable in mormyrids. Other brain structures seen from the side: T, telencephalon; OB, olfactory bulb; OT, optic tectum; Valv., valvula of cerebellum; PLLN, posterior branch of the lateral line nerve, which carriers electroreception to the brain.

poles remains constant throughout the EOD cycle. Other species of gymnotiform fishes are spatially and temporally more complex. *Apteronotus leptorhynchus* generates an electric dipole that appears to propagate from the head to tail and then back again during each cycle of the EOD. The electric field vector recorded at a distance rotates once per EOD cycle. The pulse-discharging hypopomid, *Brachyhypopomus*, has a complex multipole EOD with one dipole located in the head and a second in the tail. This pattern is also seen in several species of *Gymnotus* in which the more anterior parts of the organ contain columns of electrocytes with novel innervation that anticipate the firing of electrocytes in the rest of the organ by a fraction of a millisecond. Other pulse-discharging gymnotiforms have 'accessory' electric organs in the head in addition to a main electric organ in the tail. Both organs fire together, but slightly out of phase. One remarkable Hypopomid, *Steatogenys elegans*, has two accessory electric organs composed of parallel columns of approximately 100 electrocytes in superficial grooves on the underside of head. The communicative significance of accessory organs and the spatial patterns that result is unknown.

Active Space

The active space of a communication signal is the volume of space within which a signal evokes a response from a receiver. The following factors determine its size: the amplitude of the signal at the source, the rate of signal decrease due to geometric spreading, the amplitude of masking or background noise in the environment, and the sensitivity of the receiver. Empirical measurements of the active space surrounding a 10–20 cm weakly electric gymnotiform or mormyrid reveal an ellipsoidal volume approximately 1 m in diameter. Electric signaling is limited to short range because of the rapid falloff of signal amplitude with distance. For an electric fish to double the distance of communication, it must increase the magnitude of the discharge at the source eightfold. This brings high costs to communication and places limits on how far an electric fish can signal. Many species of electric fish exhibit energy-conserving adaptations for signaling, including the slowed pulse repetition rates, reduced amplitude, and shortened pulse waveforms during the daytime, when the fish are inactive. Males also reduce their seasonally elongated pulse widths during the nonbreeding season, when they are not displaying to attract females, and they turn their discharges off when hiding. Some fish even maximize the external signal energy by matching the impedance of the electric organ to that of the environment, discussed next.

The Economy of Impedance Matching

The active space of communication is greatly influenced by water resistivity, as might be expected from the Thevenin equivalence theorem, which states that any electrical source can be modeled as an ideal voltage source in series with a fixed internal resistance. In water, the electric organ is under load, so the external resistance which is in series with the internal resistance experiences a voltage drop proportional to resistance. For a fish in high-resistivity water, the external voltage drop will consequently be higher

Figure 5 Isopotential lines (black) and current lines (color) at the peak of the electric organ discharge (EOD) of an *Eigenmannia virescens* seen from above and recorded in the midhorizontal plane of the fish. The lower insert shows 1.5 EOD cycles from the head region with a peak voltage amplitude, A, measured relative to an electrode located at infinity. Values of the isopotential lines indicated in the figure are in millivolts. Adapted from Heiligenberg W (1977) Principles of electrolocation and jamming avoidance in electric fish: A neuroethological approach. In: Braitenberg V (ed.) *Studies in Brain Function*, pp. 1–85. New York: Springer.

Figure 6 The spatial geometry of the electric organ discharge (EOD) potential from the gymnotiform fish, *Eigenmannia virescens*, as seen from above (above) and from the side (below) as measured using a robotic electrode array. The scalar magnitude of the voltage at one phase of the EOD cycle (shown as inset) is plotted as color contours. The spatial pattern of potential resembles that from an electric dipole. One pole is located at the tip of the tail, the other approximately a third of the body length from the end of the tail. The EOD is a wavelike quasi-sinusoidal discharge. The anterior pole goes positive for approximately 1.5 ms, then negative for the remainder of the EOD. The electric field is computed as the gradient of the potential. Current lines run perpendicular to the isopotential lines shown here. From Assad C, Rasnow B, Stoddard PK, and Bower JM (1998) The electric organ discharges of the gymnotiform fishes: II. Eigenmannia. *Journal of Comparative Physiology. A, Sensory, Neural, and Behavioral Physiology* 183(4): 419–432.

than the internal, so that most of the signal is external, not across the skin. In low-resistivity water, most of the voltage drop will be across the skin, not the environment. A fish adapted to high-resistivity water will experience a serious reduction in active space if it is transferred to water with low resistivity.

Some species of electric fish in the gymnotiform family Hypopomidae appear to be adapted to a narrow range of water resistivity (Figure 7). Those found in relatively low-resistivity (high conductivity) water have short but thick caudal filaments containing the electric organ, with five or more longitudinal columns of electrocytes in parallel. These organs have low internal resistance and are good for generating current, even in low-resistance environments. Fish from high-resistivity (low conductivity) water have extremely elongated caudal filaments containing only three longitudinal columns in parallel. These organs have higher internal resistance but also higher voltage capability, and both are adaptations for generating stronger signals in high-resistivity water. Fish from intermediate resistivity water have intermediate-length caudal filaments containing an intermediate number of columns in parallel. These hypopomids thus appear to have evolved electric organs that are impedance matched to their external environment. Since impedance matching appears to involve rigid restructuring of electric organs, a most interesting consequence may be that these fish might confront invisible barriers when they attempt to disperse into river systems that differ in water

Figure 7 Fishes in the genus *Brachyhypopomus* are impedance-matched to the conductivity of their aquatic environment. (a) Outlines of females (F) and males (M) of three different species adapted to differing-conductivity water. (b) Cross sections through the electric organ in the caudal filament for each of the three species (color coded same as text). (c) Number of longitudinal columns of electrocytes for five *Brachyhypopomus* species as a function of the water conductivity of their environment. The fishes in low-conductivity water tend to have long slender tails with many electrocytes in series but few in parallel. Those in high-conductivity water have many electrocytes in parallel but few in series, and those in intermediate-conductivity water have intermediate characteristics. In all three cases, the length and width of the tail is exaggerated in the male compared with the female of the same body size. From Hopkins CD (1999) Design features for electric communication. *Journal of Experimental Biology* 202(10): 1217–1228.

conductivity from that to which their electric organs are most efficiently matched.

Nonpropagated Signals

Because electric communication signals are nonpropagating electrostatic fields, signals are unaffected by the echoes and reverberations that corrupt acoustic signals during transit. Electric receivers, therefore, may be able to make use of precisely encoded properties of signals, including zero crossing times, details in waveforms on a submillisecond timescale, signal polarity, and minor inflection points on signals that might be altered in transit if propagated as a wave. Electric fish exhibit remarkable sensory specializations for encoding, preserving, and recoding the temporal features of communication signals, often with a precision on the order of microseconds.

Since there is no delay to an electric communication signal, receivers will not be able to use signal arrival times at different parts of the body surface to localize electric sources. Nevertheless, research has shown that electric fish can align their body axis parallel to the local electric field vector as an alternative strategy for finding signal sources even if the pathway leading there might be curved.

Noise

The greatest source of environmental electrical noise in the signal bandwidth of electric fish comes from distant lightning activity, which propagates globally over hundreds or thousands of kilometers as electromagnetic waves. The signature clicks, 'chirps', 'tweeks', and other disturbances from lightning can be recorded continuously using dipole electrodes immersed in water. Although there is no evidence that electric fish respond to this noise, quantitative measurements suggest that its magnitude in different environments correlates with the sensory threshold of electroreceptors of the inhabitants. In marine environments, where the magnitude of noise from lightning is 0.01 that found in freshwater, electroreceptor thresholds tend to be 100 times more sensitive than those of freshwater fish. Many resting mormyrid seem to take advantage of this noise, blending into it by discharging at irregular intervals when they are alone and standing out with more regular intervals of discharge in the presence of conspecifics.

Signal Reception

Electric communication depends on sensitive lateral-line-derived electroreceptors located on the head and trunk of certain fishes. These sense organs direct the flow of current through low-resistance canals and through loosely layered patches of epithelial cells to a sensory epithelium where specialized transducer cells carrying voltage-gated ion channels in their cell membranes convert outside electrical stimulation into internal neural responses. Receptor organs filter the stimulus waveform, impart directionality to signal reception, adjust the sensitivity of the receptor, and

ensure that the sensory epithelium is ideally positioned for maximal sensitivity.

Electrosensory cells make synaptic contacts with afferent nerve fibers which project to the electrosensory lateral-line lobes in the medulla via the acusticolateralis or VIIIth nerves. Ampullary receptors are found in every electroreceptive species; tuberous receptors are unique to gymnotiforms and mormyriforms. Receptors resembling tuberous organs were once reported from a species of blind catfish, *Pseudocetopsis*, from South America, but this has not been confirmed physiologically. Figure 8 shows the morphology of ampullary and tuberous electroreceptors in mormyrids, *Gymnarchus*, and gymnotids.

Ampullary Electroreceptors

Ampullary receptors have a sensory epithelium at the base of a blind, mucus-filled, low-resistance canal leading from the external environment. Receptor cells are sensitive to electric stimuli in the range of 0.05–50 Hz. The receptor cells contact tonically active afferent nerve fibers and modulate their firing rate upward or downward depending on stimulus polarity.

Ampullary receptors typically function in the passive electrolocation of predators and prey. For example, sharks and rays detect fish buried in sand by sensing the weak electric fields of a fraction of 1 μV cm^{-1}. In tanks they dig up buried electrodes playing electric potentials from prey. Male round stingrays

Figure 8 Anatomy of ampullary and tuberous electroreceptors in the freshwater teleosts: Gymnotiformes, Mormyrids, and *Gymnarchus*. Ampullary receptors have a highly conducting jelly-filled canal leading from the receptor epithelium at the base of the ampoule to the skin surface; tuberous receptors have a loose plug of epithelial cells over the receptor organ. Mormyromasts have two receptor subclasses, RC_1 and RC_2, which are innervated by separate nerves: two nerve axons innervate RC_1 receptors (also called Type A receptors); one axon innervates RC_2 receptors (Type B). Tuberous receptors function in amplitude coding or in time coding. RC, receptor cells; n, nerve axon; b.m., basement membrane. Adapted from Szabo T (1965) Sense organs of the lateral line system in some electric fish of the Gymnotidae, Gymnarchidae, and Mormyridae. *Journal of Morphology* 117: 229–250 and Hopkins CD (1999) Design features for electric communication. *Journal of Experimental Biology* 202(10): 1217–1228.

(*Urolophus*) use ampullary receptors to find females which produce low-frequency electric signals during ventilation. Electric rays, skates, and catfishes use ampullary receptors to sense conspecific EODs.

In addition to prey sensing, wave gymnotiforms use ampullary organs for sensing brief discharge interruptions (see below). A resting-wave EOD lacks energy in the range of 0.05–50 Hz and will not stimulate ampullary receptors, but during discharge cessations, a residual head-negative offset strongly stimulates them.

Tuberous Electroreceptors

Tuberous organs have an interepidermal cavity lined with sensory-receptor cells but lack an open canal to the exterior. Instead, a plug of loose epithelial cells covers the receptor and behaves like a series capacitor to block direct currents. Tuberous organs are sensitive to stimuli in the range of 100–10 000 Hz and are used for communication and for active electrolocation of objects. They are electrically tuned to the most prominent frequencies of the species-typical EOD (Figure 9). Mormyrid fishes have two types of tuberous organs: Knollenorgans, which are used for communication, and mormyromasts, which are used for active electrolocation (Figures 8 and 9). Gymnotiforms also have two physiological types of tuberous organs (Figure 8), but each is used for both communication and electrolocation. One receptor type is specialized for detecting stimulus amplitude; the other is specialized for timing.

Three lines of evidence suggest that Knollenorgan electroreceptors are used exclusively for communication. First, they have low thresholds, so they are ideally suited for detecting the weak signals from distant fishes; second, the spikes from Knollenorgan afferents are inhibited, or 'blanked,' in the hindbrain by neurons carrying a corollary discharge of the EOD command so that a mormyrid never 'hears' its own EOD on the Knollenorgan pathway; and third, lesions to the nucleus *exterolateralis* in the midbrain, which receives all Knollenorgan receptor inputs, blocks responses to all electric communication signals while having no effect on a fish's ability to electrolocate.

Tuberous receptors are electrically tuned to the peak of the power spectrum of the species-specific EOD waveform both in gymnotiforms and mormyrid fishes (Figure 9).

Figure 9 Tuberous electroreceptors in mormyrids are electrically tuned to frequencies characteristic of the fast Fourier transform (FFT) of the electric organ discharge (EOD). Tuning curves are generated by measuring the spiking threshold of single receptor afferents of Mormyromasts (solid lines) or Knollenorgans (lines with filled symbols in color). Each curve represents a separate electroreceptor. The EOD waveform is shown in the upper left and the FFT power spectrum of the EOD in the upper right. Brienomyrus brachyistius. From Hopkins CD (1983) Functions and mechanisms in electroreception. In: Northcutt RG and Davis RE (eds.) *Fish Neurobiology*, vol. 1, pp. 215–259. Ann Arbor: University of Michigan Press.

Temporal Dimensions of Social Communication Signals

Electric signals have both tonic features, which are invariant for an individual over a period of days, months, or years, and phasic features, which change from moment to moment, depending on social conditions.

Tonic Signals in Electric Communication

An individual's signature EOD, typically a pulse waveform lasting only 1 ms or more, is one example of a tonic signal. It is typically invariant for days or months and serves to advertise the species, sex, and even individual identity of signalers. The EODs from different species diverge from one another (Figure 10). Pulse duration, number of phases or peaks, order polarity of peaks, and characteristic inflection points all contribute to a signaler's signature waveform.

EOD waveforms have communicative significance. Males will court electrodes playing female EODs while ignoring the same electrodes playing male EODs or heterospecific female EODs. They will ignore female EODs played backwards, as well as phase-shifted EODs (Figure 11), suggesting that the precise form of the EOD is important, not the spectrum of the signal. In some genera, such as *Brienomyrus*, *Campylomormyrus*, *Marcusenius*, and *Mormyrops*,

Figure 10 Pulse-discharging species of electric fishes in the families Mormyridae, Gymnotidae, and Hypopomidae all produce electric discharges which have a low duty cycle and variable intervals. Wave-discharging species in the families Apteronotidae, Sternopygidae, and Gymarchidae produce quasi-sinusoidal discharges with high duty cycle and extremely regular interpulse intervals. The waveform of the discharge is shown to the left in each case, and the amplitude spectrum of the discharge is shown to the right. From Heiligenberg W (1977) Principles of electrolocation and jamming avoidance in electric fish: A neuroethological approach. In: Braitenberg V (ed.) *Studies in Brain Function*, pp. 1–85. New York: Springer.

EOD waveforms are highly divergent within close relatives (congeners) living in sympatry. In some species of *Mormyrops* and *Brienomyrus* from Central Africa, EODs may even be polymorphic, exhibiting more than one stable EOD type within a population.

Of course the EOD waveform is also used for active electrolocation of objects, so its properties may be adapted to navigation as well as to advertisement and identification. Consider, for example, that many mormyrid fish sense the electrical capacitance of objects, and the duration of the EOD waveform duration sets the range of capacitances over which they are sensitive. By adopting an EOD waveform with a short rather than a long duration, a fish may be better at detecting low-capacitance objects. Consider also that most mormyriforms and gymnotiforms produce pulse discharges in which positive and negative phases of the EOD are balanced so that there is very little signal energy below 10 Hz. This appears to be an important adaptation for avoiding exposure to predatory catfishes, which have ampullary electroreceptors sensitive to low-frequency or DC components of signals. For electrolocation, which must function continuously, electric fish must avoid signals with DC components, but for communication displays which are infrequent, DC may be used. In several species of Hypopomidae (pulse-discharging gymnotiforms), juvenile and female EODs are balanced and have little energy at low-frequency while breeding males have seasonal EODs with stronger DC components. Males of the gymnotid *Brachyhypopomus pinnicaudatus* modulate their EOD waveform over 24 h so that DC components of the discharge are present only at night, when the fish are active, and only during the breeding season. A similar pattern is seen in mormyrids. In *Marcusenius macrolepidotus* from South Africa, males have a stronger DC component to their discharge than females do, and catfish predators

Figure 11 (a) A species of mormyrid in the genus *Brienomyrus* from Gabon exhibits a gender difference in the electric organ discharge (EOD) waveform, the pulse duration for the male (m) being nearly double that for the female (f). During the breeding season, which starts with the seasonal rains, males court passing females by producing bursts of EODs at high frequency, making stereotyped displays called 'rasps.' (b) In experiments, males produce rasps in response to digitized EOD waveforms of females, as shown in the histograms of responses in (c). If the female EOD is phase-shifted by 45°, 60°, or 90° or if the EOD is reversed (played backwards in time), the male shows reduced responsiveness, but if the female EOD is phase shifted by 180°, responses are as strong as for the normal female EOD. This is not surprising given that a 180° phase shift is equivalent to inversion of polarity of the waveform, which would happen if the a real female were to turn around in space. These experiments strongly suggest that males attend to the temporal properties of EOD waveforms, not the amplitude spectral characteristics, which are all identical. In addition to courting digitized female EODs, males will also court a highly simplified square wave as long as the duration of the square wave is 0.5 ms, a close approximation to the duration of the head-positive phase of the female EOD (not shown). This can be explained by showing that female EODs and 0.5 ms square waves evoke from Knollenorgan electroreceptors the same neural code based on spike timing. (c) Reprinted from Hopkins CD and Bass AH (1981) Temporal coding of species recognition signals in an electric fish. *Science* 212: 85–87, with permission from AAAS.

seem to take more of the long-duration EOD males than females, as revealed by analysis of stomach contents of *Clarias gariepinus* in South Africa. *Clarias* appears to use its ampullary receptors to detect the DC component of the male EOD.

The physiological basis of EOD waveform diversity – whether between species or between sexes – traces to the type, the density, and the distribution of ion channels in electrocyte membranes; to the anatomy and pattern of innervation of electrocytes within the electric organ; and to the diversity of accessory electric organs in the fish. Much of this diversity is understood at a gross anatomical level but has yet to be fully explored at the molecular level. This is an area of active research that will undoubtedly reveal interesting patterns of evolution, especially within species flocks which show a large diversity of EOD waveforms.

Figure 12 shows variation in anatomy of electrocytes of selected species of mormyriforms arranged on a cladogram which is derived from analysis of mitochondrial and nuclear DNA sequences. Superposition of the pattern of electrocyte morphology on the phylogenetic tree gives insight into the evolution of the electric organs. Complex EOD waveforms emerge in the family Mormyridae very early with the evolution of penetrating stalked electrocytes. Reversions to nonpenetrating electrocytes with simpler EOD waveforms occur frequently. There are also cases in which electrocyte innervation is reversed anterior for posterior and others in which stalks are doubly penetrating electrocytes. All this diversity illustrates how signal diversity parallels species diversity in this remarkable radiation (Figure 12).

A second component to tonic diversity arises from the firing pattern of the pacemaker or command nucleus in the medulla. Wave discharges differ from pulse discharges in both the duty cycle of the discharge waveform and the variance in interpulse intervals. Wave discharges have a high duty cycle and low interval variance; pulse discharges have a low duty cycle and a high interval variance. Figure 10 shows wave versus pulse discharges of Gymnotiforms and Mormyriforms.

Wave or pulse discharges vary by taxonomic lineage. For example, all the gymnotiform species in the families Apteronotidae and Sternopygidae have wave discharges (Figure 10), whereas all others have pulse discharges. *Gymnarchus niloticus* has a wave discharge, but all other mormyriforms have pulse discharges (Figures 10 and 13). Wave discharges are a derived character in gymnotiform signal evolution; only the Apteronotidae and Sternopygidae produce waves. It is unknown whether the common ancestor of Gymarchidae (wave) and Mormyridae (pulse) was pulse or wave.

The average frequency of a pulse or wave discharge is another important tonic signal. It is controlled in the pacemaker in the medulla. Discharge frequency varies between species and sometimes between sexes. The first documented case of a sex difference in electric signaling was the firing rate of the gymnotiform wave species, *Sternopygus macrurus*. Adult males discharge in the range of 50–90 Hz, and females discharge in the range of 100–150 Hz (Figure 14(a)). This tonic feature has communicative significance, as shown by playing pure sine waves to male *Sternopygus*

Figure 12 A hypothesis for the evolution of electrogenesis among mormyroid fishes of Africa based on a phylogenetic tree of *Gymnarchus* and 31 species of mormyrids. The tree, which is derived from mitochondrial and nuclear DNA sequence data, is largely consistent with classifications based on osteology and other morphological characters. Taxa sampled are shown as outlines to the right. The structure of electrocytes in the electric organs is shown to the left, color coded. Type S electrocytes are 'stalkless.' They are found in adult *Gymnarchus niloticus* and in larval stages of all known mormyrids. The innervated faces of these electrocytes are nonspecialized, lacking the 'stalk' system which characterizes electrocytes in adult organs of mormyrids. Type S electrocytes are innervated on the posterior face (post.), which fires an action potential that produces a head-positive monophasic electric organ discharge (EOD). The anterior face (ant.) is electrically unexcitable. *Gymnarchus* has a wave type EOD in which the monophasic potentials are superimposed on a head-negative DC potential. All the fishes in the family Mormyridae have electrocytes with 'stalks.' The electrocytes are located in an adult electric organ in the caudal peduncle. All the species in the genus *Petrocephalus*, toward the base of the tree, have stalked electrocytes in which the stalks are 'nonpenetrating' and are innervated on the posterior side (type NP_p). Many of the Mormyridae have electrocytes with type P_a 'penetrating' stalks in which an elaborate stalk system, innervated on the anterior side, penetrates through the electrocyte to fuse with the posterior face. Action potentials are generated in the stalk, in the posterior face, and in the anterior face. The EOD is typically triphasic. Penetrating stalked electrocytes appear first in the genus *Myomyrus* at the base of the phylogenetic tree. Penetrating stalked electrocytes appear throughout the family tree, although there are multiple paedomorphic reversals to nonpenetrating stalked electrocytes. Two additional morphologies are known: doubly penetrating with nonpenetrating stalked electrocytes (DPNP) and penetrating stalks with posterior innervation (P_p). These occur in isolated lineages. Tracing the evolution of electrocyte diversity gives insight into the origin of signal complexity in this group of fishes. In this reconstruction, arrows point to the hypothesized origin of a novel electrocyte morphology. Representative EOD waveforms accompany each type of electrocyte. Alternating color bars to the left of a clade indicate that the ancestral type of penetrating stalk electrocyte is equivocal. From Sullivan JP, Lavoué S, and Hopkins CD (2000) Molecular systematics of the African electric fishes (Mormyroidea: Teleostei) and a model for the evolution of their electric organs. *Journal of Experimental Biology* 203(4): 665–683.

Figure 13 Phylogenetic hypothesis for gymnotiforms from South and Central America derived from morphological and molecular sequence data and representing 88 of the more than 170 species of gymnotiforms that have been described. Those fishes with wave discharges are indicated in red, those with pulse discharges in black. From Albert JA and Crampton WGR (2005) Diversity and phylogeny of neotropical electric fishes (Gymnotiformes). at night during their breeding season in small creeks in Guyana. The males responded with electrical courtship songs (Figure 14(b)) whenever the stimulus frequencies were in the females' range of 130–150 Hz (see Figure 14(c)). The males did not sing to electrodes playing sine waves in the male range or to signals in the ranges of two other sympatric wave species, *Eigenmannia* and *Apteronotus* (Figure 14(c)).

Figure 14 Sex differences in the discharge frequency of *Sternopygus macrurus* observed under field conditions in Guyana. (a) A plot of discharge frequency versus standard length for males (squares), females (triangles), and juveniles (circles) shows that sex differences emerge in individuals longer than 300 mm. The inset shows the fish's outline and a sample of the electric organ discharge waveform. From Hopkins CD (1974) Electric communication in the reproductive behavior of Sternopygus macrurus (Gymnotoidei). *Zeitschrift für Tierpsychologie* 35: 518–535. (b) Sound spectrogram of a male *Sternopygus* producing electrical courtship song in presence of a female. The male's discharge is a wave discharge in the 50–70 Hz frequency range. During courtship, males produce 'rises' in discharge frequency and 'interruptions' in the discharge song. (c) When presented with an electrical sine wave stimulus, delivered via electrodes placed in the water near the fish, the male *Sternopygus* gives courtship rises and interruptions if the frequency of the sine wave is in the 130–141 Hz range of a female *Sternopygus*. The male does not court sine wave frequencies in the 55–72 Hz range typical of other males, nor in the 450–550 Hz range typical of *Eigenmannia*, nor in the 900–1010 Hz range typical of Apteronotus, two other species that are sympatric to Sternopygus. (C) Reprinted from Hopkins CD (1972) Sex differences in electric signaling in an electric fish. *Science* 176: 1035–1037, with permission from AAAS.

Phasic Signals

Phasic signals vary rapidly in response to changes in the social environment, typically over a period of seconds or minutes. Phasic signals are produced by modulating the firing rate of the command or pacemaker nucleus in the medulla or by interrupting or silencing the discharge in the pacemaker or in the descending neural pathway from the command nucleus. Pulse and wave fish both produce two types of phasic signals: frequency modulations and discharge interruptions. Frequency modulations are either upward or downward shifts in the pacemaker frequency, last seconds to minutes, and consist of small shifts in frequency (long rises, low-frequency modulations, warbles, and jamming avoidance responses) or large shifts in rate (sudden increases in frequency, followed by decrease, 'chirps,' 'rasps,' 'scallops,' 'accelerations,' and a variety of other types of pulse bursts). Discharge interruptions are either short cessations in the discharge, lasting less than 0.5 s, or long-lasting periods of silence. All these phasic signals contrast with the constant rate of the tonic discharge.

Figure 14(b), showing the courtship singing of a male *Sternopygus macrurus*, illustrates both types of signals. There are short interruptions in the 50–90 Hz wave discharge, lasting less than 0.5 s, and there are brief modulations in the fundamental frequency upward by as much as 50 Hz above base rate. Interruptions and frequency modulations make the complex patterns of song, which may continue for hours at night during the breeding season.

There are striking parallels in the phasic displays of *Gymnarchus* and *Eigenmannia*, which independently evolved wave discharges in the range of 300–500 Hz on separate continents (Figure 15). Both produce short interruptions during attacks, approaches, head butts, and other aggressive acts. These acts are most common from dominant fish. They are rare from subordinates.

They both also produce subtle frequency modulations as displays of submission. Subordinate *Eigenmannia* produce long rises, which are elevations in frequency in the range of 5–10 Hz, when being attacked (Figure 15), and subordinate *Gymnarchus* produce similar displays if attacked, but the frequency decreases by 5–10 Hz rather than increasing (Figure 15). Subordinate *Gymnarchus* turn their discharges off altogether for many minutes or hours when attacked. The similarity in both form and function of these displays is striking, considering their independent evolution in Africa and South America.

Pulse fish also produce phasic displays, as illustrated in Figures 11 and 16, and these can be evoked by playback of the appropriate stimulus. Figure 11

Figure 15 Sound spectrograms comparing the communication displays of *Eigenmannia virescens* from South America with those of *Gymnarchus niloticus* from Africa. Both species have wave discharges in the same range (300–500 Hz), and both produce discharge interruptions as aggressive threat displays (solid arrows) and frequency modulations (dashed arrows) as signals of submission. The sound spectrograms on the left are on an expanded timescale and broad bandwidth so that the rapid temporal features of the displays may be seen. The spectrograms on the right have a compressed timescale and narrow bandwidth to better visualize the small but slow changes in frequency over time. There are two fish in each interaction; the lower-frequency fish is labeled F1, the higher, F2. Fundamental and higher harmonics are clearly evident for fish 1 on left. Adapted from Hopkins CD (1977) Electric communication. In: Seboek TA (ed.) *How Animals Communicate*, pp. 263–289. Bloomington: Indiana University Press.

Figure 16 Two types of temporal displays, 'interruptions' and 'frequency modulations,' produced by pulse-discharging gymnotiforms in the family Hypopomidae (above) and Mormyridae (below) as illustrated by waveforms and pulse rate plots. The gymnotiform *Brachyhypopomus brevirostirs* produces discharge interruptions by turning its discharge off for brief or extended periods. Shown here are two types: one (a) in which the discharge is turned off suddenly without a decrease in pacemaker frequency, and the other (b) preceded by a frequency drop. Similar patterns are seen for mormyrids in the genus *Brienomyrus* (c) and (d). In (c), pulse intervals are plotted as a function of time; in (d), pulse rate is plotted against time. During agonistic behavior, a fish may turn its discharge off for short periods (less than 1–2 s) as an aggressive threat. During courtship, males may turn their discharges off for several seconds, in alternation with rasp displays. Cessations contrast with the regular resting discharge intervals of 250–500 ms. Both groups of pulse fish also modulate the frequency of their discharge. (e), (f) *Brachyhypopomus* also produces frequency drops, frequency rises, and 'chirps' or 'decrement bursts.' Chirps are male courtship signals. *Brienomyrus brachyistius* (g)–(i) produces accelerations, scallops, and rasps as communication displays, with the rasp display used for male courtship calling. (a, b, e, f) From Kawasaki M and Heiligenberg W (1988) Distinct mechanisms of modulation in a neuronal oscillator generate different social signals in the electric fish Hypopomus. *Journal of Comparative Physiology A* 165: 731–741. (g, h, i) From Carlson BA and Hopkins CE (2004) Central control of electric signaling behavior in the mormyrid *Brienomyrus brachyistius*: Segregation of behavior-specific inputs and the role of modifiable recurrent inhibition. *Journal of Experimental Biology* 207: 1073–1084.

shows the 'rasp' display from a pulse-discharging mormyrid. The displays are strong, sudden bursts of pulses, up to 100 s^{-1}, lasting 200–400 ms. Males make these high-frequency bursts when courting females.

Some phasic displays in mormyrids consist of 'regularization' of the irregular tonic discharges. Female *Pollimyrus adspersus* regularize their discharge at low rates when entering a male's territory for spawning. This signal appears to indicate that the female is ready to spawn, and in response, males allow the females to enter their territory without attacking them.

Jamming Avoidance Responses (JAR)

Several species of electric fish which electrolocate objects in their environment have evolved behavioral

strategies for avoidance of the jamming effects of EODs from other fish. These complex reflexlike responses were studied extensively by WH Heiligenberg and others, especially in the wave species *Eigenmannia*, which uses its 500 Hz discharge for electrolocation of objects. *Eigenmannia* is jammed when a second individual's EOD is in the range of 4–10 Hz above or below its discharge frequency, and it is unable to sense objects. It shifts its frequency upward or downward by as much as 10–20 Hz to prevent frequency overlap with the external stimulus. Electrolocation performance is then restored, and the jamming effects avoided by this behavior. Later, on removal of the stimulus, the jammed fish relaxes its EOD back to its original resting frequency. In some species, which move in shoals and are routinely jammed by other fish, prolonged jamming avoidance may produce a long-term elevation in frequency that persists for many hours or days.

Species with different tonic discharges have differing avoidance strategies. Wave fish avoid overlapping discharge frequency by moving upward or downward in frequency; pulse fish avoid temporal overlap of EODs by delaying or advancing their pulse times with transient increases in pacemaker firing rate or by making rapid, short-latency echo responses to jamming pulses.

Jamming avoidance responses resemble some of the phasic signals used in social communication, and they are generated by the same neural circuits in the brain. The 'long rises' of *Eigenmannia* and the frequency decreases in *Gymnarchus* are both used by subordinate fishes as signals of submission, and the transient rate increases seen in jamming avoidance responses among the pulse gymnotiforms also resemble the burst discharges and rate increases seen in agonistic behavior. The close resemblance of the jamming avoidance responses to social communication displays may not be accidental but may be yet another example of ritualized behavior – adopting physiological reflexes as displays for communication. This may help explain the remarkable convergence in signal form and function in unrelated groups of electric fish.

Brain Mechanisms of Signal Generation

Gymnotiform and mormyriform fishes generate patterns of discharges using a hierarchy of control nuclei in the medulla, the midbrain, and the thalamus. There are many parallels between the electromotor control areas in the brains of these two groups of fishes. Each time the electric organ fires, it is triggered by the firing of neurons in the pacemaker or command nucleus in a ventral medulla. In gymnotiform fishes, this ventral nucleus is called a pacemaker nucleus since it is spontaneously active and generates a regular repetitive discharge frequency. In mormyrids, the equivalent nucleus is called a command nucleus because these cells make the decision to fire each EOD pulse after integrating synaptic inputs from a variety of higher centers in the brain, but they do not show pacemaker-like regularity. In both groups, the pacemaker or command nucleus is located on the ventral midline and is composed of cells which are electrotonically coupled, ensuring synchrony of firing. Command or pacemaker neurons project to cells in a nearby relay nucleus containing very large neurons that project down the spinal cord to the electromotor nucleus near the electric organ.

The primary inputs to the command and pacemaker nuclei come from a column of cells located in the dorsal thalamus. For gymnotiforms, the central posterior nucleus projects to the pacemaker and causes smooth rises in EOD firing frequency. In mormyrids, the dorsal posterior nucleus produces smooth discharge accelerations or bursts. These two thalamic nuclei are heterogeneous along their lengths such that the firing of cells in the rostral regions produces smooth accelerations in discharge rate while the firing of cells in the caudal regions produces sharp transient bursts of pulses.

A secondary input comes from smaller groups of cells in the midbrain. In gymnotiforms, the sublemniscal prepacemaker nucleus (sPPn) causes frequency decreases or discharge interruptions; in mormyrids, the ventral part of the ventral posterior nucleus within the torus semicircularis projects to the command nucleus, but its effects are unknown.

Both these nuclei receive inputs from sensory and motor nuclei which get inputs from a variety of sensory modalities, including electric, auditory, lateral line, and visual pathways. These inputs are important means by which other sensory systems affect the discharge of the electric organ. In gymnotiforms, the nucleus *electrosensorius* sends inputs to both the sPPn and to the PPn and the central posterior nucleus; in mormyrids the *tectum mesencephali* sends fibers to the dorsal part of the ventral posterior nucleus in the torus and to the dorsal posterior nucleus in the thalamus.

Physiological work spanning four decades has resulted in good understanding of the electromotor control system of electric fishes. Building on earlier work by Bennett, Szabo, Fessard, and others, which described command and relay nuclei and electromotor nuclei in spinal cord, more recent work by M Kawasaki, C Keller, WF Heiligenberg, G Zupanc, BA Carlson, K Grant, G von der Emde and others has uncovered many of the higher electromotor control centers in the brain that generate many of the social communication signals discussed here.

Electric communication is a fascinating example of a novel modality of communication that has undergone independent adaptive radiations in two separate lineages of fishes. Both groups exploit electroreception to the fullest, using tuberous electroreceptors for active electrolocation and reception of communication signals. Both have diverse electric organs and diverse signal types. Together, their systems of electric communication provide insight into the evolution of signals; strategies for coping with noise, predation, and jamming; and energetic costs of signaling while maintaining signal diversity. Work on electric fish has led to the development of several model systems for the comparative study of nervous systems and behavior.

Electrical Self-Stimulation

R A Wise, National Institute on Drug Abuse, Baltimore, MD, USA

Published by Elsevier Ltd.

Introduction

James Olds and Peter Milner discovered in the early 1950s that rats will perform arbitrary responses that result in direct electrical stimulation of the septal area, the lateral hypothalamus, and related regions of the brain. At about the same time, Russel Monroe and Robert Heath discovered that humans found stimulation in this region pleasant. Subsequent studies have revealed that many vertebrate species will learn to work for what has come to be called brain stimulation reward (BSR). While stimulation at some sites is only weakly rewarding or can cause aversive or motoric side effects, stimulation in the lateral hypothalamic and more caudal regions of the medial forebrain bundle can be very powerfully rewarding. Rats will lever-press several thousand times per hour for half-second trains of lateral hypothalamic stimulation. Rats given unlimited access to such stimulation have been known to lever-press for 2 or 3 days without stopping; one rat averaged almost 30 responses per minute over a continuous 20-day period, despite occasional 2- to 3-h naps and two long periods of equipment failure. Experienced rats accept painful levels of footshock to gain access to such stimulation, levels they would not accept to get to food or to retrieve their pups. If forced to choose between food and lateral hypothalamic stimulation during the single hour a day when each is available, the animals 'self-starve,' choosing stimulation over food to the point of death. Olds termed the lateral hypothalamus a 'pleasure center' in the brain, and argued at the time that it was the site of convergence of reward-related fibers from a variety of other brain sites.

Multiple Reward Sites

There are perhaps two dozen brain regions where stimulation is rewarding. However, the fact that stimulation is rewarding in many brain regions does not mean that there are many independent systems supporting BSR. The boundaries of the various regions are not well defined, stimulation is not equally effective in each of the different regions, and stimulation activates fibers passing through the regions more effectively than it activates the cell groups for which the regions are usually named.

Positive sites for BSR include the olfactory bulb, a sensory structure, the region of the motor branch of the trigeminal nerve, a motor pathway, and many structures ambiguously labeled 'associational.' Medial forebrain bundle reward sites include the anterior, lateral, and posterior hypothalamus, the ventral tegmental area, and ventral portions of the bundle that extend caudal to the ventral tegmental area on the midline of the pons. Cortical reward sites include the medial prefrontal, sulcal, cingulate, and entorhinal cortex. Limbic sites include hippocampus, amygdala, and medial and lateral septal regions. Stimulation of the deep cerebellar nuclei and the region around the decussation of the brachium conjunctivum is rewarding. Stimulation near several monoamine nuclei is rewarding: these include the regions of the noradrenergic locus coeruleus and nucleus of the solitary tract, the serotonergic dorsal and medial raphe nuclei, and the dopaminergic ventral tegmental area and zona compacta and pars lateralus of the substantia nigra.

An early theory of BSR was that noradrenergic fibers from nucleus locus coeruleus are the substrate of reward in most or perhaps all of these structures. Locus coeruleus fibers ascend to the diencephalon and telencephalon, descend to the brain stem and spinal cord, and invade the cerebellum. While subsequent studies have ruled out the noradrenergic fibers of the locus coeruleus and the bed nucleus of the lateral hypothalamus as primary substrates of reward function, Olds' notion that reward fibers from many structures converge on a final common path involving (passing through) the lateral hypothalamus remains widely accepted.

Role of Monoamines

Early evidence for involvement of monoamine systems in BSR came from pharmacological studies: chlorpromazine and reserpine attenuate intracranial self-stimulation (ICSS) while amphetamine enhances it. Following the discovery that dopamine is a transmitter in its own right, not just a precursor of noradrenaline, it became clear that it was the ability of these agents to alter dopamine rather than noradrenaline function that explained their effects on self-stimulation. Mapping studies revealed that the boundaries of the reward system did not correspond precisely with the boundaries of the noradrenergic system but did correspond precisely to the boundaries of the dopamine system (including the boundaries of the pars compacta and pars lateralis of the substantia nigra). Selective pharmacological blockade of dopamine function

confirmed its importance for the rewarding effects of lateral hypothalamic self-stimulation, and the fact that the meso-corticolimbic and nigrostriatal dopamine fibers pass through the lateral hypothalamus (as part of the medial forebrain bundle) led to the view, now largely discredited, that it was direct activation of dopamine fibers that made lateral hypothalamic stimulation rewarding.

These conclusions were reached slowly, largely because pharmacological studies of BSR were hampered by the possibility that the drugs disrupted the ability of animals to perform the required response, rather than the rewarding effects of the stimulation *per se*. Of particular concern were the possibilities that noradrenergic antagonists might be altering arousal or attention, and that dopaminergic antagonists might be disrupting motor capacity. Two approaches confirmed that blockade of dopaminergic but not noradrenergic neurotransmission attenuates the rewarding effects of medial forebrain bundle stimulation. First, the gradual attenuation of responding in animals pretreated with selective dopamine antagonists parallels that of animals tested with reduced stimulation current or frequency. The animals initiate responding at normal rates, but decrease their responding progressively as they gain access to the reduced stimulation or to the normal stimulation under the drug condition. After responding has ceased, normal performance can be reinstated, temporarily, by presentation of conditioned stimuli associated with normal reward. Thus the animals remain capable of responding at times when the stimulation fails to maintain that responding. In contrast, responding in animals pretreated with selective noradrenergic antagonists is impaired even before the animals sample the stimulation and does not deteriorate progressively as the animal experiences earned stimulation in the drugged condition.

The second approach to separating the effects of drugs on reward function from their effects on performance capacity is known as the 'curve-shift' approach. In this method, rate of responding is determined as a function of the strength of the rewarding stimulation. Reward strength can be controlled by varying the frequency, intensity, train length, or pulse width of the stimulation. For pharmacological studies, stimulation frequency is varied because stimulation pulses given at different frequencies always reach the same subpopulation of fibers near the electrode tip. Like the dose-response function in pharmacology, the function relating response rate to stimulation frequency (the 'rate-frequency' function) is an ogive (Figure 1): chance performance is seen with a range of low frequencies, asymptotic performance is seen with a range of high frequencies, and

Figure 1 Lever-pressing rate as a function of stimulation frequency for BSR under various drug conditions. (A) Baseline condition. (B) Morphine injection into the ventral tegmental area reduces the amount of stimulation necessary for normal performance. (C) A high dose of a dopamine antagonist causes two independent effects; it decreases the performance capacity of the animal, reducing the maximum rate of responding (lower doses need not have this effect) and it increases the amount of stimulation necessary for normal performance. (D) When the treatments are combined, morphine cancels the effect of the dopamine antagonist on the rewarding effect of stimulation but does not restore the normal performance ceiling.

increasing performance is seen over a range of intermediate frequencies. Reducing the reward by reducing the stimulation intensity shifts the rate-frequency function to the right; increasing the reward by increasing the intensity shifts the function to the left. Making the task harder or easier – for example, by adding or subtracting weight from the response lever – shifts the asymptote down or up, respectively. Dopamine antagonists at low doses shift the rate-intensity function to the right (high doses shift it to the right and down), while indirect dopamine agonists like amphetamine and cocaine shift the function to the left. The effects of a dose of amphetamine that halves the stimulation frequency needed to maintain normal responding are exactly offset by a dose of a dopamine antagonist that doubles the required frequency. These findings not only establish that dopamine antagonists reduce the effectiveness of BSR, but also establish a metric for comparing the relative effectiveness of various drug treatments on reward function and performance capacity.

Fast Descending Reward-Relevant Fibers in the Medial Forebrain Bundle

While pharmacological studies establish the importance of the dopamine system for the rewarding effects of medial forebrain bundle stimulation, electrophysiological studies challenge the assumption that the relevant dopamine fibers are directly

depolarized at the electrode tip. While high levels of stimulation are required to activate dopamine fibers, low levels of stimulation are rewarding in the medial forebrain. A series of sophisticated parametric studies suggest that the bulk of the 'first-stage' fibers (the fibers that are depolarized at the electrode tip) are fast myelinated fibers that descend the medial forebrain bundle to activate the dopamine system trans-synaptically. In contrast, the dopamine fibers are slow, unmyelinated, and ascend the bundle.

The first set of parametric studies that identify fast descending fibers as the primary component of the first stage of medial forebrain bundle BSR involved studies in which the distribution of refractory periods for the populations of directly activated populations are estimated. For this determination, the intervals between stimulation pulses are manipulated to form trains of pulse 'pairs,' where the interval between the first ('C') and second ('T') pulses of each pairs is systematically varied. When the intervals between the C and T pulses are long, each pulse triggers an action potential and the animal responds frequently for the stimulation. When the intervals are shorter than the refractory period of the first-stage neurons, however, each C pulse triggers an action potential but each T pulse fails to do so. In this case, the animal receives half the reward and performance is much weaker. The distribution of refractory periods for the first-stage medial forebrain bundle fibers suggests two subpopulations, one with refractory periods ranging between 0.4 and 0.5 ms and one with refractory periods ranging from 0.6 to about 2 ms. These refractory period estimates are consistent with large myelinated first-stage fibers.

The second set of parametric studies also utilized paired-pulse stimulation; here the C pulses were delivered at the tip of one electrode, and the T pulses were delivered at the tip of a second electrode aligned a distance down the same axon trajectory. The goal is to stimulate the same first-stage fibers at two sites along their length to add estimates of conduction velocity to estimates of refractory period. When two electrodes are properly aligned along the same fiber path, paired pulse stimulation again proves normally effective, so long as the interval between C and T pulses is sufficiently long. Here the necessary interval between the two pulses of each pair must be long enough not only to allow recovery from the C pulse; it must also be long enough to allow the action potential triggered by the C pulse to pass the site where the T pulse will be delivered. With short C–T intervals, the action potential triggered by the C pulse will collide with an action potential triggered at the second electrode by the T pulse, and only one action potential will survive to reach the synapse (while this is not intuitively obvious, the collision test works regardless of which electrode is closer to the synapse). Since the refractory period can be estimated by paired pulse stimulation at either of the two electrodes, the conduction time between electrodes, and thus the conduction velocity, can be determined. The first-stage medial forebrain bundle conduction velocities are in the range of 1–11 m s^{-1}. The faster fibers implicated by such studies are again consistent with large myelinated first-stage fibers, not small unmyelinated dopamine fibers.

The two-electrode experiment lends itself to a third determination, that of directionality. If cathodal pulses are given at one electrode and anodal pulses are given at the other, stimulation-induced conduction will fail at the anodal electrode and reward signals will only propagate to the synapse when the anode is between the cell body and the cathode. Such studies confirm that at least the major portion of the first-stage reward fibers in the medial forebrain bundle conduct reward signals in the rostral–caudal direction, whereas the dopamine fibers project in the caudal–rostral direction.

Taken together, the parametric studies suggest that the bulk of the first-stage reward-relevant medial forebrain bundle fibers are not monaminergic, as was suggested by early pharmacological studies. Dopaminergic fibers are the wrong size and conduct in the wrong direction to be first-stage fibers. Nonetheless, the pharmacological studies implicate dopamine fibers as a final common path for medial forebrain bundle reward, and the current view is that the dopamine fibers are activated trans-synaptically by the descending myelinated fibers of the first stage.

Second-Stage and Third-Stage Candidates

Two hypotheses have been advanced for how the descending reward fibers might activate the ascending dopamine fibers of the medial forebrain bundle. The first hypothesis rests on evidence that the dorsal–ventral and medial–lateral boundaries of the descending fiber system correspond to the dorsal–ventral and medial–lateral boundaries of the dopamine cell layer of the ventral tegmental area and substantia nigra. Thus the descending fibers or collaterals from them may synapse on the dopamine cells directly, making the dopamine cells the second-stage neurons of medial forebrain bundle reward.

The second hypothesis is that descending medial forebrain bundle fibers synapse on cholinergic pedunculopontine tegmental neurons known to project back to the ventral tegmental area and substantia nigra, which would then serve as the third

stage. Rewarding lateral hypothalamic stimulation causes acetylcholine release in the ventral tegmental area, and muscarinic antagonists in this region cause an approximate doubling of reward thresholds. Muscarinic blockade of cholinergic autoreceptors at the level of the cholinergic cell bodies increases dopamine release and augments lateral hypothalamic BSR. Thus cholinergic neurons of the pedunculopontine and adjacent laterodorsal pontine tegmental nucleus are strong candidates for a link between first-stage reward fibers of the medial forebrain bundle and high-threshold third-stage dopamine reward fibers that project back past the stimulated region, but are too insensitive to respond to the stimulation directlyt.

Interaction with Addictive Drugs

Several addictive drugs potentiate the rewarding effects of lateral hypothalamic brain stimulation. This is reflected in leftward shifts of the rate-frequency function, as illustrated for morphine in Figure 1. Strong potentiation is seen with amphetamine, cocaine, and nicotine. While opiates potentiate the rewarding effects of the stimulation, particularly if given in the ventral tegmental area of the brain, opiates have sedative side-effects in rats that can impair responding when the drugs are given systemically. Cannabis and ethanol potentiate BSR in some strains and some individuals but not in others, and the potentiation is generally less robust with these drugs. The findings with barbiturates and benzodiazepines are mixed, and caffeine seems to inhibit BSR.

The brain sites at which addictive drugs act to enhance brain stimulation are often sites where the drugs are rewarding in their own right. Thus, amphetamine potentiates BSR, establishes conditioned place preferences, and is directly self-administered when injected into the nucleus accumbens. Morphine potentiates BSR, establishes conditioned place preferences, and is self-administered when injected into the ventral tegmental area. Both μ and δ opioids potentiate BSR and are self-administered when injected into the ventral tegmental area, and are effective as reward potentiators and rewards in their own right in proportion to their ability to cause nucleus accumbens dopamine release. Thus it is widely held that the pathways identified by BSR studies are pathways activated pharmacologically by habit-forming drugs.

Electrical Self-Stimulation in Perspective

BSR circuitry in general and the dopaminergic link in that circuitry in particular must be viewed in the context of millions of years of evolution. This circuitry cannot be specialized for a laboratory artifact. Natural rewards exert dramatic control over behavior patterns in vertebrates, and this control must be mediated by brain circuitry in some way or another. The fact that electrical stimulation of some regions of the brain is rewarding tells us that those regions are likely candidate substrates for the control of behavior by natural rewards like food, water, and sexual interaction. Indeed, food and sexual interaction, like rewarding brain stimulation and most addictive drugs, are known to elevate extracellular dopamine levels in nucleus accumbens and other brain regions. How this circuitry modifies behavior is not yet understood, but it is known that the lateral hypothalamic stimulation that animals will work for has the ability to enhance the consolidation of learning and memory, even when the stimulation is unearned and bears no relation to the learning and memory in question. Thus, when response-independent stimulation is given after a training trial, it enhances consolidation of whatever was learned in that training trial. Presumably the same mechanism is involved when the animal learns to self-stimulate its own brain.

Electrocommunication

G K H Zupanc, Jacobs University Bremen, Bremen, Germany

© 2009 Elsevier Ltd. All rights reserved.

Several taxonomic groups of fishes generate, by means of specialized organs, electric discharges. Based on the voltage of the signals produced, two groups of electric fish can be distinguished. Strongly electric fish generate powerful discharges of up to several hundred volts; in contrast, the electric signals produced by weakly electric fish rarely exceed a few volts. Whereas the powerful discharges of the strongly electric fish are used for prey hunting, the electric signals of the weakly electric fish play important roles in orientation and localization of objects in the closer vicinity of the fish (electrolocation) and in species recognition and intraspecific communication. This article focuses on the latter two functions.

Electric Organs and Electroreceptors

The discharges of the electric fish are produced by specialized electric organs, which, in the vast majority of species, are derived from various types of muscles and hence are termed myogenic (Figure 1). The only exceptions are members of the family Apteronotidae within the order Gymnotiformes, in which the electric organs are formed by modified spinal motor axons. The organs are, therefore, referred to as neurogenic. The cells making up the electric organs are commonly called electrocytes. In many species, they are stacked behind one another along the anterio-posterior body axis, thus forming a column of cells. Depending on the species, between a few columns and several hundreds of such columns, they are enclosed within tubes of connective tissue, running parallel to one another – thus resembling rolls of coins wrapped in paper, all facing the same way.

The synchronous activity of the electrocytes defines the output of the electric organ, called the electric organ discharge (EOD). The number of electrocytes arranged in series determines the voltage; the number of electrocytes arranged in parallel determines the current of the EOD. Typically, individual electrocytes generate potentials of the order of 100 mV.

The electrogenic system is complemented by the ability to sense electric signals. This capability is found in many fishes, both electric and nonelectric. It is mediated by specific sensory cells, called electroreceptors. Together with support cells, the electro receptor cells form encapsulated end organs known as electroreceptor organs (Figure 2). These receptor organs are located in invaginations of the fish's epidermis, but communicate with the body's surface through canals filled with mucous substrate or loosely packed epithelial cells. Typically, electroreceptor organs are distributed over most of the fish's body surface, with especially high densities in the head region.

Two anatomically distinct classes of electroreceptor organs can be distinguished: ampullary and tuberous. Ampullary receptors are maximally sensitive to direct current (DC) and low-frequency electric fields of both biological and nonbiological sources. In the context of electrocommunication, ampullary receptors have been shown to be involved in the detection of low-frequency components associated with modulatory signals used for communication among conspecifics. Tuberous receptors, on the other hand, are tuned to frequencies within or near the fundamental discharge frequency of the respective species, a feature that plays an important role in species recognition and male–female discrimination (see the sections titled 'Sexual dimorphisms in the electric organ discharge,' 'Species recognition,' and 'Electrocommunication').

Patterns of Electric Organ Discharges

In the two best-examined orders of electric fish, the Gymnotiformes from South and Central America, and the Mormyriformes from Africa, the EODs are produced either continuously, resulting in a wavelike appearance of the signals on the oscilloscope screen, or intermittently, so that the individual discharge pulses are separated by relatively long periods of silence. These two groups of electric fish are, therefore, referred to as wave-type and pulse-type fish, respectively.

As examples of wavelike discharges, the EODs of two gymnotiform species, the brown ghost knifefish (*Apteronotus leptorhynchus*) and the knifefish (*Eigenmannia* sp.), are shown in Figure 3. Both species belong to the group of weakly electric fish. Typically, the number of discharges produced within 1 s (defined as the EOD frequency) is highly regular in an individual fish, even over longer time periods of hours and days. On the other hand, the EOD frequencies may differ among different individuals within a certain range, thus defining the species-specific frequency band. Also quite characteristically, different species may occupy different frequency bands, often with no or little overlap. Like the discharge frequency, the waveform of the EOD is extremely constant in an individual fish, but may differ among different individuals and different species.

In pulse-type species, the individual discharge pulse is highly stereotyped in a given individual, but the

Figure 1 Electric organ of the knifefish, *Eigenmannia* sp. The parasagittal section through the tail shows, in addition to muscle fibers of the anal fin (A) and dermis (D) with scales, electrocytes (EL), which are distinguished by their long slender shape. These cells are arranged in series along the longitudinal axis of the body, thus constituting the electric organ. At the caudal end, where the membrane exhibits pronounced evaginations (arrow), the electrocytes are innervated by axons of spinal motor neurons. Courtesy of GKH Zupanc and F Kirschbaum.

Figure 2 Electroreceptor organs in the skin of the knifefish, *Eigenmannia* sp. The photomicrograph shows two different types of these receptor organs: a tuberous (TU) electroreceptor organ with its individual receptor cells (one is indicated by r) and an ampullary electroreceptor organ (AM). The latter type is characterized by a long large-diameter canal (arrow). Courtesy of GKH Zupanc and F Kirschbaum.

intervals between the pulses are often quite variable, resulting in a nonperiodic pattern of discharge (Figures 4(a) and 4(b)). Thus, in addition to the average number of pulses produced per second (commonly referred to as the pulse repetition rate), the frequency distribution of the interpulse interval lengths is usually analyzed and plotted in the form of interpulse interval histograms to characterize this variability (Figure 4(c)). Such histograms have revealed that the mode of discharge pattern (for instance, a highly rhythmic discharge pattern vs. a more random discharge pattern) changes with the behavioral context and may be used by the fish to encode information important for communication.

Sexual Dimorphisms in the Electric Organ Discharge

Sexual dimorphism in the EOD has been found in a number of electric fish species. In *Sternopygus macrurus* (a wave-type gymnotiform species) sexually mature males discharge on average at 67 Hz, whereas sexually mature females discharge on average at 120 Hz. The mean EOD frequency of sexually immature fish is somewhat intermediate, at 93 Hz. The development of this sexual dimorphism is controlled by steroid hormones. Treatment of *Sternopygus* with the androgen testosterone or 5α-dihydrotestosterone leads to a pronounced decrease in EOD frequency, whereas the administration of estradiol causes a slight increase in EOD frequency. Hormonal control of the sexually dimorphic EOD also occurs in *Apteronotus leptorhynchus*. In this wave-type gymnotiform fish, mature males discharge at higher frequencies than sexually mature females. Implantation of estrogens causes a gradual decrease in EOD frequency, whereas treatment with 5α-dihydrotestosterone results in a slight increase (Figure 5).

Sexual dimorphism in the EOD may also involve the waveform of the electric discharge. Such a phenomenon has been found in both wave-type and pulse-type species. In the pulse-type mormyriform fish *Brienomyrus brachyistius* (long biphasic), the duration of the EOD pulse produced by mature males is, on average, 2.3 ms long, compared to 0.9 ms in mature females and immature specimens. The treatment of females with the androgen 17α-methyltestosterone or 5α-dihydrotestosterone causes a marked increase in EOD duration over a 2- to 3-week period.

In the pulse-type gymnotiform fish *Hypopomus occidentalis*, mature males are distinguished from females and immature males not only by morphological characteristics, such as their larger body size and the thicker tail, but also by differences in the waveform of the individual pulse (Figure 6). Both males and mature females produce biphasic EOD pulses, the first phase of which is head positive and the second phase head negative. However, whereas in mature females and immature males the durations of the first and second phases are equal, thus resulting in a symmetrical pulse, in mature males the EOD pulse is asymmetrical, which is caused by a longer duration of the second phase compared to the first phase. Treatment of females with 5α-dihydrotestosterone leads to the development of broader tails and asymmetric EOD pulses, caused by an increase in the size of individual electrocytes.

The hormonal effect on the EOD is paralleled by alterations in receptor tuning. In *Sternopygus*, in which the tuberous receptors are closely tuned to the EOD frequency of the individual fish, treatment with steroid hormones also leads to alterations in receptor tuning such that the best frequency of the receptors tracks the EOD frequency.

Figure 3 Two wave-type fish: (a) *Apteronotus leptorhynchus*; (b) *Eigenmannia* sp.; (c) electric organ discharges for *A. leptorhynchus*; (d) electric organ discharges for *Eigenmannia* sp. As is evident from the oscilloscope traces at compressed timescales ((c,d), left) and at expanded time scales ((c,d), middle) and from the Fourier spectra ((c,d), right), the discharges of these two species of gymnotiform fish differ in frequency, waveform, and spectral composition. Courtesy of GKH Zupanc and JR Banks.

Species Recognition

Field studies have revealed an enormous diversity of the EODs of sympatric species. This diversity involves the pattern of discharge (wave-type vs. pulse-type); the waveform and the frequency of the EOD in wave-type species, as well as the waveform and the peak spectral frequency of the pulse; and the pulse repetition rate in pulse-type species. These divergent features of the EOD may form the basis for the recognition by the weakly electric fish of their own species. In terms of perception, this ability is mediated by an increased sensory sensitivity to cues of the EOD of their own species while filtering out unwanted EODs. In *Hypopomus*, a pulse-type species, two out of five electroreceptor types respond maximally to spectral frequencies characteristic of the peak power of the species-specific EOD, thus acting as EOD filters. In wave-type fishes, tuberous receptors are commonly tuned to frequencies in the range of their own species.

The notion that weakly electric fish are capable of recognizing their own species based on invariant features of the EOD is corroborated by behavioral studies. Conditioning experiments showed that *Eigenmannia* sp. can discriminate electric signals differing in frequency or waveform. Moreover, *Sternopygus*

Figure 4 Electric organ discharge of a pulse-type weakly electric fish, the elephant nose (*Gnathonemus petersii*): (a) oscillogram at a compressed time scale; (b) expanded time scale; (c) frequency distribution histogram. In (a), which shows the individual discharge pulses as vertical lines, there is a rather irregular discharge rhythm. In (b), the details of the waveform of an individual pulse are resolved. The frequency distribution histogram (c) is based on analysis of the interpulse intervals of the discharge sequence shown in (a). This histogram suggests two major classes of interpulse intervals: short intervals between 0.04 and 0.16 s, and long intervals between 0.16 and 0.36 s. Courtesy of GKH Zupanc and JR Banks.

Figure 5 Control by steroid hormones of the sexual dimorphism in frequency of the electric organ discharge. Individuals of the wave-type fish *Apteronotus leptorhynchus* received implants of 5α-dihydrotestosterone ($n = 13$ fish; circles and dotted lines), received implants of 17β-estradiol ($n = 12$ fish; triangles and dashed lines), or were sham-treated (controls; $n = 12$ fish; squares and solid lines). In each of the three groups, the frequency of the electric organ discharge was measured on four consecutive days before the implantation (days 3–0) and on the 13 days following the surgery (days 1–13). The fish received the implants immediately following the measurement of the discharge frequency on day 0 (indicated by arrow). The frequency measured on each day was then normalized relative to the frequency determined on day 0 and averaged over the number of fish examined. Also indicated is the standard error of the mean. The diagram shows a pronounced decrease in the discharge frequency in the estradiol-treated fish and a slight frequency increase in the 5α-dihydrotestosterone-treated fish compared to the control fish. Courtesy of GKH Zupanc.

macrurus males produce electric courtship signals preferentially in response to electric sine waves in the frequency range of females of their own species, but less to sinusoidal signals outside this range.

Electrocommunication

Wave-Type Weakly Electric Fish

In wave-type fishes, both the normal EOD and transient modulations appear to play roles in communicatory behavior. As already mentioned, the normal EOD is extremely stable in a given fish, but may differ among individuals. Often, such differences reflect sexually dimorphic signals. In the brown ghost knifefish (*Apteronotus leptorhynchus*; Figure 3(a)), males discharge at a higher frequency than females. In the knifefish (*Eigenmannia* sp.; Figure 3(b)), the EOD frequency of females is higher than the frequency of the males. Moreover, in the latter species, females generate a quasi-sinusoidal signal, whereas the EOD waveform of males is more distorted, with the positive half-wave being markedly shorter than the negative half-wave. Conditioning experiments have demonstrated that *Eigenmannia* sp. is capable of distinguishing electric signals differing in frequency and/or waveform, including male and females EODs. These results are in agreement with the hypothesis that the fish identify the sex of a conspecific based on sexually dimorphic characteristics of the signal.

Transient modulations of the EOD are quite rarely produced spontaneously. In *Apteronotus leptorhynchus*, the most common form of such modulations are chirps (Figure 7). This name was given to this behavior to reflect the quality of the modulation, as

Figure 6 Sexual dimorphisms in morphology and electric organ discharge of the pulse-type fish, *Hypopomus occidentalis*: (a) males; (b) females. Males are larger and have a thickened tail ((a), left). Their discharge pulse is asymmetrical, which is caused by the longer duration of the second, head-negative phase, compared to the first, head-positive phase ((a), right). In contrast, females are smaller and have a slender tail ((b) left). Their discharge pulse is of shorter duration and exhibits a symmetrical form ((b), right). Adapted from Hagedorn M and Carr CE (1985) Single electrocyctes produce a sexually dimorphic signal in South American electric fish, *Hypopomus occidentalis* (Gymnotiformes, Hypopomidae). *Journal of Comparative Physiology A* 156: 511–523.

Figure 7 Chirplike modulations of the electric organ discharge in the brown ghost knifefish (*Apteronotus leptorhynchus*) during electric interaction with a conspecific: (a) type 1 chirp; (b) type 4 chirp. In these two graphs, a frequency–time plot is shown in the upper trace and the corresponding oscillogram is shown in the lower trace. Type 1 chirps are characterized by a rapid and pronounced increase in frequency, followed by a similarly rapid decrease, which finally results in an undershoot of the discharge frequency (a). By contrast, type 4 chirps are distinguished by their long duration of the frequency increase (b). In each of the two types of chirps, the amplitude is markedly reduced during the modulatory phase. Adapted from Zupanc GKH, Sîrbulescu RF, Nichols A, and Ilies I (2006) Electric interactions through chirping behavior in the weakly electric fish, *Apteronotus leptorhynchus*. *Journal of Comparative Physiology A* 192: 159–173.

perceived by the human observer when transforming the electric signal into an audible one. In isolated individuals of *Apteronotus leptorhynchus*, chirps occur at an average rate of just 1 chirp per 10 min. During social interactions, however, the chirp production may increase 1000-fold to rates of over 2 chirps s^{-1}. Chirps are predominantly generated by males and involve complex frequency and/or amplitude modulations. They last between some tens and a few hundred milliseconds. Thus far, six distinct types of chirps, differing in various physical parameters of the signal, have been described. It is thought that these different chirp types subserve different behavioral functions.

Closer analysis has shown that the chirps produced by two electrically interacting fish are not independent of one another. Instead, the chirps generated by one fish follow the chirps of the other individual with a preferred latency of roughly 500–1000 ms. This coordinated production of alternating chirps is called echo response. One function of this behavior may be to avoid coincident discharges, which could compromise the fish's electrolocation ability. An alternative explanation is that the echo response serves a communicatory function during encounters, such as aggression and courtship.

Pulse-Type Weakly Electric Fish

Studies have demonstrated that both the waveform of the individual pulse and the sequence of the interpulse intervals play important roles in intraspecific communication. The functional significance of the pulse waveform for sex recognition was first examined in *Brienomyrus brachyistius*. During the breeding season, males of this species occupy territories in shallow streams and produce courtship EODs consisting of a burst of EOD pulses at a pulse repetition rate of 100–150 Hz. This behavior is called rasp. In playback experiments, it can be used as an indicator of the male's response to the presumptive presence of a female because EODs recorded from females are more effective in eliciting rasps than discharges from males or other electric fish living in the same habitat. Experiments in which digitized EOD pulses were presented at various sequences of interpulse intervals demonstrated that males use the EOD waveform, rather than the sequence of interpulse intervals, to recognize a female signal. Because sex differences in EOD waveform have been found in many other species of weakly electric fish, presumably sex recognition based on EOD waveform is a widespread, and possibly even a universal, phenomenon.

Whereas the waveform of the individual EOD pulse is highly stereotyped and undergoes alterations only in the course of weeks and months (see the section titled 'Sexual dimorphisms in the electric organ discharge'), the sequence of interpulse intervals is highly variable and subject to modulations, particularly in the context of social interactions between two or more fish. This can be demonstrated by the following experiment. Two elephant nose fish (*Gnathonemus petersii*), a pulse-type mormyriform species, are kept isolated in two separate tanks (**Figure 8(a)**). Their EODs are recorded by electrodes placed close to each fish and, on the closure of an electric switch, transmitted into the other tank. Thus, only electric cues, but no others, are exchanged during stimulation. During the experiment, the discharges of the two fish are monitored through a second pair of electrodes installed in one of the two tanks. Through this single pair of recording electrodes, not only can the discharges of the fish in the recording tank be monitored but also those of the fish in the neighboring tank because the discharges of the latter are transmitted via the electric circuit used for stimulation. In the recordings, the EODs of the fish in the recording tank are distinguished by their larger amplitude, whereas the amplitude of the EODs of the fish in the neighboring tank are markedly smaller (**Figure 8(b)**).

The results of such an electric interaction experiment are shown in **Figures 8(b) and 8(c)** (an expanded time plot). Within a few seconds after transmission of the first fish's signals from the neighboring to the recording tank, the second fish, in the recording tank, started to modulate the discharge pattern. First, it reduced its pulse repetition rate to almost half the rate before stimulation. Second, this brief initial phase was followed by a complete cessation of the EOD for more than 1 min. Third, the return to EOD production was characterized by an initial generation of a burst of pulses, followed by a slowing down of the discharge rhythm. A similar discharge pattern is frequently observed during aggressive encounters. This suggests that the second fish interprets the signals of the neighboring fish as those of an intruder trying to enter its territory.

In general, a variety of modulation patterns that occur during social interactions have been identified. They include complete cessations of the EODs, transient acceleration of the discharge rate, long-term shifts in the baseline EOD repetition rate, changes in the regularity of the discharge pattern, and coupling between the two discharge pattern in that the EOD of one fish affects the EOD of another individual. An example of the last type of pattern is the echo response of pulse-type fish, which is characterized

Figure 8 Electrical interactions in the elephant nose fish (*Gnathonemus petersii*): (a) experimental setup to demonstrate electrical interactions between two fish; (b) modulation of the discharge rhythm of *Gnathonemus petersii* by the electric organ discharges of a conspecific; (c) expanded timescales of bracketed areas in (b). As shown in (a), a single fish is kept in each of the two tanks. The two aquariums are electrically connected via wires attached to electrodes, which are placed near the fish. The connection can be controlled by an electrical switch. In addition, the discharges of one of the two fish are monitored through recording electrodes. The electric organ discharges of this fish are intermingled with the discharge of the second fish, which are visible as pulses of significantly lower amplitude. These discharges are transmitted into the tank of the first fish as long as the electric circuit connecting the two tanks is closed. As shown in (b), a few seconds after closing the electrical circuit (indicated by arrow), and thus stimulating the first fish with the discharges of the second, the first fish slows down its discharge rhythm and, another few seconds later, even completely ceases discharging. During this period of silence, the neighboring fish generates a salvo of discharge pulses, to which the first fish responds only with a delay of some 20 s (indicated by *). This response of the first fish is distinguished by the production of discharges at an extremely high pulse-repetition rate within the first few seconds. Courtesy of GKH Zupanc and D Meissner.

by a short (12–14 ms in *Gnathonemus petersii*) latency of pulse generation in response to the EOD pulse of a conspecific.

The production of specific EODs displayed in different situations of social interactions suggests a role in intraspecific communication. This hypothesis has been tested by the use of electric fish dummies. Isolated fish are stimulated with recorded EOD sequences or artificially generated EOD-like patterns via electric dipoles, and the behavioral response is

Figure 9 The behavioral significance of various parameters of the electric organ discharge can be explored by the use of electric fish dummies, consisting of electric dipole electrodes. Here, an elephant nose fish (*Gnathonemus petersii*) approaches such an electric fish dummy, via which recorded electric signals are played. Courtesy of GKH Zupanc.

analyzed (Figure 9). In *Gnathonemus petersii*, such fish dummy experiments have demonstrated clear differences in the response to signal trains recorded from resting and attacking fish. In contrast to the resting discharge, the attack discharge, characterized by its higher mean pulse repetition rate and the production of short sequences of EOD bursts, elicits a larger number of attacks on the dipole electrodes.

Neural Control of Chirping Behavior

Weakly electric fish have proven to be excellent model systems to study the neural basis of specific behavioral patterns, including those occurring during electrocommunication. One particularly well-studied example of such a behavior is the previously described chirping of the gymnotiform fish *Eigenmannia* sp. and *A. leptorhynchus*. In each of the two fish, the EOD is driven by command pulses originating from the pacemaker nucleus, an endogenous oscillator in the medulla oblongata. The major cell types forming the pacemaker nucleus are pacemaker cells and relay cells. The pacemaker cells, which remain intrinsic to the pacemaker nucleus, converge on to relay cells. Cells of the latter type, in turn, send axons down the spinal cord to command, through their spiking, the discharges of the electric organ in a one-to-one fashion. The neurons of the pacemaker nucleus fire both *in vivo* and *in vitro* at a very constant frequency, a phenomenon that parallels the regularity of the EOD.

Chirplike modulations of the EOD are mediated by input to the pacemaker nucleus arising from the prepacemaker nucleus (Figure 10). Because this diencephalic nucleus forms part of the central posterior nucleus, it is commonly referred to as the central posterior/prepacemaker nucleus. Stimulation experiments have indicated that the chirping behavior is controlled by a ventrolaterally located portion of the central posterior/prepacemaker nucleus. This subnucleus comprises large multipolar cells projecting to the pacemaker nucleus, where they synapse predominantly on the relay cells. Signal transmission at these synapses appears to involve a non-*N*-methyl-D-aspartate (NMDA) type of glutamate receptors. Iontophoresis of L-glutamate into the region, or electrical stimulation, of the ventrolaterally located large multipolar neurons of the central posterior/prepacemaker nucleus evokes EOD frequency modulations resembling natural chirps. This effect is thought to be mediated by a rapid depolarization of the relay cells in the pacemaker nucleus. Because pacemaker cells are intensively connected with one another and also with relay cells via mixed chemical and electrical synapses, this depolarization can spread within the pacemaker nucleus and, finally, lead to an acceleration of the spike frequency of both the pacemaker neurons and the relay cells.

Chirps can be elicited by sensory stimulation of the intact fish through an electric dipole with recorded discharges or sinusoidal electric signals in the frequency range of the fish's own EOD frequency. The perception of these EOD-like stimuli is mediated by the electroreceptors on the fish's body surface, which project via primary afferents to the somatotopically ordered electrosensory lateral line lobe in the

Figure 10 Neural circuitry involved in the neural control of chirp production in the weakly electric fish *Eigenmannia* sp. The electric organ discharge is driven by the activity of the pacemaker nucleus (Pn). This endogenous oscillator in the brain stem area receives input from neurons of the central posterior/prepacemaker nucleus (CP/PPn) in the diencephalon. The side view (top) shows the location of these two nuclei in a drawing. The connection between pacemaker nucleus and CP/PPn has been revealed by neuronal tract tracing. As shown in the two microphotographs, the application of the enzyme horseradish peroxidase to the pacemaker nucleus (bottom right) results in retrogradely labeled neurons in the CP/PPn (bottom left). Courtesy of GKH Zupanc.

hindbrain. This brain region, in turn, sends axons to the torus semicircularis in the midbrain. Axons from the latter innervate, among other targets, the nucleus electrosensorius in the diencephalon. This brain region projects to the central posterior/prepacemaker nucleus, which, therefore, can be regarded as an interface between the electrosensory system and the electromotor system.

Electroencephalography (EEG)

Definitions

The electroencephalogram (EEG) is traditionally defined as the electrical activity of the brain recorded from the human scalp. This is the common translation of *elektrenkephalogram*, the term coined by Hans Berger (1873–1941). However, this term may also be applied to the electrical activity of neuronal masses as recorded anywhere at the surface of the cortex (i.e., the electrocorticogram) or within the brain, both in humans and in animals.

Despite the important recent developments of other powerful techniques capable of imaging functional states of the brain (positron emission tomography, single photon emission computed tomography, and functional magnetic resonance imaging (fMRI)), the scalp EEG occupies an important position as a diagnostic and research tool because of four main characteristics: (1) it has an exceedingly high time resolution since it can monitor the activity of neuronal populations at the millisecond time scale, (2) it is noninvasive, (3) it is simple to record and it is inexpensive, and (4) it is the only technique by means of which the dynamics of brain activity can be monitored in the freely moving subject. Electroencephalography shares the first two of these characteristics, but not the last one, with the recently developed technique of magnetoencephalography (MEG).

Neuronal Sources of the EEG/MEG

The electrical activity of neuronal populations consists of ionic currents generated by cellular sources, flowing in a volume conductor formed by the brain and surrounding tissues. These ionic currents cause electric and magnetic fields that can be measured at a distance from the cellular sources, and thus they form the sources of the EEG (and MEG). In order to understand EEG phenomena, one has to take into consideration both the organization in space of the cellular sources and their time-dependent properties.

Synchronously active neurons arranged spatially in an ordered way can form macroscopic sources of potential fields measurable at a distance (i.e., EEG signals). A favorable spatial organization in this respect is the arrangement of the neurons in palisades, where they are aligned with the main axes of the dendritic trees oriented parallel to each other and perpendicular to the cortical surface. When such a neuronal population is activated in a more or less synchronous way by synapses organized in well-defined layers, the resulting extracellular currents flow mainly parallel to the main axes of the neurons. In this way, a well-organized distribution of sinks and sources is formed (Figure 1).

The characteristics of EEG signals depend on the amount of correlation between the active neurons. This correlation is determined by the synchrony of the incoming signals and by the synaptic organization of the local circuits. Typically, a population of neurons sharing the same type of inputs and strongly interconnected can form a macroscopic source of an EEG signal. An essential feature of such a population is that the neurons are interconnected by way of feedback loops, involving excitatory and inhibitory synapses. This fact, in conjunction with the intrinsic oscillatory properties of some types of neurons, is responsible for the occurrence of brain rhythms, that is, oscillatory phenomena of EEG.

EEG Rhythms: Phenomenology and Functional Significance

Since EEG signals consist of time series that can vary from low to high frequencies, it is the general consensus to divide the frequency range within which EEG signals can occur in a number of frequency bands that have been named after Greek letters: δ (delta) = below 3.5 Hz, θ (theta) = 4–7.5 Hz, α (alpha) = 8–13 Hz, β (beta) = above 13 Hz, and the term γ (gamma) is often used for frequencies above 30–35 Hz. There are different α rhythms depending on brain area and behavioral state. The posterior (occipital, parietal, and posterior temporal areas) α rhythm is the classical brain rhythm that occurs in a state of relaxed wakefulness, particularly evident when the eyes are closed. The α rhythm is strongly attenuated, or even blocked, at the opening of the eyes, and it is also attenuated as the state of alertness is enhanced, such as by sensory stimulation or mental activities. The term μ (mu) is used for a special rhythm occurring over the rolandic or central area within the α frequency range. Most conspicuous is the blocking of the μ rhythm with contralateral movement (Figure 2), or even with the mental intention to perform a movement. The latter property can be used to activate a brain–computer interface with the aim of controlling robotic devices in paralyzed patients. In addition to these two rhythms in the α range, a

Figure 1 (Left) Schematic representation of a palisade of cortical pyramidal neurons and of the tissues enveloping the brain. These neurons receive synaptic activation at the dendrites. This results in the flow of an intracellular current along the dendrites toward the soma. These currents are compensated by volume currents in the extracellular medium, resulting in the formation of extracellular sources and sinks. (Right) Drawing of a head with the representation of the current dipole that is responsible for the EEG signal and the corresponding MEG field. The latter is oriented perpendicularly to the electric field.

Figure 2 Dynamic changes in EEG signals recorded from the central scalp area in a normal subject correlated to a brisk finger movement in three frequency bands: mu (10–12 Hz), beta (14–18 Hz), and gamma (36–40 Hz). Vertical scale indicates the change in power within a given frequency band relative to the baseline recorded seconds before the event. ERD, decrease in power or event-related desynchronization; ERS, the opposite. Note the μ ERD starting approximately 2 s before the movement, the γ burst just before the movement, and the postmovement β rebound.

midtemporal α rhythm was described over the temporal lobe in MEG recordings, although it is difficult to detect in EEG recordings unless there are bone defects. This rhythm is attenuated by sound stimuli but not by opening of the eyes.

Some authors consider that there is a basically functional similarity between the rolandic μ and the posterior α rhythms since both would represent 'resting states' of the corresponding cortical areas: the sensorimotor cortex in the case of the former and the visual cortex in the case of the latter. This would correspond to a resting state during which the underlying neuronal networks are not actively processing specific stimuli; for this reason, this state was described in the classic literature as 'idling' by Adrian and Mathews in 1934. Nevertheless, the functional significance of α rhythms, which has been a matter of some heated arguments, cannot be simply described as corresponding to an 'idling state' of some brain systems. The functional significance of α rhythms has to be derived from basic neurophysiology. In this respect, it is known from detailed electrophysiological investigations and comprehensive models that oscillations within the α frequency range, in general terms, can be generated by two interacting populations; in the thalamus such populations consist of the thalamocortical relay neurons (TCR) and the reticular nucleus neurons (RN), which form a feedback loop. The TCR neurons form excitatory synapses on the RN, whereas these form inhibitory synapses on the TCR neurons. During an oscillatory bout of activity in the α frequency range, the RN neurons are in an active state, although this results in inhibition of TCR neurons. The latter display oscillations around a mean membrane potential relatively hyperpolarized, but this hyperpolarized state does not imply that these neuronal populations are idling. On the contrary, they can play an active inhibiting role in gating the transfer of information in certain neuronal pathways. In summary, the α rhythm state may fulfill, in itself, a relevant functional role, namely a 'gating function.' In this context, it is also interesting to consider what additional information about the state of excitability of the neuronal population underlying α power enhancement may be gained by combining EEG recordings with other methods. Experiments in which EEG recordings and transcranial magnetic stimulation (TMS) of the sensorimotor cortex were combined showed an association between the inhibition of a motor response and a significant increase of 11–13 Hz oscillatory activity. How this is reflected in the blood oxygen level-dependent (BOLD) fMRI signal is still not absolutely clear.

Discussion about the relationship between EEG/MEG rhythms and the level of activity of the underlying neuronal populations has to take into consideration that different brain rhythmic activities may have different kinds of relationships. In the case of the relation between rolandic beta activity (approximately 15–30 Hz) and levels of neuronal activity, a clear

temporal relationship with peripheral electromyography (EMG) activity during isometric contractions was found using MEG recordings. The MEG signals in the beta frequency range lead the EMG signals in time, whereas the time lag increases with increasing brain–muscle distance. This means that this beta rhythmic activity corresponds to an active state of the populations of the motor rolandic cortex in terms of efferent bursts of action potentials that constitute the central drive to spinal motor neurons. Nevertheless, there are also conditions in which beta rhythms do not represent an active state in the sense defined previously. This is the case for the postmovement beta event-related synchronization (ERS) that occurs after the completion of a finger (16–21 Hz) or foot (19–26 Hz) movement over the contralateral cortical area when the muscles relax (Figure 2).

The ERS in the beta band (around 20 Hz) found after a movement corresponds to a period of decreased corticospinal excitability determined by applying TMS. Thus, this beta rebound ERS represents a state of cortical disfacilitation that takes place at the cessation of the movement. Indeed, a generalized statement regarding the correspondence between beta EEG activity at the scalp and the activity state of the underlying cortical neuronal populations, without further specification of cortical area, frequency band, and behavioral conditions, is not adequate.

In the case of activities within the gamma frequency range (above 30 Hz), it was found that bursts of gamma activity may occur just before a brisk finger movement that is associated with motor cortex activation (Figure 2); this was further demonstrated using direct electrocorticography. The underlying neuronal mechanism responsible for these cortical gamma oscillations was further unraveled by finding that synchronized gamma frequency oscillations are enhanced with arousal and attention or by electrical stimulation of the mesencephalic reticular formation, and they are mediated by cholinergic muscarinic receptors. Interestingly, a close correlation between hemodynamic signals and the power of local field potentials in the gamma frequency range in the visual cortex of the cat was reported. Gamma ERS currently plays a prominent role in neurocognitive investigations.

In general, we may state that information processing in the brain occurs in a parallel fashion, where distinct brain areas are active either simultaneously or in short succession. The corresponding activities can be reflected in the local EEG signals. However, these networks are very often not anatomically contiguous; that is, they may occupy quite different locations within the cortex, such that the corresponding EEG signals form a complex spatiotemporal pattern distributed over the scalp. To determine the functional interactions between the distinct cortical areas involved in a given cognitive task, the spatiotemporal relationships of different EEG signals have to be determined. In this context, several analytic measures of signal similarity and synchronization are used. When a subject actively processes information, β or γ activity is enhanced in the EEG. It has been hypothesized that these β or γ rhythms may represent the activity of integrative processes responsible for binding the activities of distributed neuronal networks in such a way that integrated percepts may be constructed or coordinated motor activity may occur.

EEG Signals in Vigilance and Sleep Stages

With the onset of drowsiness (sleep stage 1), the EEG changes gradually: the classic α rhythm becomes less continuous (α dropout), the amplitude declines, and the dominant frequency decreases toward the θ range. With the deepening of drowsiness, there is an enhancement of slow-wave components, and trains of 2 or 3 Hz and 4–7 Hz tend to appear. Typical of deep drowsiness is the appearance of sharp transients that are particularly evident in recordings from the vertex (vertex waves and K-complexes). These transients represent impulse responses of the neuronal networks when the δ mode of activity begins to dominate. In sleep stage 2, sleep spindles, or sigma waves, with frequencies between 12.5 and 15.5 Hz, also appear. In sleep stage 3, δ frequencies in the 0.5- to 3-Hz range are dominant, particularly over the anterior areas, whereas sleep spindles become less conspicuous and K-complexes occur frequently. In very deep sleep (stage 4), the slow waves within the δ frequency range are even more abundant than in the preceding stage. A most conspicuous phenomenon in the evolution of sleep is the sudden change of the deep-sleep EEG to the pattern of rapid eye movement sleep, characterized by a dramatic decrease of the EEG amplitudes and by the overwhelming presence of high frequencies. The neuronal mechanisms underlying different features of sleep are becoming better known. The discovery of the cortically generated very slow oscillation (0.5–1 Hz) that groups both low-frequency (spindles and delta) and high-frequency (beta/gamma) rhythms by Steriade's group is particularly interesting. These investigations showed that the low-frequency rhythms are generated by the synchronous firing of cortical neurons during the depolarizing phase of the slow oscillation, which impacts on the thalamic circuitry to generate spindles and delta EEG activity. These findings of the generation of sleep rhythms, initially described in intracellular studies of neocortical and thalamic neurons, are now supported by EEG/MEG studies during human

sleep. The activity of neocortical neurons during slow-wave sleep is likely associated with neuronal plasticity that may play a role in consolidating memory traces acquired during the state of waking.

Spatial Resolution of EEG

Both for research and for clinical applications, the general use of microprocessors has made possible the development of comprehensive digital (paperless) EEG systems. These systems offer the possibility of data acquisition, artifact rejection, editing and processing of the data, brain mapping, and statistical treatment of the EEG and derived data such as frequency spectra. Brain maps represent the spatial distribution of a given variable, such as the peak amplitude of an evoked potential, a spectral component, or a correlation measure. Although brain maps suffer from several handicaps due to the limited sampling in space commonly applied in clinical settings, and due to the ambiguity introduced by the montage used, they are becoming very popular. The poor spatial resolution of the EEG is an important handicap in the application of this methodology to the study of brain functions. Research is being carried out in an attempt to improve this situation. An essential aspect is that the EEG has to be recorded with a sufficiently large number (>64) of scalp electrodes to improve its spatial resolution. In addition, some forms of spatial deblurring need to be applied. One way is to compute the Laplacian derivation (LD). Another methodology uses a 'finite element deblurring' algorithm to correct the EEG potential field for distortion due to the transfer from the cortical surface to the scalp, and thus to estimate the electrical potentials that would have been measured at the cortical surface, given the EEG scalp distribution. These new methodological advances permit using EEG signals with a higher spatial resolution in order to obtain objective correlates with cognitive functional states.

Still another methodology used to improve the localization power of EEG is to make a parametric model of its underlying generators and to estimate the model parameters from the observed EEG distribution using standard parameter estimation techniques. Such models generally describe the activated synapses as current dipoles, embedded in a conductor consisting of different compartments, with different electrical conductivities: the brain, the skull, and the skin. Various assumptions can be made to parameterize the temporal variations of the current dipoles: either all dipole parameters vary over time (moving dipole models) or only the amplitude (stationary dipole models), or all dipole moments vary over time (rotating dipole model).

To reduce systematic errors in the estimated dipole parameters, it is of crucial importance to use the appropriate geometric description of the conductor and the appropriate electric properties. Currently, several volume conductor models are in use: concentric spherical models or, recently, realistic models of the subject's heads obtained from magnetic resonance imaging (MRI) scans and considering usually at least three head compartments – brain, skull, and scalp. Because the dipole position parameters appear in a nonlinear way in the regression model, equivalent dipolar sources are found using iterative numerical methods. The electric resistivities of the head compartments can be estimated *in vivo* and individually for each subject using a parameterized iterative nonlinear model. This procedure highly decreases systematic errors due to the use of inadequate electric parameters describing the head compartments based on literature values derived from *in vitro* measurements containing large systematic errors. Thus, it also reduces the systematic errors associated with the estimation of dipole position.

This dipole modeling approach has been most useful in the analysis of transient EEG phenomena localized to restricted brain areas, such as evoked potentials and epileptiform spikes. Estimating equivalent dipolar sources of such events using realistic head models based on MRIs can be used to analyze spatial relations between those sources and epileptogenic zones associated with a lesion visible on the MRI (Figure 3).

The Combined Recording of EEG and fMRI

Despite several sophisticated modeling approaches, the use of EEG for localizing sources in the brain is restricted to situations in which it is known *a priori* that the number of sources is limited and that their geometry is relatively simple. In many of these cases, the sources can be described approximately by equivalent dipoles. Such conditions typically occur at short latencies of evoked potentials (when mainly primary cortices are activated) or when isolated events such as interictal spikes are considered. For the analysis of phenomena such as spontaneous rhythms, dipole models should be applied with care. New technological developments partly circumvent the limitations of dipole modeling. It has become possible to combine EEG and fMRI scans in order to enhance the possibilities of dynamical brain imaging, by recording EEG inside the MR scanner, during constant acquisition of echo-planar imaging (EPI) images. This mode of recording is identical to that used in fMRI studies, in which the presence and absence of a stimulus or task given to the subject is

Figure 3 (Left) Spatial MEG map of the average of a cluster of interictal epileptiform spikes. (Right) Corresponding equivalent dipole (yellow dots and pointers) projected on three MRI slices (sagittal, horizontal, and coronal) and location of epileptogenic lesion. Note the location of the equivalent dipoles on the edge of the lesion.

correlated to the time variations of the MR signal at each pixel element of the EPI images. The localization power of fMRI is based on the fact that the fMRI signal from brain regions that are involved in processing the stimulus or task tends to correlate to the presence/absence of the stimulus/task, in contrast to brain regions that are not involved. The same underlying principle can be used in studies in which EEG and fMRI are recorded simultaneously. Under these conditions, the reference function correlated to fMRI is not necessarily the presence/absence of a task, but it can be derived from the EEG signal instead – for example, an epileptiform event. Combined EEG–fMRI was developed during the late 1990s with such clinical applications in mind, but the technique can also be applied to study other types of phenomena, such as sleep spindles and other spontaneous rhythms, whether or not they are in relation to cognitive tasks (Figure 4).

Although the simultaneous registration of EEG and fMRI is a very powerful combination with great potential, especially to study unpredictable phenomena that are thus impossible to study consistently with each technique separately (e.g., spontaneous brain rhythms), it should be realized that several technical precautions are necessary before it can be applied in practice. One point of concern is the safety of the subject, which is an issue because the long copper wires can pick up radiofrequency (RF) signals used in the MR scanner, and this can result in harmful currents if no safety resistors are used to reduce them. Other points of concern are the fact that standard EEG equipment does not have enough shielding and causes additional noise in the fMRI images. Finally, both the RF pulses and the gradient switches of the MR scanner cause large artifacts in the EEG that must be removed with dedicated software algorithms during postprocessing of the raw data.

Toward a New Era of Dynamical Brain Imaging

The EEG is an important aid to diagnosis in clinical neurology, mainly of irritative functional disturbances and particularly in epilepsy. Both the interictal and ictal EEG patterns of seizure disorders can yield important information for the diagnosis and

Figure 4 Correlation maps of the fMRI BOLD signal and the simultaneously recorded EEG (alpha rhythm frequency band). Correlation maps corresponding to the spontaneous variations of the alpha rhythm. The maps were obtained by computing the alpha power (occipital derivations) during each of the 600 coregistered EPI scans and correlating it with each of the BOLD signals, thereby accounting for confounders as motion, trends, and heartbeat effects. In the regression model, the alpha profile was shifted in time and multiplied with parameters, which constitute the hemodynamic response function. The significance of the partial correlation was tested using an *F* test, and the significances for all voxels were converted into a false detection rate (FDR). The map presents a color scale (cool colors – low; hot colors – large correlation values) of the (partial) correlation coefficient, which is thresholded at a correlation value of 0.22, corresponding to an FDR of 1%. The estimated hemodynamic responses (not shown) are mainly negative for voxels at the cortex and positive at the thalamus. The physiological meaning of this finding is that the thalamus is activated during generation of alpha band activity, whereas the cortex is relatively deactivated during these periods of time.

follow-up of these patients. The EEG is indispensable for the study of sleep disturbances and to characterize states of altered consciousness, such as in monitoring toxic effects of drugs, uremia, hypoglycemia, and, in general terms, coma. It is also of interest in monitoring some forms of anesthesia and in intensive care situations. Another interesting application of the EEG is to construct brain–computer interfaces, with the aim of controlling robotic devices in paralyzed patients using EEG-derived signals that can be modulated by mental imagery. Although the usefulness of the EEG in the diagnosis of brain lesions, such as tumors and stroke, has become less important because of the general availability of fine structural brain imaging techniques, mainly CAT and MRI scans, it still maintains its power in estimating the concomitant functional disturbances of the brain tissue. In addition, the modern quantitative EEG methodology is of increasing utility

in cases of difficult differential diagnosis and in the evaluation of functional disturbances related to psychiatric conditions.

The coregistration of EEG and fMRI opens new doors to the fundamental knowledge of the brain. In particular, it offers novel perspectives in the study of phenomena such as the spontaneous brain rhythms which play an important role as signaling elements associated with neurocognitive processes. This knowledge will eventually increase our understanding of neurocognitive processes in general and their disturbances in particular. However, the coregistration of EEG and fMRI also has the potential to shed more light into the fundamental relationship between electric and hemodynamic phenomena. The clinical relevance of this latter aspect is illustrated by the application of coregistered EEG and fMRI in epilepsy.

Technological developments of the EEG show that it is not a technique of the past but, on the contrary, holds the promise of contributing to a better understanding of the dynamics of the working of the brain.

Electrolocation

L Maler, University of Ottawa, Ottawa, ON, Canada

© 2009 Elsevier Ltd. All rights reserved.

Electric organs, found in several species of fish, produce weak electric discharges by the use of a modified muscle or nerve (electric organ discharge (EOD)). These feeble discharges (<1 V) are sensed by specialized electroreceptors (tuberous electroreceptors) distributed over the skin of the fish. Together, the electric organ and electroreceptors comprise the active electrosensory system; these fish also have a small number of ampullary-type electroreceptors sensitive to the low-frequency electric fields produced by other organisms (not discussed in this article). It is believed that electroreceptors evolved from lateral line receptors. However, unlike lateral line receptors, electroreceptors do not receive efferent input from the brain.

Active electroreception has independently evolved in two freshwater teleost families: the African mormyrid fish and the South American gymnotiform fish. The electrosensory system, like most other sensory systems, is used for two very different purposes: electrolocation and electrocommunication.

The patterning of EOD pulses can be either 'pulse' or 'wave' type (Figure 1). For a pulse fish, the pulse duration is far shorter than the interpulse interval, and the interpulse interval is, in many species, quite variable (i.e., an irregular electric discharge). For a wave species, the pulse duration and interpulse durations are similar and very constant in duration; the EOD of wave species therefore resembles a sine wave. Almost all mormyriform fish have pulse-type discharge (*Gymnarchus niloticus* is the one exception and is not discussed). Both pulse- and wave-type species are common in the gymnotiform family. There are many parallels in the electromotor/electrosensory circuitry of mormyrid and gymnotiform fish. Perhaps the greatest difference between African and South American electric fish is the presence of a corollary discharge or efference copy in the mormyrid, but not the gymnotiform, fish. Thus, in mormyrid fish, the medullary command nucleus sends a 'copy' of each EOD command spike to the electrosensory system, where it can be used to modify sensory processing. In gymnotiform fish, such a corollary discharge is not present, although a specialized type of time-coding electroreceptor can also signal the occurrence of each EOD.

Electrolocation

The EOD creates an electric field surrounding the fish. This field is distorted by the presence of conductors or nonconductors (Figure 2). For example, a crustacean such as *Daphnia* is more conductive than the water that electric fish inhabit. The EOD current will preferentially flow through the *Daphnia* and therefore activate a patch of electroreceptors in the skin below this tiny crustacean. A nonconductive object such as a rock will have the opposite effect: it will reduce the electric current over a localized patch of electroreceptors. The EOD is therefore a carrier; the signals important for electrolocation are amplitude modulations (AMs) of the EOD carrier. Electric fields fall off very rapidly with distance so that electrolocation is effective over only a few centimeters. Furthermore, unlike the visual system, the electric field has no focusing mechanism so that electric images are blurry. Despite these apparent disadvantages, the localized distortions of the electric field are still a sufficient cue for navigation and the electrolocation of small prey in total darkness.

Electric fish can locate their prey, as well as obstacles, in the dark. Like the visual system, and unlike the somatosensory system, this requires localization in three dimensions; accurate three-dimensional localization has in fact been behaviorally demonstrated in electric fish. Localization with respect to the fish's body axes (nose to tail and back to belly) is presumably carried out, as in the visual and somatosensory systems, with the aid of topographic maps. Work in both mormyrid and gymnotiform fish has suggested that the localization in the third dimension (distance from the fish's body) requires that the electrosensory system estimate the amount of blur of the electric image. The computations underlying this ability are not known and are the subject of current research.

There are now accurate models of the electric field for a number of species of electric fish. These models can be used to predict the effects of perturbations of the field by conductors and nonconductors at different distances from the fish's body. There are two major conclusions of these analyses: (1) the perturbations caused by prey are minute (<1 μV), and (2) at the swimming speeds used during prey capture, the perturbations caused by prey will produce low-frequency AMs (<20 Hz).

Gymnotiform fish have a ribbon fin that permits them to hover or swim forward and backward with ease. Excellent models of the mechanics of swimming in these fish are available. Combined, the models of electrosensory input and motor output provide insight into general questions of sensorimotor control during navigation and prey capture.

Electrocommunication

Electric fish can detect the EOD of nearby conspecifics; depending on the species, electrocommunication

Figure 1 (a) The top panel shows a single EOD pulse of the high-frequency species, *Apteronotus leptorhynchus*, and the bottom panel illustrates the typical wavelike appearance of its EOD. This fish's frequency was 770 Hz. (b) The top panel shows a single EOD pulse of the low-frequency species, *Gymnotus carapo*, and the bottom panel illustrates the typical pulse train appearance of its EOD. The resting EOD frequency was 70–75 Hz for this fish. Data for this figure were provided by Jason Middleton.

Figure 2 Electric images. An gymnotiform fish, *Apteronotus leptorhynchus*, is illustrated. The electric organ of these fish, located in the caudal half of the trunk and stretching back through the tail, forms an electric dipole at each electric organ discharge. The electric field created surrounds the fish and creates electric current flow through the cutaneous electroreceptors. Objects distort this electric field. A conductive object such as prey will cause an increase of local current density; this results in a blurred electric image (red) of increased electric current that increases the firing rate of the affected electroreceptors. In contrast, a nonconductor such as a rock will decrease the local current density. This results in a blurred shadow of decreased current flow (blue) and a reduction in firing rate of the affected electroreceptors. This is the basis of electrolocation.

is thought to be effective at distances up to at least 50 cm. The EOD is typically, at least over a short time scale, almost constant in amplitude. Electric communication signals are therefore based on changes in the EOD rate, and either increases or decreases in rate have been hypothesized to be important signals. A great deal of research in this area has focused on a 'wave-type' species of gymnotiform fish, *Apteronotus leptorhynchus*; the EOD of this species resembles a nearly constant high-frequency sine wave (species range, 650–1000 Hz), with males having a higher frequency than females. The frequency difference between males and females is an important signal for these fish. Some wave species forage in groups, and it has been proposed that the complex patterns (envelopes) produced by the summation of their EODs might act as an additional signal for identifying individual fish in the group.

Two major types of active electric communication signals have been described for this species: chirps and rises. Chirps are transient (~20 ms) increases in EOD frequency that are emitted mainly by mature males. Therre are two types of chirps: small (~100 Hz frequency increase) and large (~400 Hz frequency increase). Small chirps occur in response to the EODs of other males (EOD frequencies similar to those of the chirping fish) and are believed to be an aggressive signal. Large chirps are elicited by the EODs of females (EOD frequencies lower than those of the chirping fish) and are believed to be involved in courtship behavior. In contrast to electrolocation signals, chirps cause high-frequency amplitude modulations of the carrier EOD. The population of electroreceptors codes for small and large chirps with very different patterns of discharge. The extraction of these different patterns and final identification of the chirp type by higher order neural processing is an important problem under investigation.

Rises are long, slow increases in EOD frequency made primarily by females in response to the EODs of other females. Again, there may be several varieties of rises. It has been suggested that different types of rises represent submissive signals and female–female aggressive signals.

The neural circuits controlling the EOD have been worked out in some detail for both mormyrid and gymnotiform fish. A medullary command or pacemaker nucleus initiates each EOD and projects to the spinal electromotor nucleus. Diencephalic and mesencephalic prepacemaker nuclei in turn project to the command nucleus and control modulations of EOD frequency. As might be expected, the prepacemaker nuclei receive highly processed electrosensory input. However, these nuclei also receive substantial serotonergic input from the medullary raphe nuclei as well as multiple peptidergic inputs (enkephalin, galanin, substance P, and somatostatin) from hypothalamic sources. Presumably, these inputs mediate 'motivational' control over electric communication signals. It is therefore not surprising that the sexual dimorphism of chirp signals seen in some species is paralleled by the sexual dimorphism of serotonin and some peptidergic input to the prepacemaker nucleus. In addition, hormones such as testosterone, cortisol, and vasotocin can modulate electric communication signals, although the site of their action is not known. The ease of recording and manipulating electric communication signals has made electric fish a useful model system for studying the neural basis of animal communication.

Electroreceptor Coding

There are many types of electroreceptors and each utilizes different signal encoding strategies. In general, there are different types of electroreceptors tuned for conveying precise information on the timing versus the amplitude of electrosensory signals; the time and amplitude coding pathways are kept separate up to the midbrain. The most detailed computational analyses have focused on an amplitude coding electroreceptor found in wave-type electric fish termed the P-unit; P-units discharge in a probabilistic manner in response to the unperturbed EOD. Thus, for a fish with an EOD frequency of 1000 Hz, a P-unit with a p value of 0.15 would discharge at 150 spikes s^{-1}. The firing rate of a P-unit is controlled by the intensity of the electric field it senses; thus, a P-unit with a rock (nonconductor) above it might decrease its discharge to less than 10 spikes s^{-1}, whereas the presence of a *Daphnia* (conductor) near the receptor would increase its discharge to more than 300 spikes s^{-1}. The spatial pattern of the P-unit firing rate is one key coding strategy used by electric fish, as well as many other sensory systems, to gain information about spatial features of their environment.

The spontaneous discharge pattern of P-unit receptors is highly irregular, but careful statistical analysis reveals that it is not entirely random (not a renewal process). The statistical structure of the P-unit spike train optimizes these receptors for the detection of both low-frequency (electrolocation) and high-frequency (communication) signals. The mechanisms responsible for detecting such a wide frequency range of signals include biophysical reduction of noise levels by spike frequency adaptation and also frequency-dependent synchronization across the population of P-units. There are now very accurate models of P-unit electroreceptors; combining these models with those of the electric field permits researchers in this field to accurately predict the electroreceptor input to the brain in response to environmental signals such as rocks and prey as well as to communication signals such as chirps. Electroreceptors have been useful for investigating neural coding since the 1960s and are a useful model system for this purpose.

Central Pathways for Electroreception

Electroreceptors project to a hypertrophied medullary nucleus, the electrosensory lateral line lobe (ELL) (Figure 3). The ELL is a layered structure with separate layers for electroreceptor input, interneurons, principal cells, and feedback/descending input. The principal cells are mainly pyramidal cells with both basal and apical dendrites: The basal dendrites can receive input from electroreceptors, the soma receive input from interneurons, and the prominent apical dendrites receive extensive descending and feedback input. The ELL is also segmented. In mormyrid fish, there is one segment in receipt of ampullary input and two segments in receipt of different types of tuberous electroreceptors. In gymnotiform fish, one segment also receives ampullary input, whereas three segments receive identical collateral input from tuberous receptors including P-units. Thus, in gymnotiform fish, all three tuberous segments receive identical inputs; the specialized roles that these segments might play in electrosensory processing are under investigation. In all cases, the electroreceptor input is topographically arranged (all maps in both mormyrid and gymnotiform ELL). Thus, the familiar topographic principle of sensory representation seen in the somatosensory (somatotopy), visual (retinotopy), and auditory (tonotopy) is also expressed in the electrosensory system.

There are many subtypes of interneurons found in the ELL; a subset of these are GABAergic and, as in other sensory systems, engaged in regulating neural processing in both the temporal and spatial domains. In the temporal domain, inhibition allows the electrosensory system to respond to transient and high-frequency input.

Pyramidal cells in ELL have typical receptive fields: input to electroreceptors in a small patch of skin is capable of exciting these cells. In the spatial domain, specific types of inhibitory interneurons participate in the generation of surround receptive fields. Thus, many pyramidal cells have receptive fields with the center-surround organization very similar to that described for retinal ganglion cells. There is an even more remarkable similarity between retina and ELL. One morphologically defined population of ELL pyramidal cells is functionally equivalent to ON center–OFF surround retinal ganglion cells (receptive field center responsive to conductive objects); a morphologically distinct population is functionally equivalent to OFF center–ON surround retinal ganglion cells (receptive field center responsive to nonconductive objects). The presence of multiple topographic maps with different tuning curves is highly relevant to current theoretical analyses of the effect of tuning curves (center–surround organization in this case) on population coding.

Electroreceptors utilize glutamate as a neurotransmitter, as do most of the feedback pathways to the ELL. Both AMPA- and NMDA-type ionotropic glutamate receptors have been localized in the ELL as well as other regions of the electric fish brain (both gymnotiform and mormyrid). The NMDA receptors of gymnotiform fish have been cloned and found to

Figure 3 Simplified schematic of major neuronal pathways of a gymnotiform fish; there are similar pathways in mormyrid fish, but there are additional complex pathways related to the corollary discharge to sensory regions that are not illustrated here. Ascending electrosensory pathways are shown in red, feedback pathways in blue, and electromotor pathways in black. Only the most prominent contralateral projections are indicated. Electroreceptors project topographically onto the ipsilateral electrosensory lateral line lobe (ELL); the presence of three maps is not indicated here. The structure of a major projection neuron, the basilar pyramidal cell, is also indicated; the basal dendrite is in receipt of electroreceptor input. The ELL projects to the nucleus praeminentialis (nP) and the midbrain torus semicircularis (TS). The TS in turn projects topographically to the optic tectum (TeO) for control of movements associated with prey capture and navigation. The TS also projects diffusely to the nucleus electrosensorius (nE), a diencephalic region that extracts species-specific electric communication signals. The nE projects to the prepacemaker nucleus (PPn). The PPn also receives extensive additional input from hypothalamic and other brain regions and initiates electric communication signals by modulating the activity of the pacemaker nucleus. The PPn projects to the pacemaker nucleus (PM); cells in the PM cause the baseline (unmodulated) electric organ discharge (EOD). The PM projects to electromotor neurons in the spinal cord; these in turn project to the electric organ in the tail of the fish to generate the electric field that stimulates the electroreceptors. The nP receives both ascending (ELL) and feedback (TS) electrosensory input. In turn, it provides feedback projections to the ELL; these terminate predominantly on the apical dendrites of ELL pyramidal cells. The direct and indirect feedback pathways are not shown.

be highly conserved; ELL pyramidal cells express high levels of NMDA receptor. As discussed later, it may be critically important in adaptive plasticity of descending and feedback projections to ELL.

The dendritic specialization of ELL pyramidal cells (basal and apical dendrites receive different inputs) has prompted extensive work on the possible molecular and biophysical correlates of these anatomical differences. At least in the gymnotiform ELL, there appear to be important differences in the distribution of at least Na^+ and K^+ voltage-gated channels on the basal versus apical dendritic trees and perhaps in the distribution of various second messengers as well. Such differential dendritic distribution of ion channels has frequently

been reported for pyramidal cells of mammalian cortex, but its function remains unknown. In ELL, some of these dendritic ion channels appear to mediate and regulate dendritic backpropagating potentials that are important for spike bursts. Spike bursts have specific coding properties in the pyramidal cells (they detect low-frequency input). Thus, in ELL, it may be possible to directly link dendritic biophysics to sensory computations.

The ELL projects to predominantly contralateral higher brain centers via the lateral lemniscus, a thick myelinated fiber track. There are two main targets: a hindbrain nucleus termed nucleus praeminentialis (nP) and the midbrain torus semicircularis (TS). The nP is involved solely in feedback projections to ELL and is discussed later. The TS is similar to the inferior colliculus of mammals; there are far more neurons in TS than in ELL. The TS of gymnotiform fish has a complex layered structure, whereas that of mormyrids is organized into discrete nonlayered nuclear groups. For both families of electric fish, the different ELL maps converge in TS, as do the time and amplitude coding pathways.

The TS of gymnotiform fish has been studied in detail. It projects mainly to three target regions: the nP, the optic tectum, and the nucleus electrosensorius. The projections to the nP imply that higher order electrosensory processing can influence first-order processing in ELL (since nP is a feedback nucleus projecting back to ELL); this is a common theme in mammalian sensory systems in which cortical sensory areas provide strong feedback to brain stem sensory regions. The exact role of TS to nP feedback projections is not known.

The optic tectum (superior colliculus in mammals) is a highly conserved midbrain nucleus of vertebrates that typically receives retinal input and directs the eyes and body toward salient visual features. It is also typical that other senses, such as touch or audition, project to the deeper layers of the superior colliculus and can therefore also initiate orientation toward these stimuli. It is not surprising that TS (electrosensory) projects topographically to the deeper layers of the gymnotiform tectum and that there are tectal cells which respond to both electrosensory and visual input. Although this has not been studied in-depth, it is assumed that the tectum acts as the interface between the electrosensory and motor systems.

The TS projections to the nucleus electrosensorius (a diencephalic brain region) appear to be diffuse (not topographic). Electrophysiological recordings from this nucleus demonstrate that it responds to various types of communication signals, including chirps. Thus, there appears to be a segregation of neural processing by which electrolocation is mediated via the optic tectum, whereas electrocommunication is mediated by the nucleus electrosensorius. The nucleus electrosensorius projects to both the prepacemaker nuclei and the hypothalamic regions; the hypothalamic projections presumably mediate motivational functions of electrosensory input but have not been investigated in detail.

The TS of gymnotiform fish has been intensely investigated with respect to both its morphology and its electrophysiology. There are approximately 50 different cell types in TS, and a subset is tuned for specific frequency modulations of the EOD. The frequency selectivity is dependent on both voltage-gated ion channels and synaptic plasticity. Furthermore, some of these neurons are also very sensitive to object motion, and in some cases they are directionally selective (i.e., they may respond preferentially to head-to-tail movements or vice versa). Like the ELL pyramidal cells, different neurons are selectively responsive to conductive (prey) or nonconductive (rocks) objects. The TS clearly has far more specific tuning than its input ELL pyramidal cells (more sparse coding); the role of synaptic plasticity in sparsifying the ELL input is a key topic of research for the TS.

Feedback and Descending Pathways and the Cancellation of Redundant Signals

The nP of gymnotiform fish projects back to the ELL via three pathways: direct inhibitory and excitatory feedback and an indirect excitatory feedback.

A small group of GABAergic neurons project back directly to ELL pyramidal cells. These cells appear to be responsible for gamma range oscillations (30–40 Hz); the role of such oscillations in sensory processing remains to be firmly established, but it has been suggested that they may enhance directional movement detection.

A subset of glutamatergic nP cells (stellate cells) project directly back to the proximal apical dendrites of ELL pyramidal cells (both mormyrid and gymnotiform fish). This is a topographic, excitatory projection and has been hypothesized to mediate a 'searchlight' of attention to movement of objects such as prey.

Several different types of glutamatergic nP cells project back as mossy fibers to the granule cells of the caudal cerebellum. The recipient granule cells then project their parallel fibers down to the distal apical dendrites of ELL pyramidal cells. These parallel fibers make excitatory synaptic connections onto dendritic spines that utilize both AMPA and NMDA receptors. Studies have demonstrated that this pathway (in both mormyrid and gymnotiform fish) supports anti-Hebbian plasticity, likely implemented by NMDA receptors. This plasticity in turn mediates the cancellation of predictable sensory input.

In mormyrid fish, the corollary discharge is a predictive signal arising from the electromotor command nucleus. The corollary discharge signal reaches the caudal cerebellum; when descending corollary discharge input to the pyramidal cell's apical dendrites is consistently paired with electroreceptor input, the descending input is modified so as to form a 'negative image' that cancels the electroreceptor input. The corollary discharge represents a very brief signal (each EOD), and in this case the anti-Hebbian plasticity was shown to require spike-timing-dependent plasticity (STDP). This was one of the first demonstrations of STDP and is still the only one linked to a well-defined function.

In gymnotiform fish, a similar circuit is also present. In this case, however, the predictable signal comes from sources such as tail bending. The rhythmic tail bending of many gymnotiform fish causes predictable amplitude modulations of the EOD. These low-frequency AMs are readily detected by the electroreceptors but are ignored by most ELL pyramidal cells. The cancellation of such redundant low-frequency signals is also mediated by the cerebellar feedback fibers to distal apical dendrites of ELL pyramidal cells; again, the mechanism is that of anti-Hebbian synaptic plasticity. In this case, the circuitry has also been analyzed in detail and involves nonadaptive pyramidal cells driving the plasticity of the adaptive ones. Presumably, the cancellation of such redundant signals improves the detection of more important unpredictable signals such as moving prey.

In both mormyrid and gymnotiform fish, NMDA receptors associated with the cerebellar feedback/descending input are critically involved in the cancellation of predictable input. It is also likely that second messenger cascades, including protein kinase A (cAMP-dependent phosphorylation) and calcium/calmodulin-dependent kinase, are essential for this process. Further work in this area promises to link molecular and cellular mechanisms directly to systems processes such as redundancy reduction.

More Complex Learning

The forebrains of gymnotiform and (especially) mormyrid fish are both larger and better differentiated than those of most other teleosts. Furthermore, there are high levels of both NMDA receptors and protein kinases in the dorsal (pallial) forebrain of gymnotiform (and likely mormyrid) fish. This suggests that the weakly electric fish might be capable of learning complex tasks. Work in this area is only in its initial stages but does suggest that the electric sense can support the learning of spatial shapes and patterns.

Electromyography (EMG) and Nerve Conduction Studies

Definitions

Electromyography (EMG) is a technique whereby extracellular current fluxes are recorded from muscles at rest and during voluntary activation. Most commonly, signals are recorded from an intramuscular concentric needle electrode, but recordings can be made from surface electrodes placed on the skin overlying the muscle to be studied. Signals are amplified and filtered digitally and displayed in real time. When needle electrodes are used, action potentials from single muscle fibers that are spontaneously active (fibrillation potentials) may be recorded, as may the combined response of all muscle fibers innervated by a single motor axon (motor unit potential). Motor unit potentials may occur spontaneously (fasciculation potentials) but usually are seen in response to voluntary, reflex, or electrically stimulated activity of motor neurons within the central nervous system. With appropriate processing, motor unit potentials can sometimes be isolated from signals recorded with surface electrodes, but responses of individual muscle fibers and motor units in deeper muscles usually cannot be seen without intramuscular electrodes.

Electromyographic signals are recorded for research purposes to assess the timing and level of voluntary, reflex, or other muscle activation; simultaneous recordings from multiple muscles can also be used to investigate central control of motor activity. However, EMG is primarily a clinical tool used to evaluate a variety of diseases in which the peripheral neuromuscular system is affected. Motor unit potential morphology and discharge patterns are altered by both muscle and nerve disease, usually in opposite ways. Because only muscle membrane activity is recorded (and not force), disorders that primarily affect the contractile apparatus within muscle will not affect individual motor unit potentials but may alter discharge rates.

In clinical laboratories, EMG is usually performed in conjunction with nerve conduction studies (NCSs); these studies usually involve electrical stimulation of a mixed sensory and motor nerve bundle with recording of compound sensory responses from cutaneous fibers, or they involve compound motor action potentials from muscle fibers innervated by the nerve being stimulated. Because only current fluxes rather than transmembrane potentials are being recorded, sensory NCSs assess conduction only in the largest diameter myelinated fibers that produce the greatest current flows, whereas motor studies reflect activity in most or all of the alpha motor axons directed to the muscle being recorded. NCSs are particularly useful to evaluate generalized and focal disorders of nerves rather than primary muscle disorders. Although NCSs have evolved primarily as a clinical tool, research applications continue to appear. One current research application is in the area of excitability testing, in which NCSs are used to evaluate the local sources and time courses of ionic currents that occur in response to an evoked action potential. Finally, neuromuscular transmission can be studied using both EMG and NCS.

With a specially designed EMG needle and filters that attenuate spatially remote signals, action potentials from two muscle fibers within the same motor unit may be recorded simultaneously (single-fiber EMG). The precise temporal relationship between the firing patterns of the two fibers provides information about the effectiveness of neuromuscular transmission. In addition, if motor nerves are stimulated repetitively, the extent to which the compound motor action potential amplitude declines with repeated stimulation is a measure of the inability of the neuromuscular junction to sustain transmission. Although EMGs and NCSs are typically used to evaluate processes peripheral to the spinal cord, more central systems may also be studied. The mono/oligosynaptic stretch reflex may be studied electrically by stimulating muscle primary (Ia) afferents and recording motor potentials from the corresponding muscle (H reflex). Prior stimulation or concurrent sensory stimulation to evaluate, in particular, spinal circuitry subserving recurrent, reciprocal, and presynaptic inhibitory pathways may modify this reflex. In addition, the recently developed technique of transcranial magnetic stimulation can be used to evaluate the integrity of motor pathways from cortex to muscle.

Studies of Nerve Conduction

Many aspects of axon conductivity may be assessed with nerve conduction studies; in the clinical laboratory, however, only conduction velocity and response amplitude are measured. Motor axons and sensory axons can be evaluated separately, and different subtypes of sensory fibers can be selectively studied. Axon numbers are reduced in a variety of clinical disorders. In generalized neuropathies, axons of many or all modalities are lost, often with a distal-to-proximal gradient, whereas focal neuropathies reduce axon numbers in a particular nerve distribution. More proximal disorders of nerve roots or spinal cord will

also result in axonal dropout; however, if the site of the disease process is proximal to the dorsal root ganglion, only motor fibers will be affected. Thus the ability to distinguish between loss of motor or sensory axons is of clear clinical importance.

Measurements of conduction velocity are useful to evaluate the pathogenesis of different neuropathic conditions. When the primary site of pathology is the nerve cell body or axon itself, the number of functioning axons will be reduced but conduction will be unaffected in those axons remaining. In contrast, other disease processes affect the Schwann cell or the myelin sheath that surrounds large-diameter, rapidly conducting axons. Disruption of the myelin sheath may produce slowing of conduction in some or all myelinated fibers, sometimes with relatively little associated axon loss. In addition, focal areas of demyelination can render an axon locally unexcitable, even though conduction may persist both proximal and distal to the area of damage. Such an axon would be unable to transmit impulses between the spinal cord and the appropriate target organ. Such focal dysfunction is known as conduction block.

Clinicians perform nerve conduction studies by applying an electrical current pulse to the skin overlying a mixed (sensory and motor) peripheral nerve. With such stimulation, individual axons can be stimulated to produce action potentials. Nerve fibers are much more sensitive to electrical stimulation than muscle fibers are, so even when a nerve lies beneath muscle it is almost always preferentially stimulated by surface electrodes. So-called direct electrical stimulation of muscle with current pulses less than a few milliseconds in duration actually produces contraction indirectly by stimulating motor axons as they pass through the muscle. Within the nerve itself, certain axons are more apt than others to give rise to action potentials. In general, larger-diameter axons have higher sensitivity (lower thresholds) to external electrical stimulation; therefore, when a mixed nerve is stimulated, large-diameter sensory fibers are activated most easily, followed by axons of alpha motor neurons. Geometric considerations are also very important; fascicles lying closer to electrodes on the skin surface will be stimulated more effectively than will be deeper-lying fascicles. With appropriate stimulus intensities, it is usually possible to stimulate all large-diameter (sensory and motor) axons; to stimulate smaller myelinated sensory fibers and any unmyelinated fibers, extremely strong (and therefore quite painful) stimuli are required.

Motor Conduction Studies

A stimulus of appropriate intensity and location will cause action potentials to arise in all motor axons present in a mixed nerve, and a compound muscle action potential (M response) can then be recorded using a surface electrode placed over the motor point of a muscle innervated by the stimulated nerve, with an indifferent electrode placed over a bony prominence. The recorded potential can be characterized in a number of different ways; the two clinically most useful measures are (1) onset latency and (2) baseline to peak amplitude. The onset latency reflects conduction in only the fastest few fibers and is a function of nerve conduction velocity, speed of neuromuscular transmission, and conduction along the muscle membrane. If, however, the same nerve is stimulated at a second location, the difference in onset latencies can be used to calculate nerve conduction velocity if the distance between the stimulating electrodes is known. Obviously, the accuracy of such measurements depends on the ability to determine the length of nerve between the two locations.

Because motor axons conduct with a fairly restricted range of velocities, and the duration of muscle action potentials is much longer than nerve action potentials, the amplitude of the compound response directly assesses the number of muscle fibers activated. This number is not a direct measure of the number of motor axons responding; in conditions of chronic axon loss, surviving axons reinnervate muscle fibers that have lost synaptic contact. Thus a reduced number of motor axons may still contact all available muscle fibers. Therefore, motor action potential amplitude is not a sensitive measure of axon loss.

The compound motor action potential can be studied in a way that more directly assesses both axon loss and resultant terminal reinnervation. This technique, known as motor unit number estimation (MUNE), was first proposed more than 30 years ago, but continues to be refined and is increasingly employed clinically and as an outcome measure in clinical trials. A number of MUNE techniques have been developed and remain in use; all rely on the same basic premise: the response amplitude of an average single motor unit potential (SMUP) is calculated, then it is divided into a maximum response, the compound muscle action potential (CMAP), to derive a number that estimates the total number of units present (the MUNE). Of the MUNE techniques that have been devised (incremental, multiple point stimulation spike-triggered averaging, F wave, and statistical methods), only the method of sampling the SMUP responses varies. Although differences of opinion remain among MUNE investigators as to which method should be used, the statistical and the multiple point stimulation (MPS) MUNEs currently enjoy the most widespread use.

In diseases characterized by progressive motor unit loss, such as amyotrophic lateral sclerosis (ALS),

MUNE can be used reliably in the longitudinal evaluation of patients. Multiple studies have demonstrated a decline of the number of the motor neurons with disease progression. MUNE has been employed as an outcome measure in several multicenter ALS treatment trials. MUNE can be used for assessing the effects of both neuroprotective therapies and therapies designed to enhance collateral reinnervation as it enables quantitation of motor unit numbers while simultaneously estimating the collateral reinnervation. MUNE may also have a significant potential in clinical decision making, as suggested by studies showing that a single MUNE evaluation and a demonstration of rapid decline of MUNE are both strong predictors of survival in ALS. In addition, it was shown that MUNE could be used to detect motor neuron loss prior to onset of symptoms.

In most situations, amplitude and shape of the compound muscle action potential is invariant to changes in stimulating electrode position, so that proximal and distal stimulations produce responses that differ in onset latency only. However, diseases that affect myelin may cause dispersion in conduction velocities, so that the amplitude of the compound response may decrease with proximal stimulation even though the number of stimulated fibers remains the same. This may be confused with true conduction block; however, because the pathophysiology of both events is segmental demyelination, the distinction is not critical.

Sensory Conduction Studies

Sensory conduction studies require recording of nerve action potentials directly. Because electrical current fluxes surrounding nerve are much smaller than those surrounding muscle, up to 1000 times greater amplification is often required to record from the former. Typically a mixed nerve is stimulated, and recordings are made from electrodes placed on the skin over the cutaneous field supplied by the nerve. Conductive gels and mild skin abrasion are used to reduce the impedance between skin and recording electrode. The compound sensory action potential is a more direct reflection of nerve function than is the motor action potential just discussed, because no intervening neuromuscular junction exists and the response amplitude is a more direct reflection of total number of nerve fibers responding. Thus conduction velocity can be calculated from a single recording site. However, given that the distribution of axon diameters is considerably greater for sensory than for motor axons, both onset latency and response amplitude are indicators of conduction in only the largest diameter, fastest conducting axons.

Conduction in slower-conducting sensory fibers can be studied in several different ways. Instead of recording from electrodes applied to the skin surface, needle electrodes may be placed within several millimeters of the nerve (near-nerve recording technique). With appropriate amplification and filtering, recordings from these needle electrodes reflect activity in axons with diameters as small as one-fourth of the largest diameter sensory axons (small myelinated fibers in Aδ range). Although many myelinated and all unmyelinated fibers are still left unrecorded, the ability to analyze activity in smaller myelinated sensory axons is very useful in the evaluation of a variety of different neuropathic conditions.

To be able to record the response of unmyelinated fibers (C fibers) the technique of microneurography was developed. As unmyelinated fibers have a diameter of less than 1 μm and conduct as slow as 0.5 m s^{-1}, the current fluxes generated by action potentials are too small to be recorded by electrodes outside the nerve bundle. With microneurography, a tungsten electrode is inserted directly into the nerve bundle being studied and single unmyelinated C fiber responses can be recorded. Important applications of this technique include analysis of sympathetic efferent activity, as well as investigation of the receptive field properties of different afferents, such as receptive field size and preferred stimulus.

Small-diameter sensory and motor axons can also be evaluated using tests of autonomic function. Changes in skin resistance can be measured; they are mediated by activity in unmyelinated autonomic efferent sudomotor fibers to the hand or foot after one or other innocuous stimulus. The latency of this sympathetic skin response is very long, because efferent conduction velocity is about 1 m s^{-1}. This response (sometimes called the psychogalvanic reflex) is absent in conditions that interrupt conduction in unmyelinated efferents. Because conduction in unmyelinated fibers cannot be slower than it is normally, abnormalities are manifested by absence of the response rather than increases in its latency. In addition, autonomic afferent and efferent pathways can be studied by recording the variability of heart rate as a function of controlled deep breathing.

Axons may be affected by disease or external stress in ways that are reflected by changes in membrane excitability. A noninvasive battery of excitability measures has been developed that yield information about specific ion conductance channels, as well as how such channels are affected by disease processes. Threshold tracking measures, rheobase, and activity-dependent axonal conductance measures have been obtained in normal individuals, as well as in patients with neuropathy and motor neuron disease. Results in patients with diabetic neuropathy suggest a defect in inward rectification, while ALS patients tend to

show a pattern of abnormalities suggesting a persistent sodium conductance not seen in normal persons. Such insights are not available using traditional methods of clinical neurophysiology; thus, excitability testing holds the promise for more detailed study of membrane processes in a variety of peripheral nerve disorders.

H Reflex and Late Responses

To study conduction in more central segments of peripheral nerve, including plexus and roots, volleys of impulses produced by peripheral stimulation pass centrally into the spinal cord and then back out to muscles where the activity can be recorded. Tendon reflexes are produced by activity traveling toward the cord in large-diameter Ia sensory fibers and then back to muscles in alpha motor axons. Their neurophysiologic counterpart is the H reflex, in which afferent volleys are produced by electrical stimulation of spindle primary afferents rather than by mechanical stimulation of their intramuscular endings, and the compound muscle action potential is recorded rather than the clinically observed joint movement. Absence of the H reflex or marked prolongation of its latency usually reflects abnormalities in peripheral nerve conduction, but it may not be possible to separate sensory from motor abnormalities. Supramaximal stimulation of a mixed nerve produces, in addition to impulses in sensory axons and in motor axons conducted distally to the muscle, impulses in the same motor axons that travel antidromically through the ventral roots into the motor neuron pool. An impulse in some of these axons, once it reaches its motor neuron, fails to die out and, in that motor neuron, gives rise to another impulse that is then conducted orthodromically back out, where it can be recorded from muscle as an F wave. Neural activity responsible for F waves travels both to the spinal cord and back out again through motor axons: F waves are therefore not reflexes – their afferent arcs are not made up of sensory fibers. The F wave latencies are nevertheless useful, because they are inversely proportional to conduction velocity throughout the entire length of a motor axon.

Clinical EMG

EMG provides invaluable information about the functional status of individual motor units, including, of course, their spinal motor neurons. Electromyographic evaluation of a single muscle involves investigation of three distinct properties. First, electrical activity present during complete relaxation is studied. Normal muscles are silent; that is, no significant spontaneous activity occurs in the motor neuron or muscle fibers. However, any process that causes loss of motor axons will, at least acutely, result in the presence of some denervated muscle fibers. Initially, such fibers are silent; however, over the course of 2–3 weeks (and associated with the proliferation of postsynaptic acetylcholine receptors along the sarcolemmal surface), they become spontaneously active and generate action potentials called fibrillation potentials. Once established, fibrillations from a denervated muscle will persist until contact with another motor axon is established. In addition, if a motor axon is damaged but not destroyed, spontaneous activity may also occur, the origin of which is the axon itself; such potentials are called fasciculations. Muscle diseases usually do not involve destruction of motor axons, so it might be expected that spontaneous activity would be absent. However, in many (particularly inflammatory) myopathic processes, muscle fibers split. Under those conditions, part of the fiber may remain connected to a motor axon but the other part is functionally denervated. If an axonal connection is not rapidly established, fibrillation potentials will occur in this latter part.

In addition to analyzing spontaneous activity, EMG involves the study of voluntarily activated motor units. Mild voluntary contraction usually results in the activation of one to three different motor units within the region being recorded by the needle electrode. The morphology of an individual motor unit potential is a product of the number of muscle fibers in that unit and the spatial distribution of those fibers with respect to the recording electrode. Within a muscle, a normal motor unit includes some but not all muscle fibers in a specific location (Figure 1). The amplitude of the recorded potential from that unit will be a reflection of both the number of fibers activated and their proximity to the electrode. The duration will reflect primarily the spatial extent of the motor unit. Diseases that produce a loss of motor axons will, after 2–3 months, also be associated with remodeling of existing motor units, so that more muscle fibers are innervated by a single axon. This will produce the electrical changes shown in Figure 1; motor unit potentials will be larger and more prolonged than normal. In contrast, diseases that are primarily directed at muscle itself will not alter the number of motor units but will reduce the number of functioning muscle fibers; motor unit potentials will then be abnormally small in amplitude and short in duration.

In most clinical laboratories, evaluation of motor unit morphology remains a subjective task; electromyographers view the potentials in real time on a computer screen and derive an impression of whether potentials are small or large, brief or prolonged.

Figure 1 A single motor unit branches terminally to innervate some but not all muscle fibers within an area of muscle. The action potential produced by each motor unit is seen in the upper right of each section. The normal-appearing but unshaded fibers belong to other motor units. (a) In a normal motor unit, some but not all muscle fibers in a local area are innervated by the same axon. (b) In a myopathic unit, terminal axons are attempting to innervate dysfunctional muscle fibers, resulting in an action potential that is reduced in amplitude and duration. (c) In a reinnervated motor unit occurring as a consequence of chronic axon loss, a single axon innervates more muscle fibers than in the normal situation, resulting in an action potential that is larger in amplitude and longer in duration.

Usually the signals are stabilized by a triggering mechanism. Quantification of duration and amplitude using either weighted averaging or template-matching algorithms is available in most EMG machines, but is not often used in routine studies. In addition to analysis of spontaneous activity and motor unit morphology, EMG also evaluates the pattern of motor unit activation. The central nervous system encodes an increase in muscle activation in two ways: (1) motor units that are initially active at low levels of force production increase their firing rates and (2) motor units that had previously been silent are recruited into activity. Thus an EMG needle recording from a muscle with increasing activity should note these two parallel processes. If the number of motor units is reduced because of motor axon loss, the EMG should show the normal increase in firing rate in those motor units available to discharge, but a reduction in the number of additional motor units recruited as force is increased. This reduced motor unit recruitment occurs immediately after nerve injury preceding the development of fibrillation potentials or changes in motor unit morphology. In contrast, if the number of motor units is normal but the number of muscle fibers is reduced because of muscle disease, an attempt to increase muscle activation will result in both the increase in firing rate of previously active units and a rapid involvement of other units, because the force generated by a single unit will be less than normal. Thus muscle disease is characterized by early recruitment of smaller than normal motor units.

To further obtain accurate data regarding motor unit potential (size, configuration, and firing characteristics), a number of quantitative EMG techniques have been developed. An automated method of decomposition-based quantitative electromyography (DQEMG) can be applied to interference patterns recorded simultaneously from intramuscular and surface electrodes. The EMG-interference pattern can be decomposed into its constituent motor unit potentials. Both motor unit morphology and firing pattern may be studied. Surface-recorded motor unit potentials derived from decomposition may be averaged to yield an average motor unit size, from which a motor unit number estimate may be calculated. Currently, decomposition techniques are primarily research tools; however, the potential exists for DQEMG to provide a reliable method for evaluating the disease progression as well as the response to treatment interventions.

The MUPs recorded via concentric needle electrodes reflect the electrical activity of a portion of a motor unit. To obtain information regarding the entire motor unit, another technique using macro needle electrodes was developed. By using a modified single-fiber EMG needle electrode, a single-fiber potential is first recorded and then used as a trigger for recording and time-locking surface potentials, which are averaged to determine the surface electrical activity of a whole motor unit. The parameters measured are the amplitude, area, and duration of the averaged SMUPs. Comparing the macro-EMG with a concentric-needle EMG, regarding their sensitivity in detection of neuromuscular disorders, it was shown that the techniques appear to have similar sensitivities and that by combining the results of both methods additional increase in sensitivity can be achieved.

Studies of Neuromuscular Transmission

Single-Fiber EMG

A standard concentric needle EMG electrode has a large recording surface, designed to record potentials from at least 20 neighboring muscle fibers. However, by reducing the size of the recording area and by filtering out distant potentials, it is possible to record from a small number of individual muscle fibers within the same motor unit (single-fiber EMG).

The average number of fibers from the same motor unit seen with repeated electrode penetrations is called the fiber density, and is a measure of the geographic concentration of single muscle fibers belonging to a given unit. In addition, when two to three fibers from one motor unit are recorded simultaneously, variability in the temporal relationship between activation of both fibers can be studied. This variability is called jitter and is extremely small under normal conditions. However, diseases of the neuromuscular junction, such as myasthenia gravis, cause variability in the time taken by neuromuscular transmission and therefore increase the jitter. Occasionally, neuromuscular transmission is so tenuous that one of the fibers being recorded fails to fire at all; this is called blocking and is a sign of severe disease. Jitter is the most sensitive measure of dysfunction at neuromuscular junctions but it is not specific, and increased jitter can be seen with neuropathic processes as well.

Repetitive Stimulation

Compound motor action potential response area is positively correlated with the number of muscle fibers activated and, if neuromuscular transmission is intact, with the number of motor axons activated. Repetitive supramaximal stimulation of motor nerves is used clinically to assess function at neuromuscular junctions. With supramaximal electrical stimuli (all alpha motor axons being stimulated), changes in M amplitude, duration, or area with repetitive stimulation reflect disturbances in neuromuscular transmission. Disorders such as myasthenia gravis produce a typical decremental pattern of M response amplitude/area, but only in an affected muscle, when the motor nerve is stimulated at 2–3 Hz. The first M response is usually not as large as normal, but each subsequent one becomes smaller until the fourth or fifth response is reached, at which time the decrement ceases; subsequent responses often become slightly larger. This pattern (because of reduction in number of functional postsynaptic acetylcholine receptors) reflects normal quantal rundown; the number of quanta of acetylcholine released by each successive impulse decreases, as does the postsynaptic response, until presynaptic potentiation increases acetylcholine release. Because many more quanta are normally released than are necessary for maximal postsynaptic depolarization (a large safety factor), quantal rundown is only seen when neuromuscular transmission is compromised. In contrast, presynaptic neuromuscular junction disorders (such as botulism or Eaton–Lambert (myasthenic) syndrome) may show some decrement with 2–3 Hz of stimulation but show striking increases in response amplitude at either rapid rates (30–50 Hz) of stimulation or immediately after a short period of maximum voluntary exertion.

Central EMG/NCSs

Historically, EMG and NCSs have been used as aids to the diagnosis of peripheral nervous system disorders. However, they can provide insight into central processes as well. By recording either needle or surface EMG signals from multiple muscle groups simultaneously, movement disorders such as tremor and dystonia can be studied. Different types of tremors are characterized by distinct patterns of EMG activity in agonist and antagonist muscle groups. For example, parkinsonian tremor is electromyographically alternating; that is, one set of muscles is active during relative silence of its antagonists. Enhanced physiologic tremor and essential/familial tremor, in contrast, are characterized by co-contraction; agonist and antagonist muscle groups are active simultaneously. EMG also aids analysis of dystonias, allowing clinicians to determine which muscle groups are active during the assumption of specific postures. This information is of critical importance in planning treatment, which frequently consists of weakening individual muscle groups with local injections of botulinum toxin.

In addition to evaluation of conduction in peripheral nerve, it has recently become possible to stimulate brain or spinal cord directly and record peripheral responses. This can be done with high-voltage electrical stimuli applied to the scalp or spinal column; perhaps not surprisingly, this is an uncomfortable procedure. Magnetic stimulation is a less painful alternative, with stimulators that produce brief, powerful magnetic fields. When coils producing these magnetic fields are placed over the skin near nervous tissue, these fields in turn induce in that tissue an electrical field that can stimulate neighboring cortical, spinal cord, or peripheral nerves, therefore providing a method for testing the functional integrity of the corticospinal tract as well as the motor cortex excitability. By using transcranial magnetic stimulation (TMS), motor-evoked potentials can be recorded from arm or leg muscles and, after estimates of peripheral conduction time are subtracted, an estimate of central conduction time can be made. Central conduction

has been demonstrated to be abnormal in a variety of neurologic diseases, including multiple sclerosis and amyotrophic lateral sclerosis, even prior to onset of symptoms. Therefore, TMS represents a useful investigational tool, allowing early diagnosis, monitoring of disease progression, and estimating prognosis. In addition, a newer TMS technique, repetitive transcranial magnetic stimulation (rTMS), has been developed as a promising therapeutic tool, by modifying the excitability of the cerebral cortex. Tentative therapeutic applications at this time include Parkinson's disease, epilepsy, stroke, and depression.

Spasticity, another central disorder, has also proved amenable to study with methods adapted from routine NCSs. As discussed previously, the H reflex is analogous in many ways to a deep tendon reflex; as such, it provides a qualitative measure of upper motor neuron abnormalities. More information about spinal cord processing can be obtained by conditioning the H reflex in a variety of ways. Rapid tendon vibration effectively stimulates primary afferent fibers and acts as a potent stimulus for presynaptic inhibitory pathways; H reflexes conditioned by tendon vibration therefore vary in size as a function of amount of presynaptic inhibition. Prior activity in motor neurons activates Renshaw cells; H reflexes obtained at certain intervals after such activity can therefore be used to evaluate inhibitory activity in recurrent pathways. Thus although EMG/NCSs are primarily tools for evaluation of the peripheral nervous system, they also provide information about central nervous system function.

Introduction and Relationship to Neuroscience

This article focuses on electronic noses as they relate to the neuroscience of olfaction, on which they are based. Less emphasis is placed on details of the differences among artificial or 'e-nose' systems, with more attention paid to what aspects of the olfactory pathway have been, and may in the future be, useful for enhancing e-nose function. As in development of all biomimetic engineering, the relationship between the biological system being mimicked and construction of the device which uses the biology model is a reciprocal one in which biology informs the engineering, while, the engineering process can be a useful heuristic tool to inform further analysis of the biology.

As discussed later, the concept of an artificial nose developed directly from analyses of the biological olfactory system. At the time of the first e-nose development and for many years before that, it was widely appreciated in the olfactory research community that monomolecular odors were encoded by processes widely distributed across the circuits of the pathway. Physiological studies had shown that the sensory elements in the nose, the second-order neurons in the circuits of the olfactory bulb, and the neurons of olfactory cortex routinely respond to ranges of chemically unrelated odorants, indicating that odors are not obviously encoded by neurons or circuits dedicated exclusively to single odorous compounds at any level of the pathway. Based on these observations, a number of hypotheses were formulated to explain how combinatorial and pattern recognition processes could be the basis for these findings.

Combinatorial, disseminated representation of specific odorants by relatively nonspecific sensing elements was not a concept that readily resonated with the classic chemical view of highly specific ligand/receptor interactions. Despite this, the data available at the time supported the prevailing view that the extraordinary sensitivity and discriminability widely recognized in animals such as dogs were, in fact, emergent processes that arose from activation of large populations of neuronal elements. The specific molecular signatures of the vapor phase stimuli were thus encoded in these populations by spatial and temporal activity that was then interpreted at various levels of the pathway to give rise to perception.

In 1982 Persaud and Dodd used these two ideas – activity patterns across arrays of relatively nonspecific primary sensors and pattern recognition algorithms for associating the response patterns with odorants – as the basis for the first artificial nose. These principles remain as guiding paradigms underlying virtually all modern e-nose devices. It is notable that Persaud and Dodd set out to implement these fundamentals of olfactory function before many of the biochemical mechanisms that underlie the primary sensory process were well understood.

Principles of Operation

Defining Odorant Stimuli

To understand how artificial noses use biological principles to capture odor information, the major steps in the volatile detection process need to be defined since these need to be captured by both natural and engineered systems (Figure 1).

The essence of all sensing systems is to convert different forms of sensory information in the external world (visual, auditory, mechanical, chemical) into information encoded by the biological world of neuronal circuits in the brain or by the electronic circuits of the biomimetic system. In the brain, this encoding process usually takes the form of transformation (transduction) of sensory information into trains of neuronal impulses propagated in the biological circuits of a neural pathway. In engineered devices, this takes place as conversion of odorant chemistry into electrical charges moving within analytical computer circuits.

For odor detection systems, the target information in the outside world is the vapor phase molecules arising from odorous substances volatilized to a degree dependent on their vapor pressures. The essence of the odorant encoding problem then is to convert the chemical and physical information about these gas phase molecules (structure, charge, size, molecular weight, polarity, solubility, volatility, concentration, and so on) into neuronal information that can be manipulated by brain circuits to ultimately give rise to odor perception and/or behavioral output. A single, volatile molecular species is usually referred to as an odorant (e.g., acetone, propionic acid, ethyl acetate, or methyl mercaptan), while volatiles perceived by an organism (usually a complex mixture of many odorants, for example, coffee, jasmine, orange, and chocolate) are

Figure 1 Steps in detecting vapor-phase compounds in the environment: encoding their molecular information by a detection system, recognizing the vapor-phase signatures, storing the results, and resetting the system for another detection event.

defined as an odor. An odor perception can, of course, also be generated by single, pure odorants (single compounds) such as acetone; thus, one can perceive the odor of chocolate or the odor of acetone.

Getting Odorant Stimuli to the Detectors

Vapor phase odorant detection requires that molecules arising from a volatile source come into physical contact with either the receptors of a biological olfactory system or detectors of an electronic nose. There is no distance detection in either biological or artificial olfaction – the source giving rise to the vapor may be distant, but vapor phase molecules from the source must reach the sensors. From a complex source such as coffee, odorant molecules are released into the air in different concentrations based on their individual vapor pressures and may arrive at the sensory detectors either by movement of the carrier air (wind) to the detector or by movement of the detector system through the air. Odorant plumes are invariably heterogeneous, chaotic, turbulent, and temporally variable, and therefore their physical structure is impossible to define completely. Insects and certain other animals such as sharks rely on their own movement through the medium in which they live to bring odorants to their sensing elements, whereas most air-breathing animals have active inhalation (sniffing) mechanisms to bring odorants to receptors that are often sequestered in complex nasal cavities that provide another aerodynamic dimension to the odorant delivery process.

For both biological and engineered odor-sensing systems, this access process and the subsequent, usually underappreciated, removal process are both crucial to the effective function of the systems. An additional important component of the access process is the relationship between the complex turbulent nature of odorant plumes and the physical structure of the sensory surfaces with which the plumes interact. The sensing surfaces in biological systems are usually physically complex structures consisting of amplified surfaces (cilia or microvilli) and elaborate turbinate folds, whereas sensing surfaces in engineered devices have, so far, been virtually flat and uniform. How to best deploy sensors on surfaces in order to optimally capture turbulent odorant plumes is still poorly understood and not usually a rationally designed feature of engineered devices.

Converting Chemical Information into Electrical Information

Coding paradigms Over the past 20 years, much has been learned about the biochemical cascades and receptors underlying the initial transduction events in biological olfactory systems. For example, many details about receptors, downstream amplification mechanisms, and changes in membrane conductance triggered by odor binding have been elucidated. Precise descriptions of how specific structural odorant features interact with the receptors have just begun to evolve. Relatively little is known about the binding constants of odorants to various receptors, and as yet there is no information on how receptor structure revealed by X-ray crystallography relates to odorant binding.

What is firmly established is that biological olfactory systems, in general, do not encode odor information by activation of specific neurons by specific odorants. Thus, the system does not operate by encoding odorant 'A' with cell type 'A' and does not appear to function by having so-called 'labeled lines,' one for each odorant of interest to the organism. Rather, with the exception of some apparently highly specific pheromone pathways in insects and certain vertebrate olfactory neurons, both first order sensory receptor cells in the nose and neurons in the higher order brain circuits tend to respond to variable, broad ranges of odorants, leading to an encoding process (even for

Figure 2 Schematic diagrams of the major components of biological and artificial olfactory systems: cross-reactive receptors or sensors, integration levels that receive the spatially and temporally distributed outputs from the sensor layer, and a pattern recognition level that categorizes, compares with stored information, and ultimately carries out identification.

monomolecular compounds) that is highly distributed at each level of the pathway (see Figure 2). It is the essence of these distributed events that is captured by artificial nose devices.

E-nose sensing mechanisms At the first level of e-nose design are sensing materials that interact with multiple vapor phase odorants. These interactions show moderate, overlapping specificities, thereby serving as cross-reactive sensors. The e-nose interrogates the sensing materials to read out the degree to which they interact with each odorant material and then categorizes and analyzes their response patterns.

In most e-nose systems the sensing materials are some form of hydrocarbon polymers either chosen from catalogues of commercially available polymeric materials, explicitly synthesized for detecting specified vapors, or made from DNA polymers composed of deoxynucleotide bases. E-nose sensors also are made from thin tin oxide films impregnated with various precious metals and from chemically modified metalloporphyrins. The degree to which polymer-, tin oxide-, or metalloporphyrin-based sensors interact with odorant compounds depends on their relative affinity for the vapor, which is in turn dependent on solvation, polarity, charge affinity, and other chemical and physical properties of the sensing materials. The exact mechanisms that impart the responsivity to different odorant vapors are not usually understood to the degree that one can predict *a priori* how a particular material will respond to a particular odorant vapor. Thus, selections tend to be empirical, operating on some general principles, although some highly specific detectors have been rationally constructed. Polymer responses are read out using a variety of methods, including measurement of changes in conductivity, mass (surface acoustic wave, quartz resonance, and microbalance), or optical properties (colorimetric, fluorescence).

Figure 3 illustrates responses from polymers that change their conductivity (left panels), an array of metalloporphyrins that change color (right panels), and arrays of other polymers labeled with dyes that show changes in fluorescence (bottom panels) upon odorant exposure. In most cases, the response arrays are allowed to come to equilibrium with vapor exposure (Figure 3, left and right panels), while in systems with rapidly responding sensors, the time course as well as differential sensor response can be used as part of the encoding mechanism (Figure 3, bottom panels, z-dimension going into the page). Tin oxide responses consist of changes in conductivity dependent on the affinity of the analyte vapor for the tin oxide film. See Table 1.

Figure 3 Responses from three types of sensing arrays. (Top left) Changes in conductivity from 20 individual polymer-based sensors (Osmetech: Persaud). (Top right) Colorimetric changes in 25 individual metalloporphyrin-based sensors (ChemSensing: Suslick). (Bottom) Changes in fluorescence (*y*-axis) over time (*z*-axis) from 16 individual polymer-based sensors (*x*-axis) (CogniScent: White/Kauer).

Although they are sometimes referred to as artificial noses, devices with single detectors that rely on separation of vapor phase molecules by affinity along a column (rapid gas chromatographs) or in a chamber by charge (rapid ion mobility spectrometers) are not considered here because they do not use the principles of cross-reactive sensor arrays and distributed pattern recognition based on the biological principles described earlier.

Pattern Analysis Leading to Odor Recognition

The second essential element of e-nose design is analytical. Algorithms have been developed to associate the patterned output arising from the sensor arrays with the applied odorous analytes. In the biological olfactory system, the circuits of the olfactory bulb (shown in Figure 4, top) carry out the first level of analysis of the highly parallelized input from the olfactory receptor neurons in the nasal cavity, and the output of the bulb is transmitted to a number of higher olfactory circuits such as the piriform cortex. Although little is known about how olfactory cortex works in detail, it is presumed that pattern recognition, comparison with stored memories, and subsequent storage of new information reside at this level.

In artificial devices, pattern recognition has been implemented in a number of different algorithms. In most cases recognition is carried out by a process that compares the input pattern from the test analyte with patterns that have been stored in computer memory during 'training' sessions. Training usually takes the form of generating sensor array responses to known odorants and storing the array responses in memory. Input patterns generated by unknown test odorants

Table 1 Examples of sensing materials used in artificial noses

Sensing material	*Deployment*	*Readout*
Tin oxide	SnO_2 films doped with precious metals, run at 300–400 °C	Conductivity; works like n-type semiconductor
Polymers	Onto surfaces appropriate for readouts below	• Conductivity detected by resistance measurement • Swelling detected optically or by resistance measurement • Attached to fluorophores, change in fluorescence • Changes in mass due to differential adsorption, detected by surface acoustic wave, quartz resonance, or microbalance
Metalloporphyrins	Colored spots onto paper substrates	Colorimetric

Figure 4 (Top) Integrative circuits of the mammalian olfactory system including olfactory receptors and bulbar receiving convergent and divergent inputs from receptor neurons in the nasal cavity (White and Kauer). (Bottom) An example of a simple neural network model (Rummelhart) with convergent and divergent connections among the layers of a type that has been used for analysis of responses from artificial nose detector arrays.

are then compared with the stored data using a variety of methods, including neural networks (Figure 4, bottom), principal-component analysis, self-organizing maps, and simple Euclidian distance evaluations. In principle these approaches work under many conditions, although identification can be compromised by the difficulties of differences in training/test analyte concentrations, the presence of interferent odorants that were not included during training sessions, and changes in temperature and relative humidity.

Utility for Solving Real-World Problems

The goal of artificial nose development is to exploit the intrinsic flexibility and broad responsivity of arrays of cross-reactive sensing materials deployed in arrays to detect as many different vapor phase analytes in as many different interferent backgrounds as possible. Theoretically, the combinatorial power of such sensing devices scales exponentially with the number of sensors and offers the potential for detecting molecules arising from virtually any substance with some level of vapor pressure. One can imagine perfected devices being able to detect, quantify, and identify single odorants and complex mixtures associated with medical diagnostic problems, environmental monitoring, food and beverage quality control, analytical chemistry associated with a myriad of industries, and so on. Whether the promise of detection of vast numbers of different vapor-phase species will be realized still remains to be seen. Based on theoretical grounds it would appear that combinatorial systems are the only way to go.

Strengths and Weaknesses of Artificial Noses

The strengths of artificial noses are as follows:

- simple
- potentially broad spectrum sensitivity with small numbers of sensors
- relatively inexpensive
- small, portable, low power
- flexible, trainable, improvements in detection sensitivity are under continuous development and can be enhanced by both engineering solutions (e.g., by increasing sensor surface area) and by algorithmic development.
- with explicit control over sensor chemistry, there is the potential for modifying sensor arrays in order to tailor the devices to defined problems.

The weaknesses of e-noses are the following:

- often responsive to humidity and temperature
- must be calibrated for stability
- rational ways to select sensing materials for particular target volatiles not yet well defined
- algorithms and other aspects of device design need to be fitted to the target detection task.

The Future

E-noses are only about 25 years old, and there are a number of areas in which rapidly occurring changes in technology are likely to improve functionality. Miniaturization of electronics and the increasing computational power of small circuits will be further exploited in the evolution of e-nose analytical circuitry, as will sensing elements and circuits that take advantage of nanotechnology.

Finally, artificial olfactory technology has not yet successfully entered the consumer marketplace. One can imagine that a more mature e-nose technology, improvements in stability, miniaturization, and lower costs would lead to useful devices for detecting vapor phase compounds related to many diverse aspects of human life. These might include, for example, an emergence of digitally based olfactory 'assistants' just as we have digitally based 'assistants' for scheduling (Palm Pilots), communication (cell phones), imaging (digital cameras), and acoustics (iPods), thus opening up an awareness of the unappreciated richness of the odor universe that envelops us.

Electrophysiology: EEG and ERP Analysis

S Makeig, University of California at San Diego La Jolla, CA, USA

© 2009 Published by Elsevier Ltd.

Introduction

Although studies of event-related electroencephalograph (EEG) dynamics were the first modalities to image brain activity linked to the cognitive interpretation of stimulus and other events, from the first availability of averaging computers in the early 1960s, the field was dominated by averaging of epoch time locked to some set of events considered to be equivalent, generating what was first known as the (stimulus) evoked potential, later the event-related potential (ERP), and still later the equivalently derived magnetoencephalograph (MEG) 'event-related field' time course. Currently, a wide array of techniques from spectral and time-frequency analysis, information-based signal processing, and machine learning are being introduced. Applied to currently available high-density scalp recordings of up to 256 or more channels, the study of event-related brain dynamics reveals much more about how EEG and MEG source signals, representing partial synchrony of local cortical field activities, are linked to the experience and control of behavior.

Strengths and Weaknesses of Response Averaging

Any useful method of analysis of complex signals involves some set of assumptions about the generation of the data that, if fulfilled, makes the results of the analysis truly interpretable. For response averaging of EEG (or similarly of MEG) data epochs, these assumptions are that (1) the exact times of occurrence of a set of time-locking events are known, (2) that these events produce essentially equivalent EEG responses, (3) that these responses each consist of a fixed response time course that is added linearly to the ongoing EEG, and (4) that the ongoing EEG is wholly unrelated to and unperturbed by the time-locking events. In the case that these assumptions are true, then the averaged response (ERP) reveals the approximate time course of activity added to the EEG signal time locked to the time-locking events of interest with a signal-to-noise ratio inversely proportional to the square root of the number of epochs averaged.

Difficulties arise when, as in this case, the data to which the analysis method is applied do not match the assumptions under which the results of the analysis can be truly interpreted. In the case of EEG response averaging, it is undeniably the case that the ongoing EEG may be and is typically affected by sensory and other events, contrary to assumption 4 above. This was amply demonstrated by Pfurtscheller and colleagues as early as 1979 in the form of reliable event-related changes in the strength of prominent ongoing 8–12 Hz alpha band rhythms recorded over posterior and central cortex. These changes, termed event-related synchronizations (ERSs; alpha power increases) and event-related desynchronizations (ERDs; alpha power decreases), typically did not appear in ERP averages of many similar trials. This is because, contrary to ERP assumption 3 above, they resulted from a multiplicative modulation of ongoing EEG activity, not the addition of a fixed response time series to the unchanged, ongoing EEG.

From the perspective of time–frequency analysis, response averaging retains only those portions of the event time-locked data epochs that are also reliably phase locked. This means that when a brief sinusoidal signal at a frequency of interest is fit to the single trials at a event-locked latency of interest, the phase values of the best-fitting sinusoids for each of the trials are not randomly distributed around the phase circle. To create a nonzero ERP signal, this nonrandom phase distribution requirement is necessary and nearly sufficient (except in the case that the nonrandom phase distribution is radially symmetric).

At zero frequency or DC, the concept of data phase collapses to the sign of the data, positive or negative, with respect to some baseline value. Thus, for example, if prominent signal peaks 300 ms following the sudden, unexpected but awaited occurrence of rare tones against a silent or contrasting sonic background were not all positive, but instead half positive and half negative, the resulting ERP average 300 ms following tone onsets would be zero, even though each trial contained a large potential fluctuation undeniably evoked or induced by the tone presentations. In practice, this does not happen. Rather, a predominantly positive peak, often termed P300, is produced in ERP averages over, most prominently, the central posterior scalp. However, from the ERP average, it is not possible to tell whether the event-related positivity occurred in every trial with comparable form and amplitude or whether the ERP feature was produced by a slight positive-favored imbalance in the numbers of much larger positive and negative peaks at 300 ms latency in the single trials. In practice, in such experiments the P300 positivity is recorded with highly variable amplitudes in only about 80% of trials, calling into question any interpretation, from the average

ERP record, that the P300 feature is an invariant consequence of these tone occurrences.

Lack of phase consistency explains why even strong alpha band ERD and ERS phenomena may produce no trace in the average ERP. In these cases, the multiplicative modulation of ongoing activity is independent of the phase (e.g., positive-going or negative-going) of the alpha activity 300 ms after the tone onset. Therefore, averaging a large enough set of epochs in which strong and consistent blocking or augmenting of alpha band activity takes place at a fixed latency with respect to the time-locking events may reveal no alpha activity at all, either before or after stimulus onsets, since at neither latency is the alpha activity phase distribution unbalanced. To make an analogy, say someone set up a motion camera at the beach and recorded an hour of film images and then averaged them. The average image would not reveal any waves but instead only a continuous blur near water's edge. Here, interpretation of the mean photo could be quite inaccurate, as even brief viewing of the original footage would reveal.

Event-Related Phase Resetting of Ongoing Brain Activity

In some continuously rhythmic systems, such as circadian cycles in body temperature and the cardiac rhythm, infrequently and briefly pausing the rhythm, say by an aptly timed burst of bright light or an electric pulse, is observed to first stop the ongoing rhythm briefly and then to allow its restart at a fixed phase of its cycle a fixed latency following the interrupting event. These activities, once resumed, then continue at their original frequency and amplitude. Consider, in these cases, the appearance of the stimulus time-locked event-related averages. In both cases, they would show a flat prestimulus baseline period, followed, at some time after the interrupting events, by an appearance of the rhythm, which would continue for some time. Again, a simple interpretation of the event-related average as representing the addition of a rhythmic activity to an otherwise flat record would be quite an error. In fact, no increase in the amplitude of the rhythmic activity occurs, quite contrary to the impression delivered by the average ERP.

In these cases, the term 'phase resetting' to a reliable (re)starting value has been used. Can it apply to event-related EEG dynamics? The answer to this question is not simple or uniform. The primary complication comes from the temporal instability or nonstationarity of EEG activity, either recorded from the scalp or, in the form of the electrocorticogram, from the cortical surface directly. If, for example, an arousing stimulus is delivered to an EEG subject only at infrequent moments when the subject's EEG at a channel of interest contains a prominent and steady ongoing alpha band rhythm, then an average ERP containing a flat baseline and a prominent poststimulus alpha band rhythm may indeed be recorded, and if so, this phenomenon might be said to represent phase resetting similar to the biological examples above.

More commonly, however, the delivery of stimuli in event-related experiments is not dependent on the occurrence of any EEG feature in particular, and even at posterior scalp electrodes, the alpha rhythm may or may not be observable in single trials. Here, a consistent change in average alpha band power in the single-trial signals, time-locked to the arousing events, may not genuinely represent a phase resetting, since in many trials there is actually no definable alpha phase to reset! Rather, in such a case the appearance of an ERD or ERS feature may represent only a change in the relative propensity of the revelant cortical regions to synchronize local alpha band activities so as to produce alpha band EEG signals on the scalp. The average ERD and ERS measures proposed by Pfurtscheller are also averages, as is their generalization to a whole-spectrum measure of average power at a set of event latencies, proposed later by Makeig and termed the event-related spectral perturbation (ERSP) or spectral power time/frequency image. Spectral power averages, like time–domain ERP averages, fail to accurately distinguish between different types of temporally unstable phenomena in the data and therefore are highly susceptible to inaccurate interpretation.

In the case of ERP averages, this susceptibility to misinterpretation comes into play not only for fairly rare examples of true phase resetting (e.g., in cases dubbed 'alpha ringing'). A more common and also serious misinterpretation of ERP features comes in cases when brief event-related bursts of quasi-rhythmic activity occur reliably time locked but only partially phase locked to events. In this case, the shape of the remnant ERP feature may not well represent the bursts that actually occur in single trials, depending on the exact distribution of relative phases and amplitudes of the phenomenon across the single trials. This is a more serious problem for interpretation since the average ERP in this case may give an erroneous impression that a fixed series of indistinct peak events occur in each trial, whereas in reality these may be but the shadow of much more robust dynamics occurring with variable phase and amplitude in the single trials. This instability violates ERP assumption 2 above.

A more serious form of violation of assumption 2 (temporal stability of the response) comes when the

brain shows quite different modes of responding to instances of the 'same' class of stimuli, for instance, theta bursts versus high-frequency activity. Here, all the event-related averages (ERP, ERD/ERS, and ERSP) fail to reveal the form of the nonstationarity.

Spatial Mixing of Brain and Nonbrain Potentials and Field Activities

Another source of confusion in the interpretation of event-related EEG (and MEG) data is the fact that scalp electrodes (or magnetic sensors) sum field activities reaching them through electrical volume conduction (or radial flux). This summation is linear, and the propagation is near instantaneous. But the degree of spatial mixing is quite strong, leading to the widely accepted opinion that EEG (and MEG) data are noisy or contain relatively little spatial information. In particular, a positive or negative value observed at a certain scalp electrode (with respect to the reference electrode or electrodes used in the recording) does not mean that the observed activity represents activity in cortex immediately below the electrode. Simple biophysical examples of such cases are easy to construct.

Continuous Experience versus Tachistoscopic Stimulus Presentation

Finally, assumption 1 above, that the exact times of relevant events are known to the experimenter, limits analysis to experiments in which events of interest can be known precisely. Typically, this has meant that event-related EEG and MEG experiments use unnatural tachistoscopic event presentations and do not study the more natural order of events which develop over time with no instantaneous onset or time of recognition by the subject.

New Approaches to Measurement and Modeling of Event-Related Brain Dynamics

Currently, a wealth of new approaches to the analysis of complex, high-dimensional data has been and is continuing to be developed in the fields of signal processing and machine learning or artificial intelligence. The ERD/ERS and ERSP measures are simple examples of application of the quite large, modern field of time–frequency analysis to EEG or MEG data. Of increasing importance is the attempt to directly locate and model sources of information in complex data rather than focusing on characterizing only its mean and most prominent directions of overall variance. Information-based signal processing, typified by the development over the last two decades of independent component analysis (ICA), is beginning to touch every aspect of signal processing, including analysis of event-related EEG and MEG dynamics.

Applied directly to the recorded multichannel data under favorable circumstances, ICA produces maximally independent signal components that in many cases account neatly for activity from either (a) a particular type of nonbrain artifact (eye blinks or eye movements, activity produced by the heart or a particular scalp muscle, line noise, electrode movement, etc.) or (b) synchronous local field activity within a single, oriented patch of cortex. In some cases, the pattern of projection of an independent component resembles the projection of synchronous activity at two noncontiguous cortical patches, but in this case the model patches appear to be located in bilateral symmetry with respect to the brain midline, compatible with locally synchronous field activities synchronized between patches by dense bidirectional white matter connections, possibly in the corpus callosum.

Thus, ICA provides a method for spatially filtering activity recorded at many EEG or MEG channels into the overlapping projections of brain and nonbrain sources. Although ICA does not itself identify the natures or exact locations of the separated sources, it can increase significantly their signal-to-noise ratio in single trials or the continuous data record, allowing application of many types of analysis that do not require that the brain's response to events be highly determined or similar in response to superficially similar events.

An alternative method of separating EEG or MEG source signals, termed beamforming, relies on having an accurate model of electrical conduction or magnetic flux from any source area in the head to the scalp sensors. As such a head model is difficult to obtain, and more difficult or impossible to make accurate, and the number of predetermined beamforming source locations is generally limited to the number of sensors, beamforming is not necessarily preferable to ICA, which does not require a head model and determines the nature, and ultimately the locations, of the sources (both brain and nonbrain) solely from the higher-order statistics or information content of the data.

However, spatial filtering or separation is best viewed only as a preprocessing step for event-related EEG or MEG data. Once separated, both the consistency and the variability of the individual source signals across event-related trials are to be determined and modeled, and during this analysis all forms of signal nonstationarity should be considered,

tested, and when present, characterized. In addition, EEG dynamics should not be thought of as occurring completely independently in different brain (or nonbrain) source areas, even when the putative source signals are determined to be maximally independent by some ICA definition. Rather, coordinated dynamics in some or many sources should be checked and modeled since they may reveal the action of distributed brain systems to optimize experience and behavior – the goal of the brain as a whole.

Electroretinography

L J Frishman, University of Houston, Houston, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The electroretinogram (ERG) is an electrical potential generated by the retina of the eye in response to light. It can be recorded noninvasively, using electrodes placed on the cornea, and it reflects the summed response of all the cells in the retina. The ERG arises from extracellular currents that flow in the retinal tissue as a result of neuronal signaling and in some cases spatial buffering of potassium by glial cells. With appropriately applied stimuli and analyses, the ERG can provide useful, objective information about the functional integrity of the cells and retinal circuits that contribute to its generation. This information can be used in diagnosing and defining retinal diseases in the clinic, in monitoring the effectiveness of neuroprotective treatments and gene therapies in human patients and animal models, and in studying normal aspects of retinal processing and altered function in genetically manipulated retinas.

Recording ERGs

ERG recordings can be made from the corneal surface, *in vivo*, from intact humans or other animals under physiological or nearly physiological conditions (e.g., anesthesia). A wide variety of electrodes have been used to record ERGs: contact lenses with conductive metal electrodes embedded in them, thin fibers with silver particles, or gold foil electrodes, for instance. For rodent recordings, many labs use metal wires, often in a loop that rests on the corneal surface that is kept moist with a lubricating conductive solution. The reference electrode can be positioned under the eyelid, as the speculum of a contact lens electrode (Burian-Allen is a common type), or remotely from the eye, on the temple, for example. The signal picked up by the electrode is amplified using conventional electrophysiological amplifiers, preferably with low noise because ERG signals in mammals are small, ranging from a microvolt or less up to a millivolt or more, peak to peak, for responses to high-intensity stimuli. Amplifiers and/or digital filter settings in the software are important so that relevant signals are not lost but low-frequency drift, line noise, and other noise out of the frequency range of the signal are eliminated.

Full-Field (Ganzfeld) Flash ERGs

The most common stimulus used in ERG studies is a brief (< 10 ms) flash of light that uniformly fills the entire visual field, called a full-field, or ganzfeld, flash ERG. The use of a uniformly illuminated field prevents differential local adaptation of various retinal elements that can contaminate the response of interest. In dark-adapted eyes, the full-field ERG is generated by the rod photoreceptors and the circuits that transmit rod (scotopic) signals through the retina. Figure 1 shows a rod-dominated response in humans to a moderately intense light (Figure 1(a)) and to a light 100 times brighter (Figure 1(b)). As marked in the figure, the initial negative-going wave of the ERG, occurring in the first few milliseconds after light onset for the brighter stimulus, is designated as the a-wave, and the large positive potential that follows it is called the b-wave. The small wavelets superimposed on the b-wave are called oscillatory potentials (OPs).

The rod-driven a-wave primarily reflects the rod photocurrent, and it can be used to study photoreceptor function and the effects of disease or transgenic manipulations on the response. A model of phototransduction can be fit to the leading edge of the a-wave to assess photoreceptor function (rod or cone – see Figure 2), and the entire time course of the photoreceptor response can be mapped by means of a paired flash approach. At late times in the leading edge, as shown in Figure 2, the a-wave includes contributions from postreceptoral cells in the retinal off pathways. The presence of the postreceptoral contributions was established in experiments in macaque monkeys, whose retinas (and ERGs) are very similar to those of humans, using intravitreally injected pharmacological agents such as glutamate analogs and antagonists to block specific retinal circuits. The primate scotopic b-wave, as well as that of other mammals (e.g., mice), is generated largely by the light-driven activity of the second cell in the primary rod system, the 'rod bipolar cell.' Rod signals that have entered cones via gap junctions and travel via cone bipolar cells to inner retina contribute to the response as stimulus intensity and background light are increased. The origin of the OPs has been traced to inner retina, primarily amacrine cells (although high-frequency OPs in the cone-driven ERG depend on integrity of ganglion cells, at least in primates).

To study the cone-driven, photopic flash ERG, the rods must be suppressed or unable to respond by means of the stimuli selected. Rods can be rendered unresponsive by imposition of a background illumination sufficient to saturate the rod response

Figure 1 Full-field electroretinograms (ERGs). (a) Dark-adapted ERG recorded in response to a brief test flash of about 2 log scotopic trolands seconds (scot td-sec). The dashed curve is the response of the rod photoreceptors. (b) Dark-adapted ERG recorded in response to a test flash of about 4 log scot td-sec. The dashed curve predicts the response of the rod photoreceptors. (c) ERG recorded in response to a test flash of about 2.3 log photopic td-sec presented on a background of about 30 cd m^{-2}. Amsterdam: Elsevier.

(i.e., >25 cd m^{-2}). A photopic ERG in human eyes is shown in Figure 1(c). Pharmacologic blockade studies in macaque retina have shown that the cone-driven a-wave is a mix of cone receptor and postreceptor responses from the off pathway. In contrast, the photopic b-wave is mostly the sum of responses from on-cone bipolar cells, but it is modulated by contributions from off-cone bipolar cells, off inner retinal circuits, and horizontal cell feedback to cone photoreceptors. When long-duration (e.g., 150–200 ms) stimuli are used, a positive response at light offset, called the d-wave, emerges in most mammalian retinas, although not in mice and rats. The d-wave reflects off-cone bipolar cell responses, added to the positive-going offset of the cone photoreceptors. Cone-driven responses also can be isolated from rod responses by the use of flicker presented at temporal frequencies that are too high for rods to resolve, that is, 30 Hz in humans, as illustrated in Figure 1(d). Although this flicker frequency can be used in primates to separate rod- and cone-driven responses, the flicker approach is less useful in mice, whose frequency response ranges for the different photoreceptor types and their respective retinal circuits overlap substantially.

Rod and cone signals can also be separated spectrally. In primates the long-wavelength L-cone can be stimulated with long-wavelength light presented at an intensity that hardly affects the less sensitive rods. However, mice and rats do not have an L-cone, and the spectral sensitivity of their medium-wavelength M-cone overlaps with that of rods. In these animals, it is possible to selectively stimulate the short-wavelength UV cones.

Amacrine and ganglion cells in the inner retina do not contribute as strongly to the ERG as the bipolar cells, but some signals specific to these cells can be identified. For example, in the light-adapted ERG in macaques and humans (and cats), a slow negative wave after the b-wave in the light-adapted ERG called the photopic negative response (PhNR), reflects ganglion cell activity. In rodents, with relatively fewer ganglion cells, it is likely that this same wave is generated by amacrine cells. In the dark-adapted ERG, the most sensitive responses, near absolute psychophysical threshold, named the scotopic threshold responses (STRs), also arise from amacrine and/or ganglion cells, depending on the species. In macaques, a negative-going STR wave following the b-wave is

Figure 2 Full-field ERG from a macaque monkey in response to a high-energy brief flash. The data points show the mixed rod–cone ERG (circles), the small cone-driven ERG obtained when rods were suppressed (triangles). The purple and dark blue lines plot models described in Robson JG, Saszik SM, Ahmed J, and Frishman LJ (2003) Rod and cone contributions to the *a*-wave of the electroretinogram of the dark-adapted macaque. *Journal of Physiology* 547: 509–530 for rod and cone photoreceptor responses. The red line shows the model responses for the cone-driven ERG (photoreceptor plus postreceptoral off-pathway contributions), the green line shows the mixed rod-cone ERG (modeled rod photoreceptor response plus modeled cone-driven ERG). Later portions of the response that were not modeled are connected by black lines. Oscillatory postreceptoral contributions are obvious in the late portions of the responses. sc, scotopic; ph, photopic. generated at least in part by retinal ganglion cells, whereas in rodents, a positive-going STR at the time course of the b-wave appears to be generated by retinal ganglion cells, and the negative-going STR primarily by AII amacrine cells.

Pattern ERG

A more common approach to assess the ganglion cell response is to record a pattern ERG (PERG). The stimulus for the PERG stimulus is a contrast-reversing checkerboard or grating pattern for which the mean luminance remains constant. The PERG response represents, in large part in humans, macaques, and mice as well, a response generated by the retinal ganglion cells. A drawback of the PERG is that the response is quite small, only a few microvolts, and for primates, good optical focus is desirable.

Multifocal ERGs

The development of the multifocal ERG has provided a technique for recording localized ERG responses from many small retinal regions simultaneously. Previously, study of local retinal responses was limited because of the low amplitude of focal ERG responses elicited by small stimuli and the time-consuming nature of the task, in which only one small region could be stimulated at a time. Thus the multifocal stimulus is a valuable tool for topographical analyses of normal and abnormal retinas and central visual pathways. For human and macaque studies, as shown in **Figure 3**, the stimulus display often contains 103 hexagons spread over the central 50° or so of the retina. The stimulus presentation is determined by a random binary 'm-sequence' that changes contrast at the frame rate of the stimulator (commonly at 75 Hz). In its simplest form, at any given transition, roughly half of the hexagons will be white, the other half black (**Figures 3(b) and 3(c)**). A single continuous record (**Figure 3(d)**) is obtained after about 8 min of recording, and the software computes the 103 local responses (**Figure 3(e)**) by means of a correlation approach. The results can also be plotted as a three-dimensional plot (**Figure 3(f)**) that shows the response density (the response size divided by the stimulus area). For the commonly used light levels and resolution of the hexagons, the multifocal ERG is a photopic response, dominated by cone bipolar cells, but not fully formed conventional ERG b-waves, because of the rapid transitions in contrast that occur more frequently than the integration time of the response. Some cone photoreceptor contribution can be seen, particularly in central hexagons. If blank frames are interleaved to slow the presentation so that flashes occur only every 100–200 ms, the multifocal stimulus can produce responses that are similar to flash ERGs, and this can be used to study local contributions to a more recognizable ERG waveform.

Applications of Electroretinography

ERG recording is noninvasive and is useful clinically for input to the diagnosis of retinal disease. The multifocal approach has improved the utility of electrodiagnostic testing because it has allowed clinicians to identify local functional problems objectively and to correlate them with subjective measures, such as perimetry, as well as with structural measures rendered by modern imaging approaches. Useful information for clinical testing can be found in the standards and guidelines of the International Society for Clinical Electrophysiology in Vision.

Normal retinal function in both humans and animals can be studied with the ERG. With appropriate selection of stimuli, the rod and cone systems can be examined separately, and specific levels of processing can be assessed. The ERG is particularly useful for tracking, noninvasively, the development of retinal function and the loss of retinal function as retinas in humans and animal models degenerate and modify their circuitries as a result of disease and, in the case

of animals, genetic manipulations. Because the origins of ERGs are better understood than previously, ERGs now are useful for noninvasive, *in vivo* evaluation of retinal function in physiologically intact animals, including humans, and thus can provide a useful complement to functional information obtained from studies of single cells.

Emotion and Vigilance

Introduction

A common strategy invoked by scientists who aim to understand the neural substrates of emotion is to focus on one emotion exemplar. For instance, we have learned much about the role of the amygdala and its interaction with reciprocally connected prefrontal cortical regions by studying their reactivity during fear states. Emotional states such as fear have lasting impacts on neural organization, as plastic changes in brain regions such as the amygdala, hippocampus, and prefrontal cortex subserve memories that allow us to avoid fear-inducing stimuli in the future.

Fear states also serve to protect us in the moment. For example, a scared organism often initially 'freezes' its movement, a behavioral response that is orchestrated by the amygdala. In addition to being the quintessential manifestation of a state of fear, somatomotor arrest is also useful if the organism believes that it has more to learn before resuming action. Such a response in the face of a cue that predicts a biologically relevant outcome allows an organism to physically orient sensory organs (e.g., eyes, ears) toward a stimulus, thereby optimizing sensory information processing. This strategy is particularly adaptive if the outcome predicted by this cue is not entirely clear, as it aids in processing additional environmental information that might facilitate the interpretation of a predictively ambiguous cue. Thus, a state of fear includes amygdala responsivity, which influences nonspecific attentional systems that support learning about the environment in order to facilitate behavioral responses now and in the future. A critical question currently under investigation concerns whether an extreme state of fear is necessary to engage amygdala modulation over this sort of acute information gathering. Research on this topic suggests that the amygdala is involved along a continuum of state changes, from subtle changes in the state of vigilance, to more punctate moments of surprise, to a full-blown state of horror.

The purpose of this article is to review data demonstrating that a partially shared prefrontal–amygdala neural circuit subserves more subtle fluctuations in vigilance as well as more extreme fear states. This network is responsible for monitoring the environment for biologically relevant events, learning about the cues that predict those events, and modifying behavior in order to appropriately react to those cues in the future. Thus, affective information processing is part of a greater system that facilitates biologically relevant learning, especially when learning contingencies are uncertain. This system is capable of, but does not necessitate, the generation of extreme emotional states.

The Amygdala

The anatomy of the amygdala is not detailed here. Rather, we focus on three important aspects of amygdala anatomical organization relevant to the ensuing discussion (see Figure 1). First, the heaviest feedback projections from sensory and prefrontal cortical regions are received by the basolateral amygdala (BLA). This design allows for the convergence of multimodal cortically processed information with the latest sensory stimuli being detected. Second, in addition to the known role of the central nucleus (CN) in modulating autonomic and motor responsivity, the CN also projects to all major neuromodulatory centers (e.g., cholinergic, dopaminergic, serotonergic, and noradrenergic source neurons). It is these connections that can more globally modulate the 'readiness' of cortical and subcortical sensory neurons, thereby setting an appropriate level of vigilance. Third, whether BLA activity will provoke activity within the CN (thereby affecting vigilance) is largely controlled by the gamma-aminobutyric acid (GABA)ergic intercalated cell masses (ICMs), which also receive direct prefrontal input. Thus, the functional role of the ICMs provides an answer to a long-standing conundrum concerning amygdala function: how can a detection system (e.g., BLA) effectively continue to represent the present value of a predictive stimulus (e.g., in terms of valence) without necessarily calling the action system (e.g., CN) into action? The answer lies in the ICMs. By acting as a sort of 'moat' the ICMs provide an inhibitory barrier between the BLA and the CN. In this way, the BLA can continue to represent potential threats, while the ICMs inhibit CN output, thereby inhibiting overt responses to potentially threatening stimuli that have proved to pose no threat in the present context (i.e., habituation). Thus, habituation of responsivity of the amygdaloid complex to repeated presentation of biologically relevant stimuli is an active process. It does not necessitate a time-limited role for the amygdala, but instead represents the conservation of resources (e.g., responsivity of the CN), while the BLA continues

Figure 1 Coronal depiction of the human amygdala: BLA, basolateral amygdala; ICM, intercalated cell masses; CN, central nucleus; NBM, nucleus basalis of Meynert. Adapted from Mai JK, Assheuer J, and Paxinos G (2004) *Atlas of the Human Brain*. Amsterdam: Elsevier Academic press.

to represent the present, potential, and/or future significance of these stimuli.

Nonspecific Arousal Facilitates Attention

The CN serves two primary functions. The most widely recognized role of the CN is that of an output station for the amygdala. With direct connections to the hypothalamus and numerous brain stem motor neuron targets, the CN can drive autonomic nervous system reactivity and affect the coordination of behavioral responses to biologically relevant stimuli. However, the CN also serves another primary purpose during biologically relevant learning, which is to enhance nonspecific arousal and facilitate attention to allow the animal to detect and appropriately respond to stimuli in its environment. Indeed, stimulation of the CN enhances reflexes such as the nictitating membrane reflex, startle reflex, pupil dilation, eye widening, and somatomotor arrest; all responses that indicate that an organism is gathering information. During Pavlovian conditioning, an animal is first exposed to a surprising event (e.g., shock), which automatically and nonspecifically enhances this group of attentional reflexes. This enhanced level of vigilance allows the animal to detect any additional environmental events that may be related to the occurrence of shock, specifically, another event that may aid in predicting its reoccurrence. One CN projection that aids in producing this increased level of vigilance is the projection from the CN to the nucleus basalis of Meynert (NBM). The NBM is directly superior to the CN within the substantia innominata (SI) region of the ventral basal forebrain. While the NBM comprises a compact, 'nucleus-like' portion medially, this nucleus also includes a more distributed lateral portion where individual NBM neurons can be found immediately superior to and even within the CN (see Figure 1). NBM neurons provide the primary source of acetylcholine (ACh) for the entire cortex. ACh release from the NBM serves to potentiate neuronal responsivity (i.e., decrease response thresholds) and thereby facilitates information processing throughout cortical systems. Stimulation of the CN in the rabbit produces activation of cortical neurons (as measured by cortical EEG), and cholinergic antagonists can block this effect. Driven by inputs from the BLA signaling the detection of important sensory stimuli, the CN can directly influence the NBM, thereby augmenting sensory information processing by increasing ACh release throughout the cortex. An organism in this heightened state of vigilance becomes a more efficient processor of information. Any new information collected during this state of arousal can then be communicated back to the BLA via cortical feedback projections. Such feedback serves to update information stored in the BLA, which impacts the response of the animal the next time a similar activating stimulus is encountered.

The BLA–CN Connection

Lesion data from appetitive learning paradigms support a role for the BLA in assigning motivational significance to neutral stimuli and for the CN/SI

in influencing widespread attentional mechanisms. While neither BLA nor CN/SI lesions impair the ability to associate rewarding outcomes with conditioned stimuli, more subtle deficits have been observed that help to elucidate the differential roles of these amygdaloid subregions during biologically relevant learning. For example, during second-order appetitive conditioning a neutral stimulus (e.g., a light) initially predicts a reward (e.g., food). Once the animal has learned this association, the light becomes rewarding because of its predictive value. Subsequent pairing of the light with a tone results in second-order associative learning, as the animal learns that the tone will also predict a reward. Lesions of the BLA block acquisition of this second-order association, suggesting that the light never becomes reinforcing in BLA-lesioned animals. Another phenomenon that has helped to elucidate the role of the BLA during associative learning is that BLA-lesioned animals do not show stimulus devaluation. In intact animals, it is possible to devalue a food reward by mixing it with a toxin, and later presentation of the light (conditioned stimulus – CS) no longer elicits a conditioned response, suggesting that the light has also been devalued. However, BLA-lesioned animals do not show this type of learning. Taken together, these data suggest that the BLA is necessary to assign reinforcing value to a CS, such that the light assumes some of the reinforcing qualities of food.

Lesions of the CN have no effect on second-order conditioned responding or stimulus devaluation, but do impact attentional mechanisms during appetitive learning. Intact animals orient to novel stimuli (e.g., a light), and this orienting reflex habituates as the animal learns that the novel stimuli are not biologically significant. However, if you then pair light with a food reward, orienting to the light returns. This sort of orienting is referred to as 'associative' orienting. CN-lesioned animals do not show potentiated associative orienting to light-food pairings, even though they still show basic orienting responses to novel stimuli. Thus, the CN is necessary for associative orienting, a process that facilitates attention to predictive stimuli in anticipation of a biologically relevant event.

The aforementioned research emphasizes projections from the CN/SI in increasing cortical ACh release, which lowers neuronal response thresholds, thereby facilitating attention during associative learning paradigms. However, it is important to note that other neurotransmitter systems are also modulated by amygdala function and play a role in behaviors such as associative orienting. For example, CN modulation of the nigrostriatal dopaminergic pathway is necessary for the acquisition and expression of conditioned orienting responses. This same pathway is also implicated in enhancement of attention to surprising (i.e., unpredictable) stimuli during associative learning tasks. Thus, the amygdala's influence on attention during biologically relevant learning is diffuse and likely involves multiple neurotransmitter systems.

The Amygdala–Prefrontal Connection

Once an animal has learned that a particular stimulus predicts a biologically relevant event, the motivational significance of this stimulus can be represented in the BLA. But complex representations of stimuli (e.g., contextually dependent representations) and the coordination of these representations with appropriate behavioral choices appear to be subserved through connectivity between the amygdala and prefrontal cortex. Anatomical tracing studies in nonhuman primates document reciprocal connections between the BLA and the medial prefrontal cortex (mPFC), and functional data in both animals and humans suggest that these connections support fundamental context-dependant valence calculations. Moreover, stimulation studies in the rat show that BLA stimulation inhibits mPFC, and that mPFC stimulation has inhibitory effects on both the BLA and the CN. These effects could be mediated by direct inhibition of the BLA, and/or via direct mPFC projections to GABAergic ICMs, which exert inhibitory control over CN output. Indirect routes could also support modulatory effects between these regions. For example, the amygdala projects to ventral tegmental brain stem neurons that provide the mPFC with dopamine. Interestingly, activation of these dopaminergic neurons inhibits mPFC activity, suggesting that similar effects seen following BLA stimulation could be mediated indirectly via the brain stem.

The animal literature documents that the mPFC provides an important regulatory input to the amygdala, communicating cortical valence representations as they relate to predicted outcomes. Much information about this circuitry has been elucidated through the study of the extinction process following Pavlovian conditioning, which indicates that a specific ventral portion of the mPFC (vmPFC) is necessary for the consolidation and expression of extinction memories (i.e., tone now predicts no shock). This region is referred to as the infralimbic cortex (IL) in the rat but will be generally referred to as vmPFC as we discuss data in rats and humans here. Lesions of the vmPFC do not disrupt initial extinction learning, but on the day following extinction, vmPFC-lesioned animals show no memory for their previous extinction training (i.e., continue to freeze in response to the tone, though it now predicts no shock). Single-unit

recording studies indicate that vmPFC neurons respond to conditioned stimuli, and their responses are positively correlated with extinction memory (i.e., reductions in conditioned freezing). Stimulation of vmPFC neurons during extinction training accelerates learning, and evidence suggests this active inhibition of conditioned responding works via a vmPFC–ICM–CN pathway. Thus, vmPFC inputs to the amygdala can dynamically inhibit amygdala activity, signaling either a new, more positive interpretation of a once negative predictive stimulus, or, perhaps, a more general override message that the valence of the outcome predicted by the cue has changed.

Initial neuroimaging studies of the extinction process in humans have reported results consistent with these data in animals. While amygdala activation predicts expression of a conditioned response during both conditioning and extinction training (while stimulus contingencies are changing), activity in the vmPFC only predicts a conditioned response during extinction trials 1 day later. Moreover, recent work indicates that the cortical thickness of the vmPFC is significantly correlated with retention of extinction memory. These data are consistent with the notion that the amygdala is involved in biologically relevant learning while stimulus contingencies are changing, but that the vmPFC is involved in the consolidation and expression of extinction memories via regulatory inputs to the amygdala.

Thus, consistent with the modulatory role the vmPFC appears to play during extinction, interactions between the vmPFC and amygdala may be especially important for producing appropriate responses to changes in the predictive meaning of stimuli, especially when these changes include a shift in predicted valence. These animal and human findings resonate with observations of clinical patients with vmPFC lesions, who show intact psychophysiological responses to positive and negative outcomes (e.g., GSR responses), but lack the ability to choose advantageously when these situations are subsequently encountered.

Amygdala–vmPFC Interactions to Predictive Uncertainty

Thus far we have summarized just a small portion of what we have learned about amygdala–prefrontal function through paradigms that necessarily induce a strong fear state in animal subjects. However, many neuroimaging studies in humans have also sought to assess the role of the amygdala in processing more innocuous biologically relevant predictive stimuli that likely induce more subtle fluctuations in attention. For example, static pictures of facial expressions of emotion consistently activate the amygdala during human neuroimaging studies. This is because facial expressions are salient, biologically relevant stimuli that have predicted important events for you in the past. In other words, facial expressions are conditioned stimuli. A happy facial expression likely predicts reinforcing or affiliative behavior from a conspecific, whereas an angry facial expression predicts social threat. Fearful facial expressions are of particular interest to the amygdala, presumably because they tell the viewer that something important and potentially dangerous is happening in the environment, but, unlike angry faces, do not reveal the source of this threat.

A recent neuroimaging experiment in humans delineates a functional spatial dissociation in the amygdala using facial expressions of emotion that differ in their predictive value. In an experimental environment, static pictures of facial expressions have no biological relevance to viewers, but, because of the past predictive nature of the expressions, the amygdaloid system does respond to these conditioned stimuli, at least initially. As predicted by the animal data outlined thus far, both fearful and angry facial expressions activate the BLA, which represents these faces as negatively valenced. However, these two facial expressions differ on one important dimension: angry faces are inherently embody of negativity, while in the case of fearful faces, more information is needed to determine the exact nature of the source of threat. Such a model predicts that angry expressions can be handled via BLA outputs related to the enactment of an appropriate response plan (e.g., are you going to fight or flee?). In contrast, the meaning of a fearful facial expression is context dependent and thus requires the CN and its connections to neuromodulatory centers, such as the corticopetal cholinergic neurons of the NBM, to call upon the cortex to process additional information in the environment. This assertion was validated recently in a neuroimaging study showing that both fearful and angry faces activate the ventral amygdala where the BLA is located, but only fearful faces activate the dorsal amygdala/SI region where the CN and NBM are located. Thus, facial expressions call for parallel processing across a number of different dimensions, as two different circuits through the amygdaloid complex simultaneously compute valence (fear and anger are both clearly negative and activate the ventral amygdala) and uncertainty (only fear requires greater processing of contextual information and is related to dorsal amygdala/SI activation) processes. These data predict that information processing should be enhanced following the presentation of fearful facial expressions. Indeed, recent data show that humans show enhanced

perceptual discrimination abilities following presentations of fearful faces.

One way to further understand amygdala response to fearful facial expressions would be to test an expression that, like fear, was ambiguous in terms of its eliciting event but, unlike fear, could predict either a negative or positive event. Facial expressions of surprise are similar to facial expressions of fear both configurally (e.g., wide eyes) and in terms of their information value in that they tell you that something important is happening in your environment, but you need more information to determine what it is and how to react to it. However, they differ from fearful facial expressions on one important dimension: surprised expressions can predict both positive and negative outcomes. When viewers are asked to rate surprised faces using a valence scale (see Figure 2), some viewers interpret the expression positively, while others interpret it negatively. Consistent with the previously discussed data comparing amygdala response to fear and anger, surprised faces produce greater ventral amygdala activation only in viewers who interpret them negatively. Further, this effect within the amygdala appears to depend on inputs from the prefrontal cortex. In this same study amygdala activity was inversely correlated with vmPFC activity. That is, viewers with a more positive interpretation of surprised faces show greater vmPFC and lower amygdala activity. Thus, viewers showing a stronger vmPFC reaction in an area known to send inhibitory projections to the amygdala interpret the ambiguous facial expressions more positively.

Linking Amygdala–vmPFC Response and Surprised Faces to the Fear Extinction Literature

The amygdala is necessary for the acquisition and expression of learned fear associations. Typically, animals learn to fear a CS (e.g., tone) that predicts an unconditioned stimulus (US; e.g., shock). Thalamic and cortical afferents communicate CS and US information to the BLA, where CS–US associations are thought to be formed. As described earlier, the behavioral and autonomic expression of conditioned fear, however, is thought to result from excitatory influences of the BLA on the coordinated efferent systems of the CN.

As already discussed, extinction involves the attenuation of a conditioned response when a tone CS is repeatedly presented in the absence of a US. Behavioral studies have demonstrated that extinction does not expunge the CS–US association, but rather a new memory trace is formed that inhibits the previously established conditioned response. After extinction, therefore, the CS is inherently ambiguous, potentially predicting either shock or the absence of shock.

Relevant to the present discussion, lesions of the vmPFC in the rat affect the ability to use this new information learned about the CS during extinction, when the CS is subsequently encountered. For example, while neurons of the vmPFC are not responsive to a tone CS during conditioning or extinction training, these same cells show robust CS-evoked firing when the animal is recalling extinction the following day. In addition, electrical stimulation of the vmPFC is sufficient to inhibit the expression of freezing, mimicking the effects observed following extinction training. This suggests that the vmPFC can regulate the response of the amygdala to extinguished tones that now have ambiguous predictive value.

It is hoped that the reader sees the parallel between this discussion (vmPFC control of the amygdala to extinguished tones in rats) and the preceding discussion (vmPFC–amygdala response to surprised faces) (see Figure 3). Like extinguished tones, surprised faces also have an inconsistent reinforcement history, predicting both positive and negative outcomes. Viewers who show strong vmPFC activation to extinguished tones, or surprised faces, are readily able to recall the more positive interpretation of the presented stimulus. While these effects have been shown to be causal in

Figure 3 Ventromedial prefrontal cortex (vmPFC) activity and behavior are inversely correlated in the rodent and human. (a) Single-cell recording sites in the rodent vmPFC. (b) Functional magnetic resonance imaging data in the human; blue color indicates surprised < neutral faces. (c) Scatter plot showing that less activity in vmPFC is related to increased recovery of freezing on day 2 (i.e., reduced extinction memory) in rats. (d) Scatter plot showing that less activity in vmPFC is related to more negative interpretations of surprised facial expressions in humans. Study participants view surprised facial expressions and are asked to rate how positive or negative the expression on the face is (see **Figure 2**; higher ratings indicate more negative interpretations). Adapted from Milad MR and Quirk GJ (2002) Neurons in medial prefrontal cortex signal memory for fear extinction. *Nature* 420: 70–74; and Kim H, Somerville LH, Johnstone T, et al. (2003) Inverse amygdala and medial prefrontal cortex responses to surprised faces. *NeuroReport* 14: 2317–2322.

the animal model and necessarily remain correlational in the human model, we believe a vmPFC–amygdala circuitry similar to that which extinguishes conditioned fear accounts for subjective interpretations of valence in humans who encounter an ambiguously valenced facial expression (such as surprise).

The animal and human data lead us to the following working hypothesis: upon encountering the expression of surprise, the amygdala initially sends out a 'first pass' message, identifying the uncertain nature of these faces with respect to valence, and likely categorizes these faces as 'potentially threatening' in all viewers. The vmPFC, based upon additional inputs from multiple brain regions providing information about past experiences or present context, could then communicate alternative hypotheses back to the amygdala, including the 'potential positivity' of these faces. Individual differences in the strength of this vmPFC 'override' message would account for the observed differences in valence ratings. This scenario is consistent with numerous models and examples of inverse amygdala–vmPFC interaction, and suggests a mechanism by which complex representations of valence, communicated via the vmPFC, can influence the amygdala's representation of the predictive value of a stimulus. These valence representations are used to calculate appropriate behavioral responses within a given environmental context and can change the way that the amygdala influences cognitive functions such as attention and memory.

The notion that the amygdala is sensitive to environmental uncertainty *per se* and that it will first test whether this uncertainty is potentially negative was demonstrated in a recent study using mice and humans. The amygdala was shown to be more active

during segments of time when unpredictable tones were played compared to segments when tones were played in a predictable pattern. Critically, unpredictable tones also biased the study participants to treat other biologically relevant environmental events as potentially threatening. Thus, unpredictablity *per se*, even for events that are not biologically relevant, is enough to engage the amygdala. This activity creates a vigilance state that augments an animal's reaction to subsequent potential danger.

Role of the Amygdala in Vigilance: Resolving Associative Ambiguity

Resolving associative ambiguity is a complex process requiring access to memory, temporal contexts, spatial contexts, and visceral contexts in order to make a probabilistic 'guess' as to the best course of action. More than simple uncertainty, when one does not yet have a working hypothesis about predicted outcomes, the term 'associative ambiguity' very specifically refers to a situation in which a predictive stimulus has more than one potential meaning (based upon prior learning) that must be selected in a given situation. Here we consider the role of vmPFC–amygdala interactions in determining which valence representation (positive or negative) will be invoked in a particular circumstance. Stimuli with inconsistent reinforcement histories (such as extinguished tones and surprised faces) are inherently ambiguous, potentially predicting either a positive or negative outcome, and this vmPFC-amygdala circuit appears to subserve the calculation and/or retrieval of this information.

The vmPFC is ideally situated for this function, given its access to working memory, spatial (hippocampal) function, and visceral inputs, as well as to outputs able to override subcortical fear expression centers. Each of the divergent brain stem autonomic and somatic targets of the amygdala CN also receives a projection from these medial prefrontal areas, most of which are inhibitory. This arrangement, in a healthy human brain, effectively gives the vmPFC 'veto power' over subcortical conditioned responses, allowing the organism to respond appropriately based on recent experience.

Failure to resolve associative ambiguity appropriately can lead to pathological outcomes, and the vmPFC has been implicated in a variety of affective disorders, as well as the genetic predisposition to inappropriate or pathological expression of affect. For example, posttraumatic stress disorder (PTSD) is characterized by an inability to suppress fear responses to stimuli that were once associated with trauma but now no longer predict danger. Consistent with impaired cortical regulation of the amygdala, PTSD patients show decreased volume and decreased activity in vmPFC, coupled with increased amygdala activity. As mentioned previously, a similar area of the vmPFC was recently shown to correlate (in thickness) with memory for fear extinction in normal study participants, suggesting that PTSD patients may be deficient in the neural circuitry underlying extinction. Thus, similar to those persons showing a negative bias in the interpretation of surprised faces, persons with smaller vmPFC volume tend to interpret conditioned stimuli that had been extinguished (and were therefore ambiguous) as dangerous.

Conclusions

The amygdala coordinates emotional responses and also modulates cognitive functions such as attention that affect subsequent learning and memory. The amygdala is consistently implicated in learning about, and assigning emotional meaning to, biologically relevant events and the stimuli that predict those events. Interactions between the amygdala and vmPFC provide flexible, context-dependent representations of emotional valence. If a stimulus predicts a certain aversive or appetitive event, then the amygdala can coordinate an appropriate behavioral response to that stimulus. If the predictive value is uncertain, because more contextual information is needed, or perhaps because of a stimulus' inconsistent reinforcement history, vigilance networks are recruited to gather additional information from the environment. Here we have highlighted the amygdala's influence over this process through the NBM cholinergic system. But the amygdala projects to all major neuromodulatory centers. Indeed, amygdala projections to substantia nigra dopaminergic corticopetal neurons have been specifically implicated in response to surprising outcomes. Through these networks, the amygdala influences cognition in the service of protecting us from danger or leading us toward reward. This not only happens in extreme emotional circumstances, but it also happens on a more subtle, moment-by-moment basis. By constantly monitoring the environment for biologically relevant cues, the amygdala maximizes our ability to avoid danger or avail ourselves of reward.

The complementary animal and human findings discussed in this article are consistent with a role for the vmPFC in the regulation of amygdala responsivity during the subjective interpretation of ambiguous stimuli. Indeed, these results join a diverse list of experimental paradigms implicating the vmPFC in regulatory control when stimuli are associatively ambiguous. Associative ambiguity is high following extinction, when conflicting facts about a CS have been

learned. Associative ambiguity is also high during reversal learning, set-shifting, and other situations requiring behavioral flexibility. Taken together, these studies support the more generalized involvement of frontotemporal interactions in behavioral flexibility. As more unified theories of limbic function advance, such theories must include a role for vmPFC–amygdala integration and regulatory control of biologically relevant information processing, particularly when contingencies are ambiguous.

Emotion-Related Vocal Acoustics

Speech sounds are imbued with indexical or personal cues, meaning nonlinguistic aspects of the signals that provide acoustic correlates of talker characteristics such as sex, individual identity, age, and emotional state. Indexical cues are provided in nonlinguistic vocalizations, such as laughter, as well. Regardless of the type of vocal signal being analyzed, the source–filter model of speech production has been central to selecting which acoustic measurements to make. In this model, vocal acoustics arises from the combination of an underlying energy source and filtering effects that are due to the resonance properties of the supralaryngeal vocal tract. Although source energy is noisy for some speech sounds, those of greatest interest involve quasi-periodic vocal-fold vibration, which produces phonated or voiced phonemes such as vowels. The basic rate of vibration in the sounds is referred to as the fundamental frequency (F_0), which largely contributes to their perceived pitch. Associated acoustic properties examined in searching for cues to vocalizer emotional state often include mean F_0 and a number of measures associated with F_0 variability. The latter are, for instance, overall range, F_0 contour, and moment-to-moment perturbations in vocal-fold vibration. Physical amplitude or perceived loudness of vocal signals has also been shown to be important.

Supralaryngeal resonances are also studied, with the frequency of these formants being of specific interest. Supralaryngeal filtering exerts a shaping effect on the frequency of voiced sounds, resulting in prominent energy bands at resonance locations and attenuated source energy elsewhere in the frequency spectrum. Close tracking of formant changes has the potential to reveal the effects of momentary emotional states as they occur, although there has to date been little evidence for this kind of effect. However, global frequency characteristics of emotion-laden speech sounds have been described by calculating a long-term average spectrum (LTAS) over speech samples of 30 s or more. LTAS is quick, robust, and well-suited to capturing longer-term trends in vocal expression, but is less likely to capture the fleeting effects of brief emotional experiences as they occur.

Vocal Expression of Emotion in Speech

The most common approach to understanding vocal expression of emotion in speech can be called the cue-configuration perspective. In this view, discrete affective states experienced by the vocalizer are reflected in specific patterns of acoustic cues in the speech being produced. In contrast, the dimensional perspective holds that emotional cues in speech acoustics more closely reflect arousal and valence dimensions. Although the relative merits of the two perspectives are debated, there are few if any empirical studies that have compared them directly.

It has been challenging to make that kind of direct comparison, with most studies examining predictions derived specifically from one or the other of the two perspectives. One common approach is to record speech meant to portray particular emotions, as performed by trained actors or naïve experimental participants. Trained or naïve listeners are then asked to judge the intended emotions, followed by acoustic analysis of the best exemplars (and sometimes further perceptual testing). Of the many acoustic properties that can be measured, F_0 and mean acoustic amplitude are most often found to show clear connections to the emotions being portrayed. These findings are important because, regardless of theoretical position, researchers widely agree that these features probably index vocalizer arousal rather than more specifically valenced states. Although other acoustic measures also show links to particular emotional portrayals, they typically account for much less of the variance involved. When many acoustic features are included in the analysis, classification based on discrete emotion categories (e.g., joy, sadness, anger, and fear) is approximately 40% correct, on average. This moderate but reliable classification success might be expected based on findings about other kinds of indexical cueing in speech. For example, classification of talkers from neutral speech segments results in classification accuracies of approximately 70%. The classification task is arguably more difficult when operating on the variability inherent to emotional utterances. On the other hand, these recordings are often carefully screened before classification begins, which probably improves apparent success. In addition, because emotions are also expressed emblematically both in everyday life and in acting, stimuli based on simulated rather than spontaneous emotional states may not be capturing the kind of cueing that occurs under natural circumstances.

As already noted, the most reliable empirical outcomes in testing the acoustics of emotional speech have been arousal related. Numerous studies have, for example, shown that both anger and joy are associated with increased F_0 and higher amplitude. Associations between valence and vocal acoustics are less clear-cut and often emerge only in complex interactions among variables such as sex of talker, task-dependent positive and negative feedback, and trait differences in emotional intensity.

Two conclusions that can be drawn are that arousal plays a noticeably more important role in shaping speech acoustics than does valence and that it is difficult to demonstrate clear links to discrete emotional states. However, it would be premature to therefore assume that the acoustics of emotional speech reflects only arousal or can be fully accounted for by a dimensional approach alone. Such an inference requires testing alternative predictions from the two perspectives head-to-head within the same empirical framework. The strongest conclusion that can be drawn at this point is that the acoustics of emotional speech is influenced by a variety of factors, not all of which are neatly linked with either the cue-configuration or dimensional positions. However construed, arousal and valence are not sufficient to account for the available data concerning vocal emotion effects. Other important factors appear to involve sex of talker, individual differences in emotional traits, strategic shaping of vocal acoustics in pursuit of social goals, and the social context in which the speech is being produced.

Perception of Emotion from Speech

The theory and findings associated with perception of emotion from speech acoustics generally parallel those described for production. Specifically, some researchers adopt a cue-configuration perspective, whereas others emphasize a dimensional view. When listeners are asked to identify the intended emotion in utterances produced by actors, accuracy is again moderate, approximately 55% across studies. Similar outcomes and confusions are observed across different cultures and language groups, although identification errors also reflect the degree of disparity between vocalizer language and listener language.

The standard experimental strategy has been to use forced-choice identification paradigms in which listeners select one from a small set of emotion words to best describe the affect being conveyed. Stimulus sets often include only a small number of talkers and emotions while relying on prototypical instances of the emotions in question. The strategy of using acted vocal samples and then selecting only a subset for testing may in and of itself account for some of the evidence of differentiated perception of emotion.

When listeners rate vocal samples using dimensional scales, by far the strongest associations between the ratings and vocal acoustics are arousal related. Just as in vocal production, the primary acoustic cues are F_0 and amplitude. For example, listeners report hearing stress when vocalizers show significant F_0 and amplitude variation, but otherwise fail to perceive it. The link between speech acoustics and valence perception is generally weaker, again paralleling outcomes observed in production. Moreover, rather than revealing categorical responses, listeners' responses often vary continuously in accordance with continuous changes in F_0. Overall, listeners are most likely to make errors when stimuli reflect similar arousal levels and similarly valenced members of emotion families.

Taken together, the perceptual evidence shows that listener accuracy is typically moderate. Many investigators argue that achieving approximately 55% correct identification indicates both that vocalizer emotion is associated with differentiated acoustics and that listeners perceive these cues effectively. On the other hand, the studies show incorrect identification nearly half the time, in spite of relying on stimuli that are specifically selected to be rich in emotional cueing. Under more natural circumstances, the emotional speech that humans hear is often produced by familiar individuals and is embedded in a rich social context. In real life, listeners attempting to infer a talker's emotional state are therefore likely to benefit from a history of interaction with that individual and a host of nonacoustic situational cues. Both factors are likely to significantly boost accuracy relative to that observed in laboratory testing. Even so, however, it would be difficult to conclude that the cues involved are either related to discretely organized emotions or invariant across different vocalizers.

Methodologically, it becomes important to recognize that when listeners are correct in assessing emotion from voices, they may be depending more on their own inferential processes than on veridical acoustic cues provided in the speech of vocalizers. This theme is elaborated next in an approach that shifts the focus from links between emotional states and vocalizer acoustics to the effects that sounds have on listeners. Although it is compatible with aspects of both discrete and dimensional-emotions views, this perspective argues that emotion-related cuing in vocalizers is secondary, whereas the primary function of nonlinguistic vocalization is to influence a listener's state and behavior.

Affect Induction as an Alternative to Representation

A central theme so far is that investigators have expected to find veridical links among vocalizer

affect, vocal acoustics, and listener perception. An implicit assumption of this approach is that vocalizers are signaling in order to convey to listeners that particular affective states are occurring. But simply informing listeners about such states is not necessarily beneficial. Instead, the evolution of signaling is necessarily shaped by the effect that signals have on listeners' behavior. The most fundamental selection pressure acting on signalers is to influence others in ways that benefit themselves. This premise leads to viewing affect-related acoustics more broadly as a means of influencing listeners by any means possible using sound, not just by conveying encoded information. Arguably the most fundamental way to sway a listener's behavior is to produce sounds that in and of themselves have an effect on that individual's emotional state.

Affect Induction through Sound

Everyday experience shows that auditory events of all kinds can influence listener emotion, from spectacular thunder claps to quietly dripping faucets. In humans, crying and laughter readily come to mind as examples of potent, affect-inducing vocal signals. Although speech acoustics can also elicit emotion in listeners, the affect-induction properties of sound have received little overall consideration in research examining vocal expression of emotion. Instead, both the cue-configuration and dimensional perspectives adopt the approach that emotional vocalizations carry affective information in coded form and that listeners decode the signals to recover that information. Conceptually, emotion expression is thus treated as an almost linguistic-like, representational communication system.

The affect-induction model of vocalization presents an alternative view. Originally proposed for nonhuman primate vocalizations, the approach has been shown to be applicable to human affective signaling, too. Rather than construing emotional communication as a process of encoding and decoding, the model argues that the primary function of nonlinguistic vocal signals is to change listeners' affect and thereby influence their behavior. Whereas representational accounts of communication implicitly rely on information encoding and decoding processes, the affect-induction approach argues that vocal signals can affect listeners by eliciting low-level affective responses that then influence listeners' behavioral decisions. The effects can be direct, meaning that signal acoustics itself has an impact, or indirect, meaning that listeners experience a learned affective response to a sound as a result of previous experience. For direct effects, acoustic salience is critical, with aspects such as F_0 range and amplitude being primary. For indirect effects, learning occurs through social interactions in which individually distinctive sounds produced by a particular vocalizer are paired with affect being experienced by the listener.

Comparisons between the affect-induction and representational perspectives can be illustrated by describing some of the similarities and differences between them. One important point of contact is that both approaches assume an association between signaler state and signal acoustics. The representational approach argues that this is a strong association, with the connection between a particular internal state and corresponding vocal signal being sufficiently specific that the listener can infer that it is occurring. The affect-induction approach also proposes that the vocalizer's internal state is critical in triggering signal production, but it proposes that the function is not to convey emotion so much as to induce emotion in the listener. As a result, signal features are not expected to be tightly linked to differentiated vocalizer states because it may benefit the signaler to induce similar responses in the listener across a variety of situations. Conversely, producing a diverse set of sounds in a given situation might serve a common function in influencing listener arousal and emotion. In this view, relationships between signaler state and physical signal are probabilistic rather than being highly specific.

A second point of contact is that listeners are able to draw inferences about vocalizer states or likely upcoming behaviors. From a representational perspective, such inferences are part and parcel of why communication occurs; listeners receive encoded information about vocalizer state, decode that information, and act on it. The affect-induction perspective instead views listener inference as a secondary outcome, with the primary function of vocalizing being to influence listener affect and behavior. Regardless of what particular mechanism may be involved, signaling must first and foremost benefit the signaler. Vocal behavior is therefore expected to show substantial variability, although general patterns will be discernible given that similar vocal strategies will be used by a variety of signalers. Listeners who attend to those patterns will therefore be able to draw some inferences about vocalizer states and likely behavior, both consciously and unconsciously. However, those inferences will be of a probabilistic, rather than highly specific, sort. A critical difference between the affect-induction and representational views thus concerns what is primary versus what is secondary to signal function.

The affect-induction perspective proposes that, although emotion-related signals are not representational *per se*, they can still be informative in the sense that listeners can draw inferences about their significance. Those inferences are based on a number of factors, including not only the acoustic attributes of the sound but also listener affective state and familiarity with both the signal and the vocalizer, as well as

the overarching context in which signaling is occurring. A corollary is that affective responses to highly similar sounds may be quite variable. For example, the same high-pitched, high-amplitude laugh might induce positive affect when heard at a party but elicit a strong negative response when heard while walking down a dark isolated street. In both cases, the acoustics of the loud laugh will probably capture the listener's attention, increase arousal, and thereby exacerbate whatever positive or negative affective state is already being experienced. In addition, if the sound has distinctive acoustic features that have previously been paired with either positive or negative affect in the listener, the sound will also activate corresponding learned responses. Finally, sounds can trigger more complex inferences, for instance, when hearing a loud laugh signals to the listener that the vocalizer is inebriated and will need a ride home.

Parallels between Speech and Laughter

Human laughter provides a good example of a nonlinguistic, emotion-related vocalization that is typically interpreted as a representational signal through which vocalizers convey information about their emotional states to listeners. Laugh acoustics is therefore expected to vary in accordance with variation in those emotions, which have been proposed to include emotional states as diverse as joy, amusement, anxiety, embarrassment, aggression, and submissiveness. There are as yet no data that specifically test this hypothesis, but the data that are available show laughter to be acoustically variable, even in situations involving only comparatively uniform positive states. Rather than being differentially associated with different emotions, laugh acoustics may be more closely associated with factors such as the sex and familiarity of the laughers' social partners. Males, for instance, laugh most and use acoustics likely to have the greatest direct impact when the listener is a friend, especially a male friend. Females, on the other hand, are more likely to produce high-impact sounds when the listener is a male than a female. The upshot is that both males and females appear to use laughter strategically, producing high-impact sounds when the likely effect on listeners would be positively toned arousal and using laughter rich in identity cues with friends who have learned positive affective associations with these sounds.

In both cases, F_0 emerges as a critical component of laughter's affect-induction effects. Males, for instance, report being more interested in female strangers when these women produce more laughter. Voiced laughter in particular has this effect, meaning that the laugh sounds are vowel-like, produced through regular vocal-fold vibration and with a prominent F_0. Noisy, unvoiced laughter that lacks vocal-fold vibration has little influence on listeners, even though this kind of laughter is extremely common. In perceptual testing, listeners consistently rate voiced laugh sounds as eliciting positive emotion, whereas unvoiced laughter is reported to have a slightly negative effect. F_0-related acoustics thus plays a crucial role in shaping listener responses to laughter, just as in emotional speech. In the affect-induction view, vocal-fold vibration and F_0 characteristics exert their impact in at least two ways. First, the F_0 component of voiced sounds is extremely salient, and a high or strongly modulated F_0 has direct impact on listener attention and arousal. Second, research on indirect learned responses to laughter has also highlighted the importance of voicing as being critical in cuing the vocalizer's identity.

Vocal Expressions of Emotion as Social Tools

Both speech and laughter are inherently social events and play critical roles in the communicative processes that are central to human relationships. There also appear to be some telling commonalities in how acoustic features of these two signals function in the emotional aspects of vocal communication. A central conclusion for speech is that F_0- and amplitude-related features play a primary role. On the one hand, speech produced while experiencing salient emotion shows significant changes in these particular characteristics, which also clearly impact listener perception and attributions of emotion. On the other hand, there is little indication that these or other acoustic features of speech can be linked to either discrete emotional states or valenced affect, and when listeners are asked to assess vocalizer states, performance based on speech acoustics alone is only moderate. Although less information is available for laughter, outcomes are similar. For example, the degree of variability occurring in laugh sounds produced during positive states alone argues against the possibility of emotion-specific laugh acoustics. Laugh sounds nonetheless have an unambiguous impact on listener emotion, with F_0, in particular, being found to play a central role.

It has thus been difficult to demonstrate differentiated, state-specific acoustic effects for either speech or laughter, but quite easy to show that acoustics has general and robust effects on listener emotions and evaluations of vocalizers. These results raise substantial questions about the adequacy of representational perspectives concerning emotion-related vocal signaling, and they are more compatible with the view that vocalizers use relatively undifferentiated acoustics that nonetheless has potent effects on listener affect.

The evidence is far from definitive, particularly because much of the research conducted on vocal expression of emotion in speech has assumed rather than tested the proposition that representational signaling is involved. It is therefore noteworthy that this research has largely failed to find compelling evidence of representational value in either production or perception. Although listeners are able to discern emotional content to a moderate degree, their judgments are constrained and context dependent. An alternative interpretation is that these inferences primarily reflect the listeners' own emotional responses, richly interpreted in the context of other about the vocalizer and the situation. Affective communication in both speech and laughter thus becomes a process of attributing emotion to vocalizers rather than one of recovering encoded information.

A larger implication of this view is that emotional expressions primarily function as nonconscious strategies of social influence rather than as veridical representations of internal state. Rather than informing, emotion-related signals are designed to shape the perceiver's affect and attitude in ways that ultimately benefit the signaler. The information value of a signal thus depends on a perceiver's previous experience, relationship with the signaler, and ability to incorporate signaling context.

However, much more data are needed to settle these issues than are currently available. It will be especially useful to focus on vocalizations acquired under controlled but naturalistic circumstances in which vocalizers are experiencing actual rather than simulated emotions. Further, it will be important to contrast the various alternatives as directly as possible within the same experimental framework, for instance, including comparing cue-configuration versus dimensional approaches and representational versus affect-induction perspectives. Finally, the scope of inquiry should be broadened to include the inferential processes that listeners use to make attributions about vocalizer states. Taking these steps will lead to a deeper understanding of how humans communicate through emotion-related vocal signals.

Emotion Systems and the Brain

J LeDoux, New York University, New York, NY, USA

Introduction

In 1884, William James asked, "What is an emotion?" Although his answer was not universally accepted, the way James framed the problem continues to influence how we think about emotions today. Particularly important was James' distinction between the bodily expression of emotions and conscious emotional experiences or feelings.

James' goal was to explain feelings. But to do so, he felt he had to first dispel the common sense notion that feelings cause us to behave in certain ways. He argued that this was flat out wrong – in fact, backwards. In his view, the expression of an emotion in behavior and other physiological responses of the body actually determine what we feel. James' paper gave rise to two questions that have occupied emotion researchers and theorists ever since. One is, "how do emotional stimuli elicit emotional responses?" The other is, "what are feelings?" The first is a relatively straightforward empirical question. The second is considerably more complicated. In this overview of emotion concepts, this article begins by summarizing progress that has been made on these two questions. This article also discusses how the two questions sometimes get confused.

How Do Emotional Stimuli Elicit Emotional Responses?

James put his finger on a very important point when he rejected the idea that feelings cause emotional responses. Because different emotions (say, fear vs. joy) are elicited by different kinds of stimuli, the brain must have already determined the emotional nature of the situation before the feeling or the response occurs. James did not dwell on this, since he wanted to know what causes feelings. But implicit in his formulation was the notion that emotional responses are elicited on the basis of unconscious processing of emotional stimuli, since the conscious aspect of emotion, the feeling, does not emerge until the responses are expressed. Regardless of whether you accept James' theory, unless you accept the common sense view, that feelings cause responses, unconscious emotional processing must be the basis of the responses. The following sections, outline how emotional stimuli, via unconscious processes, lead to the expression of emotional responses. Then, research aimed at revealing the brain mechanisms is summarized through which emotional responses are controlled by external stimuli.

Unconscious Emotional Processing

In the first half of the twentieth century, behaviorists eliminated 'consciousness' from psychology and only allowed the description of psychological processes in terms of observable behavior. With the rise of cognitive science, the possibility arose for viewing psychological functions in terms of internal representations, without equating those internal processes with consciousness. That is, psychological functions involve information processing. Such processing could, but does not have to, lead to conscious experiences. Information processing, in other words, is by definition unconscious. This notion was originally about cognitive processes such as perception and memory, but it was subsequently extended to emotional processing.

The processing of emotional stimuli is typically referred in psychology to as 'evaluative processing,' or appraisal. Appraisal is said to underlie both the emotional responses and the conscious feelings that occur in the presence of emotional stimuli. Nevertheless, appraisal theorists have traditionally focused on the role of appraisals in feelings, and have viewed appraisals in terms of higher cognitive processes. However, as we will see, basic evaluative or appraisal mechanisms that operate unconsciously are also involved in the elicitation of emotional responses by external stimuli.

Everyone has, in some situation, found his or her heart pounding before recognizing the nature of the eliciting event. Considerable scientific evidence also supports the idea that unconsciously processed stimuli can control emotional responses. This does not mean that conscious appraisal never occurs. It simply means that conscious appraisal is not necessary for the elicitation of emotional responses. The idea that emotional responses are based on unconscious appraisal processes is actually of tremendous value from the point of view of brain research. It allows us to do research on emotional behavior without having to first solve the mind–body problem, and allows us to treat the control of emotional responses in animals and humans similarly.

There are two basic ways in which emotional stimuli can elicit emotional responses by activating appraisal mechanisms. Some appraisals are hardwired by evolution and others are learned through individual experience. All organisms, including humans, have innate appraisal capacities that help ensure their survival. Stimuli that signal sexual partners, palatable

and poisonous foods, painful stimulation, predators, or aggressive members of one's own species are common examples. Such stimuli activate innate appraisal mechanisms and lead directly to the expression of species-typical responses and accompanying autonomic responses. For example, a rat that encounters a cat for the first time will express signs of fear, even if it was reared in a laboratory and never previously exposed to a cat. When organisms encounter stimuli that innately activate appraisal mechanisms they often form associations (through Pavlovian conditioning) with other stimuli present, since these may be predictive of harm or benefit in the future. These conditioned stimuli acquire the capacity to elicit species-typical emotional responses.

Species-typical behavioral and autonomic responses are often just the first stage of emotional responding to an innate or conditioned emotional stimulus. In addition to these reactions, organisms also often perform instrumental actions. Avoidance behavior is a canonical example of a learned aversive instrumental action. Thus, when you encounter an innate or conditioned danger signal, your first reaction may be to freeze. But you may also try to escape from or avoid the danger. Sometimes avoidance of danger becomes pathological, as when a patient with panic disorder stays inside her home in order to reduce the chances of having an attack. Positive instrumental responses are also important. We seek stimuli and situations that lead to desirable outcomes. But these too can have pathological consequences. Eating disorders and drug addiction are common examples.

Instrumental responses are often learned through trial-and-error processes in which the probability of the response changes depending on the rewarding or punishing consequences of the behavior. Once learned, these are performed as habits. However, instrumental responses can also be based on spontaneous decisions; cognitive estimation of outcomes eliminates the need for trial-and-error leaning.

In summary, the brain unconsciously appraises the value of external stimuli. Some stimuli are significant because of innate wiring, while the significance of others is learned through experience. Stimuli that are appraised as significant then lead to the expression of responses. Both innate and learned stimuli can lead to the expression of hard-wired species-typical emotional responses. These reactions are then often followed by instrumental responses that reflect past learning or spontaneous decisions.

Brain Mechanisms of Emotional Processing

William James not only speculated about the nature of emotion, he also proposed the first modern brain theory of emotion. By the late nineteenth century researchers had discovered sensory and motor regions in the cortex. James therefore asked whether an emotion 'center' was yet to be discovered or whether it might be possible to explain emotions as functions of cortical sensory and motor areas. He preferred the latter idea, arguing that emotional stimuli elicit emotional responses by way of sensory cortex activation of motor cortex. This idea was then challenged by Walter Cannon on the basis of studies showing that emotional reactions were preserved in decorticate animals, but were disrupted after damage to the hypothalamus. On the basis of these and other observations, Papez, in 1937, proposed a circuit theory of emotion involving the hypothalamus, anterior thalamus, cingulate gyrus, and hippocampus. Later, MacLean then named the structures of the Papez circuit, together with several additional regions (amygdala, septal nuclei, orbitofrontal cortex, portions of the basal ganglia), the limbic system, which he viewed as a general-purpose system involved in behaviors that ensure survival of the individual and the species.

MacLean's writings were very persuasive and for many years the problem of relating emotion to brain mechanisms seemed solved at the level of anatomical systems. However, the limbic system concept is now believed to suffer from imprecision at both the structural and the functional levels. For example, it has proved impossible to provide unequivocal criteria for defining which structures and pathways should be included in the limbic system. A standard criterion is connectivity with the hypothalamus. However, because studies have shown that the hypothalamus is connected with structures at all levels of the central nervous system, from the neocortex to the spinal cord, the limbic system would occupy much of the brain. Further, classic limbic areas, such as the hippocampus and mammillary bodies, have proved to be far more important for cognitive processes, such as declarative memory, than for emotional processes.

The post-Jamesian theories of the emotional brain were fairly consistent in their view of how sensory stimuli lead to the expression of emotional responses. Sensory information transmitted from the thalamus and/or cortex to specialized subcortical emotion circuits regulates the expression of emotional responses. In these theories, the subcortical circuits were centered on the hypothalamus. Electrical stimulation studies provided strong support for the role of the hypothalamus in the control of emotional responses, including autonomic responses.

Today, the emphasis has shifted from the hypothalamus to the amygdala, especially in the control

of the bodily responses that occur during fear reactions in both animals and humans. The animal studies indicate that one region of the amygdala, the lateral nucleus, receives sensory information from the thalamus and cortex. It then connects with the central amygdala, which in turn connects with lower areas, including the hypothalamus, that then connect with specific motor neuron groups that control emotional responses. Circuits within the amygdala in essence mediate the appraisal of danger, including learning about stimuli associated with danger. The amygdala has also been implicated in appraising positive emotional stimuli, but the circuit details are less well understood.

The scenario just described mainly applies to aversive emotional responses that are elicited automatically in response to a stimulus. But, as noted earlier, in addition to reacting in an automatic fashion to emotional events, organisms also perform instrumental responses. The amygdala is also involved in instrumental responses, but in a different way than for automatically elicited responses. Specifically, the central amygdala and its connectivity with lower brain regions is not involved. Instead, connections from the lateral nucleus to the basal amygdala, and from there to the striatum, seem to be important.

A prominent idea in recent years has been that the prefrontal cortex, especially the ventromedial prefrontal cortex, interacts with the amygdala in the regulation of emotional responses. The amygdala is often thought of as an emotional accelerator and the prefrontal cortex as the brakes. Prefrontal cortex is also likely to play an important role in the decision-making processes through which instrumental behavior is regulated in emotional situations.

In summary, much has been learned about the neural circuits through which sensory stimuli come to elicit emotional responses. Progress has been made for both negative and positive emotions, and for both automatic and instrumental responses.

What Are Feelings?

As noted previously, what William James really cared about was the nature of feelings. And throughout the following century, up to this day, there has been much debate about just what feelings are, both in psychology and brain science.

The Psychology of Feelings

After several decades of acceptance, James' theory of feelings was dethroned by Walter Cannon. He rejected the idea that feelings are due to feedback from responses, since, he said, the bodily responses would be too slow and too vague to define the difference between fear and joy and love and grief.

The debate stalled for decades, but took a new turn in the 1960s when Stanley Schachter and Jerome Singer proposed that both James and Cannon were right. Cannon was right that body arousal is not specific enough. James was right that body arousal was important. The solution, they said, was that through cognitive processes we interpret nonspecific body arousal in light of the context which exists at the moment. Later theories eliminated the need for bodily responses at all, emphasizing the importance of cognitive processing.

By the 1980s, emotion had become a full-fledged cognitive process. Some, such as Robert Zajonc, felt this went too far. On the basis of the results of clever experiments he performed, Zajonc argued that feelings are the products of unconscious affect. Because he objected to the cognitive take over of emotion, he avoided the use of the term unconscious processing. Nevertheless, his work made the idea that conscious feelings might be based on unconscious appraisal palatable.

Feelings and the Brain

The various aforementioned theories of the emotional brain each proposed that feelings are products of information processing in the cerebral cortex. For Cannon, feelings occurred in this way: sensory information split at the thalamus, with some going to the hypothalamus and some to the cortex. The hypothalamus then communicated with the cortex. When hypothalamic information interacted with sensory information in the cerebral cortex, a feeling was the result. Papez had a similar theory, but with more anatomical specificity, proposing that feelings occurred when the cingulate cortex integrated external sensory information with information processed by the hypothalamus. For MacLean, feelings resulted in the limbic system when the hippocampal cortex integrated information from the internal and external environments.

After several decades of dormancy, research and theory on the brain mechanisms of emotion began to pick up in 1980s. For the most part, this work was focused on emotional learning and the control of emotional behavior. However, attention was also returning to questions about the nature of feelings. William James, you'll recall, proposed that feelings result when the cortex perceives body sensations produced during an emotional reaction. Thus, fear feels different from love because these two emotions have different effects on the body. Although James emphasized the entire bodily response, critics such

as Cannon focused on the autonomic nervous system response. While autonomic responses are indeed slow and nonspecific, feedback from the muscles through proprioception can be fast and specific. A contemporary theory that emphasizes such responses is the facial feedback hypothesis. This theory proposes that the specific facial responses associated with certain emotions provide feedback to the brain that determines what we feel. Another feedback theory was proposed in 1994 by Antonio Damasio. Building on James, Damasio argued that we use 'gut feelings' to figure out what we are feeling, and that this information plays an important role in the way we make decisions. For example, when trying to decide between two courses of action, we play these out in our minds and the body sensations that result in one versus the other, according to Damasio, help us decide which to choose (which one 'feels' better). According to Damasio, the orbitofrontal cortex and the body-sensing regions of the cortex (somatosensory and insular regions) are involved in feeling states.

From authors viewpoint, feedback from the body such as that described by James and Damasio adds intensity and duration to emotional experiences, but the quality of the experience is a product of working memory. Because working memory is believed to be the cognitive operation that makes consciousness possible, it may be the basis of conscious feelings as well as cognitive states of consciousness. The basic idea is that we have one mechanism of consciousness, and qualitatively different states of consciousness are defined by the kind of information that we are conscious of at the moment. Through working memory we are able to integrate the way something looks and sounds with past memories of this thing, and with the way this thing is making us feel at the moment. If you encounter a rattlesnake on a path, for example, the following kinds of information will likely come to be present in working memory: a visual representation of the snake, an auditory representation of the rattling sound, information retrieved from long-term memory (things known about snakes as well as experiences with them), and information about the state of your brain (the fact that a certain emotion system is activated and that you are aroused). These will combine to produce an integrated representation in working memory of the entire experience. The cognitive appraisal of this experience in working memory is the initial feeling. At the same time, bodily responses, which are slower to occur, are expressed. These then feed back to the brain and add to the feeling that is evolving. The difference between an emotional conscious experience and a nonemotional one is simply that working memory is working with additional information in the case of the emotional experience – namely, information about the emotional aspects of the experience. The difference between different kinds of emotional experiences (fear vs. joy) is due to the particular emotion system that is active at the moment and monopolizing consciousness.

Considerable evidence implicates the dorsolateral prefrontal cortex (PFC) in working memory. While the brain networks of working memory were once narrowly viewed as mainly involving the dorsolateral PFC, this is no longer the case. The various medial areas of PFC, including the orbital cortex and anterior cingulate, as well as insular cortex, are now viewed as being involved, especially in emotional situations. This broader view of working memory overlaps with Damasio's somatic hypothesis but without placing too much burden on peripheral feedback.

Can Responses Tell Us about Feelings?

A final issue to consider is the relation of responses and feelings. This issue has two parts. One has already been discussed: do responses cause feelings? James and Damasio emphasize this view. Others take issue with it. But the part that we want to consider here is this: can responses tell us what other organisms are feeling?

Some years ago, Nagel pointed out that each species is likely to have its own kind of subjective experience of world. Because working memory plays a key role in human conscious awareness of the world, the brain mechanisms of working memory may give us clues about the kinds of experiences different organisms can have. Interestingly, the brain regions involved in working memory are more highly developed in humans than in other primates and more highly developed in other primates than in other mammals. Adding in the fact that language is likely to change the way experiences are interpreted (and appraised), and that only humans have natural language, we are led to the conclusion that whatever kinds of experiences other organisms have, they are likely to be distinct from those typical of humans.

The bottom line is that two organisms may have identical behavioral and autonomic responses but have completely different conscious experiences. You can trust to some extent that when another human is acting fearful or joyful they are likely to be feeling what you refer to as fear or joy. The reason we can trust this conclusion is because we have the same basic brain plan as do other members of our species. We can therefore take what we know from our own experiences and apply it to others. We do this all the time in social interactions. People also often do this for pets and other animals. The reason this 'anthropomorphic' reasoning is inappropriate was

explained earlier: because the brain mechanisms of consciousness are likely to be different in different organisms, mainly because of the development of the prefrontal cortex in primates and language in humans, conscious experiences are likely to be different.

Conclusion

This brief survey, much of it including historical material, provides an overview of some of the major concepts of emotion that are relevant to the pursuit of brain mechanisms of emotion. Many of these concepts have been explored in depth in the large body of literature on emotion theory.

Emotion: Computational Modeling

J-M Fellous, University of Arizona, Tucson, AZ, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Understanding the neural basis of human emotions is difficult because emotions are, to a large extent, subjective and nondeterministic. The same stimulus may create different emotions in different individuals, and the same individual may express different emotions in response to the same stimulus, at different times. However, in spite of this variability, it is assumed that there are basic principles, perhaps even basic neural mechanisms, that make a particular event 'emotional.' To find these principles and their underlying mechanisms, neuroscientists typically study specific emotions, using specific tasks. As is appropriate, they use a combination of animal and human preparations, yielding various types of data, from single neuron firing patterns, to activation levels of a whole brain area. The approach, while rigorous, is slow and yields an increasingly complex body of often conflicting data. An integrative approach is needed. Computational models of emotion have emerged as a promising tool for integration. Because they require that all assumptions be made explicit, they offer a new language in which to express and test hypotheses, as well as explain and predict neural mechanisms.

It is paradoxically the advances in cognitive neuroscience that have allowed for the emergence of emotion research. The paradox is in the fact that usually, the 'cognitive' is opposed to the 'affective.' We now know from experimental and modeling work that both cognition and emotion develop and work hand in hand. Fortunately, as a result of the cognitive neuroscience push to understand emotion, the techniques used in that field have carried over to emotion research. Models once used to understand cognitive functions, such as perception or memory, are now extended and sometimes fundamentally modified, to address issues pertaining to emotion.

The past 10 years has seen an explosion of artificial intelligence (AI) models that have directly addressed issues on the role of emotion. Though generally not neurally motivated, these models have emphasized several important functional aspects of emotions, such as their role in communication (human–machine interface), in decision making, in general body homeostasis, and in environmental adaptation (in autonomous robots). Several books have been published, one of the first being that of Rosalind Picard, *Affective Computing*. Artificial intelligence focuses on basic principles, without necessarily the need to find neural mechanisms that support them (e.g., chess playing). Neural modeling, on the other hand, focuses on mechanisms and hopes to emerge basic computational principles. The elucidation of the underlying mechanisms is powerful in that it explains how a system works and fails, and predicts the behavior of the system under conditions not yet tested experimentally. This aspect of modeling is particularly interesting for the understanding and treatment of emotional disorders; the focus here is on such neural modeling approaches, leaving AI approaches for further reading.

Building neurally motivated models of emotions or specific aspects of emotion processing can be achieved at many levels of abstractions. At the one end of the spectrum are models that implement a specific neural pathway, involving specific neural populations. These biophysical models typically describe neurons at the level of individual action potentials. Their explanatory and predictive power comes from the emergence of interesting dynamical network behaviors (e.g., oscillation, competition between neuronal pools) on millisecond timescales. At the other end are models that are mainly concerned with neural processing principles, where emphasis is brought on the connectivity and level of activation of typical neurons, or groups of neurons. They are primarily designed on the basis of anatomical and imaging data. These connectionist models can effectively give a larger view of the computations achieved by a set of brain areas. The vast majority of connectionist models implement some form of learning, whereby interesting network behavior emerges from the reconfiguration of the synaptic connection patterns. They can often explain and predict neural activity on behavioral time scales. There is of course a wide range of hybrid models in between those two extremes, as will be seen in the following discussion.

There has been a flurry of experimental work producing data on various aspects of the neuroscience of emotions in the past few decades. These data have given rise to many anatomical models, and have been reviewed by Tim Dalgleish. However, computational models of emotions have been possible because of the emergence of complementary mechanistic theories of emotions. Four of those conceptual models (as seen in the work of Joseph LeDoux, Edmund Rolls, Antonio Damasio, and Klaus Sherer) are at the basis of several neurally inspired models of emotions. Negative emotions are approached through the modeling of various aspects of fear processing in the amygdala. Positive

emotions are addressed through the study the neural substrate of reward processing and decision making.

Fear and the Amygdala

According to LeDoux's conceptual model of auditory fear conditioning, the amygdala neurons receive fast and broadly tuned inputs from the thalamus, and slower and more refined inputs from the cortex. Armony and co-workers built a computational model of auditory fear processing whereby synaptic connections were modified so that each amygdala neuron 'learned' to represent a restricted range of tone frequencies; together, the neurons cover the audible spectrum. Interestingly, when the learning was conducted under conditions in which fear was associated with certain tones but not with others, a subset of neurons retuned and shifted their preference to those frequencies that were paired with fear elicitation. This fear-driven remapping of neural tone preference was later confirmed experimentally by recording from the amygdala of animals trained to associate tones and fearful electrical footshocks. Surprisingly, the model also showed that the removal of cortical inputs to the amygdala cells did not affect their stimulus preference, as would be expected from computational units that have access to less incoming information. This result, again confirmed experimentally by lesion studies, predicted that noncortical inputs (thalamic in origin) may have more influence than previously expected. The model, constrained by experimental data, was therefore able to make experimentally testable, and later confirmed, predictions about fear processing, and lent support to the notion of dual routes of fearful stimulus processing.

Other more abstract models using genetic algorithms and artificial neural networks showed how these fast and slow routes of processing could emerge from the necessity for survival when discrimination between predator and prey (i.e., positive and negative 'emotions') was made difficult by environmental circumstances.

Beyond its involvement in fear, the amygdala has also been modeled as a component of the general motivational system. One of Stephen Grossberg's models was designed to explore the cognitive–emotional interactions at play during various learning paradigms. This model included a sensory (visual) perceptual system that consisted of the thalamus, primary visual cortices, and temporal lobes, a motivational system that represented the activity of the hypothalamus and amygdala, and a generic motor system that included overall cortical and cerebellar motor outputs. The amygdala acted as a motivational bias to the sensory stream, and through its interaction with the prefrontal cortex influenced action selection. The activity of the amygdala relied on the dynamical interplay between opponent emotional representations such as fear and relief. With the proper tuning, arousal-like inputs to these representations could lead to a characteristic inverted U-shaped behavioral response, whereby too little or too much arousal decreased motor output. Mechanistically, the model predicted that a large arousal input may yield a depression of amygdala activity that in turn caused a decrease in prefrontal cortex activation (hypofrontality). This chain of event lead to the emergence of negative symptoms characteristic of schizophrenia, such as flat affect (modeled as low amygdala activation), decrease of motivation (modeled as low prefrontal activity), and attentional deficits (modeled as a lack of prefrontal cortex control on sensorimotor information flow).

The idea of emotion as a component of the motivational system, and of emotional behavior as a result of the competition between different motivational systems, is also at the basis of a connectionist model of anxiety in rats. In the Salum model, spatial exploration was the result of a dynamical conflict between exploratory behavior (curiosity) and avoidance for open/high places (anxiety generating). While based on experimental behavioral data obtained in rats, the model did not, however, explicitly address the role of the amygdala, but rather, as in Grossberg's model, illustrated the basic principle of dynamical competition between conflicting motivational biases.

Other connectionist-like models by Taylor and Fragopanagos have attempted to clarify the link between emotion and attention. Their models relied on a fast, preattentive, processing route inspired by LeDoux's conceptual model. The amygdala evaluated the negative nature of incoming stimuli, and exerted a gain enhancing, excitatory effect on sensory processing which moved the focus of attention on the emotional stimulus (bottom-up attentional modulation). Alternatively, and perhaps complementarily, the focus of attention could also be modified by an amygdala-triggered interaction between ventromedial and dorsolateral prefrontal cortices modules that eventually changed the active cognitive goal (top-down attentional modulation). This model was used to explain various emotion–attention experiments and confirmed the view that the amygdala may have a fast, subattentive modulatory role in attention through both the production of saliency and the cognitive control of behavior. This model, as with that of Grossberg, points to a crucial interaction between the amygdala and prefrontal cortices. This interaction

has been further studied in the context of reward processing.

Reward Processing and the Prefrontal Cortex

The involvement of the orbitofrontal cortex (OFC) in emotion relies on a large body of data on reinforcement learning. For Rolls, this type of learning is at the basis of the processing of emotions in general, and the orbitofrontal cortex is in charge of decoding the reinforcement value of the stimuli and the rapid associations and reassociations between the stimuli and reinforcers. His experiments have shown that normal OFC function mediated one-trial reversal of stimulus–reward association. This phenomenon is mechanistically problematic because its time course is incompatible with learning mechanisms such as typically proposed by connectionist models, whereby synaptic modifications occur after multiple stimulus–response associations (i.e., training). Deco and Rolls' model needed to account for fast time scales, and had therefore to rely on spiking (biophysical) neurons. The model was based on 'biased competition' between pools of explicitly simulated neurons. A particular stimulus–reward association was represented by a pool of actively spiking neurons, and, interestingly, a change in association was simply a change in which pool of neuron fired (and not a change in synaptic strength). The change was dynamically achieved by a small input bias coming from a specialized OFC group of neurons called 'rule-specific' neurons. These neurons were context dependent and allowed for the same object to be perceived as rewarding or punishing, depending on the task contingency (context). They responded to punishment or the nondelivery of an expected reward by delivering an inhibitory bias to the currently active neuronal pool (a particular stimulus–reward association). When inactivated, the pool became momentarily refractory, and a new pool (a new stimulus–reward association) emerged rapidly, in one trial. This model made a number of testable predictions, one of which was the existence of specialized pools of OFC neurons that fired when a particular object–value combination (e.g., rewarded square, but not punished square) was presented. Such neurons may be used for general emotional reactions to a variety of cognitive contexts. Some experimental evidence indeed points to the existence of such neurons.

The idea that emotional signals bias the activity of competing active circuits is also at the basis of Damasio's somatic marker hypothesis. According to this theory, the perception of ones' own action in response to a particular stimulus has the potential to activate emotional memories that were previously associated with that stimulus. These memories ('somatic markers') in turn bias further cognitive processing, decision making, and action selection mechanisms. Several brain areas are known to be involved in this type of emotional bias, and special attention has been drawn to the ventromedial prefrontal cortex (VMPFC). The VMPFC is part of the executive system of the brain whereby actions are selected and plans are made. Because of its connection to the amygdala, the VMPFC also contains associations (the 'somatic markers') between previous actions and their expected consequences ('emotional' in nature). In the Wagar and Thagard model, when a stimulus is perceived, several potential actions are activated in the VMPFC. Some of these actions are part of somatic markers, and activate amygdala-dependent representations that 'reenact' the bodily state predictive of the action's consequences. These unconscious representations (representing emotional valence) in turn bias decision-making processes. The model further proposes that this bias depends on the context (hippocampus activation) in which the stimulus is perceived, and that it is gated by the nucleus accumbens.

The nucleus accumbens receives inputs from the VMPFC, the amygdala, and the hippocampus, and is thought to be key to high-level cognitive processes and action selection. However, because the nucleus accumbens is generally inhibited by dopamine (from the ventral tegmental area), these inputs are not sufficient to make it fire. The model showed that firing occurred only if the amygdaloid inputs (appraisal of a stimulus) arrived first, followed by a VMPFC input (a possible action to perform), and provided that the hippocampus is active throughout (the correct contextual information). In a simulated 'Iowa gambling' task, the model correctly showed that in normal conditions, choices are made according to long-term predicted outcomes (VMPFC activity), while in VMPFC lesions conditions (as in the case of the famous Phineas Gage), choices are made instead on the basis of immediate outcomes (amygdala activity). In the specific case of positive and negative stimulus evaluation taken as different 'emotional states,' this model offered insights on the role of the nucleus accumbens in the integration of cognitive, contextual, and emotional information flow.

One major issue in both the Deco and Rolls and the Wagar and Thagard model is that learning is assumed. The connectivity patterns among the various components of the model are configured 'manually' and emphasis is brought on the dynamical aspects of the network. Frank and Claus attempted to explicitly model the learning phase, and their model focused on the interactions between OFC and the

dopaminergic system of the basal ganglia. They showed that the probability of reward/punishment was likely to be encoded by the basal ganglia. In contrast, the variations in the magnitude of reward and punishment were both encoded by the amygdala and actively maintained in the medial and lateral portions of the OFC, respectively. The model was tested on the Iowa gambling task, reversal learning, and devaluation paradigms. They explained various aspects of decision-making deficits in OFC-damaged patients, Parkinson's disease patients, and in drug abusers, and offered a partial explanation for individual differences in risk-averse and risk-seeking normal individuals.

Modeling Emotions

Mainly because of the availability of experimental data, the focus of neural models of emotions has been on fear and reward processing; there have been relatively few attempts at using neural networks to model emotions in general. One step in this direction was taken by Scherer and co-workers, on the theoretical basis that emotions may be understood as the result of a complex sequence of appraisals. According to Scherer, emotions have five major components: a cognitive component (rational evaluation of objects and events), a peripheral efference component (homeostasis, body regulation), a motivational component (preparation for action), a motor component (expression of emotion, communication to others), and a subjective 'feeling' component (monitoring of emotional expressions). Formulated in this framework, an emotion is the dynamical coactivation of these components in response to the evaluation (by, e.g., the amygdala) of an internal or external stimulus that is particularly important to the subject. The architecture of the model is that of a feed-forward network, with lateral connections. The stimulus activates a set of interacting representational units that are specialized in the recognition of predefined aspects of the stimulus, such as its novelty, intrinsic pleasantness, or outcome probability. Together these units determine the significance of the stimulus, and activate a second layer of interacting units that prepare the organism for action. These units assess the relevance of the action, its appropriateness with respects to a set of standards, its potential consequences on the world, and the potential for coping with those consequences.

Emotion is therefore a pattern of activity, an emergent property of the interaction of these units, rather than the weighted activation of some set of basic and independent emotion 'nodes,' or modules. Unfortunately, no implementation of this connectionist model has yet been performed, so while conceptually useful, the model has not quantitatively explained or predicted emotional phenomena. In particular, such a model would be useful to understand the appraisal basis of emotional disorders, as well as the extent to which differences in appraisal processes explain individual differences in emotional processing in normal individuals.

For Mischel and Shoda, the emotional system is indeed at the core of what defines personality, individual differences, and the way we interact with others. In their connectionist model, abstract units representing cognitive and affective knowledge are randomly interconnected and interact dynamically. In some conditions, the response of the network to different situations (activation of a subset of the units) displays the same variability as that of human behaviors when individuals are repeatedly presented with a fixed set of situations. In other conditions, the network shows response consistencies across different situations, as would also be observed in humans. According to their model, individual differences and variability of behavior reside in the different connections between cognitive and affective units, rather than depending on the exact nature of the units.

Conclusion

Computational models of emotion, being biophysical or connectionist, point to several important conclusions regarding the neural bases of emotions. First, it has become clear that there are no 'emotional centers' in the brain. Models show that individual modules (being neurons, populations of neurons, or brain areas) do not work in a sequential manner. They are part of complex recurrent networks, so much so that their activity intimately depends on the activity of many other modules, being emotional or not. No region is specifically dedicated to the generation of emotions in general, or of a specific emotion in particular. Furthermore, models show that the dichotomy between cognitive and emotional processing is probably too simple, if not fundamentally incorrect. Brain areas such as the prefrontal cortex or amygdala are inherent parts of the 'computing' networks of stimulus perception and decision making, yet also mediate 'emotional' functions such as stimulus evaluations and emotional expressions.

Second, emotions are not simple 'states,' or patterns of activations of a few brain areas. While previous stimulus–emotion–action associations are a large part of what triggers an emotional behavior, it has become clear that emotions are dynamical modes of functioning. They temporally wax and wane as internal (e.g.,

memory driven) or external (e.g., perceptions) events occur. They develop over short timescales, as in fear, or over long timescales, as in moods or depression. As such, perhaps it is more useful to think about emotional flow, rather than emotional states.

Third, emotions have a functional role, and are not simple by-product of neural activity. The current computational models of emotions have so far focused on the notion of computing bias, whereby information flow is redirected or modulated in various ways. This view is in contrast with the notion of a parallel stream of 'emotional computations' that would simply be added as an additional information channel. The functional aspects of emotion are also clearly apparent in the AI literature.

In sum, the convergence of conceptual, experimental, and computational models seems to be key to the advancement of our understanding of the various aspects of emotional processing, emotional expression, and emotional experience.

Background

Emotions, of which fear is a prime exemplar, are unique among mental states in having in equal measure psychological and somatic referents. The former embody the subjectivity of all psychological states, whereas the latter are evident in stereotyped behavioral patterns of facial expression, comportment, and states of autonomic arousal. Emotional states exert global effects on virtually all aspects of cognition, including attention, perception, and memory. They also exert biasing influences on high-level cognition, including decision-making processes. An informed neurobiological account of emotion must incorporate how these wide-ranging effects are mediated.

Historically, emotional behavior and experience have been attributed to the functions of the limbic system. But an increasing body of evidence suggests that there is widespread propagation of emotional signals within the brain, and this has diminished the general utility of the concept of a limbic-based emotional system. Consequently, contemporary perspectives on emotion emphasize a dynamic brain configuration of emotional states, which to a large extent are determined by an emotion-eliciting context. Within this framework, emotional states are not unique to any single brain region but are expressed in widespread patterns of brain activity, including within early sensory cortices.

Notwithstanding these considerations, the structure most closely affiliated with emotional processing is the amygdala, an anatomically and functional heterogeneous bilateral collection of nuclei in anterior medial temporal cortex. The importance of the amygdala in emotional and behavioral control was first highlighted by reports that rhesus monkeys with bilateral temporal lobe ablations no longer showed appropriate fear or anger responses. The importance of the amygdala derives in part from its extensive anatomical connections with the sensory-processing cortices, hippocampus, basal ganglia, limbic cortex and homeostatic regulatory regions of the hypothalamus and brain stem. This connectivity means that processing within this structure can exert diffuse modulatory influences, including influences on effector autonomic and motor output systems.

Although much of what we can infer about emotional processing in the human brain is derived from the type of studies already described, the advent of high-resolution, noninvasive, functional neuroimaging techniques, such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), have greatly expanded this knowledge base.

Imaging Emotional Stimuli

Studies of human emotional processing using functional neuroimaging techniques have invested intensely in an experimental approach that involves presenting to healthy subjects stimuli that represent basic emotions as expressed in facial expressions of fear, anger, sadness, disgust, happiness, and surprise. The key finding from these studies is an enhanced amygdala response to the presentation of fearful faces, as well as enhanced activation in the sensory-processing regions specialized for faces, the fusiform gyrus. A notable observation is that an emotional response to fear in facial expressions is conveyed principally by a specific feature, namely the eyes, such that the presentation of fearful eyes alone can elicit an amygdala response.

The selectivity of amygdala for processing fearful faces, as suggested in neuropsychological studies, is challenged by neuroimaging findings of an amygdala response to a range of emotional faces (Figure 1(a)). Thus, although fearful faces provide reliable stimuli for eliciting amygdala responses, other emotional expressions, including sad, anger, and disgust, also evoke increased amygdala activity (Figure 1(b)). Indeed, when brain responses to multiple emotions are studies within the same experiment, a reliable amygdala activity is elicited to an entire range of emotions.

A widely held view is that emotion is reducible to dimensions of arousal and valence. A key question arising from this conceptualization is whether amygdala activation due to the presentation of emotional stimuli, seen using functional neuroimaging, reflects a specialization for processing emotional intensity (a surrogate for arousal) or, alternatively, for processing valence. There is good evidence for an amygdala response profile that suggests a more complex profile involving an intensity-by-valence interaction. Consequently, it seems that the amygdala codes neither intensity nor valence *per se* but, instead, an interaction between intensity and valence that reflects the overall emotional value of a stimulus.

Figure 1 Amygdala responses to emotion: (a) bilateral amygdala activation in response to the presentation of multiple exemplars of emotion; (b) response magnitude for four exemplars of emotion taken from a voxel in the left amygdala.

Imaging the Acquisition of Emotion

In classical or Pavlovian conditioning, a neutral stimulus, through pairing with an emotional stimulus (e.g., an aversive noise in fear conditioning), acquires the ability to predict its future occurrence. Associative learning provides a highly conserved means by which organisms acquire knowledge regarding the causal structure of the environment. Such knowledge endows an organism with the ability to anticipate future events of value, such as the likelihood of food or danger, on the basis of predictive sensory cues. The amygdala plays a central role in this type of causal learning. Thus, amygdala activation is seen when a previously neutral item (the conditioned stimulus (CS+)) acquires predictive significance through its pairing with a biologically salient reinforcer (the unconditioned stimulus (UCS). This pattern of activation is seen both for aversive and appetitive events. Thus, across a wide range of experiments, an enhanced amygdala response is evident when subjects learn that a neutral stimulus predicts the occurrence of an emotion-inducing event, for example, an aversive event.

Theoretical accounts of associative learning based on the Rescorla–Wagner rule and their real-time extensions, such as temporal difference (TD) reinforcement models, provide plausible descriptions of the computational processes underling associative learning. Crucial to these models is the expression of a teaching signal, referred to as the prediction error. A prediction error is used to direct acquisition and refine expectations relating to predictive cues, and it records a change in expected affective outcomes, being expressed whenever predictions are generated, updated, or violated. Functional neuroimaging studies have demonstrated that such a prediction error is expressed in the human brain in structures such as amygdala, striatum, and orbital-prefrontal cortex (OFC) during aversive and appetitive associative emotional learning.

Imaging Updating of Emotional Value

Predictive contingencies acquired through associative learning are limited in their ability to provide a basis for optimizing future behavior. For example, the value of the states associated with predictive cues can change in the absence of further pairing with these cues. Thus, a cue that predicts that the occurrence of food that is valued when a person is hungry has diminished value when the person is sated with that same food. Consequently, maintaining an updated representation of the current value of a sensory-predictive cue that does not depend on new learning in relation to that cue greatly enhances behavioral flexibility.

In human functional neuroimaging studies, neuronal responses elicited by predictive stimuli (such as a CS+) that have been subject to devaluation are associated with parallel response decrements in the left amygdala and OFC. This response pattern suggests these regions contribute to updating the reward value of predictive stimuli. This pattern of value-related response expressed in these regions may explain why pathologies that impact on the medial temporal and basal orbital-frontal lobes, such as fronto-temporal dementias, are associated with behavioral aberrations such as indiscriminate eating, food cramming, change in food preference, and hyperorality. In these contexts, damage to the OFC and amygdala entails that subjects can no longer recruit motivationally appropriate representations of food-based reward value, either appetitive or aversive, in response to predictive cues.

Imaging Emotion in Social Contexts

The amygdala may be important for social cognition and a functional dysregulation within this structure is often suggested as important in the genesis of disorders of social cognition, such as autism. A role for the amygdala in social cognition is suggested by observations of increased activity to the presentation of faces that subjects rate as untrustworthy. An increased amygdala response in White American subjects viewing pictures of unfamiliar Black (African American) faces has also been reported. Increased amygdala activity was not seen when White Americans viewed familiar positively regarded Black (African American) faces, suggesting that this response pattern reflects a learned, culturally specific phenomenon and not innate processes. Observations such as these have led to a view that increased amygdala responsivity to facial expressions actually indexes the occurrence of potential threat. This idea has gained support from other functional neuroimaging studies which show that threat, as embodied in threatening words, aversive tastes, and aversive odors, all evoke an amygdala response. Thus, a stimulus within any modality perceived as a potential threat evokes increased amygdala activity.

Imaging Modulatory Effects of Emotion on Cognition

The domain in which the modulatory influences of emotion are best characterized is episodic memory. The benefit of emotion to episodic memory function is confirmed across numerous studies which show a mnemonic enhancement for material that encompasses personal autobiographical and picture- and word-based items, an effect best seen in free recall tasks. The critical role played by the amygdala in this modulation is evidenced within functional neuroimaging experiments in which amygdala activity during encoding predicts a benefit in the later recall of emotional material. Thus, enhanced amygdala activity at encoding for both positive and negative stimuli is predictive of later episodic memory function, as determined in free recall tasks.

The role of the amygdala in modulating episodic memory function is not restricted to the encoding of emotional events. This structure is also engaged during the retrieval of emotional items and contexts. Connectivity analysis performed on neuroimaging data indicates that contextual recall of emotional events leads to enhanced amygdalar–hippocampal coupling under a controlling influence from OFC. This finding of enhanced interactions between the amygdala and hippocampus is also supported by observations from patients who have lesions to either the amygdala alone or jointly to the amygdala and hippocampus. During the encoding of emotional items, there are bidirectional interactions between these structures, such that an enhanced amygdala response to emotional items is dependent on an intact hippocampus, whereas, conversely, an enhanced hippocampal response to emotional items is dependent on an intact amygdala.

The neurochemical mediation of emotional memory effects has been a subject of increasing interest. Emotional memory enhancement in human subjects can be blocked by the administration of the β-adrenoreceptor blocker propranolol prior to the study. In subjects who are pretreated with propranolol, functional imaging experiments show an absence of emotion-evoked activation of the amygdala. Intriguingly, the encoding of negative emotional items has anterograde and retrograde amnesic effects such that, for example, in word-list presentations there is a relative amnesia for antecedent and preceding items.

Imaging Emotional Enhancement of Perception

An evolutionary perspective on emotion suggests that environmental events of value should be susceptible to preferential perceptual processing. There appear to be two distinct mechanisms by which emotion influences perception. One of these is through emotion interacting with attention, leading to enhanced deployment of attention, leading to the preferential detection of emotional events. For example, in spatial-orienting tasks there are faster responses to targets appearing on the same side as an emotional cue (e.g., faces, spiders, threat words, or conditioned shapes) and a slower response to those appearing on the opposite side. Neuroimaging data, using spatial-orienting paradigms, indicate that the OFC is the site of the expression of this type of interaction between attention and emotion.

Attention is not the sole means by which emotional stimuli influence perception. There is now evidence for mechanisms that are independent of attention. In visual backward-masking paradigms, a target presented for a brief instance can be rendered invisible if it is immediately followed by a second masking stimulus. In situations in which the hidden target stimulus is an emotional item (e.g., a conditioned angry face or a spider), there is preserved processing indexed by differential skin conductance responses (SCRs) to fear-relevant compared to fear-irrelevant targets. Similar findings are evident using the attentional blink paradigm which refers to a situation in which the detection of an initial target stimulus in a stimulus stream leads to impaired awareness, or

inattentional blindness, for a successive second target. Neuroimaging data show that the processing of emotional stimuli outside the window of awareness is mediated by the amygdala.

Studies of patients with focal brain lesions provide additional evidence for a degree of independence between emotional processing and attentional mechanisms. Following brain damage to the right inferior parietal cortex, patients frequently fail to perceive a stimulus presented in their contralesional hemifield (spatial neglect). This contralesional deficit is greatly attenuated for emotional stimuli (e.g., faces with happy or angry expressions or images of spiders). Nonconscious processing of emotion has also been demonstrated in the blindfield of patients with damage to the primary visual cortex. In terms of the anatomical substrates of these effects, functional neuroimaging evidence implicates the amygdala. In functional neuroimaging experiments, using visual backward-masking paradigms, an amygdala response discriminates between unseen emotional and unseen nonemotional targets. In other experiments that involve overt stimulus presentation but in which attention is systematically manipulated, such that emotional items are presented out of the window of attention, an amygdala response to fearful faces is independent of concurrent attentional focus. Likewise, patient studies of subjects with either blindsight or visual extinction demonstrate an amygdala response to emotional stimuli presented out of awareness in the damaged hemifield. Interestingly, residual processing abilities for the unaware presentation of emotional stimulus are associated with the engagement of a subcortical retino–collicular–pulvinar pathway specific to unaware emotional stimulus processing. The involvement of this pathway is of considerable interest because it is implicated in residual visual processing evident in patients with blindsight. The suggestion here is that certain classes of emotional stimuli, for example fearful faces, can be processed by a noncortical pathway to allow rapid adaptive responses to danger.

How the pre-attentive processing of emotional events influence, and enhance, perception is a question addressed by studies in normal subjects and patients with discreet lesions. One possibility is that inputs from emotional-processing regions, in particular the amygdala, modulate the very regions involved in object perceptual processing, specifically those related to the emotion-eliciting object. Anatomically the amygdala receives visual inputs from ventral visual pathways and sends feedback projections to all levels of this pathway. Neuroimaging data provide evidence for the enhancement of functional connectivity between the amygdala and extra-striate visual regions, expressed during the processing of an emotional visual input. Crucially, neuropsychological data from patients with amygdala damage indicate that a perceptual enhancement for emotional items is abolished following damage to this structure. Furthermore, in patients with amygdala lesions, the enhancement of activity seen in early extra-striate visual areas during the encoding of emotional items (e.g., faces) is no longer expressed. This type of evidence is consistent with a proposal that early sensory cortex boosting of activity reflects a direct modulatory influence from the amygdala. Indeed, an emotion-induced enhanced connectivity between the amygdala and extra-striate regions associated with boosting of perception has been demonstrated in a visual detection.

Imaging Feeling States

Human emotion research often conflates neurobiological mechanisms that index the perception or occurrence of an emotional event with their subjective experiential counterparts, referred to as feeling states. Feelings can be defined as mental representations of physiological changes that characterize, and are consequent on, processing an emotion-eliciting objects or image. This definition assigns an important causal role in the genesis of subjective feeling states to afferent feedback to the brain, both sensory and neurochemical. At a broader level, feeling states can be subsumed within homeostatic mechanisms that underlie the survival of the organism. In a recent theoretical model, based on neurological observations, prime emphasis is given to the cerebral representation of bodily states as providing the substrate for emotions and conscious awareness.

The key neurobiological question is whether brain systems supporting emotional perception are distinct from those supporting feelings states. Candidate structures that mediate feeling states encompass those that receive inputs regarding the internal milieu and include the brain stem periacqueductal gray (PAG) and parabrachial nuclei, tegmentum, hypothalamus, and insular, somatosensory and cingulate cortices. Functional neuroimaging provides strong evidence that feelings are mediated by neuronal systems distinct from those that support emotional perception. Thus, volunteer studies have shown that the generation and rerepresentation of peripheral autonomic states involve structures such as the anterior cingulate and insular cortex. Recall of subjective feeling states associated with past emotional experiences engages regions encompassing upper brain stem nuclei, hypothalamus, somatosensory, and insular and orbito-frontal cortices. In subjects with pure autonomic failure (PAF), where there is an absence of visceral afferent information regarding the peripheral body state due to selective

peripheral autonomic damage, there is attenuation of subjective emotional feelings and of emotion-elicited neuronal activity in regions implicated in mediating feeling states. A notable feature of these studies is an absence of any deficit in amygdala activity, in keeping with a more critical role for this structure in emotional perception.

Among the regions most strongly implicated in mediating feeling states is the insular cortex. Direct evidence for its role in representing subjective feeling states comes from a study that used a task that taps awareness of internal bodily states, namely a heartbeat detection task. When subjects detect their own heartbeat, there is enhanced activity in the anterior insular cortex. The proposal that this area mediates feelings is also bolstered by evidence that empathetic awareness of the subjective feeling states of others, for example the awareness engendered when we observe another person receiving pain, is reflected in enhanced activity within the anterior insular cortex and anterior cingulate.

Imaging Emotional Influences on Decision Making

Real-life decision making often involves choices between actions which yield rewards with varying probabilities and magnitudes. Decisions that seek to optimize rewards require an estimation of an expected future reward that will follow from choosing a particular action and the subsequent use of these values to guide action selection. In its simplest form, reward prediction based on expected value can be studied through classical conditioning, in which an arbitrary cue (or CS+) takes on predictive value by association with the subsequent delivery of an affectively significant stimulus or UCS (which can be a reward or punishment or, strictly speaking, an appetitive or aversive stimulus). Neuroimaging studies implicate the OFC alongside other structures such as the amygdala and ventral striatum in reward prediction. Enhanced responses to cues predictive of delivery of either a pleasant or aversive odor result in significant orbitofrontal responses suggesting the OFC maintains predictions for negatively valenced as well as positively valenced stimuli. Human neuroimaging studies of classical conditioning for reward report prediction error signals in prominent target areas of the dopamine neurons, including the OFC. The finding that neural prediction error signals are present in the OFC and throughout the reward network is consistent with the possibility that this mechanism is implemented in the human brain to mediate flexible learning and updating of stimulus–reward associations, a function frequently ascribed to the OFC.

Theoretical accounts of human decision making emphasize a rationalistic perspective of utility maximization, which invokes analytic processes mediated by the executive prefrontal cortex. An emotional or value-based contribution to high-level decision making is evident following ventromedial prefrontal cortex damage where, despite the absence of intellectual deficits, patients make real-life decisions that are disadvantageous. The somatic marker hypothesis arising from observations with these type of lesions suggests that this region provides access to feeling states in relation to past decisions during contemplation of future decisions of a similar nature. Thus, the evocation of past feeling states biases the decision-making process toward or away from a particular behavioral option. However, alternative frameworks that might explain the behavioral deficits seen following damage to this region include an inability to represent the value of competing options for action or a discounting of future rewards. Neuroimaging evidence indicates that this region is activated both during anticipatory states in relation to rewards or punishments and by actual outcomes associated with reward or punishment.

To make effective behavioral decisions between different types of reward requires that the rewards be encoded in a common representational space or currency. A distinct representation of value for different rewards can facilitate goals pertaining to specific motivational states. A candidate region that is activated to different types of reward is the anterior sector of the medial OFC, and this region is a potential candidate for mediating a representation of unitary stimulus–reward value.

It is well recognized that human decision making does not always accord with rationalistic perspectives of utility maximization. An influence of prior outcomes on decision processes is captured by regret theory, in which counterfactual thinking involved in comparing an obtained and forgone outcome indicate that the latter, if chosen, would have been more advantageous (Figure 2(a)). It is known that subjects who experience regret show a subsequent bias away from the maximization of expected value in their choices. This behavioral bias is associated with engagement of the amygdala and orbito-frontal cortices, regions that are also engaged by the actual experience of regret (Figure 2(b)). This pattern is consistent with theories that suggest that the evocation of past emotions in the context of decision making provides a biasing influence on rational decision processes.

A tenet of rational behavior is invariance or extensionality, in which human decisions are held to be consistent regardless of how choices are presented. A deviation from this axiom is described within

Figure 2 Influence of regret on choices in a gambling task: (a) proportion of subject choices that can be attributed to experiencing regret; (b) brain activity during choice. In (a), the graph shows an increasing attribution of choices to prior experiences of regret; In (b), amygdalar (1) and orbito-prefrontal (2) engagement correlates with the increasing influence of regret on choice.

prospect theory as the framing effect. In simple terms, the framing effect describes a bias in decision making observed when a gamble is presented in terms of gain, leading to choices of a sure option, versus the same gambles presented as a loss leading to risk seeking, when subjects are biased to choose a gamble option. Functional neuroimaging data show that a framing-engendered bias in human decision making, risk aversiveness in the gain frame and risk seeking in the loss frame, is associated with enhanced amygdala activity. The suggestion here is that an emotional heuristic, mediated via key emotion-processing brain regions, is invoked when humans make decisions in situations in which information is incomplete or overly complex.

One common situation that can engender emotion is when an individual makes a decision under risk (the probability distribution of possible outcomes is known) or under ambiguity (where the probability distribution of outcomes is unknown). Subjective utility theory embodies the idea that the outcome probability should influence choice but also that there should no influence on confidence about these probabilities. The Ellsberg paradox shows that subjects behave irrationally when presented with a choice between a risky and ambiguous option, when choices can be shown to depend on subjective probabilities and on ambiguity of events. The possibility that this influence on rational decision making reflects an input from an emotional system is supported in neuroimaging data which show that the level of ambiguity in choices correlates positively with activation of the amygdala.

Conclusion

Neuroimaging has radically altered our conceptualization of emotion. Key observations include evidence that emotion-related activity is expressed across widespread brain regions. A fine distinction between regions that process sensory emotional signals and regions that contribute to the actual experience of emotion has become possible. Furthermore, it has become possible to identify activity in the brain that reflects key computational strategies implemented during emotional learning and emotion-guided decision making.

Emotional Control of the Autonomic Nervous System

P Carrive, University of New South Wales, Sydney, NSW, Australia

Introduction

Fear and anxiety are the two main forms of aversive emotion in human and animals. These emotions are basically stress responses with a psychological origin. They are triggered by environmental stimuli that would otherwise be innocuous but that the individual perceives as potentially harmful, either because they are linked to unpleasant memories or because the individual is in an altered state of mind. Like stress responses of physical origin (e.g., pain, cold), stress responses of psychological origin can be associated with marked autonomic and cardiovascular changes. Presumably, these changes prepare the organism for an active response in case it may have to confront or escape from the expected danger (i.e., the traditional 'fight or flight' response). The responses are preprogrammed, and as we all know, they can be difficult to control.

This article focuses on the structures that link the limbic forebrain (where emotions are processed) with the thoracic cord (where sympathetic preganglionic neurons are located), with a particular emphasis on blood pressure and heart rate. It is divided into two parts, for the two experimental approaches that have been used in studies of emotional control of the autonomic nervous system. The first part describes the central autonomic circuitry as revealed by direct activation of brain regions presumed to mediate aversive responses. This approach is used mainly in the anesthetized preparation, which is convenient for the recording of physiological variables, but is limited because of the confounding effect of anesthesia. It sprung up from the discovery in 1943 that hypothalamic stimulation evokes integrated defensive behavior. The second part deals with the same circuitry but as revealed by the effect of intracerebral lesions on naturally evoked aversive emotional responses. This other approach is used in awake animals, which is obviously the only way that emotional responses can be evoked, but it is limited experimentally by the difficulties of recording physiological variables in conscious animals.

The Centrally Evoked Defense Reaction

Early Work with Electrical Stimulation

The term 'defense reaction' (German, Abwehrreaktion) was first introduced by Hess and Brugger in 1943 to describe the effect of electrical stimulation in the hypothalamus of conscious cats. The responses they observed were well coordinated, had a clear emotional component, and looked similar to the characteristic patterns of defensive behaviors seen in normal cats. The most responsive area of the hypothalamus was in the dorsal tuberal hypothalamus, around the fornix. Further work in the 1950s and 1960s showed that this hypothalamic defense region extended caudally into the periaqueductal gray (PAG) and rostrally into the amygdala and bed nucleus of the stria terminalis, leading to the idea that defensive behavior was integrated along a system descending from the amygdala to the midbrain via the hypothalamus.

Then, in 1960, it was demonstrated that the same sites that produced the defense reaction in the conscious cat also produced a characteristic cardiovascular response under anesthesia. The response consisted of marked increases in blood pressure and heart rate associated with a fast vasodilatation in skeletal muscles and vasoconstriction in the gut and skin, all sympathetically mediated. This characteristic pattern of blood flow redistribution to the limbs was consistent with the pattern originally proposed by Cannon in 1929 for what he called emergency reactions – that is, reactions necessary for vigorous responses, such as fight and flight.

Attention then focused on the descending pathways of this response. The muscle vasodilatation, which was mediated by cholinergic sympathetic fibers in the cat, could be traced along a descending pathway from the dorsomedial/perifornical/lateral hypothalamus (DMH/PeF/LH) region and PAG, down into the ventrolateral tegmentum of the midbrain, pons, and ventral medulla. However, it was not clear if the projection was direct to the thoracic cord or if it involved a relay in the lower brain stem. Anatomical tracing has since revealed direct projections from the PeF and LH to the thoracic cord, but the discovery in 1973 of a vasomotor area near the ventrolateral surface of the rostral medulla (now known as the rostral ventrolateral medulla, or RVLM) raised the possibility of a relay in this region. Indeed, this was shown to be the case when it was found that blockade of the RVLM with glycine (an inhibitory neurotransmitter) or kynurenic acid (a glutamatergic antagonist) or lesions with kainic acid markedly reduced all components of the cardiovascular response, including the muscle vasodilatation. The tachycardic component, however, could not be reduced.

The cardiovascular response evoked from the hypothalamic defense area would later be known as the

visceral alerting response. For Hilton and co-workers, the response was a set pattern, a preparatory response for fight or flight, which was activated from the alerting stages to the full expression of the defense response. Although simple and attractive, this concept was based on studies carried out in anesthetized preparations using intracerebral electrical stimulation. Studies conducted in the conscious cat during natural defensive responses did not fully agree with this view. In particular, other investigators argued that muscle vasodilatation was only evoked with movement of the limbs (i.e., during fight or flight). Immobile confrontation with an angry cat, for example, did not evoke muscle vasodilatation but muscle vasoconstriction instead. As will be described next, the idea that there is more than one pattern of cardiovascular response was actually correct.

Excitatory Amino Acid Activation and Shift to the PAG

To circumvent the problem of electrical stimulation which activates both cell bodies and fibers *en passage*, Dampney and Bandler introduced the excitatory amino acid (EAA; e.g., glutamate) injection method in 1982 to try to identify the exact location of the neuronal cell groups mediating the defense reaction in the hypothalamus and PAG. This led to the surprising finding that EAA injection into the hypothalamus or amygdala could not evoke defensive responses nor the full visceral alerting response. Only EAA injection in the PAG could evoke the fully integrated response. Attention then shifted to the PAG.

To understand how PAG neurons could integrate both somatic and cardiovascular components of the defense reaction, Carrive, Dampney, and Bandler recorded behavioral and cardiovascular changes at the same time in an unanesthetized, unparalyzed precollicular decerebrate cat preparation. This approach proved to be very powerful and led to the concept of columnar organization in the PAG in the early 1990s. The most important finding was that different types of basic defensive behavior were topographically represented along a longitudinal column of neurons extending along the lateral PAG. Thus, EAA activation of the middle third of this lateral PAG column evoked a strong facio-vocal response and tonic extension of the limbs, but without stepping movement. This was associated with a rise in blood pressure and heart rate, a moderate renal vasoconstriction, a carotid vasodilatation, and a hind limb vasoconstriction – in other words, the same response that had been observed in cats during immobile confrontation with an aggressive conspecific. In contrast, EAA activation of the caudal third of the lateral PAG column evoked vigorous stepping movements associated with a rise in blood pressure and heart rate, a strong renal and carotid vasoconstriction, and a marked, cholinergically mediated iliac vasodilatation. This was a flight response and it was associated with the classic visceral alerting response of the defense reaction. Thus, contrary to Hilton's view of one defense reaction and a unique visceral alerting response, there were at least two different defensive responses associated with perfectly adapted cardiovascular adjustments (vasodilatation in active parts of the body coupled with vasoconstriction in inactive parts). Further work showed that lateral PAG neurons project to the RVLM in a viscerotopic fashion – that is, the hind limb and renal constrictor parts of the lateral PAG project to their respective vasoconstrictor parts in the RVLM. This work was extended to the rat, in which a similar PAG organization was revealed, although not as clear-cut as in the cat.

Thus, within 10 years of the introduction of the EAA microinjection technique, a column of neurons had been found in the PAG that could mediate not one but at least two different patterns of coordinated defensive responses. In contrast, EAA activation had failed to reveal neurons integrating defensive responses in the hypothalamus. This suggested at the time that the final integrating center for defensive behavior and possibly other forms of emotional behavior was the PAG. However, it gradually became apparent that EAA activation also had limitations and that it had failed to reveal the true properties of hypothalamic neurons.

GABA Disinhibition and Renaissance of the Hypothalamus

One reason for initially dismissing the hypothalamus as a defense integrating center was that EAA microinjections evoked depressor rather than pressor effects in the anesthetized preparation. One problem may have been anesthesia, because pressor and tachycardic effects could actually be evoked from the DMH and PeF in the conscious animal. Another problem may have been the density of output pressor neurons. EAA activation may be less effective in areas where output neurons are scattered, especially if they are mixed with inhibitory neurons, because EAA coactivation of inhibitory interneurons would result in no net effect or even an inhibition of pressor neurons.

In fact, a more effective way to activate hypothalamic neurons in the anesthetized preparation is by disinhibition with microinjection of γ-aminobutyric acid (GABA)-A antagonists (e.g., bicuculline), as was first shown by DiMicco in the 1980s. It is now well established that bicuculline injections in the DMH

and PeF produce marked tachycardia, pressor responses, and increases in renal sympathetic nerve activity. When tested in the conscious animal, the same injections produce running and jumping. Thus, the hypothalamic defense area contains neurons that can mediate flight responses associated with appropriate cardiovascular changes, and these neurons are under tonic GABAergic inhibition.

Current work is now focusing on the output relays of the DMH in the anesthetized animal. Recent studies by Dampney and Morrison show that the RVLM is a necessary relay for the renal sympathetic nerve response because it is blocked by bilateral inhibition of this region with muscimol, a GABA-A agonist. However, the tachycardia is not reduced and the pressor response is reduced only partially. The tachycardia and pressor response may in part be mediated by the rostral medullary raphe nuclei (MRN; MRN will be used here to refer to nuclei raphe magnus and raphe pallidus, not raphe obscurus), especially the raphe pallidus, because inhibition of this region with muscimol reduces these two components. In addition, there is growing evidence from independent work by Blessing, McAllen, and Morrison that MRN is as important premotor center for the sympathetic control of cutaneous vasomotor tone and brown adipose tissue. Brown adipose tissue is a thermogenic organ. Activation of the DMH reduces skin blood flow and increases core temperature, and these effects are prevented by muscimol blockade of MRN. Because stress responses, including those of psychological origin, also cause skin vasoconstriction in the extremities and increase core temperature, it is likely that the same descending DMH–MRN–sympathetic preganglionic neuron (SPN) pathway that mediates tachycardia also mediates these two additional sympathetic responses. Thus, there is good evidence that premotor sympathetic neurons in the RVLM and MRN mediate the vasopressor, tachycardic, hyperthermic, and skin vasoconstrictor responses to activation of the DMH. This is consistent with the fact that the DMH does not have direct projections to the spinal cord. The RVLM and MRN may also be relays of the PeF and LH; however, direct projections to the spinal cord, which originate from these more lateral regions of the dorsal tuberal hypothalamus, could also contribute. This has not yet been tested.

GABA disinhibition with bicuculline was also found to be effective in the amygdala, where it could evoke clear pressor and tachycardic responses when injected in the basolateral nucleus, but not the central nucleus, of conscious rats. This effect appears to be relayed in the dorsal tuberal hypothalamus as was originally suggested.

Thus, the past 15 years have seen a renaissance of the hypothalamus, in large part due to the introduction of GABAergic antagonists. So far, chemical stimulation experiments have confirmed the general organization of the defense reaction neural substrate as originally defined with electrical stimulation. There is now a better picture of the location, organization, and functions of some of the neurons that compose this network, from the amygdala to the hypothalamus, PAG, and rostral ventral medulla (RVLM and MRN). However, as pointed out in the introduction, these studies have two main limitations. One is the artificial means of evoking the emotional behavior. The other is the use of anesthetics. The risk is that this approach may become too reductionist and reveal details of organization that are not relevant to the expression of aversive emotions. Therefore it is important to consider other approaches that do not have these limitations.

Naturally Evoked Forms of Psychological Stress

The other approach that has been used in studies of emotional control of the autonomic nervous system consists of studying the effect of permanent lesions or temporary neuronal blockade on the expression of naturally evoked psychological stress responses. This approach can also be combined with maps of the expression of the immediate-early gene c-*fos* to reveal activated areas. The advantage of this approach is that a brain structure or pathway can be directly linked to an integrated response known to be part of the behavioral repertoire of the animal. A major limitation, however, is that psychological stress can only be studied in the conscious animal, which imposes serious technical challenges to the physiologist.

Different forms of psychological stress have been studied. Some can be considered pure forms of psychological stress (e.g., conditioned fear or psychosocial stress), because they depend purely on the salience of the stimuli that trigger them. Others, such as air-jet and restraint, are mixed forms of psychological stress, because the stimuli that trigger them also have a strong physical (but not noxious) component. We now describe the cardiovascular responses and what is known of the associated circuitry of these four types of psychological stress.

Conditioned Fear

Conditioned fear, probably the best studied form of psychological stress, is evoked by reexposing an animal to a tone, light, or context that has previously

been associated with an aversive stimulus, usually electric footshock. The cardiovascular response consists of a rise in mean arterial pressure and heart rate. The associated pattern of peripheral blood flow changes has not been characterized in the rat, but in the baboon it includes renal vasoconstriction and hind limb vasodilatation, as in the visceral alerting response described earlier. In the rat, the behavioral component of this response is a characteristic tense immobile posture known as freezing. Studies in the 1980s by Smith in the baboon and by LeDoux in the rat have shown that excitotoxic lesions (which destroy cell bodies, not fibers) restricted to the PeF/LH abolish the cardiovascular response of conditioned fear to a tone. LeDoux and co-workers also showed that the same hypothalamic lesions did not affect the freezing response. In contrast, excitotoxic lesions of the caudal PAG reduced the freezing response but not the blood pressure response, while large excitotoxic lesions of the amygdala reduced both the blood pressure and freezing responses. More recently, Carrive showed that large neurotoxic lesions of the DMH/PeF/LH abolished the cardiovascular responses and reduced the freezing responses of conditioned fear to context, while inactivation of the caudal ventrolateral PAG only reduced the freezing response. To summarize, although there may be differences with respect to the role of the hypothalamus in the expression of the behavioral component, these studies confirm that the hypothalamic defense area is necessary for mediating the cardiovascular response of conditioned fear, while the PAG is not. In addition, LeDoux's studies also showed that the same hypothalamic lesions did not affect the cardiovascular response to the footshock itself (i.e., the unconditioned response), suggesting that the dorsal tuberal hypothalamus may be necessary for psychological stressors but not for physical stressors.

It is not known how the effects of the hypothalamic defense area are transmitted to the sympathetic preganglionic neurons of the thoracic spinal cord during conditioned fear. Relays in the RVLM and MRN are most probably involved, but this has not been tested. Because the effective lesions appeared restricted to the PeF/LH, it is possible also that the direct spinal projections that arise from this area could play a role.

Psychosocial Stress

Psychosocial stress can be studied in the animal with the resident-intruder test. This is a relatively pure form of psychological stress that does not require conditioning. Its cardiovascular component also consists of a rise in arterial pressure and heart rate. A recent study by Kuwati and colleagues shows that orexin knockout mice have a markedly reduced cardiovascular response when confronted to an intruder. Orexin (also known as hypocretin) is a neuropeptide produced by a restricted group of neurons located precisely and exclusively in the DMH/PeF/LH area. Orexin has been implicated in the control of arousal and of many autonomic functions, including cardiovascular ones. Orexinergic neurons project not only to the RVLM and MRN but also to the thoracic cord, and in each region orexin evokes pressor and tachycardic responses. Interestingly, the pressor and tachycardic responses to disinhibition of the PeF area are also reduced in these orexin knockout mice, but the cardiovascular response to a noxious cutaneous pinch is not. This supports the idea that the hypothalamic defense area is involved in the cardiovascular response to psychological but not physical stressors and strongly suggests that orexin neurons are implicated. It also supports the idea that the response could be mediated, at least in part, by direct spinal projections.

Air-Jet Stress

Application of a jet of pressurized air to the face (air-jet stress) is another form of psychological stress, although not as 'pure' as conditioned fear or psychosocial stress. The cardiovascular response also consists of a rise in arterial pressure and heart rate. Work by DiMicco in the rat has shown that bilateral temporary blockade of the DMH with muscimol or kynurenic acid markedly reduces this response, while similar injection of muscimol in the adjacent paraventricular nucleus of the hypothalamus has no effect. Furthermore, neuronal blockade of MRN with muscimol abolishes the tachycardic response but does not significantly reduce the pressor response. The role of RVLM in the rat has not been investigated, but in the rabbit, its blockade with kynurenic acid reduces the increase in renal sympathetic nerve activity evoked by air-jet stress. These are the first demonstrations that the MRN and RVLM relay at least parts of the cardiovascular response to a mixed psychological stressor.

Restraint

Restraint or immobilization is also a mixed stressor with an even stronger physical component. The cardiovascular response is similar to that of air-jet stress and, as with that stressor, bilateral temporary blockade of the DMH with muscimol abolishes the response. However, neurotoxic lesions that abolish the cardiovascular response of conditioned fear to context do not reduce the cardiovascular response to restraint. This intriguing finding suggests that although the DMH can contribute to the cardiovascular response of restraint, it is in fact not necessary. Other centers, presumably located at lower levels of the neuraxis,

Figure 1 Schematic diagram of the descending pathways that could mediate some of the sympathetic responses to aversive emotions. Activations of the heart (tachycardia), brown adipose tissue (hyperthermia), gut blood vessels (increased peripheral resistance), adrenal medulla (release of noradrenaline and adrenaline), and cutaneous blood vessels (skin vasoconstriction) are mediated by different pathways, all originating from the dorsal tuberal hypothalamus (DMH/PeF/LH). Hypothalamic control of sympathetic preganglionic neurons (SPNs) may be direct as well as indirect via relays in the rostral ventrolateral medulla (RVLM) and medullary raphe nuclei (MRN; rostral ones – i.e., raphe magnus and raphe pallidus), which control different end organs. The efferent connections of the dorsal tuberal hypothalamus may contain the neuropeptide orexin (hypocretin). AMYG, amygdala; DMH, dorsomedial hypothalamus; LH, lateral hypothalamus; PAG, periaqueductal gray; PeF, perifornical hypothalamus.

perhaps the lateral PAG or possibly the RVLM and MRN, can take over this role if DMH neurons have been permanently lesioned. It would be interesting to know if the same is true for air-jet stress, since it is also a mixed psychological stressor. In any case, this is in sharp contrast to conditioned fear. Thus, it would appear that the dorsal tuberal hypothalamus is necessary for the purer forms of psychological stress but not for the other more physical ones, such as restraint, or for the purely physical ones, such as electric footshock and noxious pinch.

Conclusion

Periventricular structures of the forebrain and midbrain play an important role in the integration of the somatic and autonomic components of complex behaviors, including aversive emotional responses. In this article, an attempt has been made to put together a hypothetic model of the lower pathways mediating the autonomic responses to aversive emotions (Figure 1). Much remains to be done to test this model, but it is already clear that the dorsal tuberal hypothalamus (i.e., the DMH, PeF, and LH) plays a necessary role in the expression of the cardiovascular response to the 'purer' forms of psychological stress. The PAG, on the other hand, does not appear to play a critical role in these cardiovascular responses, although it can mediate integrated behavioral and cardiovascular patterns of basic defensive responses.

During aversive emotions, the dorsal tuberal hypothalamus is most probably under the control of the amygdala, which has a more integrative role. The dorsal tuberal hypothalamus in turn transmits its output to the preganglionic sympathetic neurons of the thoracic cord; however, the exact pathways mediating these effects during emotional responses have not been fully resolved. Experiments in anesthetized animals suggest relays in the lower brain stem, in the RVLM and MRN. The RVLM may mediate the

kidney and gut vasoconstrictor responses and most probably activation of the adrenal medulla as well, while the MRN may mediate the tachycardia, skin vasoconstrictor, and hyperthermic responses. Both structures may contribute to the pressor response by acting on different effectors (i.e., heart, arteries, and release of circulating catecholamines). In addition to RVLM and MRN there are also direct spinal projections originating from the more lateral parts of the hypothalamus (PeF and LH) that could make a significant contribution. This direct projection to the thoracic cord raises the possibility of a premotor sympathetic pathway that could be activated during the purer forms of psychological stress in the conscious animal. Such a direct line could mediate sympathetic changes without integration in the homeostatic centers of the lower brain stem, an idea consistent with the view that autonomic responses to aversive emotions are emergency responses.

Anxiety Disorders: Social Phobia, Obsessive–Compulsive, and Posttraumatic Stress

Social Anxiety Disorder

Social anxiety disorder, also referred to as social phobia, is characterized by a persistent fear of negative evaluation in one or more contexts involving performance and/or interaction with others. Social phobia is increasingly recognized as among the most common of psychiatric disorders in the United States. The recently published National Comorbidity Study–Revised (NCS-R) reported a 12 month prevalence rate of 6.8%, and similarly, the original NCS data reported 12 month and lifetime rates of 7.9% and 13.3%, respectively, in the community. In clinical samples, the incidence of social phobia is much higher. Individuals with social anxiety fear embarrassment (e.g., concern that others will know they are anxious) and judgment (e.g., worry that others will think they are stupid), and this anxiety is elicited consistently when confronted with the feared situations. As a result, the feared situations, commonly including public speaking, eating, or writing, are often avoided or endured with significant distress. Adults with social anxiety recognize that this fear is excessive or unreasonable. In order to meet diagnostic criteria based on the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), this anxiety must significantly interfere with their work, daily living, or social functioning. The diagnosis varies slightly in children, such that they are not required to identify the fears as excessive or unreasonable and their difficulties must persist for at least 6 months before a diagnosis can be made.

Obsessive–Compulsive Disorder

Obsessive–compulsive disorder (OCD) is an anxiety disorder characterized by recurrent obsessions or compulsions that are time consuming (i.e., more than 1 h per day) or cause significant distress or impairment in functioning. Approximately 1–2% of adults in the United States meet criteria for OCD at any one time. Obsessions are defined as persistent, intrusive thoughts or images that are experienced as being inappropriate, unexpected, and outside the individual's control. Common obsessions include thoughts of contamination (e.g., fear of catching disease by shaking hands) and order (e.g., arranging objects in symmetry). Compulsions are conceptualized as repetitive behaviors or mental acts that are designed to suppress or neutralize the obsessive thought or image in order to reduce anxiety. Common compulsive behaviors include hand washing, counting, and checking (e.g., locks on doors and appliances). In order to meet diagnostic criteria for OCD, an individual must experience either obsessions or compulsions, but not necessarily both. However, epidemiological data suggest that most individuals with OCD do have both. As with social phobia, the diagnostic criteria for OCD vary slightly for children, who may not identify their thoughts or behaviors as excessive or unreasonable.

Posttraumatic Stress Disorder

In the United States, it is estimated that 50–60% of the population will experience a potentially traumatic event, such as a physical or sexual assault or motor vehicle accident, during their lifetime. Following exposure to traumatic events, most people do not develop long-lasting psychological difficulties. Among those who do, however, the most common constellation of such difficulties is called posttraumatic stress disorder (PTSD). With regard to prevalence, the NCS-R data showed 12 month rates of PTSD to be 3.5%. In the community, the lifetime prevalence of PTSD is estimated to be 9%. Overall, rates of PTSD among those who are exposed to trauma are higher, of course, with lifetime prevalence estimated at 24%, though rates vary according to the kind of trauma experienced. The symptoms of PTSD fall into three clusters: reexperiencing the event (e.g., intrusive and distressing thoughts); avoidance of trauma-related reminders (e.g., avoidance of trauma-related thoughts or situations); and hyperarousal (e.g., sleep disturbance). In order to meet DSM-IV diagnostic criteria for PTSD, these difficulties must persist for at least 1 month and cause significant impairment in functioning. The diagnostic criteria for PTSD are the same for adults and children.

Treatments for the Anxiety Disorders

Psychosocial Treatments for the Anxiety Disorders

Several cognitive behavioral therapies (CBTs) have been developed to treat these anxiety disorders and have been tested in prospective, randomized studies.

Exposure therapies, in particular, have been among the most investigated and have received some of the strongest empirical support in the treatment of persistent, pathological anxiety. The chief aim of this type of treatment is to help patients approach feared and avoided objects, situations, memories, and images until anxiety reduces, a process called habituation. Exposure therapy for the anxiety disorders is based on the notion that once-neutral, or unconditioned, stimuli have become conditioned to evoke a fear response, or anxiety. In an effort to reduce anxiety, one escapes from, or otherwise avoids, the fear-eliciting stimuli. Avoidance interferes with new learning by preventing opportunities to habituate to objectively harmless stimuli and to disconfirm erroneous cognitions, thus maintaining unrealistic fear. Exposure, then, provides opportunities for this learning. The evidence for the efficacy of these treatments for social phobia, OCD, and PTSD will be summarized in the next sections.

CBT for social phobia Cognitive behavioral treatments for social anxiety disorder typically include *in vivo* exposure to avoided or dreaded social situations. During therapy, patients are encouraged to engage in, rather than avoid, situations like talking with neighbors, making phone calls, attending social functions, and speaking up in meetings. Individual hierarchies of avoided situations are developed with the patient, and *in vivo* exposure occurs in a graded fashion, often through homework assignments. Some treatment packages for social phobia include cognitive therapy with an emphasis on changing negative social cognitions, and some deliver exposure therapy without cognitive therapy.

Multiple randomized controlled trials have supported the efficacy of CBT for social phobia. CBTs such as cognitive behavioral group therapy have been shown to be effective in several studies. Exposure therapy without cognitive restructuring is also efficacious in the treatment of social phobia. Moreover, at least eight controlled studies have compared CBT (exposure therapy plus cognitive therapy) to exposure therapy without any explicit focus on cognitions. In only two of these trials did CBT prove superior to exposure therapy alone, immediately following treatment. Results of a dismantling study suggest that exposure without cognitive therapy is as effective as exposure plus cognitive therapy. In addition, several meta-analyses of the social phobia treatment outcome literature have shown that both CBT and exposure therapy produce comparable results with regard to improvement and dropout. With regard to the magnitude of change experienced by patients, four meta-analyses have found the average improvements in social anxiety following CBT to be large, with pre–post effects sizes ranging from 0.80 to 1.07. Overall, the evidence for the efficacy of exposure therapy with or without cognitive therapy in this disorder is quite strong.

Exposure and response prevention for OCD Exposure and response prevention (EX/RP) is widely regarded as the treatment of choice for OCD. In this treatment approach, patients are exposed to the feared stimuli in a hierarchical manner, beginning with stimuli that evoke less anxiety and gradually moving to more-distressing stimuli. During exposure therapy for OCD, patients are encouraged to refrain from engaging in any neutralizing thoughts or behaviors, which is the response prevention component of the treatment. *In vivo* exposures are commonly used, though imaginal exposure is implemented when *in vivo* exposure would not be possible or should not be implemented.

Empirical support for the efficacy of EX/RP is strong. Several randomized controlled clinical trials have investigated the efficacy of EX/RP in the treatment of OCD and have found that EX/RP results in a significant reduction in OCD symptoms that is generally maintained at follow-up, though some residual symptoms often remain. EX/RP has demonstrated superior outcomes in the treatment of OCD when compared with psychopharmacological interventions (e.g., clomipramine) and comparable outcomes when compared with CBT. Support for the effectiveness of EX/RP for OCD was reported by Franklin and colleagues, who found similar rates of improvement as a result of EX/RP among patients treated in a fee-for-service clinic, with no exclusionary criteria based on comorbidity, treatment history, or concomitant treatments, compared with those reported in published controlled clinical trials.

Exposure therapy for PTSD Exposure therapy programs for clients with PTSD also typically include both imaginal and *in vivo* exposure and aim to help the person emotionally process the trauma. Imaginal exposures are typically conducted across multiple treatment sessions and between them in the form of homework. In this procedure, the patient is asked to vividly imagine the traumatic event and to describe it aloud, along with the thoughts and feelings that occurred during the event. *In vivo* exposures are typically done outside treatment sessions as homework and involve systematic, prolonged, and repeated confrontation with external situations, places, or activities that trigger trauma-related fear and anxiety. Prolonged exposure, one exposure-based treatment for PTSD, consists of a variety of therapeutic components, including

psychoeducation, breathing retraining, repeated recounting of the traumatic event (i.e., imaginal exposure), and encouragement to systematically confront trauma-related reminders (i.e., *in vivo* exposure).

The efficacy of exposure therapy for PTSD is well established. Several well-controlled studies demonstrate that patients who receive exposure therapy experience a significant reduction in symptoms (with approximately 60% of patients being PTSD diagnosis-free following CBT) and maintain their gains through follow-up. To date, four randomized controlled trials have demonstrated the efficacy of prolonged exposure for sexual and nonsexual assault victims, though exposure therapy has also been shown to be effective for PTSD resulting from various traumas in men and women. In the recent treatment guidelines developed by experts in the field in conjunction with International Society for Traumatic Stress Studies, exposure therapy was identified as the most supported intervention for PTSD.

Impact of Treatments on Brain Functioning

In the past two decades, improved technology has made possible the identification of the brain systems involved in anxiety. Noninvasive functional imaging techniques, including positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), have been used to detect differences between adults with psychopathology and healthy controls. Recent research has investigated the role of treatments, both psychosocial and psychopharmacological, on changes in brain structure and functioning among adults with anxiety disorders. In this section, we will briefly review and compare the impact of CBT and selective serotonin reuptake inhibitors (SSRIs) on brain abnormalities among adults with anxiety disorders.

Symptom provocation is one primary methodology that has been employed to examine brain functioning across psychiatric disorders. In symptom provocation studies, stimuli are used (e.g., imaginal exposure to anxiety-producing scenarios) to illicit symptoms characteristic of the disorder under investigation. Rauch and colleagues used individually tailored symptom provocation to assess brain functioning during a PET scan for adults with OCD. When compared with resting state (i.e., neutral stimuli presented), the OCD symptomatic state (i.e., anxiety-inducing stimuli presented) was associated with significantly increased regional cerebral blood flow (rCBF) in the right caudate nucleus, left anterior cingulate cortex, and bilateral orbitofrontal cortex. Similarly, fMRI found activation in several brain areas, including the medial orbitofrontal cortex, the anterior cingulate cortex, and the amygdala, among adults with OCD during symptom provocation, whereas control participants had no areas of brain activation. A recent meta-analysis of the OCD imaging literature found reliable differences between adults with OCD and healthy controls in activity in the orbital gyrus and the head of the caudate nucleus, but no other differences in brain activation.

In the first published study to evaluate treatment effects on brain activity in OCD, Baxter and colleagues found that patients who responded to treatment by either fluoxetine or CBT (EX/RP) experienced a decrease in right caudate metabolic activity, and these results were replicated in a subsequent study of only CBT. In a study of behavior therapy for treatment-refractory adults with OCD, clinical improvement measured as global functioning was correlated with decreased activity, measured pre- and posttreatment, in the right caudate nucleus.

In imaging studies of social phobia, symptom provocation tasks have typically included the presentation of human faces expressing various emotional states. These studies have consistently demonstrated amygdala activation in adults with social phobia when they are presented with anxiety-producing stimuli.

Only one published study to date has compared the impact of CBT and SSRIs on brain functioning in social anxiety disorder. Furmark and colleagues examined the brain activation in adults with social phobia using PET and compared those who received CBT, those who received citalopram (an SSRI), and a waiting list control. The researchers used a symptom provocation methodology and evaluated rCBF during a public speaking task both pre- and posttreatment. There were no differences between the CBT and citalopram groups on any outcome measures posttreatment, both improved significantly more than controls, and across both groups, symptom reduction was associated with reduced rCBF in the amygdala, hippocampus, and anterior and medial temporal cortex.

Brain neuroimaging in PTSD is a burgeoning area of research, and a number of brain areas have been implicated in the disorder. Several studies have found increased amygdala activity and decreased activation in the medial prefrontal cortex during symptom provocation tasks in adults with PTSD. Discrepant results have been found with regard to hippocampal volume in studies that have used imaging to assess brain structure in adults with PTSD; some studies observed smaller hippocampal volume although others found no difference between PTSD patients and trauma-exposed controls.

In contrast to the breadth of studies on brain activation and structure in PTSD, research on brain

changes associated with treatment for PTSD is in its infancy. To date, only two published studies have examined the impact of psychotropic medications on brain functioning. In the study by Vermetten and colleagues, adults who received 1 year of treatment for PTSD with an SSRI (paroxetine) experienced on average 4.6% increase in hippocampal volume from pre- to posttreatment, although there was no correlation between change in hippocampal volume and PTSD symptom reduction. Bremner and colleagues examined brain structure pre- and posttreatment using a novel, anticonvulsant (phenytoin) treatment for PTSD and found that the treatment resulted in a 5% increase in right hippocampal volume although the treatment did not produce a statistically significant improvement in PTSD. Lindauer and colleagues, however, examined the impact of psychotherapy (incorporating some CBT elements) on hippocampal volume in adults with PTSD. They found that adults with PTSD had significantly smaller hippocampal volume than controls at baseline, and there were no changes in hippocampal volume as a function of treatment.

It is important to highlight that studies comparing the impact of CBT and pharmacotherapy on changes in brain functioning have demonstrated that the treatments produce similar results, suggesting that there may be a common biological mechanism through which these treatments affect the brain, though certainly further research is necessary to determine common and distinct pathways of treatment response.

Conclusion

The prevalence of the anxiety disorders reviewed here – social phobia, OCD and PTSD – is quite high, particularly in clinical populations. Fortunately, however, effective interventions have been identified for their treatment. In particular, exposure-based treatments are generally recommended as the first-line treatment for the anxiety disorders. Emerging evidence suggests that CBT may actually lead to changes in brain activation and functioning, thus broadening the scope of the very powerful impact that these types of treatments may have on individuals. It is likely that publication of the DSM-V, slated for 2011, will reflect significant changes in the classification of, and potentially the diagnostic criteria for, anxiety disorders and influence the ways in which these disorders are treated.

Emotional Hormones and Memory Modulation

J L McGaugh and B Roozendaal, University of California, Irvine, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Emotionally arousing experiences are generally well remembered. We know that from our own experiences as well as from extensive research findings. Memories of automobile accidents, fires, muggings, rapes, wartime battles, terrorists' bombings, and other intensely emotional experiences are often reported as being 'deeply etched in the brain.' We also remember significant details of special occasions such as birthdays, bar mitzvahs, weddings, graduation ceremonies, and funerals as well as horrific events such as those of 11 September 2001. Milder emotional experiences such as those induced by praises, insults, or embarrassments also tend to be well remembered.

There are some obvious and partly correct explanations of why it is that emotional experiences (of either positive or negative valence) create strong memories. We may pay more attention to details during the experiences and we may repeatedly recall the experiences and, thus inadvertently, or purposefully, rehearse them. However, in addition, as discussed below, there is extensive evidence that neurobiological processes initiated by emotionally arousing experiences act automatically to strengthen memories of the experiences. And, it certainly seems highly adaptive to have such automatic processes that enable the significance of events to regulate their remembrance.

However, stress and emotional arousal not only induce strong memories of new information but can also impair our remembering. We all have, probably, experienced situations such as stressful examinations or job interviews during which we were simply not able to recall information. The evidence from many animal and human studies now indicates that the mechanisms that enhance the consolidation of new, emotionally arousing experiences are also responsible for the impairment of memory retrieval and working memory.

Stress Hormone Effects on Memory Consolidation

Emotionally arousing experiences induce the release of stress hormones from the adrenal glands. The adrenergic hormone epinephrine (adrenaline) is released into the circulatory system from the adrenal medulla, and the glucocorticoid cortisol (corticosterone in rodents) is secreted from the adrenal cortex. The extensive evidence that stimulant drugs (e.g., amphetamine) administered to rats or mice shortly after they are trained on a task enhance the consolidation of memory of the training suggested that stress hormones released by the training experience may act as endogenous modulators of memory consolidation. Considerable evidence supports this hypothesis. Epinephrine or glucocorticoid receptor (GR) agonists administered within minutes after training produce dose-dependent enhancement of the long-term retention of many different kinds of training experiences typically used in animal memory studies, including inhibitory avoidance, contextual and cued fear conditioning, spatial discrimination, conditioned taste aversion, and object recognition. Further, adrenoceptor antagonists or drugs that disrupt glucocorticoid functioning impair memory when administered post-training. As stress hormones administered an hour or longer after training do not affect subsequent memory, the effects obtained with administration shortly after training provide strong evidence that the hormones influence the consolidation of long-term memory that is initiated by the training experiences. There is also extensive evidence that epinephrine and glucocorticoids, as well as stressful conditions that stimulate their release, enhance memory consolidation in human subjects when administered shortly before or after learning.

Although epinephrine and glucocorticoid stress hormones have similar effects in enhancing memory consolidation, their effects are initiated through different mechanisms. Epinephrine does not directly affect brain activity as it does not pass the blood–brain barrier. The effects are mediated by the stimulation of β-adrenoceptors located on the ascending vagus nerve that projects to noradrenergic cells in the nucleus of the solitary tract (NTS) located in the brain stem. These noradrenergic cells directly innervate brain regions involved in memory consolidation, including the amygdala. The NTS may also influence noradrenergic activation via its projection to the locus coeruleus (LC), which has noradrenergic cells with more widespread projections to forebrain regions, including the hippocampus, cortex, and amygdala. The key role of the NTS in mediating epinephrine effects on memory is indicated by the finding that brief inactivation of cells in the NTS with lidocaine (to block sodium channels) prevents epinephrine-induced release of norepinephrine (NE) in other brain regions and blocks epinephrine influences on memory consolidation. Further, stimulating the NTS immediately after training

by infusing β-adrenoceptor agonists directly into the NTS enhances memory. Thus, activation of receptors in the NTS plays a critical role in mediating the transmission of adrenergic signals from the periphery to brain systems that process memory for emotionally significant experiences.

Glucocorticoids are lipophilic and readily enter the brain when released or administered peripherally. Thus, they can directly activate adrenal steroid receptors located on brain neurons, where their effects on memory involve specific activation of low-affinity GRs. In contrast to the high-affinity mineralocorticoid receptors, GRs are activated only during emotional arousal. Glucocorticoid binding to GRs can affect gene transcription by direct binding of receptor homodimers to DNA. Glucocorticoids may also act postsynaptically on membrane-bound GRs to influence the β-adrenoceptor-cAMP pathway and work synergistically with noradrenergic influences to regulate activity of downstream molecular mechanisms, including that of the transcription factor cAMP response-element binding (CREB) protein. These effects may ultimately result in structural changes, for example, via modifications of cell adhesion molecules, and strengthen cell–cell interactions.

The findings of many experiments indicate that administration of glucocorticoids to animals shortly after training on learning tasks produces dose-dependent enhancement of memory consolidation highly comparable to that found with epinephrine. Importantly, memory is also enhanced by posttraining infusions of GR agonists administered directly into specific brain regions, including the NTS, cortex, hippocampus, or amygdala. Disruption of glucocorticoid synthesis by administration of the drug metyrapone prevents the memory-enhancing effects of epinephrine. Thus, although epinephrine and glucocorticoid effects are initiated by different mechanisms, these adrenal stress hormones influence brain systems involved in processing memory and induce effects, as noted briefly above and discussed further below, that interact in modulating memory consolidation.

Involvement of the Basolateral Amygdala

It is well established that emotional experiences that induce the release of adrenal stress hormones also activate the amygdala. Further, there is considerable evidence that these stress hormones affect memory consolidation either directly by activating the amygdala or indirectly through influences that subsequently activate the amygdala. Lesions of the amygdala prevent the memory-enhancing effects of peripherally administered stress hormones. The basolateral amygdala (BLA) is the region of the amygdala that is critical for stress hormone influences on memory consolidation. The BLA is a cortical-like structure that has many reciprocal connections with other higher brain regions. Selective lesions of the BLA, but not lesions of other amygdala regions such as the central amygdala, prevent the memory-modulating effects of adrenal stress hormones. Further, memory consolidation is modulated by infusions of drugs affecting adrenoceptors or GRs administered selectively into the BLA. Adrenoceptor and GR agonists produce dose-dependent memory enhancement and antagonists of these receptors impair memory when infused directly into the BLA shortly after training. Infusions of these adrenoceptor and GR agonists and antagonists administered into other amygdala nuclei are ineffective.

Role of Noradrenergic Activation of the BLA

Noradrenergic activation of the amygdala by projections from the NTS and LC plays an essential role in the modulation of memory consolidation induced by both adrenergic and glucocorticoid effects. Infusions of β-adrenoceptor antagonists administered into the amygdala block the memory-enhancing effects of peripherally administered epinephrine that, as discussed above, are known to be mediated by activation of the noradrenergic cells of the NTS and LC. Further, β-adrenoceptor antagonists infused selectively into the BLA also block glucocorticoid-induced memory enhancement. Studies using *in vivo* microdialysis techniques to assess NE levels in the amygdala provide additional evidence that noradrenergic activation within the amygdala is involved in influencing memory. In rats, footshock stimulation of the kind that is typically used in fear-based training induces the release of NE in the amygdala, and the amount of NE released varies directly with the footshock intensity. Moreover, drugs and hormones known to enhance memory consolidation potentiate the increase in NE levels in the amygdala, induced by footshock stimulation. Further and importantly, in rats given inhibitory avoidance training, the magnitude of training-induced increases in amygdala NE assessed shortly after training correlates very highly with the rats' subsequent long-term retention performance, providing additional evidence suggesting that amygdala NE regulates memory consolidation.

Noradrenergic activation of the BLA also appears to be essential in enabling glucocorticoid modulation of memory consolidation. Animal experiments investigating stress hormone and BLA involvement in memory consolidation typically use highly arousing training conditions, such as inhibitory avoidance or contextual or cued fear conditioning, that are known to induce amygdala NE release. There is evidence that such NE release is critical for glucocorticoid

enhancement of memory. When arousing training conditions are used, β-adrenoceptor antagonists administered peripherally or infused directly into the BLA block glucocorticoid-induced memory enhancement. Further, posttraining administration of corticosterone does not enhance retention of training experiences (e.g., object recognition) that induce relatively low emotional arousal. However, with such low-arousing conditions, administration of yohimbine, a drug that enhances NE release by blocking noradrenergic autoreceptors, enables glucocorticoid-induced memory enhancement.

Other findings indicate that corticosterone also does not directly induce activation of the BLA but, rather, influences BLA activity only when there is sufficient noradrenergic activation within the BLA. Such evidence strongly suggests that arousal-induced noradrenergic activation of the BLA is essential in enabling glucocorticoid-induced memory enhancement. These findings fit well with evidence from studies of human subjects indicating that glucocorticoid enhancement of memory consolidation may be limited to memories of information that is emotionally arousing. Such findings are also consistent with evidence that glucocorticoid-induced memory enhancement is blocked by intra-BLA infusions of β-adrenoceptor antagonists or Rp-cAMPS, a drug that blocks the NE signaling cascade, as well as evidence that GR antagonists do not prevent the memory-enhancing effects induced by intra-BLA infusions of the cAMP analog 8-Br-cAMP. This evidence clearly indicates that, in the BLA, cAMP activation is downstream from the interaction of glucocorticoids with β-adrenoceptors. The interaction of glucocorticoids with noradrenergic influences in the BLA is summarized in Figure 1.

Most studies of the involvement of glucocorticoid and noradrenergic influences on memory consolidation have investigated the effects of hormones or drugs administered after the initial learning of tasks. As extinction consists of the learning of new consequences of cues, for example, that a cue that previously predicted footshock no longer predicts footshock, effects of these treatments on extinction should be comparable to those found with studies of

Figure 1 Interactions of adrenal stress hormones with the noradrenergic system in the BLA in modulating memory consolidation. Adrenal stress hormones are released during training in emotionally arousing tasks and are known to enhance memory consolidation. Epinephrine, which does not cross the blood–brain barrier, induces the release of norepinephrine (NE) in the BLA by activating vagal afferents to the nucleus of the solitary tract (NTS). Noradrenergic neurons in the NTS project directly to the BLA, and indirectly via the locus coeruleus (LC). NE binds to both β-adrenoceptors (β) and α_1-adrenoceptors (α_1) at postsynaptic sites and activates cAMP and protein kinase A formation. Glucocorticoids freely enter the brain and bind to glucocorticoid receptors (GRs) in brain stem noradrenergic cell bodies to potentiate NE release in the BLA, as well as postsynaptically in BLA neurons to facilitate the NE signal cascade. Glucocorticoids may influence the β-adrenoceptor-cAMP system via a coupling with α_1-adrenoceptors. These stress hormone effects on noradrenergic activation in the BLA are required for regulating memory consolidation in other brain regions. PGi, nucleus paragigantocellularis; CREB, cAMP response-element binding protein. Reproduced from Roozendaal B (2000) Glucocorticoids and the regulation of memory consolidation. *Psychoneuroendocrinology* 25: 213–238, with permission from Elsevier.

original learning if the same modulatory systems are involved. The findings support this implication. When administered after extinction training, systemically or intra-BLA-administered glucocorticoids or NE enhance the consolidation of extinction memory.

Effects of Corticotropin-Releasing Hormone (CRH) in the BLA on Memory Consolidation

Although most studies examining emotional arousal or stress effects on memory consolidation investigated the effects of adrenal stress hormones, emotional arousal is known to induce the release of a variety of neuromodulatory hormones within the brain, including opioid peptides, γ-aminobutyric acid (GABA), vasopressin, and adrenocorticotropic hormone (ACTH). Importantly, many findings have shown that intra-BLA infusions of drugs that either mimic or block the action of these transmitter systems enhance or impair memory for emotionally arousing training. Moreover, disruption of BLA activity prevents these drugs from influencing memory consolidation. One transmitter system that is of particular interest is CRH. CRH is a neuropeptide that is released by emotional arousal into the hypothalamus and plays a crucial role in regulating activity of the hypothalamic–pituitary–adrenocortical axis and circulating glucocorticoid levels. However, CRH is also released in extra-hypothalamic sites, including the amygdala as well as several other brain regions, in response to arousing or stressful stimulation. Blockade of endogenous CRH in the BLA with infusions of a CRH receptor antagonist impairs memory for emotionally arousing training, whereas infusions of CRH dose-dependently enhance memory consolidation. Furthermore, CRH is known also to interact with noradrenergic mechanisms in the BLA in influencing memory consolidation. Thus, this evidence indicates that BLA activation by emotional arousal is a general gateway in mediating stress hormone and neurotransmitter effects on memory consolidation.

BLA Interactions with Other Brain Regions in Modulating Memory Consolidation

Although the evidence summarized above clearly indicates that the BLA is a critical brain site for integrating adrenergic, glucocorticoid, and other stress-activated influences on memory consolidation, other evidence clearly indicates that the BLA is not the locus of the long-term memory processes modulated by stress hormones. Rather, the evidence indicates that BLA activation acts via efferent projections to influence memory processing in other brain regions. The BLA is richly interconnected with very many brain regions, including the hippocampus, caudate nucleus, nucleus accumbens, and cortical regions known to participate in different aspects or forms of memory. Posttraining noradrenergic activation of the amygdala influences memory in tasks known to involve functioning of different brain regions, including water-maze spatial and cued tasks, inhibitory avoidance, contextual and cued fear conditioning, conditioned taste aversion, and object recognition. Lesions of BLA efferent pathways block the memory-modulating effects of BLA stimulation. Additionally and importantly, lesions of the BLA, the nucleus accumbens or stria terminalis (a fiber pathway that connects the BLA with the nucleus accumbens) block the effects of glucocorticoids administered systemically after training.

The finding of many studies indicating that noradrenergic inactivation of the BLA or lesions of the BLA or its efferent pathways block the memory-modulating influences of drugs administered posttraining to other brain regions provides additional strong evidence that interactions with efferent brain regions are critical in mediating BLA influences on memory consolidation. The memory enhancement induced by a GR agonist infused into the hippocampus after training is blocked by selective lesions of the BLA or infusions of a β-adrenoceptor antagonist into the BLA. An intact and functioning BLA is also required for inducing memory modulation by adrenergic and muscarinic cholinergic drugs administered after training directly into cortical regions, including the entorhinal cortex, anterior cingulate cortex, prefrontal cortex, and insular cortex. The BLA also projects directly to the nucleus basalis (via the stria terminalis) that provides cholinergic activation of the cortex. Such activation is essential for learning-induced cortical plasticity. The evidence that stimulation of the BLA enhances cortical activation and that reversible inactivation of the nucleus basalis blocks the activation suggests that BLA activation may influence memory via such cholinergic activation of the cortex or that such activation is a co-requirement. Findings indicating that lesions of the nucleus basalis-cortical projections block the memory enhancement induced by NE infused into the BLA posttraining support this hypothesis.

There is also considerable evidence indicating that the BLA regulates neuroplasticity in efferent brain regions. Stimulation of the amygdala enhances long-term potentiation (LTP) in thalamocortical synapses. Lesions of the BLA or infusions of β-adrenoceptor antagonists into the BLA prevent the induction of LTP into the dentate gyrus of the hippocampus as well as stress-induced influences on hippocampal and cortical LTP. In contrast, stimulation of the BLA facilitates LTP induction in these brain areas, whereas blockade of adrenergic or glucocorticoid mechanisms reduces this BLA effect on hippocampal neuroplasticity. Other

Figure 2 Emotional arousal-induced modulation of memory consolidation. Experiences initiate memory storage in many brain regions involved in the forms of memory represented. Emotionally arousing experiences also release adrenal epinephrine and glucocorticoids and activate the release of noradrenaline in the basolateral amygdala (BLA). The BLA modulates memory consolidation by influencing neuroplasticity in other brain regions. NE, norepinephrine. Reproduced from McGaugh JL (2000) Memory: A Century of consolidation. *Science* 287: 248–251.

evidence suggests that synchronized oscillatory activity within the BLA may facilitate cortical processes involved in memory consolidation. A single footshock of the kind typically used in training increases the duration and synchrony of firing of BLA neurons lasting for up to 2 h. Such findings suggest that the increased firing may act to facilitate neuroplasticity underlying memory consolidation in efferent brain regions, including the cortex. Figure 2 summarizes the roles of adrenal stress hormones and BLA activation in modulating memory consolidation in other brain regions.

Influence of Emotional Arousal on Human Memory: Stress Hormones and Amygdala Activation

The findings of studies of the influence of stress hormones on human memory are highly comparable to those obtained in experiments with animals. Several studies have reported that epinephrine and glucocorticoids enhance memory and suggest that the effects are obtained selectively with emotionally arousing material. Cortisol administered to subjects prior to presentation of emotionally arousing words or pictures enhanced long-term memory. Similarly, epinephrine or cold pressor stress (known to induce the release of epinephrine and cortisol) administered shortly after subjects view emotionally arousing pictures enhanced their long-term memory of the pictures. In hospitalized patients undergoing intensive care treatment, the strength of subsequent memory of the experiences varied directly with the amount of cortisol and epinephrine they received during the treatment. Additionally, administration of a β-adrenoceptor antagonist prior to subjects' viewing of an emotionally arousing series of pictures blocked the enhancing effect of emotional arousal on long-term memory.

There is also considerable evidence from human studies supporting the conclusions of animal studies indicating that the enhancing influence of emotional arousal on memory involves activation of the amygdala. In human studies, however, the experiments have not as yet investigated the possible selective involvement of the BLA. Evidence that in human subjects with amygdala lesions, unlike subjects with an intact amygdala, emotionally arousing stimulation does not enhance long-term memory supports the view that amygdala activation may be critical for emotionally enhanced memory. Alzheimer's patients' memory of a serious earthquake assessed months after the experience varied directly with the sizes of their amygdala, as examined by magnetic resonance imaging (MRI).

The involvement of amygdala activation in emotionally influenced memory has also been investigated in many studies using positron emission tomography (PET) and functional MRI (fMRI) in healthy humans. These studies reported that activity of the amygdala assessed during the presentation of emotionally arousing stimuli correlated highly with memory of the stimuli tested weeks later. Further, the relationship between amygdala activity during encoding and subsequent long-term memory was greatest for the most emotionally arousing stimuli and for subjects who showed a large increase in endogenous cortisol in response to the arousing stimuli. Importantly, β-adrenoceptor antagonists blocked both the increase in amygdala activity and the enhanced retention induced by emotional stimuli. Other findings are consistent with evidence from animal experiments, suggesting that amygdala activity modulates memory processing in other brain regions. Amygdala activity is highly correlated with the activity of hippocampal and parahippocampal regions during the encoding of emotional stimuli.

Stress Hormone Effects on Memory Retrieval and Working Memory

Although most studies investigating stress hormone effects on memory have focused on the neurobiological mechanisms underlying the consolidation of recent experiences, evidence indicates that these hormones also influence other memory functions. Stress exposure or glucocorticoids administered immediately after a learning session impair retention performance tested shortly after the session, that is, at a time when the memory trace has not yet been consolidated into long-term memory. Extensive evidence now indicates that glucocorticoids can affect such retention performance by impairing the retrieval of previously learned information. Stress exposure or glucocorticoids administered peripherally to rats shortly before retention testing, 24 h after training, impair retention performance. Likewise, administration of stress-level doses of glucocorticoids to human subjects shortly before memory testing impairs delayed recall on episodic memory tasks. Importantly, in contrast to stress hormone effects on memory consolidation, the impairing effects of emotional arousal on memory retrieval are temporary and subside when the hormone levels return to baseline. Extensive cognitive and neurobiological research indicates that the hippocampus is an important brain region implicated in memory retrieval. Glucocorticoid-induced memory retrieval impairment depends, in part, on GR activation in the hippocampus. Additionally, evidence from a PET study of memory in human subjects indicates that a stress-level dose of cortisone reduces activity of the parahippocampal gyrus, an effect that correlates with impaired episodic memory retrieval. The effects of epinephrine on memory retrieval have not been investigated.

The effects of glucocorticoids on memory retrieval are highly comparable to those obtained in studies of memory consolidation in that the effects depend critically on an interaction with noradrenergic mechanisms. Systemic administration of a β-adrenoceptor antagonist blocks the memory retrieval impairment induced by concurrent injections of corticosterone. Other evidence from animal studies indicates that the BLA interacts with the hippocampus in mediating glucocorticoid effects on memory retrieval impairment. BLA lesions or a β-adrenoceptor antagonist infused into the BLA block hippocampal glucocorticoid impairment of memory retrieval.

Such evidence clearly indicates that the role of BLA noradrenergic activity in regulating emotional arousal effects on hippocampus-dependent cognitive processes is not restricted to modulating memory consolidation but extends to memory retrieval. The evidence from animal studies is consistent with that from human studies examining stress hormone effects on memory retrieval. Glucocorticoids or psychosocial stress only impair retrieval of emotionally arousing information or during emotionally arousing test conditions. Further, the glucocorticoid-induced impairment of memory retrieval in humans is blocked by concurrent administration of a β-adrenoceptor antagonist. Findings of imaging studies indicate that successful retrieval of emotionally arousing information induces greater activity in and connectivity between the amygdala and hippocampus than retrieval of emotionally neutral information.

Stress exposure or glucocorticoid administration also impairs working memory, which is known to rely on the integrity of the prefrontal cortex. Mild uncontrollable stress impairs performance of rats on a delayed alternation task, a task commonly used to assess working memory in rodents. Such stress also increases NE (and dopamine) turnover in the prefrontal cortex. Excessive levels of NE in the prefrontal cortex are known to induce working memory impairment. Like stress, glucocorticoid administration impairs working memory. Stress doses of corticosterone or a GR agonist administered either peripherally or directly into the prefrontal cortex impair delayed alternation performance in rats. In addition, cortisol administration impairs working memory performance in human subjects. Importantly, glucocorticoids appear to interact with noradrenergic mechanisms in inducing working memory impairment. A β-adrenoceptor antagonist administered peripherally blocks the impairing effect of corticosterone on working memory in rats.

Further, animal studies have shown that glucocorticoid effects on working memory depend on functional interactions between the BLA and the prefrontal cortex. Disruption of BLA activity blocks the effects on working memory of a GR agonist administered into the prefrontal cortex. This evidence provides strong support for the hypothesis that BLA activity modulates stress or emotional arousal effects on working memory in other brain regions. There is also evidence from human studies supporting the hypothesis that glucocorticoids interact with noradrenergic mechanisms in inducing working memory impairment. Psychosocial stress impaired working memory only during conditions inducing concurrent activation of glucocorticoids and the sympathetic nervous system.

Emotional Arousal and Traumatic Memory

It is, of course, essential for our adaptation and survival that we record and retain lasting memories of our significant experiences. But can the activation of stress hormones and the amygdala by emotional arousal strengthen memories more than is necessary? Several kinds of studies have addressed this issue. In children who experienced traumatic injuries, elevated levels of epinephrine and cortisol measured immediately after the children were admitted to the hospital correlated with symptoms of posttraumatic stress disorder (PTSD) assessed 6 weeks later. Moreover, the administration of a β-adrenoceptor antagonist to recently traumatized patients attenuated the development of PTSD symptoms. Propranolol administered to patients (for 10 days) within 6 h after they experienced an acute psychologically traumatic event reduced the symptoms of PTSD assessed 3 months after the trauma. As with humans exposed to other types of extreme trauma, patients who have been treated in an intensive care unit often report traumatic memories. Extremely traumatic memories from intensive care treatment in some of these patients are associated with the development of PTSD. Many patients with stress-associated diseases, such as PTSD, show sustained neuroendocrine abnormalities, which include increased catecholaminergic activity and impairment in glucocorticoid signaling. Severely ill patients also often show insufficient endogenous glucocorticoid signaling which has recently been termed critical illness-related corticosteroid insufficiency (CIRCI). In several controlled trials in patients with suspected CIRCI, the administration of glucocorticoids (stress doses of cortisol) during intensive care treatment resulted in a significant reduction of PTSD symptoms in long-term survivors. Cortisol administration may help to surmount impaired glucocorticoid signaling from CIRCI during critical illness resulting in a downregulation of the stress response. Sustained cortisol administration might also prevent PTSD by interfering with memory retrieval.

As discussed above, high levels of glucocorticoids impair memory retrieval. Thus, low cortisol levels such as found in some patients after trauma at risk for PTSD or with established PTSD could lead to excessive retrieval of traumatic information. As it has been proposed that PTSD develops over time because of positive feedback mechanisms in which traumatic memories are constantly retrieved and restored; the administration of stress doses of glucocorticoids after a massive stress exposure could inhibit the recall of traumatic information and thereby reduce the probability of PTSD. In addition, glucocorticoid administration might also reduce the development of PTSD by facilitating the extinction of traumatic memories. Some evidence indicates that administering stress doses of cortisol might also be useful for the treatment of established PTSD as a result of major traumatic experiences of nonmedical origin. Thus, the findings of studies investigating memory of traumatic experiences offer support for the hypothesis that emotions can and do strengthen memories more than is necessary. And, the findings of the experimental studies provide some understanding of the neurobiological processes that underlie such strengthening as well as some possible implications for therapeutic intervention to ensure that significant events are well remembered, but not excessively remembered.

Emotional Influences on Memory and Attention

E A Phelps, New York University, New York, NY, USA

Introduction

The interaction of emotion and cognition is obvious to most people. It is not uncommon for traffic to slow because the attention of the drivers ahead is distracted by the view of an accident. It is also not uncommon for someone to proclaim that his or her memory for an event is vivid or detailed because the event is highly emotional, or what is often called 'memorable'. In spite of the common recognition that emotion and cognition are intertwined, the study of emotion in the scientific investigation of cognitive processes, such as memory and attention, has only recently blossomed. The reasons for this have to do with both the philosophical foundations of the discipline of cognition within psychology and the emergence of cognitive neuroscience as a dominant approach in understanding cognitive functions. When one examines brain function, it is apparent that the neural systems of emotion and cognition are intertwined from perception to reasoning and decision making. This recent emphasis on understanding the neural representation of human behavior has resulted in a new appreciation of the important role of emotion in cognitive functions.

One brain region that plays a prominent role in the interaction of emotion and cognition is the amygdala. The amygdala is a small structure in the medial temporal lobe that sits adjacent and anterior to the hippocampus (see Figure 1). The amygdala is known to be important in a range of emotional behaviors, most notably the ability to learn that stimuli in the environment predict potential aversive consequences, referred to as fear conditioning. The amygdala is critical for the acquisition, storage, and expression of fear conditioning. In addition to its role in emotional learning, the amygdala is widely connected to other brain regions that mediate a range of cognitive functions. It has been suggested that through these connections, the amygdala can influence cognition in the presence of potentially important stimuli. This additional role for the amygdala in the tuning of cognition by emotion helps assure that events that may be important for our survival receive priority in processing. This article reviews what has been learned from the study of the amygdala concerning the interaction of emotion, attention, and memory.

Emotion's Influence on Attention and Perception

Attention and perception are the first stages of stimulus processing. Factors that influence these processes will also influence downstream cognitive functions, such as memory. An early example of emotion's impact on attention is the classic 'cocktail party effect' described by Cherry in 1953. This effect gets its name from the observation that when we focus our attention on one stream of information and ignore others, such as paying attention to a single conversation at a cocktail party, we might inadvertently pick up on some of the unattended information if it is salient or important, such as when one's own name is mentioned in another conversation at the party. This finding and others suggest that emotion can facilitate awareness for emotionally salient stimuli in situations in which attention is limited.

Recent cognitive neuroscience research indicates the amygdala may mediate the facilitation of attention with emotion. This was investigated using a paradigm that tests the temporal limitations of attention, called the attentional blink. In this paradigm, stimuli, such as words, are presented in rapid succession – so quickly it is difficult to identify any words. However, if participants are told that they can ignore most of the words presented and selectively attend to a few target words, such as those printed in a different color ink, they can usually identify the target words. However, this ability to selectively attend to and identify specific words in the rapid stream of words is limited by the temporal relation between the targets. If the second target word is presented a few items after the first target word, participants will often miss it. It is as if noticing and encoding the first target word results in a temporary refractory period during which it is difficult to notice and encode a second target. When this occurs, it is as if attention 'blinked'. However, if the second target word is emotional and arousing, this temporal limitation of attention is not as great. During the 'blink' period, when attentional resources are limited, arousing words are more likely to be identified than are neutral words. This attenuation of the attentional blink effect is not apparent for patients with damage to the amygdala. Unlike normal controls, patients with damage to the left amygdala experience a similar decrement in the ability to report emotional and neutral words. This finding is consistent with previous studies indicating that in situations when one has limited attentional resources, emotional stimuli are more likely than neutral stimuli to reach

Figure 1 The human amygdala (blue) and the hippocampus (green).

awareness. It also indicates that the amygdala plays a critical role in this facilitation of attention with emotion.

It is suggested that the amygdala has its influence on attention by modulating processing in brain regions known to mediate perception. Two distinct mechanisms have been explored that may explain the amygdala's facilitation of attention. The first was proposed by Weinberger and colleagues, who demonstrated that fear conditioning can tune the representation of emotional stimuli in sensory cortices. In studies with rats, they showed that the representation of simple tones in the auditory cortex is changed through fear conditioning when a tone is paired with, and comes to predict, an aversive shock. This change in the cortical representation creates a heightened sensitivity to the tone that predicts shock. This sensory tuning with emotional learning depends on the amygdala. If the amygdala is damaged, fear learning does not occur, and the representation of the tone in the auditory cortex is unchanged. It is interesting that once fear learning has occurred, this change in the auditory cortex will last, even if new learning diminishes the fear response to the tone or the amygdala is damaged and the learned fear is no longer expressed. In other words, the amygdala is needed to create this change in the auditory cortex to an emotional stimulus, but it is not required to maintain it. A recent study that used functional magnetic resonance imaging (fMRI) in humans showed a similar lasting change in the auditory cortex in response to a tone that predicted a shock. Although it has been suggested that a change in the cortical representation of stimuli in the visual cortex might also occur with emotional learning, this has yet to be explored. It is clear, however, that one way that emotion can influence attention is by creating a lasting change in the cortical representation of stimuli that have acquired emotional properties through learning.

The second mechanism that has been proposed to underlie emotion's influence on attention is more transient and has been demonstrated primarily in studies of visual processing. Anatomical studies have shown that there are reciprocal connections between the amygdala and the sensory cortices, including the visual cortex. It is proposed that early in stimulus processing, the amygdala receives input about the emotional significance of a stimulus and, through projections to the visual cortex, modulates further attentional and perceptual processes. Three lines of evidence from brain imaging studies in humans support this model: (1) studies demonstrating that emotional stimuli are processed automatically, (2) findings of enhanced responses in visual cortical regions for emotional stimuli, and (3) findings demonstrating that the amygdala mediates this enhanced cortical response.

The idea that emotional stimuli are processed automatically is consistent with suggestions in the psychological literature that the emotional qualities of stimuli are detected quickly and prior to awareness. Similarly, it is proposed that the amygdala receives input about the emotional significance of a stimulus quickly and prior to awareness. In support of this hypothesis, fMRI studies have demonstrated robust amygdala activation in response to subliminally presented images of faces with fear expressions, in contrast to the response to neutral expressions. In addition, a number of studies have shown that attention and awareness have little impact on the amygdala's response to fearful stimuli. It is suggested that this early, automatic amygdala response to fear or threat stimuli is an important factor in the amygdala's ability to modulate further cognitive processes and responses to potential danger.

One of the first brain imaging studies to examine emotion demonstrated that visual cortical regions show enhanced activation to novel emotional scenes compared with novel neutral scenes. This finding has also been observed in comparisons of responses in the visual cortex to faces with fear versus faces with neutral expressions. The studies of facial expression have also demonstrated an enhanced amygdala response to fearful versus neutral faces, the magnitude of which is correlated with the enhanced visual cortex activation to these same stimuli. This line of research is consistent with the proposed mechanism by which the amygdala detects the emotional significance of a stimulus quickly and modulates further perceptual and attentional processing. However, one drawback of these studies is that most brain imaging findings are correlational in nature and thus cannot determine the precise function of a given brain region or the

direction of the communication between two regions. In an effort to demonstrate that the amygdala's input mediates the enhanced response observed in the visual cortex to emotional stimuli, Vuillimier and colleagues combined functional imaging and lesion methodologies. During brain imaging, patients with varying degrees of damage to the amygdala were shown pictures of faces with fear and neutral expressions. The amount of amygdala damage predicted the magnitude of the response in the visual cortex: the more damage to the amygdala, the smaller the enhanced visual cortex response to fear faces. This finding strongly supports the suggestion that the amygdala mediates the enhanced response in the visual cortex.

If the amygdala is responding to the emotional significance of a stimulus in the environment quickly and prior to awareness, and modulating further processing in the visual cortex, then certain properties of emotion's influence on attention should emerge. First, any enhanced visual response should be transient and evoked by the presence of an emotional stimulus. Second, the enhanced response with emotion should be apparent in perception, since this is the job of the visual cortex. This enhanced perception may underlie the observed facilitation of attention in that it requires less attentional resources to detect something that is easier to perceive. Finally, the enhanced processing with emotion is not necessarily tied to the emotional stimulus itself, but should extend to neutral stimuli that are cued by emotional stimuli and presented close in time.

To explore whether these properties emerge, researchers have used a psychophysical paradigm to examine the effect of a fearful face cue on sensitivity to changes in contrast – that is, the subtle gradations of gray that help us differentiate edges of lines. The ability to detect contrast is an early perceptual function that has been linked to primary visual cortex. In this study, a fear or neutral face cue was presented in one or four quadrants of a computer screen. Then 40 ms later, four patches with lines appeared in the corners of the screen (adjacent to the location of faces). The lines in one of the four patches were tilted, and the participants had to indicate whether the lines were tilted to the right or to the left. If only one face was presented, then the patch with tilted lines was presented in the same quadrant as the face. This single-face condition allowed participants to covertly attend to the location of the subsequent patch. Across trials, the contrast in the patches varied so that the ability to detect the orientation of the lines was easier or harder. Two effects for the emotional expression of the face cue were observed. First, irrespective of whether the face cue directed covert attention, a fear face enhanced contrast sensitivity. That is, less contrast was needed to detect the orientation of the lines if the lines were preceded by a fear face rather than by a neutral face. Second, if a fear face cue directed covert attention, contrast sensitivity was enhanced more than would have been predicted by the independent effects of a fear face cue and covert attention on perception. In other words, emotion potentiates the perceptual benefit of covert attention. These psychophysical results are consistent with a model in which the emotion, via the amygdala, modulates processing in early visual regions in a transient manner for stimuli cued by emotion.

The amygdala, through its extensive connectivity with sensory processing regions, is ideally situated to influence perception. The existing evidence supports two independent means by which emotion influences perception, one of which is long lasting and affects perception of an emotional stimulus that predicts an aversive outcome, and the other of which is transient and can affect the perception of stimuli cued by emotion. It is suggested that the amygdala's influence on perception may underlie emotion's facilitation of attention. Discussions of the adaptive function of emotion's facilitation of attention emphasize the preferential detection of stimuli that signal potential importance or threat and suggest a primary role for the amygdala is the modulation of vigilance in the presence of these stimuli. The current evidence of emotion's influence on attention and perception is largely consistent with this interpretation.

What is less clear at this point is whether these mechanisms that lead to the facilitation of perception with emotion also play a role in any perceptual cost that may emerge for other stimuli. It has been suggested that emotion can capture attention. When attention is captured by emotion, there is impaired processing of nonemotional aspects of the stimulus or event. A number of behavioral studies have demonstrated the capture of attention with emotion, and it is suggested that this effect is due to difficulty disengaging attention from the emotional qualities of a stimulus. Only a few studies have examined the neural systems underlying the capture of attention with emotion, and these suggest that emotion may decrease activity in regions of the parietal lobe thought important for the allocation of attention. It is not known how this effect may or may not be related to the facilitation of attention and perception observed when people are processing emotional aspects of a cue or stimulus.

Emotion's Influence on Memory

"An impression may be so exciting emotionally as almost to leave a scar upon the cerebral tissues." This

phrase is attributed to William James in his classic textbook, *Principles of Psychology*, which was first published in 1890. Although James did not have the benefit of experimental research to support his claims, his intuition was that emotion should strongly influence how impressions are remembered. This intuition has been largely supported by scientific research since 1890. The questions remain, how does the brain enable this 'scar' to form, and what are its qualities?

Memory can be broken down into a series of stages. The first, called encoding, occurs when a stimulus is first encountered. After the encoding stage, the memory is stored. Although storage may seem like a passive stage, it is known that during storage, processes occur over time that allow the memory to become more or less stable. This time-dependent storage process is called consolidation. Finally, when a memory is called to mind, it is retrieved. There is evidence that emotion might influence all three of these stages of memory processing. Although episodic memory critically depends on other brain regions, most notably the hippocampus and surrounding cortices (see **Figure 1**), the amygdala appears to play an important role in modulating the neural circuitry of memory with emotion.

To start with the first stage, emotion can influence the encoding of to-be-remembered stimuli through its modulation of attention and perception. Research has indicated that manipulations of attention will significantly affect memory encoding. Therefore, the changes in attention and perception that occur with emotion, outlined earlier, should lead to differences in memory performance. In support of this hypothesis, a recent study found that patients with amygdala damage show impairments only in memory for details of emotional scenes that are central to the event, with intact memory for details that are more peripheral. This study suggests that the amygdala may be involved in highlighting and narrowing attention around central, emotional details, leading to enhanced encoding of these details in normal study participants. However, most studies to date have failed to differentiate the amygdala's influence on encoding and consolidation. In fact, with many studies, it is not clear how to differentiate emotion's impact on encoding and consolidation since both are assessed with retrieval and occur close in time. Although a number of brain imaging studies have demonstrated that amygdala responses during encoding can predict later recognition or recall for emotional stimuli, these studies often attribute this effect to emotion's influence on the modulation of memory storage rather than on attention and perception.

The primary neural mechanism that has been explored in an effort to understand emotion's influence on episodic memory is the amygdala's modulation of consolidation. Evidence across species suggests that the consolidation of episodic memory critically depends on the hippocampus. Emotion, specifically arousal, is proposed to enhance hippocampal-dependent consolidation. Research by James McGaugh and colleagues conducted in rats has identified the neural mechanisms underlying the effect of arousal on memory consolidation. These studies have shown that physiological arousal results in activation of β-adrenergic receptors in the amygdala. The amygdala, in turn, modulates hippocampal processing, resulting in enhanced consolidation or storage for events that elicit an arousal response. Damage to the amygdala does not impair episodic memory for a stimulus, but it eliminates any enhancement observed with physiological arousal. Evidence that this effect is due to the modulation of consolidation, as opposed to encoding, comes from studies demonstrating that manipulations of amygdala function after stimulus encoding will alter arousal's influence on episodic memory. McGaugh suggests that one adaptive function of having a slow consolidation process is to allow for the emotional reaction to a stimulus, which occurs after presentation, to influence memory strength. In this way, events that result in an emotional response, and are more likely to be important for future survival, are less likely to be forgotten.

Consistent with the proposed mechanisms outlined by McGaugh and colleagues, a number of studies in humans have reported that arousal enhances the retention of episodic memories so that they are less likely to be forgotten over time. Evidence that the human amygdala plays a role in this enhanced memory with arousal comes from studies using a range of cognitive neuroscience techniques. As mentioned earlier, brain imaging studies have reported that activation of the amygdala at encoding can predict later retention for emotional stimuli. The amygdala has direct projections to the anterior portion of the hippocampus. A recent study found that the activation of the amygdala and anterior hippocampus is correlated during the encoding of emotional scenes that were later remembered. In addition, patients with amygdala damage fail to show the normal enhancement of episodic memory with arousal. Consistent with a role for the amygdala in modulating storage or consolidation, patients with amygdala damage show similar forgetting curves for arousing and neutral stimuli, in contrast to normal controls, who show enhanced retention for arousing stimuli. In addition, pharmacological manipulations in humans that block β-adrenergic receptors also block arousal's impact on episodic memory, consistent with animal models. Taken together, these studies provide strong support for the mechanism proposed by McGaugh and

colleagues suggesting the amygdala modulates hippocampal consolidation with arousal.

Although there is substantial evidence that emotion can influence later memory accuracy, a few limitations should be mentioned. First, the magnitude of the effect of emotion on episodic memory varies depending on the paradigm. It can be quite subtle and is not always observed. Second, in addition to arousal, other factors that vary with emotion, such as the similarity of to-be-remembered stimuli, can also influence later memory. These other factors most likely achieve their influence on memory through different neural mechanisms. Finally, more-extreme stress can have an opposite effect; that is, an impairment of hippocampal function and episodic memory accuracy. In spite of these caveats, there is robust evidence that the human amygdala, through its modulation of hippocampal consolidation, plays a critical role in situations in which physiological arousal leads to enhanced episodic memory.

The final stage of memory is retrieval, when the stored information is called to mind. Processes that occur at retrieval reflect the outcome of encoding and storage, as well as additional functions related to judgment and memory monitoring. Although most studies investigate memory accuracy, there is also research indicating that the retrieval of emotional stimuli may be marked by a difference in subjective quality. Studies of episodic memory of real-life, public, emotional events have suggested that emotion may influence the subjective experience of memory retrieval, irrespective of memory accuracy. These studies examining 'flashbulb' memories have found that for highly emotional, public events, the confidence that a memory is accurate and the sense that it is detailed and vivid may not reflect actual accuracy for details. One of first examples of this effect examined memory of the explosion of the space shuttle *Challenger*. Within a few days of this tragedy, study participants were asked to record their memory for the circumstances in which they become aware of this event. Two and a half years later, the participants were asked to report the same memory. Even though the participants gave detailed recollections and were highly confident in their accuracy, most of these memories were inaccurate. More recently, a study examining memory for the terrorist attack of September 11, 2001, found that accuracy for memories of learning about this event did not differ from other, nonemotional events that occurred around the same time. However, memories of the terrorist attacks, in comparison to the more mundane events, were rated as more confident, vivid, detailed, and recollected. These studies of flashbulb memories suggest that emotion has an independent effect of enhancing the subjective sense of remembering during retrieval.

In an effort to explore the mechanisms underlying the enhanced subjective sense of remembering with emotion, laboratory studies have used the 'remember–know' paradigm. Recognition memory judgments are thought to rely on two independent processes: recollection, which includes the retrieval of contextual details, and familiarity, which is a sense that a stimulus is familiar in the absence of contextual details. The remember–know procedure is a subjective measure of these two processes. During recognition judgments, study participants view old and new stimuli and are asked to judge whether each stimulus is 'new' (not presented before), 'known' (familiar, but there is no specific recollection of details for the encoding context), or 'remembered' (recollected with details of the encoding context). For neutral stimuli, it has been demonstrated that the subjective judgment of 'remember' is correlated with accuracy for memory of the contextual details of the stimulus, suggesting that the accurate recollection of details and the subjective judgment of remembering rely on the same processes. For emotional stimuli, it has been found that the subjective judgment of remembering is enhanced, but this subjective judgment of recollection is not as closely linked to a corresponding increase in accuracy of memory of the contextual details. In other words, emotion may enhance the feeling of remembering independent of its impact on memory accuracy.

Using a similar paradigm with fMRI, researchers have demonstrated that different neural mechanisms underlie the subjective judgment of remembering for pictures of emotional as opposed to neutral scenes. Consistent with previous studies, responses in a part of the hippocampal complex, the posterior parahippocampus, differentiated 'remember' and 'know' judgments for neutral scenes. In contrast, signals in the amygdala differentiated 'remember' and 'know' judgments for emotional scenes. The posterior parahippocampus has previously been linked to memory accuracy for details of visual scenes, which is the type of information that might be expected to result in a judgment of 'remember' if this subjective judgment reflects accurate memory for scene details. However, responses in this region were not similarly enhanced for 'remembered' emotional stimuli. These results suggest that the neural mechanisms underlying the subjective judgment of recollection differ between emotional and neutral scenes. The amygdala is specifically linked to judgments of recollection for emotional scenes.

In a recent study, a similar pattern was observed when participants who were in Manhattan on September 11, 2001, retrieved autobiographical memories from that day or the summer of 2001. Although

memory accuracy could not be verified in this study, it was found that those participants who were closer to the World Trade Center (WTC) on that day reported September 11 memories that were rated as more vivid, detailed, and confident. Proximity to the WTC was not only correlated with the subjective sense of remembering but also increased activation of the amygdala and decreased activation of the posterior parahippocampus during memory retrieval. These findings are consistent with previous studies of flashbulb memories, which indicate that unique processes may underlie the judgment of recollection during the retrieval of highly emotional events.

Studies of memory retrieval suggest that for emotional stimuli, judgments of the subjective sense of remembering may be influenced by the emotional qualities of the stimulus, with less emphasis on mnemonic details. Consistent with behavioral reports of flashbulb memories suggesting emotion enhances the feeling of retrieval accuracy irrespective of actual accuracy, brain imaging results indicate emotion may alter the neural mechanisms underlying the subjective judgments of remembering. The impact of emotion on subjective quality of memory retrieval likely reflects emotion's influence on processes that occur at encoding and storage, as well as retrieval.

Although there is significant evidence that emotion interacts with episodic memory, and that the amygdala plays an important role in this interaction, an understanding of the complexity of this relationship is just beginning to emerge. Most studies in humans examining the neural systems underlying emotion's influence on episodic memory have emphasized arousal's impact on memory consolidation, perhaps inspired by the elegant animal models outlining this mechanism. However, only a few studies have clearly documented arousal's specific influence on memory consolidation in humans, independent of its effect on encoding. Disentangling the range of mechanisms by which emotion interacts with episodic memory will be a challenge for future studies. An exploration of the underlying neural systems will aid in determining the complex components of the "scar upon the cerebral tissues" that characterizes emotion's impact on human memory.

Conclusions

This article has reviewed what is known about two cognitive processes, attention and memory, that are influenced by emotion. What is clear from this limited review is that the relation between emotion and cognition is complex and nuanced. One topic that was not mentioned is the complexity of the conceptualization of emotion. Although emotion is often described as a single construct, this is clearly an oversimplification. Not only does emotion influence cognition at several stages of stimulus processing, but different facets of emotion likely have different effects on cognitive functions. In the psychological literature, the relation between emotion and cognition has often been described as two separate processes that interact at specific stages of processing. Emerging evidence from studies of human neuroscience suggest this distinction may not be sufficient. When brain function is examined, it is difficult to identify a clear dividing line between the representation of processes that are generally referred to as either emotion or cognition. Emotion affects cognition at every stage of stimulus processing, and the neural mechanisms of emotion and cognition appear to be inherently intertwined.

Introduction

The term 'emotional learning' typically refers to one of two quite different concepts. First, it may refer to the possibility that emotional responses themselves are learned. In recent years, this view was investigated most extensively in the context of what is called Pavlovian 'fear conditioning.' It has been suggested that, in such a learning situation, an emotional response (in this case, fear) is learned. Succinctly put, by this view emotion 'is' the memory. However, extensive research documents that what is learned in a typical Pavlovian fear-conditioning experiment is not an association between a stimulus and a response such as fear (termed 'S–R' learning), but a predictive relationship between two stimuli ('S–S' learning). Thus the emotion of fear appears not to be learned in fear-conditioning situations; rather, it is a response to what is learned, namely, an S–S association. Thus this first conceptualization of emotional learning appears to be a misnomer.

The second common conception of emotional learning refers to the idea that learning can occur during, and is influenced by, emotional excitement, or arousal. Broadly speaking, neurobiological research has focused on two primary factors by which emotional arousal may modulate (i.e., enhance or impair) memory storage in the brain: (1) via an 'online' modulation of attentional processing of emotional events and (2) via 'off-line' modulation of postlearning memory consolidation processing of the events. Evidence suggests that the amygdala complex, a collection of inter-connected nuclei located in the medial temporal lobe, is crucial to both types of modulation. This article reviews key findings regarding both of these modulatory factors, in particular as they concern human participants.

Emotional Modulation of Attention

Selective online processing is required for an organism to sift the wheat from the chaff of the immense amount of environmental information impinging on its nervous system. As observers can neither consciously perceive everything in their perceptual field nor remember every waking moment of their lives, information acquisition and storage must be modulated by its importance. Thus, the focusing of attention represents a prioritizing of what is important for the organism to process. It would be adaptive for the allocation of central cognitive resources to be tightly coupled with information of sufficient biological import to mobilize peripheral metabolic resources. Indeed, the classic definition (e.g., from the work of Sokolov) of the 'orienting response' to novel and important events refers to the parallel evocation of both central attentional and peripheral arousal responses. Research from the past decade has shown this coupling of arousal and attentional processes converges on the amygdala complex. Consistent with the proposed role of the central nucleus of the amygdala in arousal and attentional orienting in rodent models, recent evidence from human studies indicates that the amygdala is essential to the way emotional arousal alters attentional allocation and that this influence in turn enhances the encoding of emotionally significant events.

Emotional Arousal Influences Attention

In addition to enhancing the durability and accessibility of representations of one's past experiences in memory, it is now known that emotional arousal, by modulating the allocation of attentional resources, is also critically associated with enhancing accessibility of representations of one's present experience. Perception and memory are constructive processes. Perceivers do not provide equal access to awareness for all stimuli. This subjectivity of perception is often associated with the psychological construct of attention. The primary means by which a stimulus reaches awareness is through the allocation of attention toward its encoding. It has thus long been proposed that emotions powerfully modulate attentional processes (e.g., by narrowing the 'spotlight' of attention, as proposed in 1959 by Easterbrook). In particular, research has shown that events associated with emotional arousal acquire greater attentional resources.

Evidence showing that emotional arousal modulates attention comes from studies of what is called the 'attentional blink' (AB). Following identification of a single target stimulus, there exists a short (up to 500 milliseconds) period of impaired perceptual awareness, evidenced by the fact that a second target presented during this period may not be perceived, a phenomenon referred to as the AB. The AB impairment is substantially diminished for emotionally arousing events of both negative and positive valence and is correlated with individual differences in the subjective

arousal response to the stimuli. Also, the degree of AB reduction is found to be independent of confounding effects of familiarity, unexpectedness, semantic and perceptual distinctiveness, or altered decision criteria. Thus evidence indicates that the likelihood that a stimulus will receive attention and reach awareness is commensurate with the strength or intensity of emotional arousal induced by the stimulus, irrespective of its emotional valence. Emotionally arousing events are thus not only associated with later enhanced memory but also enhanced conscious perceptual awareness during initial encoding.

It should also be mentioned that, in addition to its effects on detection and awareness of stimuli during encoding, emotional arousal may also change the subjective phenomenological experience of a stimulus being retrieved. For example, the oft-quoted vivid 'flashbulb' quality of memories associated with highly arousing events may reflect in many instances, not the accuracy of the event, but the vividness of perceptual experience during event encoding. Similarly, some evidence suggests that 'flashbacks' that occur in posttraumatic stress disorder (PTSD) may reflect enhanced attentional allocation during the initial traumatic event combined with hyperarousal during later reexperience. Evidence from healthy people also indicates that highly arousing scenes are associated with a special visual quality that renders them more subjectively vivid.

Finally, malfunction of the mechanisms by which emotion influences attention may underlie, at least in part, various anxiety disorders. Evidence supporting this view comes in large part from studies using the 'emotional Stroop' paradigm, which reveals exaggerated attentional biases to emotional stimuli in anxiety disorders such as PTSD. It has thus been argued that the normally adaptive role of emotion in enhancing attention to emotionally salient events is rendered maladaptive when chronically activated, as in PTSD, resulting in a hypervigilant state.

Amygdala and Motivated Attention

Arousal-modulatory influences on attention and awareness are thought to depend on the integrity of the amygdala and its sensory cortical efferents. There is a striking asymmetry in amygdalo-fugal and amygdalo-petal projections, whereby the amygdala sends many more projections throughout neocortical regions, including perceptual cortices, than it receives. In fact, it has been known since the early 1950s that stimulation of the amygdala activates the cortical electroencephalograph as effectively as does the reticular activating system. The amygdala also has projections to subcortical structures important for attention and eye movements – the thalamic pulvinar nucleus and the superior colliculus, and receives input from sensory thalamic nuclei. This arrangement is consistent with the view that the amygdala receives a relatively rapid and coarse representation of the state of the world and, via its robust feedback projections to the cortex, alters the perception of stimuli, upregulating cortical encoding of stimuli of emotional importance.

Rodent models supporting the emotional modulation of perceptual processes have shown that after a few auditory fear conditioning trials, the receptive field tuning curves of neurons in the medial geniculate nucleus and primary auditory cortex are modulated such that the maximal responses are shifted toward the conditioned stimulus auditory frequency. This rapid change in neuronal tuning is consistent with the allocation of attention toward the conditioned stimulus frequency range, suggesting that the amygdala may modulate early and later perceptual processes, augmenting attention to emotionally significant events.

In humans, evidence from functional imaging studies has pointed toward a specialized attentional orienting network centered on the amygdala. For example, multiple studies have shown that emotionally arousing scenes engage both primary and secondary visual cortex significantly more than do neutral scenes. This phenomenon has been referred to as 'motivated attention' and may underlie the effects of emotion on attention discussed above. Event-related potential studies with much higher temporal resolution have similarly demonstrated that emotional significance can alter the course of perceptual encoding early in the visual processing stream, influencing visual components within the first 100 ms of stimulus processing.

These modulatory effects of arousal on attention appear to require the amygdala. For example, enhanced extrastriate cortical responses to facial expressions of fear are correlated with magnitude of amygdala response, and these enhanced extrastriate responses are abolished following amygdala damage. Direct evidence that the amygdala modulates attention to promote enhanced encoding and awareness of emotionally arousing events comes from studies of the AB, which demonstrate that emotional influences on the AB are abolished in patients with bilateral amygdala lesions. Whereas healthy people demonstrate a reduced AB to emotionally arousing events, patients with bilateral amygdala damage do not. Amygdala contributions to perceptual encoding appear to be selective for the influence of emotional arousal, as amygdala damage does not disrupt enhanced awareness associated with other manipulations of perceptual salience (e.g., increased stimulus discriminability). Furthermore, impaired arousal modulation of attentional processes in

patients with amygdala lesions is evident despite their possessing a normal ability to evaluate the arousing value of a stimulus, which suggests the amygdala is critical, not for the appraisal of event significance *per se*, but for the modulation of attention by emotional arousal. Collectively, experiments to date indicate that the amygdala facilitates perceptual encoding by influencing responsiveness of the neocortex to stimuli, thereby allowing emotional arousal to shape conscious perceptual experience.

Amygdala Modulation of Attention: Implications for Memory

Evidence suggests the brain possesses multiple attentional orienting systems with distinctive neuroanatomical and functional characteristics. Neuroimaging suggests, for example, that enhanced attention to neutral events typically activates the highest level of the cortical hierarchy, the prefrontal cortices, in conjunction with posterior parietal cortices. By contrast, as discussed, the amygdala has been associated with enhanced attention to emotionally arousing events. One critical functional difference between these frontoparietal and amygdala attentional orienting systems may be the degree to which they are voluntarily or reflexively engaged. Frontoparietal systems appear engaged during volitional attentional control, providing the flexible capacity for individuals to select what information is desired for further processing or is to be ignored. By contrast, amygdala recruitment has often been cast as relatively automatic, being recruited more readily during inattention, although the degree of this automaticity is actively debated. The amygdala may then act independently of volitional attention to ensure that emotionally salient events are encoded even when higher-order, prefrontally based attention networks are preoccupied.

The reflexive nature of amygdalar modulatory influences on attention may have important implications for memory. Human models of 'declarative' (conscious) memory suggest that attention engagement during encoding is one of the most critical predictors of the success of subsequent memory retrieval. When attention to stimuli is reduced (as, e.g., under conditions of 'divided attention'), conscious memory for neutral events is drastically reduced. In contrast, the costs to memory of reduced attention are relatively minimal for emotionally arousing events. That is, when prefrontally based attention networks are preoccupied with a concurrent task, encoding of emotionally arousing events is largely preserved. Indeed, neuroimaging evidence suggests that the influence of emotional arousal on memory formation does not necessarily depend on recruitment of the prefrontal cortices but depends more on amygdala function.

On the surface, these results may suggest that attention is not required for emotional enhancement of memory. However, as we have reviewed above, emotionally arousing events capture attention even when ignored, and this enhanced processing is orchestrated by the amygdala. Thus amygdala-based enhancement of attention at encoding, and its subsequent benefit to declarative memory, may occur even when prefrontal attentional systems are unavailable.

Emotional Modulation of Memory Consolidation

The second manner in which emotional arousal influences memory is via off-line modulation of postlearning consolidation processes. There is a very large and cohesive body of evidence documenting the ability of the amygdala (and in particular its basolateral nuclei) to modulate memory storage processes when it is stimulated soon after learning. The activity of neurons in the basolateral nuclei is elevated for hours after a single emotionally arousing event. Indeed, some experiments suggest that the amygdala may be involved in modulating memory storage for up to 2 days after an emotionally significant event. Extensive evidence also documents that the amygdala interacts with endogenous stress hormones released during and after emotional events to influence memory storage. Circulating stress hormones feed back, directly or indirectly, to the brain after an emotionally arousing event, affecting in particular the basolateral amygdala, which in turn is thought to modulate memory storage processes occurring elsewhere in the brain. This mechanism may provide an evolutionarily adaptive way to achieve memory strength that is, in general, proportional to memory importance. While this view receives its primary support from animal research, strongly convergent support comes from studies of human participants.

A few studies to date have examined the effects of postlearning stress hormone activation on memory consolidation in humans. In one study, epinephrine infusions given immediately after participants viewed a series of images enhanced long-term (1-week) memory for some of the images, in particular those associated with a small degree of arousal at initial encoding. These findings suggested the novel concept that postlearning stress hormone action interacts with the degree of arousal of experiences at initial encoding to modulate memory consolidation. This conclusion was confirmed in a study using cold pressor stress (forearm immersion in ice water) to activate the stress response immediately after learning in humans, as well as in a study of the enhancing effects of cortisol in rats. Conversely, impairment of the

adrenergic stress response (with the adrenergic blocking drug propranolol) impairs memory for emotional material.

In contrast to their generally enhancing effects on memory consolidation, endogenous stress hormones, in particular cortisol, impair retrieval of already-stored information. Studies with both animals and humans have convincingly shown that the adrenal hormone cortisol can impair the retrieval of well-stored information. This impairing effect of cortisol on retrieval, in contrast to its generally enhancing effects on consolidation, nicely illustrates the 'modulatory' concept that should be kept in mind when considering stress hormone influences on memory.

The Amygdala and Modulation of Memory Consolidation

As mentioned, a key neural element in our present understanding of emotional modulation of consolidation learning in humans is the amygdala, a structure uniquely positioned among cortical structures to widely modulate other brain regions. Many studies now indicate that, consistent with the 'memory modulation' view of the amygdala derived from animal research, amygdala activity during learning relates significantly to subsequent memory for emotionally arousing material but not to memory for nonarousing material. These studies include glucose positron emission tomography (PET), blood-flow PET, and functional magnetic resonance imaging investigations.

Studies from several labs also indicate, again consistent with the prediction from animal research, that the degree of arousal associated with stimuli (as opposed to their pleasant or unpleasant nature, or valence) is the key to amygdala engagement. In all studies to date that have directly manipulated the arousal and valence qualities of stimuli, amygdala responsiveness was significantly related to the arousing quality of the stimuli. This fact fits very well with the view that the amygdala functions especially in the context of sympathetic nervous system-activating (i.e., -arousing) situations to influence memory.

If the relationship of the amygdala to subsequent memory for emotional material is indeed dependent on adrenergic activation, then it should be eliminated in participants who view emotional material while under the influence of propranolol. And in fact, confirming evidence has come from both the studies to date that have tested this hypothesis.

Although the imaging studies mentioned to this point strongly support a selective role for the human amygdala in memory for emotional events, they do not address the possibility suggested by animal research that the amygdala influences memory storage in other brain regions. One way to produce such evidence in humans is to use analytical techniques that allow estimates of information flow between brain regions. One such method is called structural equation modeling, or 'path analysis.' Only one study to date has used path analysis to examine how the amygdala relates to other brain regions during the encoding of emotional versus neutral material. The key finding was an increased outflow from the amygdala to the ipsilateral hippocampal region in emotional compared with neutral learning conditions. Findings from other studies indicate an increased correlation between amygdala activity and that of other key brain regions, such as the hippocampus, in emotional compared with neutral learning situations. Thus the available evidence from human participants to date appears to support the memory modulation concept of amygdala function in memory.

Uncovering Influences of Sex

Finally, it is increasingly apparent that pronounced, but largely unexplored, influences of participant sex exist on brain mechanisms of emotional learning. For example, imaging studies have consistently revealed a sex-related hemispheric lateralization of amygdala activity in relation to long-term memory for emotional material. Activity of the left hemisphere amygdala while viewing emotional stimuli is preferentially related to subsequent memory for those stimuli in women, but activity of the right hemisphere amygdala is preferentially related to subsequent memory for the same stimuli in men. Other studies have revealed that sex influences stress hormone effects on memory, electroencephalograph responses to emotional stimuli, and even the nature of what is retained from an emotional experience. A straightforward, but highly important, conclusion from these studies is that investigations of the neural bases of emotional learning in humans can no longer safely assume that participant sex will not significantly influence the findings, and hence conclusions.

Summary

Emotional learning, that is, memory storage for emotionally significant events, appears to involve at least two general processes: an online modulation of attentional resources, and off-line modulation of memory consolidation processes after the event is over. Both processes seem to depend critically on the amygdala, which may be necessary, not for emotional experience *per se*, but for the effects of emotional arousal on encoding (via attentional influences) and memory consolidation. The postevent modulatory processes also involve stress hormone influences on memory

mediated by the amygdala. Finally, while these processes are likely to be broadly similar in both sexes, they also appear to differ in important ways that merit careful consideration in future work.

Encephalitis

J F Bale Jr., University of Utah School of Medicine, Salt Lake City, UT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Encephalitis denotes inflammation or infection of the brain parenchyma. Because meningeal inflammation commonly accompanies encephalitis, many authorities employ the term 'meningoencephalitis' when discussing encephalitis. Encephalitis has many distinct etiologies, including infections with parasites, bacteria, fungi, and viruses, and the clinical manifestations of encephalitis can be mimicked by several noninfectious conditions, including acute stroke, metabolic or inflammatory disorders, and neoplasia. This article focuses on the most common cause of encephalitis, viral infections. Despite remarkable advances in preventing many viral causes of encephalitis (such as polio, measles, and mumps) virus encephalitis remains a major potential source of morbidity and mortality among the world's peoples.

Many viruses can cause encephalitis (Table 1), although an etiologic agent is never identified in as many as 50% of encephalitis cases presumed due to virus infections. The incidence of encephalitis in young children, perhaps the most vulnerable age group, is as high as 18 per 100 000 child-years. Prior to the recent outbreaks of West Nile virus (WNV) infections, the Centers for Disease Control and Prevention (CDC) received reports of up to 2000 cases of viral encephalitis annually, corresponding to 0.5 cases of encephalitis per 100 000 persons living in the United States. More than 4000 human cases of WNV infection, an Old World flavivirus first observed in the United States in 1999, were identified in 2003; many were associated with neuroinvasive disease. Approximately 2500 cases of herpes simplex virus type 1 (HSV-1) encephalitis, a nonreportable disorder, occur annually among persons of all ages in the United States. Asymptomatic infections with many neurotropic viruses exceed symptomatic cases by ratios of 50 to 1 or greater.

Virus encephalitis begins with virus entry and replication at sites distant from the nervous system. Enteroviruses invade via the nasopharynx or gastrointestinal tract, herpesviruses enter the host via the mucosa of oropharynx or genital tract, and arboviruses replicate initially in the subcutaneous or lymphoid tissues near the site of virus inoculation by the tick or mosquito. Local factors, such as pH, mucosal immune responses, or the integrity of skin and mucosal barriers, influence whether a specific viral pathogen will cause encephalitis.

Many viruses reach the central nervous system (CNS) hematogenously and invade the CNS through the choroid plexus or vascular endothelial cells. Rabies virus infects neuromuscular junctions, enters nerve endings, and travels retrograde by axonal transport to the neurons of the dorsal root ganglia and spinal cord. On reaching the spinal cord, the rabies virus then ascends axonally to the brain, producing behavioral changes, seizures, and coma. Transmission via axons also has a role in pathogenesis of HSV-1 encephalitis and in reactivations of HSV-1, HSV type 2 (HSV-2), and varicella-zoster virus.

Adsorption to and penetration of human cells, the initial events of viral infection, depend on virus contact with the cell and attachment of the virus proteins to receptors on the cell surface. Although the precise molecular determinants of neuroinvasiveness and neurotropism – the capacity to infect cells of the nervous system – have not been determined for all viral pathogens, neurovirulence – the capacity to cause neurologic disease – has been linked to several viral genes and gene regions. Viruses enter host cells by phagocytosis, direct release of viral nucleic acids, or fusion of the virus envelope with the host cell membrane. Viruses utilize host cell molecular pathways to produce virus-encoded nucleic acids and proteins. Specific replicative strategies vary among viruses, depending on the DNA or RNA composition of the infecting virus. Production of viral progeny involves assembly of virions in the cell nucleus or cytoplasm and release of mature virions by budding or cell lysis. Cell death can result from stimulation of apoptotic pathways.

Clinical Manifestations

The majority of infants, children, or adults who experience virus encephalitis lack recognized predisposing factors. The incubation period for virus-induced neurologic disorders ranges from a few days to 3 or more weeks. Encephalitis begins with nonspecific, systemic features such as malaise, anorexia, myalgia, low-grade fever, vomiting, or headache. Certain viral infections can be associated with rash, diarrhea, arthralgia, pharyngitis, cough, or abdominal pain. Persons with rabies, a rare disorder in the United States and other developed countries, may have pain or paresthesia near the site of virus inoculation.

Persons with viral encephalitis have alterations of consciousness varying from mild somnolence to deep coma. Fever, a common but not invariable feature of

viral encephalitis, ranges from low grade to 40 °C or higher. Seizures, a frequent sign of encephalitis, can be partial or generalized. Although focality can be an important feature of encephalitis due to HSV-1, partial seizures accompany several types of encephalitis, including relatively mild cases caused by the La Crosse virus or the nonpolio enteroviruses.

The neurologic examination of individuals with encephalitis reveals behavioral or cognitive changes, hyperreflexia, altered muscle tone, ataxia, or focal deficits such as aphasia, hemiparesis, or ophthalmoplegia. Not all features are present in every patient. Focal neurologic features should increase the clinician's suspicion of HSV encephalitis, especially in adults older than 50 years. In severe cases of encephalitis, signs of increased intracranial pressure, including pupillary abnormalities, ophthalmoplegia, abnormal respiratory patterns, or flexor or extensor posturing, may be present.

Diagnosis

The patient with suspected virus encephalitis requires a thorough evaluation that includes neuroimaging studies, cerebrospinal fluid (CSF) examination, electroencephalography, and microbiological assays for suspected infectious pathogens. The clinician must search for abnormalities that indicate a specific, treatable viral disorder, such as HSV encephalitis, and remain alert for the clinical or laboratory findings that suggest noninfectious disorders or infections with bacteria, fungi, or parasites that may require pathogen-specific treatment.

Computed Tomography and Magnetic Resonance Imaging

Imaging studies should be performed in all patients with presumed encephalitis, especially when HSV encephalitis is suspected. The computed tomography (CT) of patients with encephalitis can be normal, have nonspecific features, or demonstrate focal or generalized cerebral swelling manifested by loss of the gray–white interface or effacement of the basal cisterns. In patients with HSV encephalitis, CT may detect focal edema of the temporal lobe, compression of adjacent CSF spaces, focal hemorrhage, or abnormal contrast enhancement.

Magnetic resonance imaging (MRI), the preferred imaging modality for patients with suspected encephalitis, has superior sensitivity, especially in the early stages of virus encephalitis. T2 prolongation (Figures 1 and 2) or enhancement of the mesial temporal lobe, insular cortex, and cingulate gyrus strongly suggests HSV encephalitis. Administration of paramagnetic contrast agents, such as gadolinium-DTPA, can enhance brain lesions in HSV and other forms of viral encephalitis (Figure 3), but the absence of enhancement does not exclude these disorders. MRI detects diffuse

Figure 1 Axial FLAIR magnetic resonance imaging in varicella-zoster virus encephalitis shows several areas of T2 prolongation compatible with acute disseminated encephalomyelitis (arrows).

Figure 2 Axial FLAIR magnetic resonance imaging in a child who recovered from Epstein–Barr virus encephalitis shows residual gliosis (arrows) and cystic encephalomalacia.

or focal abnormalities in other forms of virus encephalitis, and in certain disorders, such as Japanese encephalitis, the MRI features can be diagnostic. MRI also has utility in distinguishing viral encephalitis from acute disseminated encephalomyelitis (ADEM), a condition that accounts for approximately 15% of

Figure 3 Gadolinium-enhanced coronal T1-weighted magnetic resonance imaging in acute herpes simplex virus type 1 encephalitis shows meningeal enhancement adjacent to the insular and mesial temporal regions (arrows).

encephalitis cases in the United States. MRI in ADEM shows multiple areas of T2 prolongation in the white matter of the cerebrum, brain stem, or cerebellum and occasionally in the cerebral cortex, basal ganglia, and thalamus.

Patients with encephalitis commonly have abnormal electroencephalograms (EEGs) that demonstrate slowing of background rhythms or the presence of focal or diffuse epileptiform discharges. Detecting focal features that may suggest HSV encephalitis is an important reason to obtain an EEG during the early stage of the patient's encephalitic illness. Of patients older than 5 months studied by the National Institute of Allergy and Infectious Diseases-supported Collaborative Antiviral Study Group (NIAID-CASG), 81% with biopsy-proven HSV encephalitis had focal slowing or repetitive epileptiform discharges (periodic lateralizing epileptiform discharges). In neonates with HSV infection, EEGs are less frequently abnormal. In nonherpetic encephalitis, the EEG usually shows diffuse slowing, but focal features can be present. Approximately 40% of the children with California encephalitis exhibit focal slowing or epileptiform discharges, and nearly 50% of patients with Eastern equine encephalitis (EEE) can have focal EEG slowing. In severe cases of encephalitis, regardless of the etiologic agent, the EEG can reveal marked attenuation of background activity or a burst suppression pattern.

CSF

The CSF in virus encephalitis usually shows a lymphocytic pleocytosis, modestly elevated protein content, and normal glucose content. Total CSF leukocyte

ranges from 10 per cubic millimeter to 1000 per cubic millimeter or higher. However, patients exhibit variability in their CSF responses, and the CSF can be entirely normal during the early phase of encephalitis. Approximately 5–15% of patients with HSV encephalitis have normal CSF cell counts (<5 per cubic millimeter) initially, although pleocytosis, as well as protein elevation, typically appears. In certain viral disorders, such as EEE, the CSF may show a neutrophilic pleocytosis, thus resembling bacterial infection. Other leukocytes (such monocytes, plasmacytoid cells, and eosinophils) may be present, and ependymal cells can occasionally be detected. Erythrocytes can also be observed, although a hemorrhagic CSF has little diagnostic specificity. In some patients, the CSF examination must be deferred or omitted due to increased intracranial pressure.

In typical cases of virus encephalitis, the protein content is normal or modestly elevated (50–100 mg dl^{-1}), but it can exceed 500 mg dl^{-1}. Although the glucose content tends to be normal in most viral CNS infections, modest hypoglycorrachia can be seen occasionally in infections due to HSV and mumps, lymphocytic choriomeningitis, or EEE viruses. CSF abnormalities, especially leukocytosis and elevated protein content, may persist for several weeks after symptoms subside.

Microbiological Studies

Although molecular methods of detection have replaced conventional virus isolation in the diagnosis of many forms of encephalitis, viruses can be isolated in certain conditions from throat washings; urine; whole blood or buffy coat leukocytes; CSF; fluid from any skin lesion; or swabs of the nasopharynx, throat, or rectum. Tissues obtained by biopsy or autopsy can also be sent for virus culture, and such approaches should be considered in persons with HIV/AIDS or unusual neurologic disorders of suspected infectious etiology. Specimens for detection of bacterial, fungal, or parasitic pathogens may also be appropriate, depending on the clinical manifestations of the neurologic condition or immune status of the host.

The polymerase chain reaction (PCR) can detect the nucleic acid of numerous viral pathogens, including HSV, HIV, cytomegalovirus, the nonpolio enteroviruses, adenoviruses, Epstein–Barr virus, varicella-zoster virus, human herpes virus type 6, and certain alpha- and flaviviruses. Consequently, PCR has become the 'gold standard' for the detection of many encephalitis-causing viral pathogens. Analysis of CSF by PCR for DNA viruses is particularly useful in suspected cases of HSV encephalitis, and reverse transcription (RT)-PCR can be used to detect RNA viruses, such as the nonpolio enterovirus. Multiplex PCR methods have been developed to detect the nucleic acids of several neurotropic viruses simultaneously. The sensitivity of CSF PCR exceeds 90% in HSV encephalitis in children or adults but may be lower in neonatal HSV infections. PCR detects HSV in the CSF of approximately 70% of infants with HSV encephalitis and in serum of approximately 50%. Detection of HSV in serum reflects the hematogenous route of HSV transmission in neonatal encephalitis. The sensitivity and specificity of CSF or serum PCR in other viral encephalitides are less well established, although positive results should generally be considered strong evidence for infection. Conversely, false negative results indicate that clinicians must exercise sound clinical judgment when making therapeutic decisions in persons with suspected virus encephalitis (Figure 2).

Serologic studies remain the recommended diagnostic methods for identifying viruses that cannot be readily cultured or detected with the current molecular methods. Lymphocytic choriomeningitis, Epstein–Barr virus, and many arboviruses require serologic studies for diagnosis. Serologic diagnosis relies on detecting seroconversion, pathogen-specific IgG or IgM in serum or CSF, or fourfold or greater changes in virus-specific IgG in sera obtained during the acute and convalescent stages of infection. Infections with certain viral pathogens, especially the arthropod-borne agents, including the WNV, can be established by detecting agent-specific IgM in a CSF sample obtained during the acute stage of the illness.

Many nonviral and noninfectious disorders produce neurologic signs and symptoms that overlap with those of virus encephalitis. Consequently, the clinician must occasionally obtain studies for nonviral disorders. Such disorders include stroke, tumor, bacterial infections (e.g., *Mycoplasma pneumoniae* and Legionnaire's disease), inflammatory disorders (e.g., systemic lupus erythematosis), paraneoplastic syndromes, spirochetal infections (e.g., Lyme disease and syphilis), rickettsial disease (e.g., Rocky Mountain spotted fever), erhlichiosis, cat scratch disease, and parasitic infections (e.g., toxoplasmosis or amebic meningoencephalitis).

Treatment and Prognosis

Although many viral infections cannot be treated with specific therapeutic agents, increasing numbers of medications may benefit children or adults with viral CNS disorders (Table 2). All patients with viral CNS disorders require supportive care that must be tailored to the severity of their illness. Seizures, increased intracranial pressure (ICP), and acute respiratory failure should be anticipated as potential complications of viral encephalitis.

Table 2 Antiviral therapies

Virus	*Drug*
Herpes simplex virus	Acyclovir

Table 3 Approximate morbidity and mortality rates for selected viral encephalitides

Virus[a]	*Mortality*	*Morbidity*
HSV-1 (child, adult)	5%, 10%	50%
HSV-1 (neonatal)	15%	>50%
HSV-2 (neonatal)	15%	>50%
Epstein–Barr virus	<5%	20%
La Crosse virus	1% or less	10%
West Nile virus	10%	40%
Rabies	nearly 100%	

[a]HSV, Herpes simplex virus.

ICP contributes to the potential morbidity of viral encephalitis in children and adults. Measures that may be necessary to treat elevations of ICP include mechanical ventilation or intravenous administration of osmotic diuretics. Severely ill patients may require invasive procedures for monitoring of intracranial, arterial, and central venous pressures. Intravenous fluid and electrolyte therapy must be managed meticulously to maintain cerebral perfusion but avoid iatrogenic elevations of ICP. Seizures may require intravenous therapy with benzodiazepines, fosphenytoin, or barbiturates.

The prognosis in virus encephalitis depends on the etiologic agent and host factors, such as age, underlying medical conditions, and immune status (Table 3). La Crosse virus encephalitis has very low rates of mortality or morbidity. By contrast, human rabies encephalitis virtually always results in death despite vigorous supportive measures. Mortality in untreated HSV encephalitis ranges from 40% to 70%, whereas therapy with acyclovir reduces mortality to 20% or less. Unfortunately, many survivors of HSV encephalitis have neurologic sequelae (Figure 4) despite appropriate management and treatment with acyclovir. Survivors of virus encephalitis can have epilepsy, paralysis, movement disorders, and cognitive or behavioral dysfunction.

Figure 4 Follow-up sagittal T1-weighted magnetic resonance imaging in herpes simplex virus type 1 encephalitis shows residual cystic encephalomalacia of the right temporal lobe (arrows).

Selected Disorders

The following material summarizes the key clinical and therapeutic features of several representative disorders, including La Crosse virus encephalitis, HSV encephalitis, WNV encephalitis, and rabies. These disorders have been selected because they provide useful examples of the clinical features, diagnosis, and management of virus encephalitis.

Lacrosse Virus Encephalitis

The prototype California encephalitis virus was originally isolated in Kern County, California, but the La Crosse virus, endemic to the midwestern and eastern United States, causes the vast majority of encephalitis cases due to North American bunyaviruses. *Aedes triseriatus*, a mosquito species that inhabits stagnant water in tree holes or abandoned automobile tires, is the vector for La Crosse virus. Small mammals, such as chipmunks and squirrels, serve as amplifying hosts. La Crosse encephalitis (LE) typically affects previously healthy young children and occurs principally during the summer and early fall, when mosquitoes are abundant. Children with LE often live adjacent to or have recently entered mosquito habitat. As many as 30% or more of people living in endemic areas possess antibody to the La Crosse virus, indicating that infections are frequently asymptomatic. Until the recent emergence of WNV neuroinvasive disease, La Crosse virus was the most commonly encountered arboviral encephalitis in the United States.

LE typically occurs in children between the ages of 5 and 10 years; LE after 18 years of age is unusual. After an incubation period of 3–7 days, fever, vomiting, headache, and abdominal pain begin, and CNS

signs appear 2–4 days thereafter. Approximately, 60% of children with LE have seizures, 50% have altered mental status, and 20% have focal deficits, consisting of aphasia, mild extremity paralysis, or partial seizures that can mimic HSV encephalitis. Other than fever, systemic signs are uncommon, although cough, arthralgia, and transient maculopapular rash have been reported. Neurologic abnormalities and fever continue for 3–7 days; most patients recover within 10–14 days of disease onset.

The child with LE can have an elevated sedimentation rate and peripheral leukocytosis, often with a left shift. The CSF findings consist of a mild lymphocytic pleocytosis, normal or modestly elevated protein content, and normal glucose content. The EEG shows diffuse slowing of background activity, although focal or epileptiform features can be detected. CT or MRI is usually normal. The diagnosis of LE can be confirmed by detecting La Crosse virus-specific IgM in serum or CSF. Though the virus is not typically found in CSF or body fluids, it has been isolated from brain tissue in rare instances. The RNA of La Crosse and other California serogroup viruses can be detected by RT-PCR.

Therapy generally consists of supportive care, treatment of fever or seizures, and anticipation of syndrome of inappropriate antidiuretic hormone or increased ICP, rare complications of LE. Because LE can mimic HSV encephalitis, however, therapy with acyclovir is required until a specific diagnosis can be confirmed. Ribavirin can inhibit La Crosse virus *in vitro* and has been used in severe cases. The majority of children survive LE without neurological sequelae, although occasional children have persistent emotional lability or seizure tendencies.

HSV Encephalitis

HSV-1 encephalitis, the most common nonepidemic encephalitis worldwide, with an annual frequency of approximately one in 250 000 persons, exhibits no seasonal, gender, or racial predilections. Encephalitis can complicate primary, recurrent, or reactivated HSV-1 infections. Reactivation of HSV-1 and retrograde transmission of the virus to the CNS are assumed to cause most cases of human encephalitis after the neonatal period. In children and adults, HSV-1 exhibits tropism for the frontotemporal regions of the brain. By contrast, neonatal encephalitis, usually due to HSV-2, involves the brain diffusely as the result of hematogenous viral transmission.

Approximately 25% of HSV-infected neonates have isolated encephalitis. Encephalitis can also be a feature of disseminated neonatal HSV infections in which infants have pneumonitis, hepatitis, or disseminated intravascular coagulopathy. Nonspecific clinical manifestations, consisting of fever, lethargy, and poor feeding, usually appear during the second or third week of life but can be present as early as day 1. As neonatal HSV encephalitis progresses, lethargy, seizures (partial or generalized), paralysis, or respiratory failure predominate. Vesicular rash is observed in approximately two-thirds of HSV-infected infants.

The initial clinical features of HSV encephalitis in children and adults consist of a nonspecific prodrome of headache, fever, malaise, and vomiting. Focal neurologic signs appear subsequently in most patients and can include dysphasia, hemiparesis, visual field deficits, or partial seizures. The clinical course can be rapidly progressive, manifested by repetitive focal seizures, coma, increased ICP, and death within 2 weeks or by indolence, with hallucinations, headache, memory loss, or behavioral disturbances for several days before seizures appear. Children and adults rarely have systemic signs of HSV infection.

Infants with HSV encephalitis and disseminated infection can have thrombocytopenia, hemolytic anemia, elevated serum transaminases, and metabolic acidosis. By contrast, routine laboratory studies have no diagnostic specificity in children or adults with suspected HSV encephalitis. The CSF usually has a mononuclear pleocytosis (as high as1000 white blood cells or more per cubic millimeter), an increased protein content, and a normal or modestly depressed glucose content. Red blood cells or xanthochromia can be seen, but these findings have little diagnostic specificity.

Infants with suspected HSV infections should undergo virus cultures at multiple sites, including the conjunctiva, oropharynx, rectum, circulating leukocytes, CSF, and skin. Neonatal infection can be confirmed by isolating HSV-1 or -2 from any of these sites. Conjunctival cultures have the highest yield (>90%); the yield of oropharyngeal cultures is less (~40%). HSV can be detected in CSF samples in 40–50% of infants with CNS involvement. For maximum sensitivity, cultures should be obtained prior to acyclovir treatment (HSV CSF PCR can remain positive 24–48 h or longer after initiation of acyclovir therapy). By contrast, viral cultures rarely detect HSV in the blood or body fluids, including CSF, of children or adults with HSV encephalitis.

PCR can detect HSV DNA in the CSF of persons of any age with HSV encephalitis and has become the 'gold standard' for the diagnosis of HSV encephalitis. HSV DNA was detected in the CSF of 98% of the children and adults with biopsy-proven HSV encephalitis who participated in NIAID-CASG studies. The sensitivity of PCR is lower, however, in cases of

neonatal HSV encephalitis. HSV DNA was detected in only 26 of 34 (76%) infants with HSV-induced CNS disease in the NIAID-CASG studies.

Infants and young children with HSV encephalitis require treatment with acyclovir, 60 mg kg^{-1} daily in equally divided doses every 8 h. Older children and adolescents should receive 1500 mg kg^{-1} daily, and adults should be given at least 30 mg kg^{-1} daily in equally divided doses every 8 h. Dose reductions are necessary in persons with impaired renal function because of the drug's potential nephrotoxicity. Patients with confirmed HSV encephalitis require therapy for 21 days. Many authorities recommend repeat lumbar puncture and CSF HSV PCR at 21 days to confirm eradication of HSV. Longer courses of acyclovir may be necessary when the CSF HSV PCR result remains positive. A small number of patients with HSV encephalitis experience relapses and require retreatment with acyclovir. Corticosteroids can be considered when the relapse appears to be secondary to ADEM.

WNV

WNV, first identified in Uganda in 1937, caused occasional cases in East Africa and the Middle East until the mid-1990s, when neuroinvasive disease and fatal cases became more frequent. In 1999 WNV first appeared in the Western Hemisphere, causing seven deaths in adults during an encephalitis outbreak in the New York City metropolitan area. The WNV strain causing this outbreak was closely related to a strain identified in Israel in 1998.

In 2000 WNV activity was detected in 12 states surrounding New York State, and by the end of 2001, 27 states and the District of Columbia reported the presence of WNV. WNV spread rapidly among North American birds and mosquitoes, leading to a massive epidemic in 2003 (Figure 5) that affected more than 4000 inhabitants of 44 states from New York to California. By 2005 nearly 17 000 human cases of WNV infections had been reported in the United States, and approximately 40% were neuroinvasive. Several mosquito species serve as the natural vectors for human infection, but transmission among humans has been reported in association with breast feeding, blood transfusion, and organ transplantation.

Asymptomatic infections with WNV outnumber cases by approximately five to one. Neuroinvasive disease affects approximately one of every 150 infected persons. Although persons of all ages can be affected by WNV, adults comprise the majority of cases. To date, most persons with WNV neuroinvasive disease have been >25 years of age. After an incubation period of 2–14 days, systemic symptoms of fever, malaise, headache, nausea, and vomiting appear in symptomatic infections. Symptomatic patients can also have maculopapular rash or lymphadenopathy.

Encephalitis, affecting approximately 60% of persons with WNV neuroinvasive disease, begins gradually with a systemic prodrome or abruptly with high fever and coma. Manifestations of WNV encephalitis include altered mental status, coma, diffuse muscle weakness (proximal more than distal), respiratory paralysis, tremor, myoclonus, and parkinsonian features. Less common neurologic complications of WNV include aseptic meningitis, myelitis, optic neuritis, or the Guillain–Barré syndrome. Involvement of the anterior horn cells can produce a poliomyelitis-like disorder. A single case report suggests that WNV can also cause congenital CNS infection.

The CSF features in WNV encephalitis consist of a mild, lymphocytic pleocytosis (30–100 cells mm^{-3}), elevated protein content (80–100 mg dl^{-1}), and normal glucose content. Cranial CT is normal, whereas MRI can reveal leptomeningeal enhancement, periventricular inflammation, or abnormalities of the spinal cord. The diagnosis is confirmed by serologic studies that detect WNV-specific IgM in serum or CSF. WNV-specific IgM persists in serum for at least 16 months in more than 50% of infected persons. Infected patients experience brief periods of viremia, but infectious virus is rarely isolated from serum or CSF.

Therapy of WNV encephalitis consists of supportive care with close observation for respiratory failure. Ribavirin possesses activity against the WNV *in vitro*, but there are no controlled trials indicating efficacy in WNV encephalitis. There were 284 deaths among the 4156 cases reported to the CDC in 2003, corresponding to a mortality rate of approximately 7%. Death is more likely among older patients. A substantial proportion of the survivors of neuroinvasive disease have permanent cognitive, behavioral, or motor sequelae.

Rabies

Rabies poses a threat to persons in many regions, especially Africa and Asia, where the incidence of one case of rabies per 100 000–1 000 000 inhabitants corresponds to thousands of deaths annually. In these regions, domestic dogs or wild canines transmit rabies, and children constitute the majority of human cases. Human and animal rabies has been eradicated in a few regions as a result of quarantine and vaccination of domestic animals.

In the United States, rabies is endemic in raccoons, skunks, foxes, and bats. In the northeastern United States, the number of rabies virus-infected raccoons has risen steadily during the past 30 years. This epizootic constitutes a potential health hazard and

Figure 5 West Nile virus activity in the United States, 2003. From the Centers for Disease Control and Prevention, http://www.cdc.gov/ncidod/dvbid/westnile/Mapsactivity/surv&control03Maps.htm.

a substantial economic burden for postexposure prophylaxis among exposed humans. The CDC receives reports of one to five indigenous cases of human rabies annually in the United States. Most have no apparent history of animal bites; many are linked by molecular analysis to the rabies strain carried by the insectivorous silver-haired bat.

After an incubation period averaging 20–60 days, human rabies begins with chills, fever, headache, sore throat, malaise, nausea, or abdominal pain. Pain or itching at the site of inoculation is common. Neurologic symptoms and signs begin thereafter, being cerebral in 80% and Guillain–Barré syndrome-like in the remainder. Patients with cerebral symptoms have agitation, hypersalivation, delirium, and occasionally opisthotonic posturing. Hydrophobia, present in the range of 20–50% of patients, is associated with spasms of the laryngeal muscles, diaphragm, and accessory respiratory muscles. Seizures ensue in many cases. Eventually, patients with rabies encephalitis lapse into a fatal coma. Rabies-induced Guillain–Barré syndrome-like disease produces bulbar dysfunction, facial diplegia, and often respiratory arrest. Cardiac dysrhythmias and irreversible coma are additional causes of death in paralytic cases.

Because of its rarity in the United States and Canada, human rabies is often unsuspected, especially given the nonspecific clinical presentation. CSF may be normal or reveal nonspecific changes with a mixed or lymphocytic pleocytosis and mild protein elevation. CT and MRI are usually normal. Rabies is often diagnosed at postmortem examination. Premortem diagnosis can be established by immunofluorescence studies of skin from the nape of the neck, detection of rabies virus antibody in CSF or serum (assuming the patient was not vaccinated previously), or isolation of rabies virus from saliva or CSF. RT-PCR can be used to detect rabies virus and determine the molecular profile and animal origin of the rabies virus strain.

Because rabies cannot be treated effectively with the currently available antiviral agents, management of symptomatic human rabies consists of supportive care in an intensive care unit. The prognosis remains very grim, with few reported survivors, and most patients die within 12 days of disease onset. Because rabies virus can be present in saliva, urine, and other body fluids, patients with suspected rabies must be maintained in isolation.

Because of the strong epidemiologic relation between bat rabies strains and recent rabies cases in

humans, prophylaxis should be administered after contact with bats unless testing of the bat proves negative for rabies virus infection. Human-to-human transmission of rabies virus has not been reported except after corneal or organ transplantation. Nonetheless, persons with suspected rabies should be maintained in strict isolation to minimize contact with rabies virus-contaminated saliva and CSF and to reduce the number of healthcare workers who require postexposure prophylaxis.

Local public health officials or infectious disease experts should be consulted regarding recommendations for prophylaxis. Prevention of human rabies requires strict adherence to postexposure guidelines. The potential for rabies transmission depends on the animal species, the nature of the exposure, and the prevalence of rabies in the geographic region. All postexposure prophylaxis should begin with a thorough cleansing of the wound with soap and water. Current human diploid cell rabies vaccines are safe and effective.

Introduction

The records of cannabinoids date back more than 5000 years, to when the therapeutic and psychotropic actions of extracts of the hemp plant *Cannabis sativa* were first documented. The long history of this plant has been very vivid and has not ceased to elicit a lot of attention in our society. As with other natural products with strong pharmacological effects in humans, there has been great interest in understanding what the active components of extracts from *C. sativa* are and how they act on the human body, but success was hampered for a long time because of technical reasons. Only in 1964 was the group of Raphael Mechoulam able to chemically identify Δ^9-tetrahydrocannabinol (Δ^9-THC) as the major psychoactive constituent of *C. sativa* (Figure 1(a)). However, it took another 25 years to identify the mechanisms underlying these effects. Specific binding proteins for Δ^9-THC, called cannabinoid receptors, were discovered. Potent derivatives of Δ^9-THC such as CP55940 and HU-210 (Figures 1(c) and 1(d)) were instrumental in the pharmacological and molecular identification of these novel receptors, which belong to the G-protein-coupled receptor family. It is worth mentioning that in addition to Δ^9-THC, *C. sativa* extracts contain many other nonpsychoactive cannabinoids, such as cannabidiol (Figure 1(b)), which do not bind to cannabinoid receptors but which have interesting pharmacological effects with therapeutic potential. The molecular mechanisms underlying these effects have not yet been elucidated, but further investigation may lead to interesting insights, possibly even novel endogenous physiological mechanisms. Finally, the cloning of the cannabinoid receptor enabled the identification of the body's own molecules that can elicit effects similar to those of Δ^9-THC and that bind to and activate cannabinoid receptors. These endogenous ligands represent a novel class of lipid signaling molecules, called endocannabinoids (Figure 2).

Endocannabinoids are derivatives of the polyunsaturated eicosanoid arachidonic acid and can act as versatile neuromodulators at the synaptic level in both the central and peripheral nervous systems. Multiple roles in nonneuronal cells (such as the regulation of lipid metabolism, bone mass, and immune responses) have also been reported. Discovered in 1992 and 1995, respectively, the two major endocannabinoids are *N*-arachidonoyl ethanolamine (AEA), named anandamide, and 2-arachidonoyl glycerol (2-AG) (Figures 2(a) and 2(b)). Both of them bind to and activate cannabinoid receptors. Recently, other endocannabinoids (such as 2-arachidonoyl glycerol ether and *N*-arachidonoyl dopamine (Figures 2(c) and 2(d))) have been isolated. To date, two receptors have been characterized, both belonging to the class of seven-transmembrane receptors, coupled to the pertussis toxin-sensitive G-protein, $G_{i/o}$. Cannabinoid type 1 (CB1) receptors are predominantly expressed in neurons, but important sites of expression have also been found in peripheral nonneuronal cells, such as adipocytes and hepatocytes. Cannabinoid type 2 (CB2) receptors are present mainly in immune cells, but recent investigations were able to show functional receptors in central nervous system (CNS) neurons, too. This article focuses mainly on the CB1 receptor and its role in synaptic plasticity and memory processing as the present knowledge of CB2 receptors in the CNS is sparse. However, it would not come as a surprise if in the near future, the relevance of CB2 receptors in the CNS is better understood and receives more attention than is the case to date.

Endocannabinoids and cannabinoid receptors, together with the enzymes of endocannabinoid biosynthesis and degradation, constitute the endocannabinoid system. This system has recently emerged as an important regulator of a plethora of physiological processes in the CNS, including pain, appetite, reward, memory processing, and neuronal excitability. These functions appear to involve the fine-tuned regulation of synaptic transmission, which ultimately ensures homeostatic conditions of the nervous system. During pathological processes in the nervous system, dysregulations of the endocannabinoid system may occur. The endocannabinoid system in this state may be a therapeutic target for the treatment of particular nervous system diseases by agents that either stimulate or inhibit the activity of the endocannabinoid system, depending on the pathological conditions. During the past few years, this concept has drawn a lot of attention to the endocannabinoid system.

Cannabinoid Receptor CB1 and the Modulation of Intracellular Signaling

The prototypical signaling after activation of CB1 receptor by both plant-derived cannabinoids and

endocannabinoids is the inhibition of adenylate cyclase via $G_{i/o}$ protein, resulting in a decrease of intracellular cyclic adenosine monophosphate (cAMP) production (Figure 3), although coupling to G_s was also reported under some experimental conditions. CB1 receptor-dependent inhibition of the cAMP signaling pathway can stimulate A-type potassium channels, which are negatively regulated by phosphorylation provided by the cAMP-dependent protein kinase A (PKA). A direct coupling of the $G_{i/o}$ protein to inwardly rectifying potassium channels (GIRK1 and GIRK2) and the $G_{i/o}$-dependent inhibition of N-type and P/Q-type voltage-gated Ca^{2+} channels lead to an enhanced K^+ efflux and to an inhibition of Ca^{2+} influx, respectively. Thus, CB1 receptor activation leads to a general decrease of neuronal excitability. In addition, a multitude of other intracellular signaling systems are activated, of which many have been implicated in synaptic plasticity and memory processing. Finally, immediate early genes, including brain-derived neurotrophic factor and the transcription factors zif268 and c-fos, are switched on after CB1 receptor activation.

Figure 1 Chemical structures of plant-derived and synthetic cannabinoids. (a) Δ^9-Tetrahydrocannabinol (Δ^9-THC), identified in 1964 by Raphi Mechoulam, is the major psychoactive component in extracts from the hemp plant *C. sativa*. It binds to and activates the cannabinoid receptors. (b) Cannabidiol, a major constituent of *C. sativa*, is not psychoactive, as it does not bind to cannabinoid receptors. However, it is able to elicit distinct pharmacological effects by mechanisms that have not been elucidated in detail. (c) CP55940, a synthetic derivative of Δ^9-THC developed by Pfizer in 1974, is 40 times more potent than Δ^9-THC on cannabinoid receptors. The radiolabeled CP55940 was pivotal in the discovery and molecular characterization of the long-sought endogenous Δ^9-THC receptor, named cannabinoid receptor type 1 (CB1 receptor), as published in 1990. (d) HU-210, developed by the Hebrew University, is the most potent activator of cannabinoid receptors known to date (100 times more potent than Δ^9-THC).

Biochemistry of Endocannabinoids

Endocannabinoids are remarkable signaling molecules with multiple faces. As they are biosynthetic derivatives from arachidonic acid, they belong to the class of bioactive eicosanoids, such as prostaglandins, thromboxanes, and leukotrienes. These three well-known classes of lipophilic signaling molecules have been shown to act locally, in either an autocrine or a paracrine manner. For endocannabinoids, similar modes of actions also occur both in the CNS and in peripheral tissues.

Different from 'classical' neurotransmitters, endocannabinoids cannot be stored in vesicles. Therefore,

Figure 2 Structure of endocannabinoids. (a) Anandamide (*N*-arachidonoyl ethanolamine, AEA), the first endocannabinoid, discovered in 1992 and named from the Sanskrit word *ananda*, meaning 'internal bliss.' (b) 2-Arachidonoyl glycerol (2-AG). (c) 2-Arachidonoyl glycerol ether (noladin ether). (d) *N*-Arachidonoyl dopamine (NADA). All these four compounds bind to and activate cannabinoid receptors, but with different efficacies. AEA and 2-AG are the major endocannabinoids; the relevance of noladin ether in physiological processes has still to be elucidated. NADA represents a novel category of compounds as it is a condensation product of arachidonic acid with an amino acid derivative. Other lipids with similarity to AEA and 2-AG, such as *N*-arachidonoyl serine, dihomo γ-linolenoyl ethanolamide, docosatetraenyl ethanolamide, and oleamide, have been characterized, but these compounds do not bind or bind only with low affinity to the cannabinoid receptors CB1 and CB2.

Figure 3 Schematic representation of the possible cannabinoid type 1 (CB1) receptor-mediated signaling pathways. Activation of CB1 receptors by both Δ^9-THC and endocannabinoids (EC) leads to the stimulation of $G_{i/o}$ proteins that, in turn, inhibit the adenylate cyclase-mediated conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). Then cAMP molecules can bind the regulatory subunits of protein kinase A (PKA) and induce the liberation of the catalytic subunits. Activated PKA can phosphorylate A-type potassium (K^+_A) channels, causing a decrease of the K^+ efflux. Given the negative effect of CB1 receptor activation on adenylate cyclase, the final result is an activation of K^+_A channels. Activated $G_{i/o}$ can also directly inhibit voltage-gated N- and P/Q-type Ca^{2+} channels and activate inwardly rectifying potassium (K^+_{ir}) channels. The latter two effects are controlled by protein kinase C (PKC), which, after activation, can phosphorylate CB1 receptors in the third cytoplasmatic loop and uncouple the receptor from the ion channels. CB1 receptor activation can also stimulate several intracellular kinases, such as focal adhesion kinase (FAK), phosphatidyl inositol-3-kinase (PI3-K) and its downstream effectors protein kinase B (PKB) (also known as AKT) and Raf-1, extracellular signal-regulated kinases (ERKs), c-Jun N-terminal kinase (JNK), and p38 mitogen-activated kinase. CB1 receptor activation can also lead to increased expression levels of calcineurin, also called protein phosphatase 2B. Stimulation of cytoplasmic kinases can also mediate CB1 receptor-induced expression of immediate early genes (IEG), such as the transcription factors c-fos, c-jun, and zif268 and brain-derived neurotrophic factor (BDNF). It is important to note that several of these CB1 receptor-regulated signaling pathways have been shown to be involved in the modulation of synaptic plasticity and memory processing. P, phosphorylation.

biosynthesis (Figures 4 and 5) and degradation pathways of these compounds are the central regulatory steps in the activation and termination of endocannabinoid signaling. These pathways are currently being characterized, but some features are known: (1) Biosynthetic precursor molecules are phospholipids stored in the membrane. These phospholipids constitute a large pool and are not only specific for endocannabinoid synthesis but are also used for other metabolic processes in the cell. (2) The ondemand biosynthesis of endocannabinoids can be regulated by several intracellular pathways, including Ca^{2+}-phospholipase C (PLC)- and/or cAMP-dependent mechanisms. (3) Biosynthesis of the two major endocannabinoids, anandamide and 2-AG, can occur independently of each other in different pathways, and regulation of the on-demand synthesis of anandamide and 2-AG can also differ. (4) Biosynthetic pathways

Figure 4 Schematic representation of the biosynthetic pathways leading to anandamide (*N*-arachidonoyl ethanolamine, AEA). As a first Ca^{2+}-dependent (and possibly also cyclic adenosine monophosphate (cAMP)-regulated) reaction catalyzed by *N*-acyltransferase (NAT), *N*-arachidonoyl-PE (NArPE) is generated from two membranous precursor molecules, phosphatidyl ethanolamine (PE) and an arachidonoyl phosphoglyceride. Then, anandamide can be synthesized by two different Ca^{2+}-dependent pathways, either by *N*-acyl-PE-phospholipase D (NAPE-PLD) or by phospholipase A_2 (PLA_2) and lyso-PLD. Note the redundancy of the pathways.

appear to be redundant, as gene inactivation experiments have not yet been able to pinpoint conclusively the crucial enzymes. Pharmacological experiments using inhibitors have provided good evidence for particular pathways, but such inhibitors may not be completely specific for one particular enzyme. (5) Degradation enzymes (FAAH and MAGL for anandamide and 2-AG, respectively), although clearly able to degrade the respective compounds, appear not to be completely specific. In particular, 2-AG and its precursors are at the crossroads of several metabolic pathways and are important precursors or/and degradation products of phospho-, di- and triglycerides. FAAH is also able to degrade many other acyl ethanolamides, which are not considered endocannabinoids. (6) After action, endocannabinoids can be taken up into the cells by facilitated transport mechanisms, although the endocannabinoid membrane transporter has not been cloned yet. (7) The differential physiological functions of anandamide and 2-AG are not completely understood, although many electrophysiological studies have identified 2-AG as the most likely to act as a retrograde neurotransmitter. (8) Anandamide is promiscuous and able to modulate the activity of

Figure 5 Schematic representation of the biosynthetic pathways leading to 2-arachidonoyl glycerol (2-AG). Membranous arachidonoyl phosphoglycerides serve as precursors to react with the enzymes phosphatidic acid phophohydrolase, phospholipase C (PLC, which can be regulated by G-protein-coupled receptors), and/or phospholipase A_1. 2-AG is then formed by the enzymes diacylglycerol lipase (DAGL) and lyso-PLC. The pathways are redundant, as are the pathways for anandamide synthesis. PLA_1, phospholipase A_1.

several other receptors, in particular vanilloid TRPV1 receptor (anandamide stimulates Ca^{2+} influx, cation current, and depolarization), TASK-1 (anandamide inhibits outward K^+ current), low-voltage-activated T-type Ca^{2+} channels (anandamide blocks Ca^{2+} current), 5-hydroxytryptamine type 3 serotonin receptor (anandamide acts as a negative allosteric modulator), and glycine receptor (anandamide and 2-AG act as inhibitors).

In conclusion, the current level of knowledge about endocannabinoids is not yet comparable with what is known about 'classical' neurotransmitters, and further intensive investigations are necessary to fully illuminate the on-demand biosynthesis of endocannabinoids. This is exemplified by the observation that genetic deletion of the anandamide-synthesizing enzyme NAPE-PLD does not lead to a deficit in either basal or stimulated anandamide levels. Thus, either NAPE-PLD is not the important enzyme, or redundancy and/or efficient compensatory pathways exist to synthesize anandamide.

During past years, several other bioactive lipid mediators have been described which have structural similarities with endocannabinoids and which act, at least in some cases, via cannabinoid receptors CB1 and/or CB2. These compounds include dihomo γ-linolenoyl ethanolamide, docosatetraenoyl ethanolamide, *N*-arachidonoyl serine, and oleamide. Specific pharmacological effects *in vivo* have been described for some of them, but for many of these compounds, endogenous functions remain to be deciphered, and possible corresponding high-affinity receptors have yet to be identified. Therefore, the term endocannabinoid may not be correct in a strict sense, but it is important to note that the prototypical structures of anandamide and 2-AG have initiated the discovery of novel endogenous compounds that may be components of yet-to-be-discovered signaling systems in the body. This is exemplified by recent observations that GPR55, a G-protein-coupled receptor, may be considered a novel 'cannabinoid' receptor. Recent data indicate that endogenous peptides could also modulate the activity of cannabinoid receptors, thus opening new perspectives in the field of the endocannabinoid system.

Distribution of the Endocannabinoid System in the Nervous System

In the adult nervous system of rodents and humans, CB1 receptors are abundantly and widely expressed in neurons of numerous brain areas, in the spinal cord, and in peripheral neurons such as dorsal root ganglia and enteric nervous system. The various expression sites in the brain correspond very well with

the different physiological functions of the endocannabinoid system, including, to mention only a few, in hippocampus, cerebral cortex, and amygdala for memory processing; in striatum for motor activity; in the nucleus accumbens, cerebral cortex, and ventral tegmental area for reward processing; and in hypothalamus for the regulation of the neuroendocrine axis, feeding behavior, and energy balance. CB1 receptors are also expressed in glial cells, such as astrocytes and microglial cells. The latter expression sites have not been implicated to date in the regulation of synaptic transmission, but they are likely involved in CB1 receptor-mediated neuroprotection and repair mechanisms. CB1 receptors are also highly expressed in the developing nervous system of the embryo, where they are particularly highly present in proliferating neuronal precursor cells. Matching this embryonic expression, CB1 receptors are also described in neuronal precursors in the dentate gyrus and subventricular zone of the adult brain, promote the proliferation of these neuronal precursor cells, and endorse the switch of these newly born cells toward a glial fate, as shown in the dentate gyrus.

In neurons of the adult brain, functional CB1 receptors are shown to be localized predominantly at presynaptic sites and, as recently shown for particular cortical γ-aminobutyricacidergic (GABAergic) neurons, on the soma. Some CB1 receptor protein can also be detected intracellularly in the cytoplasma of the soma and in axonal projection, but the functional significance of these expression sites is still a matter of investigation, and the possibility exists that these CB1 receptors are merely proteins that have been newly synthesized and transported to their final sites of action.

CB1 receptors present at the presynapse mediate the endocannabinoid-mediated retrograde suppression of neurotransmitter release, while their expression at the soma is likely responsible for an autocrine endocannabinoid-mediated self-inhibition of neuronal activity. These features will be discussed later as they represent remarkable mechanisms for the short- and long-term modulation of excitatory and inhibitory transmission in the nervous system and in synaptic plasticity, with profound implications for the quest to understand how phenomena such as memory processing function.

The complexity of CB1 receptor expression is further enhanced by the fact that CB1 receptors and other components of the endocannabinoid system are found in diverse neuronal subpopulations. CB1 receptor messenger RNA (mRNA) and protein are highly abundant in GABAergic interneurons (in particular, in cholecystokinin-containing GABAergic interneurons). The expression levels in GABAergic neurons may be counted at the highest levels known for any receptor in the brain. This feature contrasts very much with the expression in cortical glutamatergic neurons. Here, the expression levels of both mRNA and protein may be estimated to be as much as 50–100 times lower than in GABAergic neurons (**Figure 6**). It is, however, remarkable that CB1 receptor expression at these low levels in glutamatergic neurons is necessary and sufficient to mediate several functions, such as protection from abnormal neuronal activities and some of the central effects of Δ^9-THC.

All other components of the endocannabinoid system also show a differential distribution. For the two major endocannabinoids, anandamide and 2-AG, levels differ depending on brain area and the diurnal cycle, but they can also grossly change in response to physiological stimuli or during pathological conditions of the brain. To terminate the signaling, the enzymes for the degradation of endocannabinoids, fatty acid amide hydrolase (FAAH, degrading anandamide) and monoacylglycerol lipase (MAGL, degrading 2-AG), are also present in the brain. It is interesting that both enzymes exhibit differential expression patterns in cortical areas, in particular in the hippocampal formation. FAAH is present in pyramidal neurons of CA1 and CA3 and in granule cells of the dentate gyrus, but not in GABAergic interneurons. MAGL is expressed similarly to CB1 receptor, present both in GABAergic interneurons and pyramidal neurons. Remarkably, FAAH is expressed specifically at the postsynapse, while MAGL is present in the presynaptic terminal. The differential distribution of FAAH and MAGL might underlie the different functions of the two major endocannabinoids, anandamide and 2-AG, in neurons. The regional distribution of the putative enzymes for the biosynthesis of endocannabinoids has not been studied in detail yet.

Cannabinoids and the Suppression of Neurotransmitter Release

Exogenously applied cannabinoids were shown to suppress GABAergic transmission in several brain regions, including hippocampus, amygdala, striatum, nucleus accumbens, and substantia nigra. These effects were inhibited by specific CB1 receptor antagonists (e.g., SR141716, also called rimonabant) and were absent in slices derived from CB1 receptor-deficient mice. Similar results were obtained for glutamate transmission. Furthermore, cannabinoids were also shown to inhibit the evoked release of other neurotransmitters, such as noradrenalin and acetylcholine in the hippocampus, dopamine in the striatum, and serotonin in the cerebral cortex. An understanding of the underlying mechanisms has been advanced by insights into the biochemistry and neuroanatomy of

Figure 6 Distribution of messenger RNA (mRNA) encoding CB1 receptor visualized by *in situ* hybridization. (a) View of the hippocampal formation of an adult mouse brain. Brown-colored precipitation, CB1 receptor mRNA; blue staining, cell nuclei. Note the very high expression in scattered neurons (GABAergic interneurons, black arrow) and the low but distinct expression in pyramidal cells (glutamatergic neurons, white arrow). (b) Co-expression (black arrow) of CB1 receptor mRNA (red staining) with the GABAergic marker γ-aminobutyric acid decarboxylase (GAD; silver grains). the endocannabinoid system. The principal mechanisms by which the endocannabinoid system can modulate synaptic transmission are depicted in Figure 7. Several specific modulatory mechanisms of synaptic transmission and the involvement of the endocannabinoid system in short- and long-term synaptic plasticity are discussed briefly in the following sections. This field of study is expanding rapidly.

Endocannabinoids and Short-Term Synaptic Plasticity

When a neuron is activated postsynaptically, it produces endocannabinoids, which travel in a retrograde direction to the presynaptic site and transiently (<1 min) suppress presynaptic neurotransmitter release. The phenomenon of short-term depression (STD) was first observed about 15 years ago, when a brief depolarization of hippocampal principal neurons was shown to trigger a transient suppression of GABAergic synaptic input. This was named depolarization-induced suppression of inhibition (DSI). Critical features of DSI were defined as follows: (1) DSI induction requires an increase in postsynaptic Ca^{2+}. (2) DSI has a presynaptic location of expression. (3) Therefore, a retrograde messenger must exist mediating the inhibition of neurotransmitter release. The molecular nature of such a retrograde messenger has remained elusive for a long time. However, in 2001, endocannabinoids, which are stimulated by Ca^{2+} and act at presynaptic CB1 receptors, were discovered to be the postulated retrograde transmitter (Figure 8). Several areas besides the hippocampus were found to express DSI, including substantia nigra, dentate gyrus, and cerebellum. In addition, this phenomenon has been observed for glutamatergic transmission, is called depolarization-induced suppression of excitation (DSE), and is found in areas, including hippocampus, cerebral cortex, hypothalamus, ventral tegmental area, and cerebellum.

Figure 7 Representation of the synthesis, signaling, and degradation of endocannabinoids at the synaptic site. Key steps and mechanisms are depicted. In the postsynapse, Ca^{2+} and G-protein-coupled receptor-induced activation of G_q protein can initiate the synthesis of endocannabinoid (EC), which reaches the synaptic cleft by facilitated diffusion through the EC membrane transporter (EMT). Cannabinoid type 1 receptor (CB1) is localized at the presynaptic site, where it is activated by EC and then reduces Ca^{2+}-induced release of neurotransmitter. AEA, anandamide; 2-AG, 2-arachidonoyl glycerol; DAGL, diacylglycerol lipase; FAAH, fatty acid amide hydrolase; MAGL, monoacylglycerol lipase; mGluR, metabotropic glutamate receptor; M1/M3, muscarinic acetylcholine receptor types M1 and M3; NAPE-PLD, *N*-acyl phosphatidyl ethanolamine phospholipase D; NArPE, *N*-arachidonoyl phosphatidyl ethanolamine; PLCβ, phospholipase Cβ.

Clearly, the number of different brain areas with proven CB1 receptor-dependent DSI/DSE expression will grow even further in the near future.

Synthesis and release of endocannabinoids is a complex process. For the initiation of endocannabinoid production, two pathways have been described in the hippocampus. (1) Postsynaptic increase of Ca^{2+} is necessary and sufficient to trigger endocannabinoid production. (2) Activation of postsynaptic metabotropic glutamtate receptors (mGluRs) or muscarinic acetylcholine receptors with exogenous agonists is also sufficient to trigger endocannabinoid release. It is interesting that metabotropic induction of DSI does not require a large increase in Ca^{2+}. It is suggested that the metabotropic pathway triggers endocannabinoid production by PLCβ and that PLC activity is facilitated by increases in Ca^{2+}. In this model, PLC acts as a coincidence detector, integrating two different postsynaptic processes: metabotropic receptor activation and Ca^{2+} increase. Two contributions for the intracellular Ca^{2+} increase are described: Influx through voltage-gated Ca^{2+} channels, and release from intracellular Ca^{2+} stores via ryanodine-sensitive receptors.

After their synthesis, endocannabinoids travel to the presynapse. This process is not understood at all. It is not clear how highly lipophilic molecules such as

Figure 8 Schematic summary of endocannabinoid-mediated short-term plasticity, called depolarization-induced suppression of excitation (DSE; depicted on the left side) and depolarization-induced suppression of inhibition (DSI; depicted on the right side). Two events can induce endocannabinoid production. (1) Postsynaptic step depolarization (experimentally by a shift from −60 mV to 0 mV) or action potential at the postsynapse induces Ca^{2+} influx via voltage-gated calcium channels. Ca^{2+} influx may be amplified by enhancement of Ca^{2+} release from intracellular stores via ryanodine receptors. (2) Brief tetanic stimulation of excitatory afferents or group I metabotropic glutamate receptor (mGluR) activation by agonists can initiate endocannabinoid synthesis. Alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPAR) activation may also contribute to this induction process. Phospholipase C (PLC) and diacylglycerol lipase (DAGL) are required for mGluR-mediated processes, indicating 2-arachidonoyl glycerol (2-AG) as an important candidate for this pathway; 2-AG will activate presynaptic cannabinoid type 1 (CB1) receptors, leading to a short depression of neurotransmitter release (<1 min). Depending on the synaptic input that is measured, either DSI or DSE will be observed. DAG, diacyl glycerol; GABA, γ-aminobutyric acid.

endocannabinoids are able to diffuse so rapidly across the synaptic cleft. Binding proteins may help to increase the solubility in the hydrophilic environment of the synaptic cleft.

In the cholecystokinin-expressing GABAergic interneurons of the hippocampus, the CB1 receptor-dependent effects at the presynaptic site are mediated mainly by an inhibition of N-type Ca^{2+} channels by a direct interaction with the CB1 receptor-induced liberation of $G_{i/o}$ $\beta\gamma$ subunits, but a direct effect on the vesicle release machinery , and/or K^+ channel activation also have to be considered.

In synapses of hippocampal GABAergic interneurons onto principal neurons, the time-to-onset of inhibitory postsynaptic current in the voltage step protocol (−60 mV to 0 mV in a particular frequency) to induce DSI was determined to be about 410 ms. In experiments using caged anandamide that can be photoactivated to exert its action, the times for three steps were determined: Time for the Ca^{2+} induction was 60 ms, time for endocannabinoid synthesis, 190 ms, and time to activate CB1 receptors, 160 ms. When mGluRs were activated to induce DSI, time for endocannabinoid synthesis was reduced to 75 ms. These observations suggest that different pathways can lead to the on-demand synthesis of endocannabinoids and that the time to activate CB1 receptors is an important rate-limiting step.

The detailed mechanisms for post- and presynaptic events can vary in different brain regions, as shown for the cerebellum in particular. There are also indications that, depending on the stimulus, variations between one synapse and another within a distinct brain region exist. These features thus provide a high level of complexity to endocannabinoid-mediated modulation of synaptic plasticity.

Endocannabinoids and Long-Term Plasticity

CB1 receptor-mediated processes also have a long-term impact on synaptic transmission. Long-term depression (LTD) of synaptic transmission can occur via a presynaptic CB1-dependent mechanism. Once established, LTD does not require continuous CB1 activation. The postsynaptic trigger is similar to the one inducing short-term depression, usually Ca^{2+} increase and/or activation of mGluRs. As compared with the 'common' LTD forms on excitatory synapses, endocannabinoid-mediated LTD is independent of postsynaptic glutamate receptors of the *N*-methyl-D-aspartate (NMDA) type. The wide occurrence of endocannabinoid-mediated LTD in the brain indicates that the endocannabinoid system is able to make long-term modifications to neural circuits and behaviors such as learning and memory.

Homosynaptic LTD on Excitatory Synaptic Input

Homosynaptic LTD on excitatory synaptic input was first discovered in corticostriatal and corticoaccumbal projections. For example, at glutamatergic cortical inputs of dorsal striatal GABAergic medium spiny neurons, high-frequency stimulation of this synapse (100-Hz trains) induces a form of LTD shown to depend on the activation of CB1 receptors. This process follows a scheme similar to the one described for DSI (Figure 8) and presents the following hallmarks: (1) requirement of postsynaptic intracellular Ca^{2+} increase; (2) postsynaptic loading with anandamide-suppressed synaptic transmission via a presynaptic mechanism, which is CB1 receptor dependent and which suggests that anandamide can travel from the post- to the presynaptic site; and (3) dependence on a convergence of several input signals, including group I mGluRs, D2 dopamine receptors, and L-type Ca^{2+} channels.

The dorsal striatum and nucleus accumbens are relevant for a variety of goal-oriented behaviors, dorsal striatum for motor planning and reward-driven motor learning and nucleus accumbens in processing of rewarding environmental stimuli and in drug addiction. Therefore, the involvement of endocannabinoids on this LTD is very relevant to understanding several motor- and reward-related behaviors.

Heterosynaptic LTD on Inhibitory Synaptic Input

This form of CB1-dependent synaptic plasticity was first discovered in amygdala (called LTD_i) and hippocampus (called I-LTD), two brain areas critically involved in emotional and declarative memory. They are heterosynaptic forms of plasticity, induced by repetitive activity of excitatory synaptic inputs onto glutamatergic neurons, resulting in LTD of nearby inhibitory synapses of CB1 receptor- and cholecystokinin-expressing GABAergic interneurons and thus generating a long-term decrease in GABA release (Figure 9). As GABAergic inputs regulate the balance between excitatory and inhibitory drive in the neural network, this durable disinhibition may have long-term effects on excitability and on the synaptic plasticity of excitatory synapses, finally facilitating the formation of new memories by use-dependent processes. However, similar to the continuing discussion of whether and in which manner long-term potentiation (LTP) on excitatory synapses is an electrophysiological correlate of memory processing, it is likely to be very difficult to establish a functional link between heterosynaptic endocannabinoid-dependent LTD and memory processing and behavior.

In contrast to DSI and homosynaptic LTD, heterosynaptic LTD does not require postsynaptic Ca^{2+} increase, but activation of group I mGluRs is both necessary and sufficient for the induction of LTD_i/I-LTD. However, there are distinct differences between LTD_i and I-LTD. In the hippocampus, I-LTD is induced by moderate- to high-frequency stimulation (10–100 Hz) and by theta-burst stimulation. PLC and diacylglycerol lipase are involved in generating 2-AG, as postsynaptic inhibition of these enzymes inhibited I-LTD. In the amygdala, LTD_i is induced by low-frequency stimulation (1 Hz, 100 stimuli), and inhibitors of adenylate cyclase and PKA, but not of PLC and diacylglycerol lipase, did affect the induction of LTD_i. It is suggested that a particular isoform of mGluRs may be linked to the adenylate cyclase-PKA pathway, which then activates *N*-acyltransferase, the first step in the synthesis of anandamide. Genetic inactivation of the anandamide-degrading enzyme FAAH facilitates the formation of LTD_i, further suggesting a role of anandamide but not 2-AG in this process. However, more experiments will be necessary to fully reveal this cAMP-regulated pathway of endocannabinoid production.

Time-Dependent LTD

This form of plasticity of glutamatergic transmission has been observed in pyramidal neurons in layer V of the visual cortex. Here, LTD on glutamatergic synapses is triggered by pairing of presynaptic stimulations with postsynaptic depolarizations or action potentials. The time schedule of the pairing of the stimuli is important for LTD formation; thus, it is also called timing-dependent LTD. Increases of postsynaptic Ca^{2+} lead to the production of endocannabinoids, which then inhibit glutamate release from the presynapse. Presynaptic, but not postsynaptic,

Figure 9 Heterosynaptic endocannabinoid-mediated long-term depression (LTD) of inhibitory current. (a) Gamma-aminobutyricacidergic (GABAergic) input onto a principal glutamatergic neuron is activated and γ-aminobutyric acid (GABA) is released. (b) In heterosynaptic LTD of GABAergic transmission, a coincident stimulation of an excitatory input onto the same principal glutamatergic neuron provokes the synthesis of endocannabinoids at the postsynaptic site. Cannabinoid type 1 (CB1) receptor-expressing GABAergic terminals receive the endocannabinoid signaling and reduce GABA transmission. This effect persists as long as 30 min. Metabotropic glutamate receptor (mGluR) activation is necessary and sufficient to induce LTD. The induction of endocannabinoid synthesis may differ in hippocampus and amygdala. First, while medium- to high-frequency stimulation is required for hippocampal I-LTD, only low-frequency stimulation induces LTD_i in amygdala. Second, hippocampal I-LTD requires phospholipase C (PLC) and diacylglycerol lipase (DAGL) activity and involves 2-arachidonoyl glycerol (2-AG), while LTD_i involves cyclic adenosine monophosphate (cAMP) pathway to generate presumably anandamide (AEA). AC, adenylate cyclase; DAG, diacylglycerol; Glu, glutamate; NAT, *N*-acyltransferase; PKA, protein kinase A.

glutamate receptors of the NMDA type are required for this process, representing a coincident signal paired with the postsynaptic endocannabinoid signal reaching the presynapse via the CB1 receptor. This mechanism is very interesting with respect to memory processing as the timing of neuronal activities induced by distinct behaviors may certainly be highly relevant and may ultimately influence synaptic strength and memory formation.

Long-Lasting Self-Inhibition

While in DSI/DSE and endocannabinoid-dependent LTD, retrograde signaling from the post- to the presynapse occurs, an autocrine mechanism has recently been described in low-threshold-spiking (LTS) neocortical GABAergic interneurons (Figure 10). This function occurs after sustained firing of the interneuron. Intracellular Ca^{2+} rises after opening of voltage-gated Ca^{2+} channels in the somatodendritic compartment, and 2-AG is synthesized from membranous precursors. Then 2-AG most likely travels laterally within the membrane and activates CB1 receptors, leading to a $G_{i/o}$-dependent inhibition of K^+ channels and a subsequent hyperpolarization of LTS GABAergic interneurons, which lasts at least 30 min. As GABAergic interneurons are centrally involved in oscillatory processes in neural networks, this endocannabinoid-mediated modulation of synaptic transmission may also be relevant for memory processing.

Figure 10 Mechanism of endocannabinoid-mediated slow self-inhibition. Depolarization of distinct neocortical γ-aminobutyricacidergic interneurons (so-called low-threshold spiking interneurons, which also express cholecystokinin) opens somatodendritic Ca^{2+} channels and induces the synthesis of 2-arachidonoyl glycerol (2-AG), which binds to cannabinoid type 1 (CB1) receptors present on the same neurons. CB1 receptor activation inhibits inwardly rectifying K^+ channels, finally leading to a hyperpolarization of the neuron.

Endocannabinoids and Memory Processing

The quest to understand the roles of the endocannabinoid system is impelled by the well-known observation that exogenous cannabinoids (e.g., from smoking marijuana) impair certain forms of memory. However, application of exogenous cannabinoids to animal models and subsequent behavioral analysis have not been particularly successful in elucidating this process of impairment. An important reason is that the endocannabinoid system is activated on demand, whereas exogenous application of agonists lacks temporal and spatial selectivity. As discussed earlier, the endocannabinoid system is involved in many different forms of modulation of synaptic transmission. These modulations can be either of short duration or long-lasting and represent important mechanisms of synaptic plasticity. Short-term and long-term suppression of both glutamate and GABA transmission is a major effect, but the endocannabinoid system is also able to influence LTP at excitatory synapses, an electrophysiological phenomenon hotly discussed in memory research. In hippocampal slices, an induction of DSI with subsequent subthreshold high-frequency stimulation (which would normally not induce LTP) enables the formation of LTP. Thus, DSI transiently reduces the inhibitory drive in the system and makes synapses more excitable and can thereby strengthen synaptic connections. Thus, the endocannabinoid system provides multiple possibilities for influencing memory processing.

To produce results that enable one to draw solid conclusions about the role of the endocannabinoid system in memory processing, the most powerful approach has been the application of specific CB1 receptor antagonists to animals, in particular to rodents, and the use of mice deficient in CB1 receptor. In several behavioral paradigms, distinct phenotypes have been observed.

Fear Conditioning

In this behavioral test, the mouse hears a loud but *per se* harmless tone. Then, the tone co-terminates with a mild electric foot shock. The animal will form an association of the tone and the context (the conditioning chamber) with the electric shock. In subsequent exposures to the tone or the context, the mouse will show a fear reaction (e.g., freezing, an innate defense response in rodents) as a harmful shock is expected. If the shock does not occur anymore, the mouse will gradually start to decrease the freezing reaction, a phenomenon called extinction. It has been shown that the endocannabinoid system is required for the appropriate extinction of both tone freezing and contextual freezing. It is noteworthy that acquisition and consolidation are the same in wild-type and CB1 receptor-deficient mice. As fear conditioning depends on the amygdala, electrophysiological properties have been characterized. CB1 receptor-deficient mice show increased LTP, normal LTD, and abolished LTD_i. How these changes can be understood in relation to impaired extinction remains to be elucidated.

Morris Water Maze

This assay investigates learning abilities in a spatial memory task. Mice have to learn the location of an invisible escape platform in a small water tank by using contextual cues to orientate themselves in the space. Efficiency and accuracy in learning this location do not depend on the endocannabinoid system, but in the reversal test, when the position of the platform is transferred into the opposite quadrant of the tank, CB1 receptor-deficient mice have shown impaired ability to find the new position and keep on searching in the original position much longer than control mice do. This behavior can be interpreted as impaired extinction of the previously acquired memory trace and impaired flexibility toward a new environment. Thus, the phenotype is similar to the one observed for fear conditioning. A possible interpretation is that the Morris water maze represents a strong aversive event for mice, and thus systems similar to those for fear conditioning may be required in a CB1 receptor-dependent manner.

Object Recognition and Social Recognition

In this assay, rodents have to learn whether a new object or another rodent can be classified as familiar or unfamiliar. Normal animals spend more time with unfamiliar than with familiar objects or animals. CB1 receptor antagonist-treated rodents and CB1 receptor-deficient mice show an enhanced ability to prefer novel objects and animals, at least when mice are young and middle-aged. This means that the endocannabinoid system acts to inhibit the formation and stability of memory traces in this period of age. In old animals, however, CB1 receptor-deficient mice are inferior to wild-type mice and show neurodegeneration in the hippocampus. This may be due to the observation that the endocannabinoid system has important functions in the regulation of stress responses, mediated by the hypothalamic–pituitary–adrenal axis. Lifelong absence of CB1 receptors may

cause sustained increases of corticosterone, leading finally to neurodegenerative effects in the hippocampus. Regarding electrophysiological properties, it is interesting that LTP is enhanced in CB1 receptor-deficient mice compared with wild-type controls, as analyzed in young and middle-aged animals.

Appetitively Motivated Learning Task

In this task, in order to obtain a food reward, mice have to learn to poke a hole at the location where a light appears. After learning, mice are tested after 1 week to evaluate memory consolidation. After this, extinction is induced by omitting the food reward when they poke the correct hole. Neither the learning phase nor consolidation nor extinction depends on the endocannabinoid system in this task. Thus, if there is no aversive component, the endocannabinoid does not seem to be involved in extinction processes.

Conclusion

During the past few years, the endocannabinoid system has emerged as an important modulator of synaptic plasticity. Both short-term and long-term effects on synaptic strength and efficacy have been reported at GABAergic and glutamatergic synapses. Numerous brain circuits are modulated by endocannabinoids. The effects are mediated either by presynaptically expressed CB1 receptors and retrograde endocannabinoid transmission or by autocrine mechanisms.

The endocannabinoid system is involved in several memory systems, particularly in the extinction of emotional memories and the acquisition of object and social recognition memory. However, further investigation is needed to bridge the gap between the functions of this neuromodulatory system in electrophysiological processes *in vitro* and the behavior of the intact organism.

Endocrine Function During Sleep and Sleep Deprivation

J M Mullington, Harvard Medical School, Boston, MA, USA

Overview

Frequently measured hormonal profiles in healthy volunteers have included the chronobiological pineal hormone melatonin; hypothalamic anterior pituitary hormones, including cortisol, growth hormone (GH), prolactin, and thyroid-stimulating hormone (TSH); and more recently metabolic hormones related to nutrient homeostasis, leptin and ghrelin. The diurnal patterns of some important and frequently measured hypothalamic anterior pituitary hormones along with the rhythm of core body (rectal) temperature and a hypnogram of a typical normal sleep period are presented Figure 1.

Melatonin: The Chronobiological Pineal Hormone

Melatonin, the hormonal timekeeper, is produced by pinealocytes in the pineal gland. The pineal is situated in the depression between the colliculi of the midbrain on the dorsal aspect, projecting into the subarachnoid, outside the blood–brain barrier. It receives a large blood supply originating from the posterior cerebral artery and eventually drains into the internal cerebral veins, which flow in turn into the great cerebral vein. The human retinal ganglion cells make bilateral monosynaptic connection with the superchiasmatic nucleus of the anterior hypothalamic nucleus via the retinohypothalamic tract. These fibers continue and synapse at the paraventricular nucleus of the hypothalamus, project through the medial forebrain bundle, and synapse at the intermediolateral cell column of the spinal cord. This fiber tract then synapses on preganglionic cells that synapse at the superior cervical ganglion.

In humans, light inhibits melatonin secretion during the day. Melatonin is a strongly circadian (from the Latin phrase *circa diem,* meaning about a day) hormone that increases regularly at the dim light-onset time of day, peaking during the nocturnal sleep period, and diminishing again with the onset of bright light. In humans, melatonin increases at night independently of sleep and is inversely related to the rectal temperature rhythm. During early sleep deprivation studies, it was thought that at night light could not suppress melatonin in humans, but this was shown to be dependent on the light level. Later studies that applied bright light (>2000 lux) when melatonin levels were high during the sleep period were able to reduce melatonin to daytime or near-daytime levels, although they returned to presuppression levels within 40 min after resumption of darkness. Studies that followed found that the application of light is more or less effective at delaying or advancing the onset of melatonin, depending on the biological time (or circadian phase) at which it is applied. Bright light applied late in the day delays the melatonin onset, and light applied early in the morning advances it. Although studies have not shown melatonin to have clinically significant hypnotic qualities, the presence of melatonin may facilitate the coordination of sleep-onset processes.

Studies of the responsiveness of the melatonin rhythm to different intensities, spectrums, and timing of light administration have laid the foundation for therapeutic approaches to the treatment of jet lag, chronobiologically related mood disorder (seasonal affective disorder), and sleep disorders such as delayed sleep-phase syndrome, in which individuals are unable to keep a consistent sleep-onset time and instead go to bed later and later each night.

Key Hormones of the Anterior Pituitary

Anterior pituitary hormones are released in a pulsatile fashion and vary in peripheral concentration throughout the day. The determining factors are in part circadian (sleep-independent biological rhythms) and in part related to sleep and other behavioral processes. Cortisol and TSH are more strongly circadian in their diurnal secretion profiles and maintain their diurnal rhythms in the absence of sleep. GH and prolactin are more sleep-dependent and are generally suppressed in the absence of sleep, and they move with the shift of the sleep period in experimental studies of the effects of shifting sleep opportunity. As can be seen in Figure 1(a), cortisol reaches its normal daily low point, or nadir, in the nocturnal sleep period, typically an hour or two after sleep onset, corresponding to the time of maximal nocturnal GH release. Cortisol increases in the early hours of the morning, peaking shortly after the time of rising.

The paraventricular nucleus of the hypothalamus synthesizes and releases corticotropin-releasing hormone (CRH), which in turn regulates the release of adrenocorticotropin (ACTH) in the anterior pituitary, leading to the production and secretion of cortisol by

Figure 1 Data from 40 healthy men and women ages 21–40 combined in smoothed tracings: (a) diurnal hormonal profiles for cortisol (based on hourly samples) and for growth hormone (GH) and prolactin (based on half-hourly samples) through the night; (b) normal diurnal rhythm of thyroid-stimulating hormone (TSH), thyroxine (T_4), and triiodothyronine (T_3); (c) normal diurnal rhythm of temperature. The inset in (c) shows a representative sleep hypnogram from one of the subjects in the group of 40, illustrating the descent into slow-wave sleep (SWS) followed by a rapid eye movement (REM) period and subsequent cycling through non-REM and REM periods of sleep for the sleep period. which spans 11 p.m.–7 a.m.

the adrenal cortex. Growth hormone releasing hormone (GHRH) is produced by the arcuate nucleus, which induces the production and release of GH by the anterior pituitary. Somatostatin downregulates the production of GHRH. In addition, insulin-like growth factor (IGF-)I is stimulated by GH. IGF-I indirectly inhibits GH through its stimulation of somatostatin in the hypothalamus.

Cortisol

Cortisol, the most important and abundant glucocorticoid, is essential for proper water, carbohydrate, protein, and fat metabolism, and without this hormone, animals die within a week. In addition to these functions, cortisol is also important for the regulation of vascular reactivity, immune cells and inflammatory mediators, and cellular transcription processes. In addition to having a diurnal rhythm under pleasant relaxed conditions, the hypothalamic anterior pituitary system acts to increase circulating cortisol in response to unpleasant or potentially unpleasant stimuli. Although the reason is not well understood, the ability to withstand noxious stimuli is critically reliant on cortisol. In humans, there is far more cortisol than ACTH measured in the periphery, with a ratio of 7:1. Stimuli which activate ACTH secretion also elevate cortisol, and it is cortisol which is more readily measured in the periphery.

Although ACTH and cortisol are considered to be under strong circadian control, sleep loss and other behaviors do influence portions of the amplitude and shape of the curve. For example, waking causes a surge of ACTH and cortisol. This increase in ACTH is not simply a response to rising, but may also play a role in preparing for rising in that it has been shown that the anticipation of an earlier than normal awakening causes ACTH to rise earlier. Cortisol is also influenced by meals, the first morning exposure to light, stress, and noxious and other stimuli.

During sustained extended wakefulness under controlled laboratory conditions, an increase in the nadir of cortisol during total sleep deprivation has been observed. An afternoon elevation of cortisol has also been described under conditions of sustained reduced sleep. Although the significance of these modifications to the cortisol rhythm under conditions of insufficient sleep is not completely understood, it is known that during aging the nadir of cortisol increases, leading some to consider sleep loss a model of aging.

Cortisol levels are increased in depression and also have been seen to be elevated in individuals suffering from sleep disturbance. Sleep that is disturbed, either by sleep disorders such as sleep apnea or insomnia or disrupted by experimental means that cause fragmentation of the nocturnal sleep period, may lead to blunted GH and an elevated afternoon and early nighttime cortisol secretion.

Growth Hormone

GH is critical for growth and development, in which it is responsible for linear bone formation during early development, as well as growth and maintenance of tissues through ontogeny. During normal sleep, slow-wave sleep is predominant in the first half of the night with the hormonal release of GH at its highest level of the day. In fact, 50–70% of GH is released during the first half of the nocturnal sleep period in men, although the tightness of this association is somewhat lower in men younger than 25 years of age and higher in men older than middle age. Of particular note, the associative relationship between slow-wave sleep and GH release is also lower in women than it is in men.

Prolactin

Prolactin is usually secreted early after sleep onset and continues to rise through the night, peaking around the middle of the sleep period. Similar to GH, prolactin is suppressed during sleep deprivation and shifts with a delayed bed period. Brief awakenings during nocturnal sleep are associated with decreasing prolactin levels.

Rapid eye movement (REM) sleep predominates in the second half of sleep period and is associated with and accompanied by a rise in cortisol. A reciprocal interaction between the CRH and GHRH systems is thought to be important for the regulation of sleep, with the GHRH system promoting sleep and the CRH system stimulating ACTH and cortisol production and promoting arousal and wakefulness. In men, there is a positive relationship between the amount of slow-wave sleep and GH measured through the sleep period. Men with lower cortisol nadirs have been found to have higher amounts of REM sleep.

Thyroid-Stimulating Hormone

TSH is produced by parvocellular neurons in the paraventricular and anterior hypothalamic nuclei. TSH is increased during the nocturnal bed period and the production of thyroxine (T_4) and triiodothyronine (T_3) by the thyroid gland is concomitantly decreased. During acute total sleep deprivation of one night, TSH and free T_3 are increased above sleep control conditions and free T_4 is unchanged. In contrast to the elevation seen during total acute sleep

deprivation, nocturnal TSH has been reported to be reduced in the context of prolonged periods of reduced sleep amount relative to TSH levels seen during extended recovery sleep.

Consolidated nocturnal sleep, initiated at a regular time, when melatonin is rising and ended after the sleep need is satiated, also at a regular time, should facilitate optimal hormonal release and support homeostasis most efficiently. Consistent with this assumption, there is evidence that disruption of sleep, whether due to experimental manipulation or to sleep disorders, leads to nocturnal elevation of cortisol and TSH and a decrease in prolactin; all patterns that are in contrast with the entrained healthy-sleep hormonal profile.

Energy Metabolism and Adipose Tissue Hormones

Because hormonal systems play key roles in the maintenance of energy balance and metabolism and because consolidated sleep is essential for the appropriate timing and secretion amplitude of these hormonal systems, it is perhaps not surprising that sleep itself appears to play a role in metabolism. Under conditions of acute total sleep deprivation and also under conditions of prolonged shortened sleep, glucose metabolism is slowed and young healthy research participants begin to respond in a prediabetic fashion to glucose tolerance testing.

Leptin

Leptin is a hormone produced by adiposites; it signals energy sufficiency and satiety to the brain. It shows a regular diurnal rhythm, reaching maximal levels at night during sleep. Leptin's primary site of action is located in the arcuate nucleus of the hypothalamus. Leptin levels drop during fasting, and it is a hormone known to be important for reproductive capacity. In women, menses ceases when leptin levels drop below normal levels and resume when leptin is supplemented as treatment. Leptin is also integrally involved in energy homeostasis and appetite regulation. Under conditions of total acute and prolonged partial sleep deprivation, leptin amplitude is reduced, with a lowered nocturnal peak.

Ghrelin

Ghrelin is primarily produced by the stomach; it signals hunger to the brain. During reduced sleep, ghrelin levels and appetite are elevated. Insufficient or disrupted sleep leads to a negative energy balance and increased appetite, leading to a higher caloric intake. Furthermore, there is evidence that the food preferences under these conditions favor a high-carbohydrate diet.

Conclusion

The field of sleep and hormonal regulation is a rapidly developing one. New peptides and hormones are currently being discovered that are important for integrating metabolic function. Sleep is critical for the homeostasis of energy systems, and much remains to be learned about the mechanisms involved in translating sleep into health maintenance.

What Is Animal Communication and Why Is It Important to Neuroscientists?

Basics of Communication

This article concerns the hormonal regulation of animal communication. The basics of communicative interactions for the purposes of this article are summarized in Figure 1. In Figure 1(A), the essential components are illustrated as a signal-generating source that sends a signal via a transmission channel. During transmission, there are several possible fates of the signal: It might miss the receiver (a), be blocked somehow while in the transmission channel (b), reach the receiver directly (c), or reach the receiver via an indirect route (d). This theoretical notion is shown with an actual example in Figure 1(B), in which a female deer is illustrated releasing a pheromone that is transmitted via the air to the male.

Significance of Animal Communication for Neuroscientists

The study of animal communication addresses many questions of fundamental importance to the field of neuroscience. Communication signals are often produced by specialized effector organs. This fact gives neuroscientists a clear starting point for neural circuitry studies and therefore facilitates the nearly complete identification of neural circuits that project to these effector organs. In many species, there are also clear co-evolutionary processes between signals and their receiver systems that also facilitate the identification of sensory specializations. Communicative interactions often involve intentional behaviors that are profoundly influenced by social context and experience. This means that systems that mediate communication are linked to forebrain circuits regulating cognitive processing in interesting ways. Communication signals often need to be coordinated with other physiological and behavioral events to function properly. One of the best examples of such coordination concerns courtship signals used in the context of reproduction. Reproduction is generally periodic so that animal populations can adjust breeding to times when conditions are favorable for the successful rearing of progeny. As a result, the timing of signal production and any specialized changes in effector systems needed for proper signal production must be regulated to ensure that they occur at the appropriate time. Reproductive hormones, such as the gonadal sex steroids, orchestrate these diverse events so that they are temporally configured in an appropriate manner. Also, neural systems controlling communication are often regulated by hormones. An important theme of this article is a consideration of the hormonal regulation of communication in the reproductive context.

Hormonal Regulation of Signal Production

To illustrate how hormones can facilitate the production of communication signals, we consider whether gonadal androgens such as testosterone enhance high rates of signaling in the context of courtship and reproduction. A causal relationship between a hormone and a behavior can be established with the use of three criteria: (1) Removal of the source of the hormone (in the case of testosterone, the testis) should lead to a decline in the production of the behavior; (2) reinstatement of plasma concentrations of the hormone via exogenous administration should also reinstate high rates of behavioral production; and (3) behavioral frequency, at least at the population level, should be positively correlated with natural variation in the plasma concentration of the hormone. Avian studies of courtship vocalizations clearly illustrate the value of these criteria. In many temperate zone seasonally breeding songbird species, the rate of male song is positively correlated with the vernal increase in plasma testosterone that is induced in part by increasing photoperiods. As illustrated in Figure 2(a), in Corsican blue tits (*Parus caeruleus*), plasma testosterone concentrations (as determined by serial blood sampling and subsequent measurement via radioimmunoassay) increase dramatically in mid- to late March just prior to an equally dramatic increase in the rate of male song in the sampled population.

Studies that have manipulated the availability of endogenous testosterone by removal of the testis also support its importance in enhancing male vocal production. For example, male Japanese quail (*Coturnix japonica*) produce a species-typical vocalization called the 'crow' when trying to attract females during the breeding season. Castration of captive male quail results in a complete cessation of this behavior (Figure 2(b)). However, replacement of testosterone via the administration of silastic capsules filled with crystalline testosterone can reinstate the behavior. As illustrated in Figure 2(b), groups of castrated male quail were implanted with capsules of increasing length (the

Figure 1 Animal communication, like every form of communication, involves signal generation, transmission, and perception. Transmission can be affected by a variety of factors. (A) Schematic representation of sound transmission from a loudspeaker to an ear. Sound can be lost in space (a), blocked by an obstacle (b), or reach its target directly (c) or indirectly (d). (B) Similarly in animal communication, a female deer in this example emits various olfactory signals originating in several skin glands. Signals will reach the receiver's nose (male deer) after diffusion in the transmission space, eventually affected by environmental factor (wind in this case). Similar concepts apply for olfactory, acoustic, and visual communication.

length of the capsules determines the concentration of testosterone in the plasma, with longer implants leading to higher concentrations of the steroid). The percentage of males in which crowing was restored increased in a dose-dependent manner. This study illustrates another principle of behavioral activation by hormones, namely that there are often individual differences within a study population in the behaviorally effective concentration of a hormone. As illustrated in Figure 2(b), 10-mm-long implants could restore crowing behavior in more than 50% of the castrated males, but to ensure behavioral restoration in the entire sample implants four times longer were required. However, results such as these only explain part of the variance related to the hormonal regulation of behavior. Variation in the target sensitivity to hormone action, in this case the central nervous system, is also important.

In the case of testosterone and male-typical courtship signals, the ability of the target tissue to metabolize testosterone to another hormone is an important factor. It has been recognized since the early 1970s that testosterone is essentially a 'prohormone,' meaning that the form of the hormone released into the blood from the testis is not the same as the form that acts on the target tissue. Testosterone, an androgen, is routinely metabolized both in the brain and in the periphery to either estrogenic or androgenic metabolites. For example, brain aromatase, which is very active in the male brain in many vertebrate species, can convert testosterone to the estrogen 17β-estradiol, whereas the enzyme 5α-reductase can convert testosterone to the potent androgenic metabolite 5α-dihydrotestosterone. Therefore, testosterone effects on the activation of male-typical signaling systems may require its conversation to another androgen, an estrogen, or both. In male zebra finches (*Taeniopygia guttata*), castration reduces the rate of courtship song production, and this is reinstated by both testosterone and another androgen, androstenedione, both of which can be metabolized into androgens and/or estrogens (Figure 2(c)). The administration of androgenic or estrogenic metabolites of testosterone alone is not effective in reinstating high rates of song. However, the combination of androgenic and estrogenic metabolites (i.e., 5α-dihydrotestosterone and 17β-estradiol) is effective in restoring song behavior to a rate similar to that induced by exogenous testosterone in the castrates (Figure 2(c)).

Figure 2 Hormones modulate the rate at which social signals are emitted by animals and this phenomenon has been particularly well documented in birds. (a) The number of songs (curve with standard errors, SEM) emitted by Corsican blue tits detected during systematic field recordings varies markedly during the spring. These behavioral changes are paralleled, actually slightly preceded and thus presumably caused to a large extent, by changes in plasma testosterone concentration (bars). (b) Treatment of castrated male quail with increasing amounts of exogenous testosterone (T) provided by subcutaneous implants of increasing length augments in a dose–response manner the percentage of males that produce crows, a call attracting females in naturalistic conditions. (c) The number of courtship songs produced by sexually mature, gonadally intact (I) male zebra finches exposed to a female is markedly decreased by castration (CX) and restored to nearly intact levels by treatments with exogenous steroids that simultaneously provide androgens and estrogens, such as the aromatizable androgens testosterone (T) and androstenedione (AE) or the combined administration of 5α-dihydrotestoeterone (DHT) and estradiol (E_2). DHT, a nonaromatizable androgen, and E_2 alone have little or no effect.

These studies also illustrate another principle of behavioral endocrinology: Hormones such as testosterone do not cause the activation of a communication signal or any other behavior in a simple stimulus–response relationship. In all these studies, vocal behavior was elicited by the presence of an appropriate conspecific female. The presence or absence of testosterone did not absolutely determine the occurrence of the behavior. In the case of the blue tits in the nonbreeding season and castrated zebra finches, the presence of low testosterone concentrations did not result in a complete decline in song behavior. Rather, the probability and intensity of the vocal response to a female are modulated by the presence of testosterone in high concentrations in the blood.

Hormonal Regulation of Signal Quality

Often, the effectiveness of a signal is not simply the result of whether it is produced at a high rate but also is influenced by aspects of its quality. For example, one of the most important functions of reproductive signals is for conspecifics to recognize that a signaler is a member of a particular species and is of a particular sex. In addition to this fundamental information essential for a successful mate choice, individuals are

sensitive to variation in the signal that seems to predict the mate's quality. Both of these aspects of signal quality can be regulated by hormones. For example, in some electric fish, males produce a markedly lower frequency of electric organ discharges (EODs) than females (Figure 3(a)). The frequency of these EODs can be significantly lowered into the male range by administering to adult females either testosterone or another gonadal androgen quite common in fish, 11-keto-testosterone (Figure 3(a)).

Male canaries (*Serinus canaria*) produce a complex song whose rate of production is enhanced in a seasonal manner by the presence of testosterone. Females also sing, but generally it is a simpler song that is not used in a reproductive context. Males sing at high rates during the breeding season to attract females. Administering testosterone to adult females induces song behavior that is much more male-like than the naturally occurring female song. Playback studies show that one component of male canary song that females find particularly attractive consists of syllables repeated at a very high rate. When females are treated with testosterone, they produce these attractive syllables. Interestingly, this particular component of male song is selectively regulated by estrogenic metabolites of testosterone. When exogenous testosterone is administered simultaneously with an inhibitor of the enzyme aromatase that results in a blockade of the production of estrogenic metabolites, the resulting song is more male-like overall but it lacks the syllables that are particularly attractive to females. Thus, testosterone can do more than just increase the rate of song production; it can also selectively regulate song quality via estrogenic metabolites. These examples of testosterone and male signaling can be generalized to a variety of species and hormone systems.

Effects of Signal Perception on Hormone Release

Another important principle is that there are reciprocal interactions between hormones and signal production. Being on the receiving end of a signal can lead to change in hormone concentrations in the receiver. This change in the receiver's physiology can then affect subsequent and ongoing social interactions. The ability of signals to regulate hormone secretion in the receiver is one criterion for assessing the signal's effectiveness. For example, if a sexual signal from a male or a female fails to induce a hormonal change in the receiver, then the reproductive sequence cannot be successfully completed. Furthermore, producing a signal can change the hormonal state of the sender as well. Thus, studies of the physiological consequences of signal production are not complete unless the effects of the signal on hormonal secretion in both the receiver and the sender are assessed, for example, by measuring physiological responses to signal production.

In Gulf toadfish (*Opsanus beta*), breeding males emit a 'boatwhistle' vocalization in territorial encounters. Playbacks of pure tones that mimicked the duration of the boatwhistle vocalization were able to elicit a behavioral response, whereas a series of other sounds were ineffective. Furthermore, this sound only elicited

Figure 3 Hormones affect the quality of the social signal emitted by animals. (a) Gymnotiform electric fish produce electric organ discharges (EODs) used for sex recognition that display a lower frequency (in Hz) in males compared to females. The lower frequency of these electric signals in males is controlled by androgens, as demonstrated by the fact that a treatment for 1 month of control (Cont) fish (groups of three males and three females in each case) with testosterone (T) or 11-keto-testosterone (11kT), a very active androgen in many fish species, markedly lowers the EOD frequency in a time-dependent manner. (b) In canaries, song quantity and quality are affected by androgens and estrogens. Song is induced in females (who rarely sing) by a treatment with testosterone (T) that provides both androgenic and estrogenic stimulation (through central aromatization of T into estradiol). Concurrent treatment with the aromatase inhibitor fadrozole (Fad) markedly changes the structure and organization of songs produced. The number of tours (syllables) per song is increased but there is a lower proportion of tours with a syllable repetition rate higher than 10 syllables/s. These modified songs produced by T + Fad females are known to be sexually less attractive.

a rapid increase in plasma 11-keto-testosterone concentrations (Figure 4(a)). This rapid increase appears to facilitate responses to territorial challenge that males of this species exhibit during the breeding season. Many species of frogs in the temperate zone exhibit explosive breeding assemblages that are tied to spring rains. Males produce species-typical vocalizations in a chorus that has profound consequences for the endocrine physiology of the participants. Studies of tree frogs (*Hyla cinerea*) reveal that the playback of a chorus of conspecific calls for ten nights to isolated males results in a marked increase in plasma testosterone, whereas in control males the presentation of a tone has no effect (Figure 4(b)). These two studies clearly illustrate how a specialized signal can have an effect on endocrine physiology.

Figure 4 Social signals affect the endocrine physiology of many species in all classes of vertebrates. (a) In Gulf toadfish (*Opsanus beta*), the playback of sounds that closely resemble vocalizations emitted by reproductively active males (tone with a duration of approximately 275 ms) markedly increases plasma concentration of 11-keto-testosterone (11kT), the major androgen in these fishes. Other tones with a similar structure but different duration or other acoustic signals do not have similar effects. (b) Exposure for ten nights of frogs (*Hyla cinerea*) to the chorus of conspecific calls markedly increases plasma testosterone (T) levels in comparison to controls or to frogs exposed to a control sound (tone) that does not share acoustic similarities with the species-typical calls. (c) In ring doves (*Streptopelia risoria*), exposure of an adult male to a sexually receptive female increases plasma levels of androgens (essentially T and DHT) within 24 h. This effect is partly masked if a physical barrier (glass partition) separates the male from the female and is completely absent if the male has been experimentally deafened, which suggests a role for both visual and acoustic stimuli in the control of androgen concentration by stimuli emanating from the female.

Communication can involve signals that are multimodal. Male and female ring doves court each other with displays that involve both visual and auditory components. These courtship signals result in physical contact between the members of the pair when they mutually preen each other and then copulate. Classic studies on captive ring doves (*Streptopelia risoria*) by Daniel Lehrman in the 1960s provided some of the first demonstrations that courtship interactions have marked effects on the endocrine physiology of the receiver of a signal. Subsequent studies by his colleagues were able to tease apart the stimulus factors that are able to elicit these endocrine responses. For example, the presentation of a female to a male that has been maintained in social isolation for several weeks results in a marked increase in his plasma testosterone concentrations that is apparent within 1 day. The ability of a female to stimulate a male is dependent on her endocrine state, which determines whether she will engage in the appropriate reproductive behaviors. This can be easily demonstrated by pairing a male with an ovariectomized female that fails to perform reproductive displays in the presence of a male. There is a significant increase in testosterone even if the male is separated from an intact behaving female via a glass partition, but if the male can see but not hear the female, the androgen rise is greatly attenuated (Figure 4(c)). Thus, experiencing just the appropriate visual and especially auditory stimuli without tactile contact is sufficient to stimulate androgen concentrations in the male in response to a female.

Two additional aspects relevant to our understanding about how the perception of communication signals can regulate endocrine physiology have been clarified by studies of ring doves. For a displaying male to stimulate endocrine activity in female ring doves, it is not enough for the female to see a displaying male: It must be clear that the male is directing his display at the female. If a female sees a displaying male through a one-way glass so that he cannot see her and direct his attention at her, the effect of this experience on her endocrine physiology is significantly reduced compared with that of a female seeing the same male and

that he can see and direct his attention toward. A second phenomenon is that the behavior of the receiver in response to the displaying male can be important in enhancing physiological responses to a sender. Female ring doves that were devocalized and experienced a displaying male exhibited a markedly reduced endocrine response compared with females who could vocalize. Furthermore, this decline in hormonal response could be reversed by playing back the cooing calls that the female usually produces in response to courtship signals from the male.

The previous two studies raise important issues for studies of changes in endocrine physiology in response to a signal. First, the social context and the experience that the receiver has with both the signal and the signaler can have a significant effect on the receiver's endocrine response. Second, the receiver's behavioral response can influence the magnitude of its endocrine response to the receiver's signal.

Neural Mechanisms of Steroid Hormone Action on Signal Production and Perception

General Principles of the Cellular Actions of Steroid Hormones on Behavior

Steroids and other classes of hormones can activate communicatory behaviors by acting on sensory inputs, neural pathways in the central nervous system, and/or peripheral effector organs that produce the signal or behavior of interest. Whether or not any of these different processes will be mediated by hormone action is determined by whether the target tissue expresses the appropriate receptors. Steroid hormones are lipophilic compounds that readily cross the cell membrane and bind to a receptor protein that is a member of the steroid/thyroid receptor family of intracellular receptors. This ligand–receptor complex then acts in the cell nucleus to induce gene transcription, which is necessary for the observed biological responses that are induced by the hormone. The hormone–receptor complex must recruit a number of other proteins in order to induce efficient gene transcription, but a discussion of the molecular basis of hormone-induced gene transcription is beyond the scope of this article.

Receptor proteins can be localized in the brain or in peripheral tissues by chemical neuroanatomical methods, such as autoradiography and immunohistochemistry. An alternative method that is commonly utilized is to localize the mRNA for the receptor gene of interest with *in situ* hybridization histochemistry methods. These methods provide behavioral endocrinologists with useful insight into the localization of hormone action in the brain (Figure 5). These types of studies can be followed up with experimental investigations such as precise stereotaxic implantation of hormones to the potential sites of interest in gonadectomized animals. In this way, the functional significance of the hormone expression can be investigated. The connectivity of hormone-sensitive brain sites of functional significance can then be described so that a neural circuit regulating the behavior of interest can be discerned. In the next section, three such circuits are discussed.

Examples of Neural Circuits Regulating the Activation of Communication Signals That Are Regulated by Steroid Hormones

Three examples of hormone-regulated neural circuits mediating the expression of male-typical vocal signals used in courtship and aggression are illustrated in Figure 5, which diagrammatically illustrates the neural control of vocalization in the midshipman fish, *Porichthys notatus* (a), in the African clawed frog, *Xenopus laevis* (b), and the generalized circuit (c) that seems to apply to all male songbirds (i.e., species in the suborder Passeres of the Passeriformes avian order). Brain areas in the circuit that are 'steroid sensitive' are defined by the stippling pattern. In this case, the term steroid sensitive means that the area expresses either androgen receptors (AR) or one of the two types (α or β) of estrogen receptor (ER). As discussed previously, the activation of many male-typical behaviors by testosterone requires the conversion in the brain of testosterone to an estrogen such as 17β-estradiol or another more potent androgen, such as 5α-dihydrotestosterone. Therefore, AR and both ERα and ERβ are relevant. The localization in the brain of the relevant metabolizing enzymes has been mapped to varying degrees in these three species, but they are omitted in order to minimize the complexity of the figure. It should also be noted that in all these species there is evidence that the relevant effector organ producing the signal (i.e., the larynx in *Xenopus* and the syrinx in the songbirds) is a target of testosterone action because cells in these structures also express AR.

Several generalizations emerge from a comparison of these figures. In all three species, there are midbrain-to-brain stem projections that ultimately synapse on motor neurons that innervate the vocal-producing effector organ (i.e., the torus semicircularis to midbrain vocal acoustic integration center and ultimately to sonic motor nucleus in the midshipman fish; the anterior thalamus ultimately to the motor nucleus of the glossopharyngeal nerve in *Xenopus* and nucleus intercollicularis to the motor nucleus of the hypoglossal nerve, tracheosyringeal part (nXIIts) in the songbirds;

Figure 5 Schematic representation of the neural circuits controlling vocalizations in batrachoidid fishes such as the midshipman fish, *Porichthys notatus* (a), in the African clawed frog *Xenopus laevis* (b), and in songbirds (c). Key parts of the vocal pathways as well as auditory pathways are illustrated. For the auditory pathways, only the last relays that interface with vocal structures are indicated and are labeled 'auditory' in the list of abbreviations. Aspects of the auditory pathways and the vocal pathways were shown to be steroid sensitive (the presence of estrogen and/or androgen receptors) and are represented in the figure by stippled areas. In songbirds, the tentative connections between the medial preoptic nucleus and the song system via the periaqueductal gray are indicated in green. The anterior forebrain pathway mediating song learning is indicated by dashed arrows. (a) AH–PT, anterior hypothalamus–posterior tubercle; CP, central posterior nucleus (auditory); f-, h-, and mVAC, forebrain, hindbrain, and midbrain vocal acoustic integration centers, respectively; PM, pacemaker nucleus; SMn, sonic motor nucleus; TOR, torus semicircularis (auditory); V, ventral telencephalon; VMn, ventral medullary nucleus. (b) APOA, anterior preoptic area; ATH, anterior thalamus (auditory); DTAM, dorsal tegmental area of the medulla; n.IX-X, motor nucleus of the glossopharyngeal nerve; Ri, nucleus reticularis inferior; TOR, torus semicircularis (auditory); VST, ventral striatum. (c) DLM, nucleus dorsolateralis anterior thalami, pars lateralis; HVC, used as proper name (formerly high vocal center); ICo, nucleus intercollicularis; IMAN, lateral nucleus of the anterior nidopallium; MLd, nucleus mesencephalicus lateralis, pars dorsalis (auditory); NCM, caudal medial nidopallium (auditory); NIf, nucleus interfacialis; nXIIts, motor nucleus of the hypoglossal nerve, tracheosyringeal part; Ov, nucleus ovoidalis (auditory); PAG, periaqueductal gray (also called substantia grisea centralis in birds); POM, nucleus preopticus medialis; RA, nucleus robustus of the arcopallium; RAm, nucleus retroambigualis.

Figure 5). In all these cases, both the midbrain and the brain stem nuclei express AR. Thus, in all these examples, neural areas exerting immediate control over the effector organ are potentially regulated by androgens. Another generalization is that these midbrain–brain stem areas in turn receive projections from diencephalic and telencephalic regions that are also steroid sensitive in that they express either AR or ER. There

are interesting taxonomic differences in this case. In songbirds, the telencephalic structure RA (robust nucleus of the arcopallium) expresses AR but sends a direct projection down to the motor nucleus nXIIts that innervates the avian vocal production organ the syrinx. Such a direct projection from the telencephalon to the brain stem is unusual in vertebrates and is not observed in *Xenopus* or the midshipman, in which a multisynaptic pathway links the telencephalon and/or diencephalon with the relevant motor nuclei. In all cases, one can observe links between the preoptic area/hypothalamus and the motor production brain regions. Again, these areas also express either AR or ER of various types. Brain areas such as subregions of the preoptic area and the hypothalamus are important sites for the hormonal activation of reproductive behaviors. They tend to integrate relevant sensory inputs, resulting in an organized motor response. Thus, the connections in all three species between these brain areas and midbrain and brain stem areas involved in signal production are consistent with general views of hormonally regulated neural circuits controlling sexual and parental behaviors.

There is still much to be learned about exactly how steroid hormones act in these target areas to activate communication signals. Although it is known that the steroid–receptor complex regulates gene expression, the field is only beginning to identify the relevant genes. One candidate gene for the control of social signal production codes for the neuropeptide arginine vasopressin (AVP) or, in nonmammalian vertebrates, the homologous neuropeptide arginine vasotocin (AVT). There is evidence in *Xenopus* as well as in Syrian hamsters, in which testosterone induces flank marking used by males as an aggressive signal in a reproductive context, that testosterone upregulates this peptide system and that is a necessary step for signal production. In this case, the evidence is particularly compelling that AVP acting in the anterior hypothalamus can reliably induce high rates of flank marking. In songbirds, testosterone acting via estrogenic and androgenic metabolites induces marked changes in the volume of key forebrain song nuclei so that they are larger in the spring and early summer, when males are producing song in a courtship and/or territorial context, and much smaller in the fall, when song is not produced at all or produced in a different context. Song, unlike the calls produced by the midshipman and frogs, is learned, and it was initially hypothesized that these changes might be related to seasonal variation in song learning. However, not all seasonally breeding songbird species change their repertoire due to song learning, yet the volume of these nuclei does clearly change with season. Therefore, these changes in the volume of the song nuclei seem to be most reliably linked to changes in song performance, such as the quantity or the quality (stereotypy or consistency) of the signal.

The physiological or biochemical cascade of events induced by steroid hormones will almost certainly be different in forebrain areas compared to motor neurons. An important future goal is therefore to identify specific genes regulated by steroids in the different brain areas that make up the communication circuit. In weakly electric fish, the rate and quality of EODs are regulated by steroid hormones, as mentioned previously. In particular, dihydrotestosterone has been shown to slow down while 17β-estradiol speeds up the rate of inactivation of Na^+ currents. This effect seems to result from steroid hormone effects on the expression of genes coding for specific ion channels or on enzymes that could influence the state of the channels such as kinases. Future studies will seek to identify the specific genes regulated by hormones that result in changes in signaling ability.

Hormone Effects on Sensation and Perception

Although most work on hormones and signaling has stressed the production of signals, hormones can also influence communication by tuning the reception of signals. In neotropical electric fish that exhibit wave-like EODs, the electrosensory receptors are precisely tuned to perceive the EOD that an individual fish produces. When exogenous steroid hormones are administered, the EOD changes, as does the tuning of the electroreceptors. This change in tuning is a direct effect of steroids on the tuning properties of electroreceptors. There are other examples of peripheral sensory organs being regulated by hormones. In nonreproductive female midshipman fish, the administration of 17β-estradiol increases the temporal encoding of frequency by the inner ear such that the phase locking matches the frequency of the male call that is produced in the breeding season. Thus, changes in the female's reproductive state mediated by sex steroid hormones result in her matching the tuning of her auditory periphery to the male's call. In one form or another, regulation of auditory tuning may be widespread. There is evidence, for example, that the accuracy in judging octave frequency varies over the menstrual cycle in women, being at the lowest level of accuracy during the midluteal phase and peaking during ovulation when plasma 17β-estradiol is at its highest concentration. Similarly, auditory brain stem responses in birds exhibit a seasonal change in sensitivity that could be related to seasonal changes in tuning to male song. Finally, hormone-induced adjustments in sensory processing in rats have been

observed in the olfactory system with 17β-estradiol enhancing sensory perception of male-typical cues based on recordings in the female preoptic area. There is also evidence that estrogen enhances the size of the genital sensory field in female rats to facilitate tactile stimulation from males that results in female receptive responses.

Overall, there is good evidence that the peripheral tuning of sensory systems relevant to the sensation and perception of specific signals can be adjusted by hormonal fluctuations, although the exact mechanisms are unclear. However, work on estradiol effects on the inner ear of midshipman fish is a promising model system for the investigation of the cellular bases of adjustments in auditory tuning that can result in an organized hormonal response, as previously discussed. The neural pathways by which sensory information is conveyed to the hypothalamic–pituitary–gonadal axis to induce an endocrine change are also not well understood. However, work in frogs and in ring doves has described projections from midbrain and thalamic auditory areas to the preoptic region that may mediate the effects of auditory stimulation on hormonal secretion in these taxa.

Conclusions

In this article, we highlighted studies of hormone, brain, and behavior interrelationships that are relevant to the study of communication. The production of specialized signals for communicatory interactions is controlled by neural circuits that can be regulated by hormones at the level of sensory inputs, central processing, and motor outputs. The perception of signals can in turn result in a marked change in the endocrine physiology of the receiver. We provided examples of all these processes that have been investigated in a variety of vertebrate taxa. One current focus of the field is to identify specific genes regulated by steroids and other hormones that result in defined changes in behavior. Some effects of hormones on signaling systems were not discussed in this article. For example, signaling systems are sex typical in many species, and such sex differences in neural organization result from early ontogenetic effects of steroid hormones. We focused on adult activational effects. Also, there is clear evidence that in addition to the well-characterized genomic effects of steroid hormones on communication circuits, relatively rapid nongenomic effects can also occur. Such rapid effects are undoubtedly important for the regulation of social interactions related to communication, but little is known about them.

Endocytic Traffic in Spines

Mechanisms of Spine Endocytosis

Endocytosis of most plasma membrane proteins is mediated primarily by a mechanism involving clathrin and several clathrin adaptor proteins. Clathrin coats are recruited to the plasma membrane and linked to receptors by adaptor proteins. Most integral plasma membrane proteins, including growth factor receptors and ligand-gated ionotropic neurotransmitter receptors, are recruited to clathrin-coated pits through the adaptor protein AP-2, a heterotetrameric complex containing $\alpha\beta_2\mu_2\sigma_2$ subunits. Most metabotropic G-protein-coupled receptors (GPCRs) employ a family of monomeric adaptor proteins known as β-arrestins. In addition to binding the serine-phosphorylated carboxyl tails of the GPCRs, the β-arrestin C-terminal domains interact with both the clathrin heavy chain and the β2-adaptin subunit of the heterotetrameric AP-2 adaptor complex, thereby targeting the activated receptor to clathrin-coated pits. Binding of adaptor proteins to receptors and to clathrin initiates clathrin coat assembly and membrane invagination, and the vesicles then pinch off via a dynamin guanosine triphosphatase-dependent process. The resultant clathrin-coated vesicle is internalized from the plasma membrane to the intracellular compartment, where it is either recycled to the plasma membrane or delivered to lysosomes for degradation. Recent electron microscopy (EM) of hippocampal neurons has shown that most of the endocytic machinery, including clathrin, AP-2, and dynamin, is expressed within spines, consistent with the ability of a spine to undergo clathrin-dependent endocytosis. Indeed, both EM and light microscope studies have been able to demonstrate coated pits and vesicles within spines. It is interesting that these studies found that the coated vesicles are in close association with, but rarely directly at, the postsynaptic density (PSD), suggesting that just lateral to the PSD exist some 'hot spots' where spine endocytosis may usually take place.

Spine Endocytosis in Controlling the Density of Postsynaptic Glutamate Receptors and Synaptic Plasticity

One general function of clathrin-mediated endocytosis is to regulate the density of plasma membrane proteins via constitutive and/or regulated endocytotic retrieval (recycling) of these proteins into intracellular compartments. Glutamate is the major excitatory neurotransmitter in the mammalian brain and acts primarily on two large families of receptors, the ionotropic and the metabotropic glutamate receptors. Ionotropic glutamate receptors are organized into three main classes: α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, which comprise various combinations of glutamate receptor subunits GluR1–4; kainate receptors, which consist of GluR5–7, KA1, and KA2 subunits; and the *N*-methyl-D-aspartate (NMDA) receptors, which comprise NR1 and NR2A–D subunits. The metabotropic glutamate receptors are a family of GPCRs comprising mGluR1 to mGluR8. Most of these glutamate receptors are expressed in postsynaptic spine membranes, and their density in the membrane is subject to regulation by clathrin-mediated spine endocytosis.

AMPA Receptor Endocytosis and Its Role in Synaptic Plasticity

Among all glutamate receptor subfamilies, the spine endocytosis of the AMPA receptor subtype is, both mechanistically and functionally, the best characterized. Structurally, AMPA receptors are presumed to be heterotetrameric structures assembled by combining homologous subunits. The current topology model suggests that each AMPA receptor subunit (GluR) consists of three transmembrane regions, membrane domain (MD) 1, MD3, and MD4, and a reentrant membrane segment corresponding to MD2. The major intracellular C-terminal region contains potential sites for protein phosphorylation and binding motifs for GluR-interacting proteins, including adaptor proteins involved in forming clathrin-coated endocytic vesicles. Three distinct types of clathrin-dependent AMPA receptor endocytosis have been proposed: constitutive, ligand-induced, and activity-dependent (regulated) endocytosis.

Constitutive endocytosis occurs across all AMPA receptors and requires a motif in the most juxtamembrane region of the C-terminus that is 100% conserved among all AMPA receptor GluR subunits. Interference with the constitutive pathway does not lead to detectable alterations in the number of AMPA receptors on the cell surface, likely because of the existence of a constitutive AMPA receptor exocytosis pathway that balances the constitutive endocytosis.

Like most GPCRs, AMPA receptors also undergo clathrin-dependent ligand-induced endocytosis. Since both agonists and antagonists evoke AMPA receptor endocytosis, this form of endocytosis seems solely dependent on ligand–receptor interactions and does

not require receptor activation. Similar to constitutive AMPA receptor endocytosis, ligand-induced endocytosis applies to all GluR subunits and requires the conserved sequences in the proximal membrane region of the GluR C-terminus. The physiological significance of this receptor endocytosis remains unknown, but analogous to what is observed for GPCRs, it may represent an important feedback mechanism minimizing receptor overactivation under certain physiological and pathological conditions.

Regulated endocytosis is specifically associated with AMPA receptors containing the GluR2 subunit. This GluR2 specificity is mediated by several sequence motifs uniquely present within the C-terminal region of the subunit, including a middle domain that binds to both *N*-ethylmaleimide-sensitive factor and AP-2 clathrin adaptor and a terminal PDZ-binding domain that interacts with a number of PDZ-containing proteins, such as GRIP and PICK1. In addition, systematic mutational analysis has revealed a novel tyrosine phosphorylation-dependent endocytic motif in the GluR2 C-terminus that is absolutely required for regulated AMPA receptor endocytosis. Given the fact that interfering with any of these motifs blocks activity-dependent AMPA receptor endocytosis, all these motifs appear to be functional and may be indispensably involved in regulated AMPA receptor endocytosis in neurons. The mechanisms by which these multiple internalization signals act in concert during various forms of synaptic plasticity remain to be illustrated.

Functionally, unlike constitutive endocytosis, regulated AMPA receptor endocytosis leads to a rapid and persistent reduction in the number of receptors expressed on the postsynaptic membrane surface of the spine and hence plays an important role in controlling synaptic strength. The ability to reduce cell surface AMPA receptors makes regulated endocytosis an ideal candidate mechanism for the expression of certain forms of long-term depression (LTD), one of the best-characterized forms of synaptic plasticity believed to be involved in learning and memory. Consistent with this hypothesis, interfering with these GluR2 C-terminal endocytic motifs by application of short 'interference peptides' comprising the tyrosine-containing motif or AP-2- or PICK1-interacting sequences can prevent the expression of hippocampal CA1 homosynaptic LTD, both in brain slices and in intact, anesthetized rats. Moreover, although the facilitated endocytosis of postsynaptic AMPA receptors is principally observed in conjunction with hippocampal CA1 LTD, it appears to be a common mechanism involved in the expression of certain forms of LTD in many other areas of the brain, including the cerebellum and the nucleus accumbens. These studies have firmly established a critical role for AMPA receptor endocytosis as a common mechanism of LTD expression. The results also suggest that these three GluR2–C-terminal endocytic signals are indispensably involved in regulated AMPA receptor endocytosis and hence LTD expression and that peptides interfering with the function of these signals may be used as specific inhibitors to probe the functional roles of LTD. Indeed, using one of these membrane-permeable interfering peptides, researchers were recently able to provide the first evidence for a causative role of LTD in the expression of behavioral sensitization induced by repeated intermittent administration of drugs of abuse, such as amphetamine, in an animal model of drug addiction. Thus, endocytosis of AMPA receptors in spines may be the principle mechanism of regulating the strength of synaptic transmission and may be critically important to both brain function and dysfunction.

NMDA Receptor Endocytosis

Because of the voltage-dependent blockade by physiological concentrations of extracellular Mg^{2+}, the NMDA subtype of ionotropic glutamate receptors contributes little to basal synaptic transmission. However, because of its high calcium permeability, activation of the receptor is thought to be fundamental to many normal brain functions, such as cognition and memory, and its overactivation is believed to be critically involved in mediating neuronal death during both acute brain injuries and chronic brain degenerative disorders. Therefore, the trafficking of NMDA receptors has recently been the subject of intensive investigation. From what is known so far, the distinctions between constitutive and regulated trafficking seen with AMPA receptors are less obvious with NMDA receptors. However, several mechanisms of clathrin-mediated NMDA receptor endocytosis have been characterized and are presumed to contribute to the maintenance of steady state receptor levels in spine membranes. Native NMDA receptors are tetrameric complexes comprised of NR1 subunits with at least one type of NR2 subunit. Different NR2 subunits (NR2A–D) confer distinct properties during spine endocytosis. At the postsynaptic spine membrane, NMDA receptors are stabilized by interacting with postsynaptic density protein 95 (PSD-95). This interaction is mediated via the PDZ-binding domain present in the C-terminus of either NR2A or NR2B and can result in rapid internalization via clathrin-mediated endocytosis in response to the binding of agonist glutamate or coagonist glycine. The NMDA receptor–PSD-95 interaction and subsequent receptor endocytosis appear to be subject to regulation by receptor phosphorylation, tyrosine phosphorylation in particular. Phosphorylation of the NR2B C-terminus

interferes with its interaction with PSD-95, thereby facilitating clathrin-mediated endocytosis via a mechanism of promoting the binding of AP-2 to NR2B. There is also evidence that dephosphorylation of NR1 and NR2A on tyrosine residues may promote clathrin-dependent endocytosis in a similar manner. Few studies have investigated activity-dependent NMDA receptor endocytosis, but a facilitated clathrin-mediated endocytosis of NMDA receptors has recently been reported to be associated with increased AMPA receptor endocytosis after the induction of CA1 homosynaptic LTD in a hippocampal slice preparation. Detailed understanding of the mechanisms underlying this phenomenon remains to be achieved, but preliminary data suggest a mechanism distinct from that involved in AMPA receptor endocytosis. Thus, there is evidence that the density of postsynaptic NMDA receptors and hence the strength of the receptor-mediated synaptic transmission is also under the regulation of spine endocytosis.

mGluR Endocytosis

The density of postsynaptic mGluRs is also under the control of spine endocytosis. Like most other GPCRs, mGluRs are subject to ligand-induced and clathrin-dependent receptor endocytosis. For instance, agonist application causes rapid internalization of mGluR1 in a β-arrestin- and dynamin-dependent manner. However, emerging evidence suggests that not all GPCRs internalize via a β-arrestin-dependent mechanism. The agonist-independent or constitutive endocytosis of mGluR1 and mGluR5 appears to be dependent on the formation of a multimolecular complex that includes phospholipase D2, Ral, and RalGDS. However, the detailed mechanisms underlying spine endocytosis of mGluRs and their roles in mediating structural and functional synaptic plasticity remain unclear and await further investigation.

Spine Endocytosis in Signal Transduction

Emerging data suggest that in addition to controlling the density of postsynaptic plasma membrane proteins such as neurotransmitter receptors via internalization, spine endocytosis may have an additional function, mediation of intracellular signal transductions ranging from the formation of signaling complexes to synapse–nucleus signal transduction. It is well characterized that in addition to mediating the G-protein-uncoupling and internalization of GPCRs, β-arrestins link GPCRs to G-protein-independent signal transduction pathways. The β-arrestins interact with a wide variety of signaling proteins, including kinases (e.g., Src, Raf-1, JNK, ERK1/2, Akt), phosphatases (PP2A), guanine nucleotide exchange factors (ARNO and RalGDS), and small G-proteins (Arf6 and Rho). The diversity of β-arrestin interacting proteins potentially links β-arrestin function to a wide variety of neuronal phenotypes, such as alterations in the actin cytoskeleton reorganization that are required for neurite outgrowth and gene transcription. With regard to spine endocytosis at excitatory synapses, activation of NMDA receptors can lead to rapid clathrin-mediated endocytosis of AMPA receptors, resulting in LTD, and can also cause excitotoxic neuronal death. It is interesting that blocking the NMDA receptor-mediated clathrin-dependent AMPA receptor endocytosis, while having no effect on NMDA-induced Ca^{2+} responses, prevents both NMDA-induced activation of caspase-3 and neuronal apoptosis in hippocampal neurons maintained in primary culture. The detailed mechanisms by which endocytosed AMPA receptors contribute to the initiation of downstream apoptotic cascades remain to be determined. However, analogous to the recently reported retinal cell apoptosis induced following stimulated endocytosis of rhodopsin and activation of epidermal growth factor receptor-mediated mitogen-activated protein kinase signaling by endocytosed epidermal growth factor receptors, it is possible that endocytosed AMPA receptors, in response to NMDA stimulation, may form, with some of the clathrin-coat protein components, a signaling complex that initiates the apoptotic cascade. These results not only identify AMPA receptor endocytosis as a critical link between NMDA-induced Ca_i^{2+} overload and intracellular cascades leading to apoptosis but also suggest that, in addition to a decrease in receptor-mediated synaptic transmission, spine endocytosed AMPA receptors play previously unsuspected roles in intracellular signaling pathways. The mediation of NMDA-induced apoptosis is one example.

Spine Endocytosis in Structural Plasticity of Excitatory Synapses

Neuronal spines dynamically change their size, shape, and number throughout the life of an animal. Synapse elimination (pruning) is a fundamental process during early development and also an important mechanism for activity-dependent fine-tuning of neuronal networks during learning and memory in the mature brain. In addition, synaptic loss is a common pathological feature of a broad range of psychiatric diseases and neurological disorders. The precise way in which synapse elimination occurs remains a controversial topic, likely involving multiple mechanisms that include synaptic activity, membrane trafficking, and spine cytoskeletal rearrangement. Evidence that spine endocytosis plays a critical role in synapse pruning in

mature neurons has come from two recent studies of hippocampal CA1 LTD in slice preparations. In one, two-photon time-lapse imaging of dendritic spines in acute hippocampal slices from neonatal rats showed that the expression of LTD is accompanied by a marked shrinkage of spines. Since facilitated endocytosis of postsynaptic AMPA receptors is the primary mechanism of LTD expression, the study suggests a potential role of spine endocytosis in spine shrinkage. Indeed, the causative link between the endocytosis of AMPA receptors and spine removal (synapse loss) was established in a second study. The researchers found that amyloid beta (Abeta), a peptide believed to underlie the pathophysiology of Alzheimer's disease, facilitates endocytosis of synaptic AMPA receptors during LTD. This facilitated AMPA receptor endocytosis is both sufficient and necessary for the loss of dendritic spines, thereby indicating the central role played by AMPA receptor trafficking in Abeta-induced modification of synaptic structure and function. Together, these studies demonstrate that spine endocytosis may have a critical role in synapse pruning or elimination, thereby controlling the number of glutamatergic excitatory synapses in both the developing and the mature brain.

Concluding Remarks

Endocytosis is a fundamental cellular process in all eukaryotic cells. In neurons, endocytosis can occur within the spine. Mechanistically, spine endocytosis is likely mediated by both clathrin-dependent and clathrin-independent pathways, but the best-characterized spine endocytic mechanism occurs via clathrin-coated vesicles. Functionally, spine endocytosis allows retrieval of postsynaptic plasma membranes, thereby modifying the size, shape and even number of synapses, and recycling of integral plasma membrane proteins, including neurotransmitter receptors, to control their density (number) at the postsynaptic membrane, thereby regulating the strength of synaptic transmission. Emerging evidence also suggests that endocytosed spine plasma membrane proteins such as AMPA receptors may form part of intracellular signaling complexes that initiate cell signaling processes, introducing a third functionality of spine endocytosis.

Introduction

Neurons communicate with each other by the temporally and spatially controlled release of secretory molecules (the so-called neurotransmitters) via regulated exocytosis. Following diffusion across the synaptic cleft the released nonpeptide neurotransmitters and neuroactive peptides bind to and activate postsynaptic receptors, which then elicit a response within the postsynaptic cell. In the case of most fast-acting transmitters, such as glutamate, γ-aminobutyric acid (GABA), or acetylcholine, signaling is elicited by ligand-gated ion channels, which are clustered at morphologically discernible zones specialized for chemical neurotransmission termed postsynaptic densities (PSDs). The PSD is opposed to a corresponding presynaptic element including the 'active zone' at which presynaptic neurotransmitter-bearing vesicles (SVs) are clustered. Presynaptic active zones are characterized by an electron-dense grid of scaffolding proteins interconnected with an actin-rich cytoskeleton, which among other functions helps to maintain a pool of vesicles docked at the presynaptic plasmalemma. To sustain chemical neurotransmission under conditions of high activity and to counter-balance net insertion of membrane by exocytic vesicle fusion, SVs undergo activity-driven cycles of calcium-triggered exocytosis and endocytosis within nerve terminals, commonly referred to as the SV cycle. Cycling of SVs must allow them to retain their specific biochemical identity, including the ability to store neurotransmitter by proton pump-driven neurotransmitter transporters, and to undergo further rounds of calcium-induced fusion with the presynaptic plasmalemma. The observed tight coupling between exocytic neurotransmitter release by vesicle fusion and compensatory endocytosis has resulted in a long and still unresolved debate regarding the precise molecular mechanisms involved in SV cycling. Here, we provide a brief summary of the pathways of SV cycling, the role of clathrin and its partner proteins in maintaining SV pools, and the temporal and spatial cues provided by scaffolding proteins and membrane lipids in maintaining presynaptic exocytic–endocytic membrane traffic.

Pathways of SV Cycling

Clathrin-Mediated Endocytic Cycling of Presynaptic Vesicles

Landmark studies in the early 1970s by Heuser and Reese showed that following fusion by complete collapse into the plasmalemma, SVs are retrieved by compensatory 'clathrin-dependent endocytosis' at specialized endocytic areas just outside the active zone. An overwhelming amount of genetic, morphological, biochemical, and physiological data suggests that clathrin-mediated endocytosis indeed constitutes an essential pathway of SV recycling, at least on the organismic level and over extended periods of time. Mutants in clathrin coat components, including the AP-2 complex or accessory and adaptor proteins such as dynamin, AP180, stoned B (the *Drosophila* ortholog of mammalian stonins 1 and 2), eps15, synaptojanin, endophilin, amphiphysin, or intersectin/DAP160, all display defects in neurotransmission owing, at least in part, to impaired SV endocytosis (Table 1). The most dramatic phenotypes have been observed following injection of dominant-negative domains or inhibitory peptides into the giant reticulospinal synapse of the lamprey. Following electrical stimulation, distinct endocytic intermediates and vacuolar structures accumulate within and around the active zones in conjunction with a partial or complete depletion of the recycling vesicle pool. Some of these intermediates resemble structures seen in neuromuscular junctions following intense stimulation or after genetic perturbation of protein function in temperature-sensitive alleles. The mechanistic details of this pathway will be discussed later.

Kiss-and-Run Mode

Based on an apparent lack of correlation between the number of morphologically distinct stable endocytic intermediates and the synaptic endocytic activity, Ceccarelli and colleagues proposed an alternative model according to which SVs release their contents through the controlled opening of a narrow fusion pore, followed by rapid closure and refilling with neurotransmitter (Figure 1). This 'kiss-and-run' mode of regulated secretion has been convincingly demonstrated to occur by combined electrophysiological recordings and membrane capacitance measurements in neuroendocrine cells, which mostly secrete peptide hormones or biogenic amines from large secretory granules (SGs; also termed large dense core vesicles (LDCVs)). In the case of SG exocytosis, flickering of

Table 1 Endocytic proteins involved in presynaptic vesicle cycling and their interaction partners

Endocytic protein	*Domains and motifs*	*Interaction partner(s)*	*Proposed function(s)*
Abp1	ADF homology domain	F-actin	Linking actin cytoskeleton with endocytosis and CAZ
	SH3 domain	PRDs of synaptojanin, dynamin, Piccolo, and synapsin1	
AP-2 (α, β2, μ2, σ2 subunits)	Trunk	PI(4,5)P_2	Plasmalemmal recruitment
	α-Appendage	FXDXF/DXW, WVXF motif proteins	Coat assembly
	β2-Appendage	$[DE]_nX_{1-2}$FXX[FL]XXR motif proteins	Cargo selection and coat assembly
	β2-Hinge	Clathrin terminal domain	Scaffolding
	C-μ2	Yxxϕ and basic motif membrane cargo; PI(4,5)P_2	Membrane cargo selection
Amphiphysins	N-BAR domain	(Acidic) phospholipids; dimerization	Membrane curvature induction/sensing; scaffolding
	PWXXW, LLDLD motifs	Clathrin terminal domain	Coat assembly
	FXDXF, DXF motifs	AP-2 via α-appendage	
	SH3 domain	PRDs of dynamin (& synaptojanin)	Vesicle fission
AP180	ANTH domain	PI(4,5)P_2	Plasmalemmal recruitment
	FXDXF, DXF motifs	AP-2 via α-appendage	Coat assembly
	DLL motifs	Clathrin	Scaffolding
Auxilin	DnaJ domain	Hsc70	Stimulation of ATPase
	DPF, WDW motifs	AP-2 via α-appendage	Coated pit recruitment
	WDW, DLL motifs	Clathrin	
Clathrin (HC, LCa/b)	HC-terminal domain	PWXXW, LLDLD, DLL motif proteins	Assembly of scaffold
	LC	HIP1, calmodulin, Hsc70	Diverse
Dynamin 1	GTPase domain	GDP/GTP	Control of membrane fission
	GED domain	Dynamin-GED	Self-assembly; stimulation of GTPase activity
	PH domain	PI(4,5)P_2	Plasmalemmal recruitment
Endophilin	N-BAR domain	(Acidic) phospholipids; dimerization	Membrane curvature induction/sensing
	SH3 domain	PRD of dynamin and synaptojanin	Coated pit maturation; fission and uncoating

Epsins	ENTH domain	$PI(4,5)P_2$	Membrane curvature induction; coat assembly
	DPW motifs	AP-2 via α-appendage	
	LLDLD motifs	Clathrin terminal domain	Scaffolding
	UIMs	Ubiquitin (Ub)	Ub-dependent cargo endoctyosis
Eps15, Eps15R	EH domains	NPF motif proteins	Endocytic protein network formation
	DXF motifs	AP-2 via α-appendage	Coat assembly (edges of CCPs)
	UIMs	Ubiquitin (Ub)	Ub-dependent cargo endoctyosis
HIP1, HIP1R	ANTH domain	$PI(4,5)P_2$	Plasmalemmal recruitment
	FXDXF, DXF motifs	AP-2 via α-appendage	Coat assembly
	LLDLD motif	Clathrin terminal domain	Scaffolding; links actin with endocytosis
Intersectin	EH domains	NPF motif proteins	Endocytic protein network formation
	SH3 domains	PRD domain proteins	CDC42-mediated actin polymerization
	Rho-GEF domain	CDC42	
Numb, Numb-like	PTB	$PI(4,5)P_2$	Plasmalemmal recruitment; coat assembly
	DXF motifs	AP-2 via α-appendage	
PIPK type Iγ	PIP kinase domain	PI(4)P, ATP; Arf6-GTP	Localized $PI(4,5)P_2$ formation; regulation of
	WYSPL tail peptide	FERM domain of talin	$PI(4,5)P_2$ synthesis at cell adhesion sites
Stonin 2	WVXF motifs	AP-2 via α-appendage	Coat assembly; coated pit recruitment
	Stonin-homology domain	?	?
	μ-Homology domain	Synaptotagmin (1,2,9)	AP-2-dependent recycling
Synaptojanin	SAC1 domain	4′-phosphate-containing phosphoinositides	4′-phosphoinositide phosphate hydrolysis
	5′-Phosphatase domain	$PI(4,5)P_2$	$PI(4,5)P_2$ hydrolysis, CCV uncoating coat assembly; coated pit recruitment
	FXDXF, WVXF motifs	AP-2 via α-appendage	
Synaptotagmin	C2A	Ca^{2+}, acidic phospholipids	Ca^{2+}-triggered membrane fusion membrane fusion; SV recycling
	C2B	$PI(4,5)P_2$; AP-2 via subdomain B of μ2	
	C2AB	Stonin 2 via μ-homology domain	SV recycling
Syndapins	BAR	(Acidic) phospholipids; dimerization	Membrane curvature sensing actin and dynamin-mediated fission
	SH3	PRD of N-WASP and dynamin	

Figure 1 Pathways of SV recycling. Schematic depiction of various proposed modes of synaptic vesicle (SV) recycling: a fast 'kiss-and-run' mechanism, where the vesicle connects only briefly to the plasma membrane without full collapse ('kiss-and-run') or a slow clathrin-mediated pathway, which either operates from large vacuolar infoldings (cisternae) or by direct recovery of vesicle membrane from plasmalemmal CCPs ('clathrin-mediated endocytosis'). SVs may also arise from endosomes. Components of the cytomatrix assembled at the active zone (CAZ) together with actin function as molecular scaffolds in the spatial organization of the active zone. The SV cycle is paralleled by a cycle of phosphorylation and dephosphorylation of phosphoinositides, including $PI(4,5)P_2$, that couple exocytosis and endocytosis.

a transient fusion pore precedes complete degranulation. However, in contrast to small clear SVs that undergo local recycling, SGs need to pass through the *trans*-Golgi network in order to allow refilling with secretory peptides generated from larger precursor proteins. The recent development of lipophilic fluorescent styryl dyes (FM dyes) that rapidly partition into membranes and exhibit a large increase in fluorescence within this hydrophobic environment and of pH-sensitive fluorescent proteins (so-called 'pHluorins'; Figure 2) has provided the means to follow exocytic–endocytic cycling of SVs in real-time. FM1–43 dye-based single-vesicle tracking in dissociated hippocampal neurons in culture has revealed the existence of at least two types of release: small-amplitude events that show tightly clustered rate constants of dye release, and larger events with a more scattered distribution. The small-amplitude partial release events have been attributed to a pool of vesicles that undergoes cycling by rapid closure of a narrow, approximately 1 nm diameter, fusion pore. One would therefore have to assume that vesicles are targeted for partial release by specific factors that prevent the dilation and thus the complete opening of the fusion pore. Whether vesicles undergoing transient opening and closure of the fusion pore remain docked ('kiss-and-stay') or undergo local cycling (as depicted in Figure 1) is under debate. The balance between partial kiss-and-run-type and full fusion events that may be followed by clathrin-dependent compensatory endocytosis can be shifted depending on the frequency of stimulation. While kiss-and-run exocytosis may prevail under conditions of low activity, high-frequency stimulation results in predominantly complete fusion events. Membrane capacitance measurements of giant terminals (e.g., goldfish retinal bipolar cells or the calyx of Held) have also provided evidence for two kinetically distinguishable cycling vesicle pools. However, all of these studies suffer from the lack of information on specific factors that target SVs for fast kiss-and-run exocytosis–endocytosis and that allow the application of genetic or biochemical tools to molecularly distinguish the proposed kiss-and-run mode from other pathways of SV endocytosis.

Vacuolar Bulk Retrieval and Synaptic Endosomes

Extensive stimulation of the presynaptic neuron results in the massive insertion of SV membrane into

Figure 2 Real-time measurement of SV cycling using pHluorins. Schematic illustration (A) of how synapto-pHluorin can be used to probe SV cycling. Its fluorescence is quenched in the acidic vesicular lumen, but not when residing at the plasmalemma. Synapto-pHluorin signals (B) during firing of action potentials. (a)–(c) synapto-pHluorin (spH) is recycled at boutons. (a) Time course of fluorescence intensity, averaged over 13 boutons expressing spH, following stimulation with a train of 600 action potentials at 20 Hz. The dark bar shows the duration of the stimulus. The decay of fluorescence was fit by a single exponential (solid line) with $\tau = 74$ s. (b) Time course of average spH fluorescence in the same boutons as those used for (a) during alkalinization with NH_4Cl (dark bar). (c) Time course of fluorescence intensity at the same boutons as in (a, b) during train of 600 action potentials followed by exposure to NH_4Cl 30 s after the end of the electrical stimulus. NH_4Cl-induced changes are completely reversible. (d) and (e) Endocytosis, not reacidification, is rate limiting during fluorescence decay. (d) Time course of the fluorescence intensity of spH-positive boutons ($n = 20$) following electrical stimulation (dark bar). Exocytosis of spH causes a rapid increase in fluorescence, followed by a slow decay (solid line is a single exponential fit to the average fluorescence decay, $\tau = 68$ s). (e) Time course of fluorescence intensity during brief exposures to acidic solution (hatched bars below trace) before and after electrical stimulation (dark bar). Exposure to acid during resting periods led to decreases in fluorescence (quenching), indicating the presence of a resistant surface pool of spH. The fluorescence after acid quenches was similar before and after electrical stimulation, indicating that most of the newly endocytosed vesicles were rapidly reacidified. the presynaptic plasmalemma. It therefore may not be surprising that at least in some experimental systems, such as the neuromuscular junction of frogs and snakes, parts of the presynaptic membrane can be internalized via large vacuolar structures and cisternae, in particular after chemical induction of neurotransmitter release by application of high concentrations of K^+ and calcium. Some of these vacuoles may still exhibit a narrow tubular connection with the plasma membrane and are sometimes seen to contain clathrin-coated buds at their cytoplasmic ends (Figure 1). Whether such cisternal invaginations are eventually consumed by clathrin- and/or dynamin-dependent processes remains unclear. Once having undergone fission from the plasmalemma, cisternae could undergo additional budding steps and thereby constitute a form of a specialized presynaptic endosome. In fact, early endosomal markers including the small GTPase Rab5 and the SNARE protein Vti1aβ are present on SVs. Rab5 mutations in *Drosophila* interfere with efficient release during repetitive stimulation, suggesting that presynaptic endosomes could play an important functional role in maintaining SV pools.

Clathrin-Mediated SV Endocytosis

Clathrin was first purified by Barbara Pearse more than 30 years ago, using coated vesicles isolated from pig brain. In fact, clathrin is most abundantly expressed in the central nervous system, where it is found to be particularly concentrated in presynaptic nerve terminals. The importance of clathrin for SV recycling is further underscored by the fact that clathrin-coated vesicles (CCVs) isolated from nerve terminals are highly enriched in SV proteins. Clathrin, the heterotetrameric adaptor complex (AP-2), and monomeric adaptors and accessory proteins (including epsin, eps15, AP180, HIP1/HIP1R, amphiphysin, endophilin, stonin 2, etc.) play an early role in coat formation. Recruitment of AP-2 to the plasma membrane is a cooperative and presumably highly regulated process involving interactions with phosphoinositides, membrane cargo, and a variety of AP-2α ear domain-binding partners. Many of these adaptor and accessory proteins also display higher expression levels in brain than in other tissues, perhaps owing to their increased half-lives. In addition, neurons contain endocytic protein isoforms, including splice variants of clathrin light chains and α_A-adaptin, AP180, auxillin, intersectin, and dynamin 1. Much of what we know about the mechanism of CCV formation has been learned from nonneuronal systems or from structural studies on clathrin, adaptor, and accessory proteins or domains thereof. In the following sections, we summarize these data and provide a tentative model for how clathrin, dynamin, and their binding partners could act at nerve terminals.

Early Steps of Clathrin-Coated Pit Formation

CCVs are formed by the coordinated assembly of clathrin triskelia built from three tightly linked heavy and associated light chains onto the plasma membrane. The recruitment and polymerization of the outer clathrin layer is assisted by mono- and heterotetrameric adaptor proteins, which simultaneously bind to clathrin, to membrane lipids, and in many cases to transmembrane cargo proteins. In addition, there is a large reservoir of preassembled flat hexagonal clathrin lattices at the plasma membrane that, however, need to undergo a structural transition involving the formation of clathrin pentagons in order to accommodate a curved membrane bud. The most important clathrin adaptor is the heterotetrameric AP-2 complex comprising two large subunits (α and β2), a medium subunit (μ2), and a small subunit (σ2). The two large subunits together with σ2 and the amino-terminal domain of μ2 (N-μ2) form the trunk or core domain of AP-2, and are joined by extended, flexible 'hinges' to the appendage or ear domains of α- and β2-adaptins. Since AP-2 associates with clathrin, a variety of accessory endocytic proteins, phosphatidylinositol 4,5-bisphosphate [PI(4,5)P_2], and membrane cargo proteins, it has been postulated to serve as a main protein interaction hub during coated pit assembly. Many accessory proteins, such as epsins, AP180/CALM, and amphiphysin, also have an adaptor function by linking clathrin assembly to membrane bud formation. These mono- or dimeric adaptors possess a folded lipid-binding domain linked to a more flexible portion of the protein harboring short clathrin- and AP-2-binding motifs, which may aid stabilization of nascent clathrin-coated pits (CCPs) during the assembly process. During CCP assembly transmembrane cargo proteins are recognized by adaptor proteins, most notably the AP-2 complex, which bind to endocytic sorting motifs within their cytoplasmic tails. These motifs include tyrosine-based Yxxø (where ø is a bulky hydrophobic residue) and acidic cluster di-leucine motifs, which bind directly to distinct sites within the AP-2 core domain. Yxxø motifs have been co-crystallized with the carboxy-terminal portion of the AP-2 μ-subunit (C-μ2), to which they bind in an extended conformation. Cargo recognition by AP-2 requires the presence of PI(4,5)P_2, which stabilizes the protein in an open conformation that enables cargo recognition by its μ2-subunit. Consistent with this, clathrin/AP-2-coated pits were

shown to become stabilized in living cells upon encounter of cargo receptors, suggesting that the process of AP-2 recruitment and initiation of plasmalemmal CCPs is highly cooperative.

Despite intense efforts, evidence regarding the presence of canonical Yxxø- or di-leucine-type endocytosis signals within SV protein cytoplasmic domains remains scarce. However, C-μ2 harbors a structurally unresolved binding site for basic internalization motifs found in a variety of multimeric membrane proteins, including the presynaptic vesicle protein synaptotagmin, the presumed calcium sensor in neuroexocytosis. Neuronal synaptotagmin isoforms also interact with the AP-2-binding μ-homology domain containing adaptor protein stonin 2, which is capable of targeting synaptotagmin for clathrin/AP-2-dependent internalization in neurons as well as in transfected fibroblasts. In addition to its interaction with the ear-domain of AP-2α, stonin 2 can bind to eps15 and intersectin, thereby linking synaptotagmin with other components of the clathrin-dependent endocytic machinery in neurons. Stonin 2 (and by analogy, stoned B in *Drosophila*) thus represents the first endocytic adaptor protein identified that is specifically dedicated to the endocytic internalization of a SV protein. Synaptotagmin may thus regulate both the exocytic and endocytic limbs of the SV cycle. In support of this hypothesis, it has been observed that genetic or chemical perturbation of synaptotagmin function by fluorophore-assisted light inactivation in mice, flies, or worms results in recycling defects and a partial depletion of SVs. Whether other SV proteins also interact with specific endocytic adaptor proteins or get co-sorted with synaptotagmin, that is, as part of a membrane microdomain, remains an open question.

CCP Maturation and Vesicle Fission

After the clathrin lattice is formed, endophilin, epsin, eps15, amphiphysins, and other proteins are involved in membrane bending and clathrin rearrangements as coated pits progressively invaginate and mature. Partitioning of the amino-terminal amphipathic helix of the ENTH domain protein epsin and perhaps other components (i.e., the small GTPase Arf6) drives the acquisition of membrane curvature. Bin–amphiphysin–Rvs (BAR) domain proteins, such as amphiphysin and endophilin, may aid membrane bending, and function as curvature sensors that signal completion of the process. Through their SH3 domains, both amphiphysin and endophilin also interact with and recruit accessory enzymes, including the large GTPase dynamin and the phosphoinositide phosphatase synaptojanin, to the nascent vesicular bud. Dynamin is required for fission of endocytic membrane vesicles by mechanochemically constricting ('pinchase') the vesicle neck. The eminent role of dynamin for SV recycling is best illustrated by the dramatic phenotype seen in *shibire*^{ts} mutants in *Drosophila*, which exhibit temperature-sensitive paralysis due to the accumulation of unbudded membrane infoldings and endocytic intermediates.

Observation of CCPs dynamics using evanescent wave microscopy indicates that during fission, dynamin recruitment to coated pits is rapidly followed by recruitment of actin. Moreover, perturbation of actin disrupts the endocytic reaction with accumulation of coated pits with wide necks, suggesting a role of actin, actin-binding factors, and dynamin-interacting accessory proteins, such as Abp1 or syndapin, in promoting constriction of the neck and removal of endocytosed vesicles from the membrane. In lamprey, snake, and fly neuromuscular synapse the invagination of the membrane into pits, occurs at distinct 'endocytic zones' surrounding the active zones of exocytosis (termed the peri-active zone). FM1–43 photoconversion and serial section electron microscopy analysis revealed that labeled clathrin-coated endocytic vesicles were clustered significantly near active zones, consistent with local exocytic–endocytic recycling vesicle pools at this synapse. Together with the regulated turnover and synthesis of membrane phosphoinositides, actin and actin-binding proteins may thus provide spatial and temporal landmarks for SV endocytosis (see the next section).

Protein Scaffolds as Spatial Regulators of Vesicle Cycling

Morphologically and functionally, the active zone can be divided into two parts: the core active zone, where regulated exocytosis (and kiss-and-run-type SV retrieval) takes place; and the peri-active zone, where clathrin-mediated endocytosis occurs (see the preceding section). At the ultrastructural level, the core active zone is characterized by the more or less regular array of electron-dense material, called the presynaptic grid, presynaptic particle web, or 'cytomatrix assembled at the active zone' (CAZ). During recent years, multiple molecular components – both CAZ-specific ones and those that are recruited through interaction with CAZ scaffolding proteins – have been identified and characterized.

Functionally, the CAZ is thought to define the site of regulated neurotransmitter release by localizing presynaptic membrane proteins, including voltage-gated calcium channels and cell adhesion molecules, to organize steps of the SV cycle, including tethering and priming of SV, and to link the exocytic machinery

Figure 3 Molecular organization of the cytomatrix at the active zone (CAZ). The scheme depicts observed physical interactions between active zone-specific scaffolding proteins (black), associated proteins with putative structural functions (yellow), effector proteins (blue-green), actin cytoskeletal and associated elements (green), small modulatory molecules (gray), proteins involved in SV exocytosis (blue) and endocytosis (red), as well as presynaptic membrane proteins (pink). Some of the interactions for Piccolo and RIM were discovered in pancreatic β-cells and will have to be confirmed for the CAZ. For further details see **Table 2**. Note: the diagram neither reflects the relative sizes of the proteins nor their exact topographic localization within the presynaptic bouton. The arrow indicates that neurexins (α-forms) are involved in the localization of calcium channels.

with elements of the endocytic zone and with the surrounding actin cytoskeleton (Figure 3). In addition, CAZ elements turned out to be essential mediators of presynaptic plasticity.

Molecular Organization of the CAZ

Relatively few CAZ-specific structural and effector proteins have been identified to date that are believed to constitute the scaffold of the CAZ and to mediate its structural and functional organization (black in Figure 3). These proteins belong to four different protein families: the Rab3-interacting molecules (RIMs), the mammalian Unc13 proteins (Munc13s), the two related giant CAZ scaffolding proteins Bassoon and Piccolo, and the ELKS/CAST proteins (Figure 3; Table 2).

RIMs are multidomain proteins that were identified as effectors of Rab3, a small GTPase associated with SVs. In particular, the α-forms of RIM1 and RIM2 are important scaffolding molecules that interact with multiple other presynaptic proteins. These include isoforms of Munc13, a liaison that might be involved in making SVs fusion-competent, as well as ELKS/CAST and Piccolo. Analysis of RIM1α-deficient mouse mutants revealed that this protein is involved in short- and long-term forms of presynaptic plasticity. For example, long-term potentiation at hippocampal mossy fiber terminals or parallel fiber synapses of the cerebellum involve protein kinase A-dependent phosphorylation of RIM1α and phosphorylation-dependent binding of 14-3-3 proteins. Further interactions of αRIMs point to a central role of these proteins in active zone organization. They can bind presynaptic voltage-gated Ca^{2+} channels, either directly or via their binding to RIM-binding proteins, and the Ca^{2+} sensor synaptotagmin, which is involved in both exocytosis and endocytosis of SVs. The interaction with α-liprins, originally identified as a cytoplasmic adaptor for the receptor tyrosine phosphatase LAR, might serve the formation and maintenance of active zones, as suggested by work in invertebrates.

Munc13 isoforms are involved in SV priming and the regulation of synaptic plasticity. They can link

Table 2 Protein components of the cytomatrix assembled at the active zone

Protein family *Relevant members and synonymous names*	*Domains and motifs*	*Interacting protein*	*Proposed function(s)*
RIMs – Rab3-interacting molecules	Zn finger	Rab3	Link to SV, tethering of SV, presynaptic plasticity
		Munc13-1, ubMunc13-2	SV priming
RIM1α; RIM2α,β,γ; RIM3γ; RIM4γ; UNC10 (*C. elegans*)	Region between Zn finger and	14-3-3	Presynaptic plasticity
	PDZ domain	cAMP-GEFII / Epac2	Insulin secretion in pancreatic β-cells
	PDZ domain	ELKS / CAST	CAZ scaffolding
	C2A	Piccolo	CAZ scaffolding
		N-type calcium channels	Channel anchoring and/or clustering
	Pro-rich motif btw. C2A & B	RIM-BPs	CAZ scaffolding
	C2B	α-Liprin,	CAZ scaffolding,
		N-type calcium channels	Anchoring and/or clustering of Ca channels
		synaptotagmin	CAZ scaffolding, organization of Ca sensing
RIM-binding proteins	SH3 domains 2 and/or 3	RIMs	CAZ Scaffolding
RIM-BP1		N-type ($Ca_v2.2$) and L-type ($Ca_v1.3$) Ca channels	Channel anchoring and/or clustering
RIM-BP2			
Piccolo–Bassoon family	Zn fingers	PRA1 (prenylated Rab3 acceptor)	Link to SV?
Bassoon and Piccolo	Between CC1 and CC2	CtBP/BARS	Membrane trafficking?
		Ribeye/CtBP2	Scaffolding of synaptic ribbons
	CC3	ELKS / CAST	CAZ scaffolding
Piccolo/Aczonin only	N-terminal Q domain	Abp1 (actin-binding protein 1)	Link to actin cytoskeleton, endocytosis
	Between CC1 and CC2	GIT (ARF-GAP)	Membrane trafficking
	Pro-rich region btw CC1 and 2	Profilin	Actin regulation
	PDZ domain	cAMP-GEFII/Epac2	Insulin secretion in pancreatic β-cells
	C2A	RIMs	CAZ scaffolding, organization of SV cycle
		Piccolo	Homophilic interaction, scaffolding
	C2A and C2B	L-type Ca channel	Channel anchoring in β-cells

	C-terminal PDZ binding site	GRIP	Receptor transport and clustering/postsynaptic

to the actin-spectrin cytoskeleton via binding to a β-spectrin isoform and to presynaptic membrane-trafficking processes via the ARF guanine nucleotide exchange factor msec7-1.

ELKS/CAST proteins display a very high content of coiled-coil structures and are considered as a major structural component of the CAZ. They can physically interact with RIMs as well as with Bassoon and Piccolo and thus might interconnect the major scaffolding proteins of the CAZ. Bruchpilot, an ELKS/CAST-related protein in *Drosophila*, is responsible for the proper anchoring of particular specializations of the CAZ, so-called T-bars, to the active zone membrane. Via syntenin, ELKS/CAST proteins also connect to neurexins, which are specific cell adhesion molecules of the presynaptic membrane occurring as long α- and short β-forms involved in Ca^{2+} channel localization and linkage to postsynaptic neuroligins, respectively. Neurexins are additionally anchored to the presynaptic cytomatrix via a trimeric protein complex of CASK, Mint, and MALS/Veli, which in turn links to Ca^{2+} channels and α-liprins (Figure 3).

Bassoon and Piccolo are considered as very large multidomain scaffolding molecules of the CAZ. Most of their interaction partners have still to be discovered. They both bind ELKS/CAST and the small prenylated Rab3 acceptor (PRA1), which potentially links into the SV cycle. In addition, Bassoon has been reported to interact with CtBP/BARS and its homolog RIBEYE, a specific component of synaptic ribbons in retinal photoreceptors and inner ear hair cells. The RIBEYE–Bassoon interaction was suggested to be essential for anchoring of ribbons to the presynaptic plasmalemma. The interaction of Bassoon (and potentially also Piccolo) with CtBP/BARS is of interest, as this protein has been implicated in vesicular fission from the *trans*-Golgi complex. By analogy, a similar function might be envisioned in the presynapse.

Links of the CAZ to the Endocytic Machinery and the Actin-Based Cytoskeleton

While multiple interactions of the previously described CAZ proteins underscore the role of the presynaptic cytomatrix in organizing the apparatus for regulated exocytosis, a link to clathrin-mediated endocytosis is less clear. Specific interaction partners for Piccolo might be of particular interest in this context, as they can provide the basis for the physical linkage of exocytic and endocytic presynaptic processes. On the one hand, Piccolo can bind directly to Ca^{2+} channels and the guanine nucleotide exchange factor cAMP-GEFII/Epac2, as revealed from studies on pancreatic β-cells. Moreover, the C2A domain of Piccolo is discussed as a candidate low-affinity Ca^{2+} sensor. These characteristics argue for a role in active zone organization and exocytosis. On the other hand, Piccolo can bind to the ARF-GTPase-activating protein GIT, which has been implicated in endocytic processes such as receptor internalization. The N-terminus of Piccolo specifically interacts with Abp1, an actin-binding factor directly regulating the GTPase dynamin. Indeed, the N-terminal Q-domain of Piccolo can interfere with endocytic processes in heterologous systems. Yet another link between Piccolo and the actin cytoskeleton is profilin, a small G-actin- and phosphoinositide-binding protein that is involved in local remodeling of the actin cytoskeleton. Thus, Piccolo might indeed be an important mediator between the neurotransmitter release apparatus and the neighboring endocytic machinery.

Regulation of the SV Cycle by Membrane Lipids

Phosphoinositide Regulation of SV Cycling

Cycling of presynaptic vesicles requires the precise spatial and temporal regulation of protein–lipid interactions. Many synaptic proteins – including synaptotagmin1, calcium-dependent activator protein for secretion (CAPS), the Munc18-interacting proteins Mint-1 and Mint-2, voltage-gated P/Q-type calcium channels, and a variety of endocytic proteins such as AP-2, AP180, epsin, and dynamin (Table 1) – directly bind to and are regulated by [PI(4,5)P_2]. SV cycling thus appears to be nested into a local cycle of phosphoinositide phosphorylation and hydrolysis. Accordingly, PI(4,5)P_2 acts at multiple stages of the vesicle cycle. Knockout mice lacking PIP kinase type Iγ, the major PI(4,5)P_2-synthesizing enzyme at synapses, display defects in neurotransmitter release and endocytic recycling that cause synaptic depression. The activity of PIPK Iγ is regulated by a variety of factors, including phosphatidic acid (PA), the small GTPases Arf6 and Rac1, and the actin cytoskeleton-associated adhesion protein talin. Association of PIPK Iγ with these factors is dependent on their phosphorylation status, providing a means for the temporal and spatial regulation of phosphoinositide metabolism. PI(4,5)P_2 is eventually consumed by synaptojanin-mediated dephosphorylation, resulting either in formation of PI(4)P and perhaps PI, cleavage via phospholipase C, or PI3 kinase-dependent synthesis of PI(3,4,5)P_3. At least in neuroendocrine PC12 cells, PI(4,5)P_2 appears to be concentrated within cholesterol-enriched microdomains near release sites, where it may aid vesicle docking and/or fusion. The recent observation that SV proteins remain clustered during their exocytic–endocytic journey, together

with the extremely high cholesterol content of SV membranes, suggests that cholesterol-enriched microdomains could serve to spatially organize the SV cycle, perhaps in part by locally concentrating PI(4,5)P_2.

At present we can only speculate about the exact mechanism of action of PI(4,5)P_2 during vesicle fusion, but its role in clathrin-mediated synaptic vesicle endocytosis is much better understood. PI(4,5)P_2 is an important factor in recruiting endocytic adaptor and accessory proteins to the membrane where these form a network of protein–protein interactions. The stability of this network critically depends on the PI(4,5)P_2 content of the membrane, as suggested by the observation that CCVs accumulate in nerve terminals of synaptojanin knockout mice. These observations also indicate that PI(4,5)P_2-hydrolysis may normally occur concomitantly with or directly after dynamin-mediated membrane fission. CCVs at presynaptic sites of synaptojanin knockout mice become trapped in a meshwork of actin filaments, consistent with the fact that PI(4,5)P_2 regulates actin polymerization and drives the formation of actin comet tails that may help to propel endocytic vesicles away from the plasmalemma.

Lipids and Membrane Deformation

SV fusion and the subsequent formation of endocytic clathrin-coated buds at the presynaptic peri-active zone involve radical geometric remodeling of the membrane in order to generate areas of different membrane curvature. While lipids with bulky polar headgroups and saturated or single fatty acid tails, including lysolipids and many glycolipids, promote positive curvature, lipids with compact headgroups and space-filling hydrophobic tails, such as PA and diacylglycerol (DAG), favor negative curvature. For example, lysophosphatidic acid (LPA) and PA, which are interconverted by LPA-acyl transferase and phospholipase A_2 activities, respectively, favor opposite curvatures.

Although differential distribution of distinct types of lipids between the two membrane leaflets may contribute to membrane deformation, it is generally assumed that membrane bending requires the action of proteins. During endocytic SV recycling, the forming bud must adopt a positive curvature at the bud center and negative curvatures at the edges. Endocytic proteins may act by one of several mechanisms to bend membranes. As stated previously, epsin, a PI-(4,5)P_2-binding clathrin accesssory protein, is able to partition into the cytoplasmic leaflet of the plasma membrane via PI(4,5)P_2-induced formation of an extra α-helical segment that drives acquisition of positive curvature. Dimeric BAR domain-containing proteins, including amphiphysin or endophilin (Table 1), induce curved membranes by an additional amphipathic helix at their amino-terminal end, largely via electrostatic interactions of their concave surface with negatively charged membrane phospholipids. Endophilin has originally been proposed to be an LPA-acyl transferase, but this activity has recently been called into question. Highly curved membranes may become stabilized in addition by other scaffolding proteins, including clathrin itself, which forms a rigid basket around the emanating vesicular membrane bud. Moreover, the transmembrane domains of synaptic vesicle proteins could provide a barrier that prevents local areas of high curvature from lateral diffusion and thereby contribute to maintaining vesicle identity. Finally, protein–lipid interactions and the formation of microdomains might also underlie the choice between fast and slow modes of SV cycling that would require a tight control of fusion pore expansion and constriction.

Multiple Pathways for Synaptic Vesicle Recycling

The synaptic vesicle cycle is initiated by a rise in intrasynaptic Ca^{2+} leading to vesicle fusion and neurotransmitter release at the active zone. According to the conventional view of this process, upon fusion, synaptic vesicles completely collapse onto the plasma membrane, and vesicle membrane components (lipids as well as proteins) intermix with their plasma membrane counterparts. Subsequently, clathrin, through its adaptor proteins, is recruited to the membrane (typically within the periphery of the active zone) and forms coated vesicles by reclustering vesicle membrane components which eventually bud off the plasma membrane with the help of the GTPase dynamin. In addition to the plasma membrane, endocytosis of clathrin-coated vesicles may also occur from membrane infoldings or endosomal cisternae, which form upon accumulation of fused synaptic vesicles. A V-type ATPase then lowers the pH in these vesicles and subsequently the vesicles are refilled with neurotransmitter. The reacidification and neurotransmitter filling steps are thought to be rapid, and the entire process for exocytosed vesicles to become reavailable for release occurs within 40–90 s (Figure 1).

Kiss-and-run refers to an additional fast pathway of vesicle recycling during which synaptic vesicles retain their identity and do not intermix with the plasma membrane or endosomal compartments. During this process, the fusion pore opens transiently without complete collapse of the vesicle and without intermixing of synaptic vesicle membrane components with the plasma membrane. In several models of cellular secretion, the vesicle fusion process is easier to access technically through direct visualization or via membrane capacitance measurements. In these systems, there are several examples of transient vesicle fusion events that resemble what would be expected from kiss-and-run fusion. In central synapses, however, limited experimental access to the fusion process restricts our ability to assess the preponderance of kiss-and-run-type fusion. Nevertheless, studies have used elaborate experimental settings to address this question.

In addition to limited morphological and functional characterization of the kiss-and-run process, the actual molecular mechanism of this pathway remains to be determined. There is evidence that this rapid component of endocytosis may operate independent of clathrin and may require the function of the synaptic vesicle protein synaptobrevin, which is also critical for rapid Ca^{2+}-dependent fusion. However, it is a matter of debate whether kiss-and-run represents a reversible SNARE-mediated fusion event or almost instantaneous fission of vesicle–plasma membrane interface upon fully executed SNARE-mediated fusion.

Clathrin-mediated endocytosis comprises a ubiquitous means for vesicle recycling in most cell types. This pathway typically possesses well-defined morphological markers (coated pits, endosomal intermediates, etc.), and adequate molecular tools are available to probe its properties in synapses (biochemical purification of coated vesicles and isolation of endocytic intermediates). The kiss-and-run pathway, in contrast, may not employ the same molecular players and structural intermediates and is more difficult to examine morphologically and molecularly. Therefore, most evidence in support of a kiss-and-run-type fast retrieval and recycling mechanism for synaptic vesicles relies on electrophysiological and optical techniques with rapid time resolution.

Cell Biological Implications of Kiss-and-Run Endocytosis

The proposal for kiss-and-run-type endocytosis emerged soon after the vesicular hypothesis for neurotransmission had been widely accepted. In the early 1970s, Bruno Ceccarelli and colleagues performed elegant experiments on the neuromuscular junction using a combination of electrophysiology and electron microscopy to examine the synaptic vesicle recycling process. The term 'kiss-and-run,' however, was introduced by Meldolesi and colleagues in 1994. A key feature of early experiments was morphological preservation of synaptic vesicle curvature during fusion events. In addition, there was limited or negligible depletion of synaptic vesicles during sustained stimulation, which released substantial neurotransmitter quanta exceeding the number of vesicles available in the terminal. Furthermore, horseradish peroxidase or dextran labeling during stimulation revealed that several vesicles are formed from the same axolemmal membrane where fusion occurs. This proposal was quite attractive because it introduced an economical means to retrieve synaptic vesicles upon fusion rapidly and with high fidelity, which would match the rapid pace of synaptic transmission compared to other constitutive vesicle

Figure 1 The synaptic vesicle cycle. During neurotransmission, a rise in Ca^{2+} level leads to vesicle fusion and neurotransmitter release at the active zone, after which vesicles completely collapse onto the plasma membrane. During this process, vesicle membrane components are thought to intermix with their plasma membrane counterparts. Subsequently, clathrin, through its adaptor proteins, is recruited to the membrane (typically at the periphery of the active zone) and forms coated vesicles by reclustering vesicle membrane components which eventually bud off the plasma membrane with the help of the GTPase dynamin. In addition to the plasma membrane, endocytosis of clathrin-coated vesicles may also occur from membrane infoldings or endosomal cisternae. This classical pathway is thought to operate on a 40–90 s timescale. During an alternative fast (within seconds) pathway of vesicle recycling, synaptic vesicles retain their identity and do not intermix with the plasma membrane or endosomal compartments. This pathway is also referred to as the 'kiss-and-run' pathway, in which the fusion pore opens transiently without complete collapse of the vesicle and without intermixing of synaptic vesicle membrane components with the plasma membrane.

trafficking events. These observations were also consistent with the later identification and exhaustive characterization of synaptic vesicles as distinct organelles in terms of their membrane lipid and protein composition relative to the plasma membrane. If synaptic vesicle components could freely diffuse on the plasma membrane upon fusion, it would be a daunting task to retrieve all the necessary components in sufficient and adequate quantities and reassemble a synaptic vesicle. Furthermore, most synaptic vesicle proteins do not contain distinct molecular tags that would dictate their targeting to synaptic vesicles. Therefore, *de novo* assembly of synaptic vesicles following fusion is difficult to envision in the limited time frame required to sustain neurotransmission and prevent disfiguration of synaptic membranes (Figure 2).

Studies using fluorescently tagged synaptic vesicle proteins, however, challenged this notion and showed that at least the synaptic vesicle proteins synaptobrevin and synaptotagmin can diffuse from the fused vesicle membrane and endocytosis involves recruitment of a distinct set of the same proteins previously resident on the plasma membrane. Although most studies to date have tested synaptobrevin or synaptotagmin in this context, recent work has examined if this observation is applicable to other synaptic vesicle proteins. In these experiments, different synaptic vesicle proteins gave different results with respect to their background fluorescence (i.e., surface exposure) and retrieval. For instance, both synaptophysin (a four transmembrane domain synaptic vesicle protein) and the vesicular glutamate transporter show

Figure 2 Preservation of vesicle identity upon kiss-and-run endocytosis. Synaptic vesicles are distinct organelles in terms of their membrane lipid and protein composition from the plasma membrane. According to the kiss-and-run model, synaptic vesicles retain their composition upon fusion and are retrieved intact. The alternative view suggests that synaptic vesicle components can freely diffuse onto the plasma membrane upon full collapse of the vesicle membrane during fusion. However, most synaptic vesicle proteins do not contain distinct molecular tags that would dictate their targeting to synaptic vesicles. Therefore, in this alternative model it is difficult to envision how all the necessary components can be retrieved in sufficient quantities to reassemble a synaptic vesicle.

very little surface exposure (thus fluorescence) in the absence of stimulation. Following stimulation, synaptophysin and the vesicular glutamate transporter show a rapid increase in fluorescence without significant

lateral diffusion upon fusion, which was a salient feature of earlier synaptobrevin-based measurements. The dependence of the properties of these GFP-based measurements on the identity of the tagged protein complicates a straightforward interpretation of the earlier synaptobrevin-based experiments in terms of synaptic vesicle recycling.

Since the early 1990s, fluorescence probes such as styryl dyes and pH-sensitive GFP-tagged synaptic vesicle proteins have revealed that synaptic vesicle endocytosis occurs within seconds in a manner tightly coupled to synaptic vesicle fusion. Classical clathrin-mediated endocytosis mechanisms operate on a slower timescale. In cellular imaging experiments in which capture of a single cargo molecule is monitored, the time course of clathrin coat assembly and mean residence time on the plasma membrane typically varies between 30 s and 1 min (mean lifetime of 46 s). The rapid and high-fidelity retrieval of a complex organelle such as a synaptic vesicle results in significant constraints to the classical clathrin-mediated endocytosis machinery, especially if *de novo* assembly of synaptic vesicles is involved in the process. However, the rapidity of endocytosis cannot be considered as proof of kiss-and-run endocytosis because clathrin-mediated endocytosis may be modified to adjust to the rapidity of the synaptic vesicle recycling. According to one hypothesis, synaptic vesicles may be preassembled at the membrane in a 'readily retrievable pool' through a clathrin-mediated process and endocytosed rapidly upon membrane fusion. During this process, patches of endocytosed membrane and fused membrane are not identical. This premise requires a means of communication between the spatially separate exocytosis and endocytosis events. One possibility for this messenger is the rise in intrasynaptic Ca^{2+} that triggers exocytosis. However, the exact role of Ca^{2+} in synaptic vesicle endocytosis remains to be tested. It is unclear if Ca^{2+} is absolutely required for endocytosis or if it is merely regulatory. If Ca^{2+} turns out to be essential for synaptic vesicle retrieval, then it would be critical to determine if it is permissive (it merely needs to be present) or instructive (it is required) for this process.

The Mechanism of Kiss-and-Run

In addition to limited morphological and functional characterization of the kiss-and-run process, the actual molecular mechanism of this pathway remains to be determined. As indicated previously, kiss-and-run endocytosis may not require clathrin and may involve the synaptic vesicle protein synaptobrevin, which is a critical component of the fusion machinery. However, it is unknown whether kiss-and-run represents a reversible SNARE-mediated fusion event.

The interaction of synaptic vesicle protein synaptobrevin 2/vesicle-associated membrane protein-2 (VAMP-2) with the plasma membrane proteins syntaxin 1 and SNAP-25 (25 k Da synaptosomal-associated protein) is an essential step for vesicle fusion. These proteins are collectively called SNAREs. During fusion, synaptobrevin 2, syntaxin 1, and SNAP-25 form an exceptionally stable complex that is resistant to treatment with the detergent sodium dodecyl sulfate, which would normally be sufficient to dissociate other macromolecular complexes. Under physiological conditions, this tight complex, referred to as the 'core complex,' can only be disassembled by the ATPase *N*-ethylmaleimide-sensitive factor together with SNAPs. Biochemical stability and molecular structure of the core complex suggest that formation of the complex can be sufficient to overcome the energy barrier to membrane fusion by bringing vesicular and target membranes into nanometer proximity or even driving the fusion reaction. In this scheme, the association of synaptobrevin with corresponding syntaxin and SNAP-25 supplies the energy required for the fusion reaction in a process accordingly termed 'zippering.' Because SNARE complex formation is an energetically highly favorable reaction, it is difficult to envision how this reaction can be reversible. Nevertheless, kiss-and-run may still be due to rapid reversibility of the fusion reaction mediated after SNARE complex disassembly presumably requiring rapid action of the GTPase dynamin for fission of vesicles from the plasma membrane. In this way, vesicles can be endocytosed at the spot where they have fused without losing their curvature. This reversible fusion reaction may also involve regulation of core complex disassembly, providing a switch between complete fusion and fusion pore flickering.

The Impact of Kiss-and-Run Endocytosis on Neurotransmission

In addition to preservation of vesicle identity and composition upon fusion and retrieval, the kiss-and-run type of synaptic vesicle recycling offers additional avenues for regulation of neurotransmission. First, rapid retrieval of synaptic vesicles from the plasma membrane without significant loss of their protein composition can make them quickly reavailable for fusion during stimulation. During sustained stimulation, neurotransmission can be maintained either by constant supply of vesicles from a reserve pool or by rapid recycling of fused vesicles. Indeed, most endocytic protein mutants as exemplified by dominant negative or null mutants of dynamin (shibire mutant in *Drosophila* or mouse knockout) manifest an extremely rapid synaptic depression phenotype

consistent with this premise. Furthermore, in hippocampal synapses, inhibition of vesicle reacidification (using inhibitors of vacuolar ATPase) leads to a selective increase in the rate of synaptic depression without significantly impairing other parameters of neurotransmitter release. Therefore, rapid synaptic vesicle recycling, possibly mediated by a kiss-and-run-like mechanism, may potently regulate the kinetics of short-term synaptic plasticity. Furthermore, the rate of recycling can be a critical determinant of a synapse's release rate at steady state during maintained stimulation once the releasable vesicles are depleted and neurotransmission solely relies on vesicle reuse. The second aspect of kiss-and-run endocytosis is its potential ability to regulate fusion pore openings to limit diffusion of neurotransmitter substances to the synaptic cleft. For instance, limited diffusion of neurotransmitter molecules can be clearly detected in carbon fiber measurements of catecholamine release from adrenal chromaffin cells. In central synapses, there is evidence that similar fusion pore-restricted release of glutamate from vesicles may only activate high-affinity NMDA receptors without evoking currents through low-affinity AMPA receptors.

Evidence for Kiss-and-Run Endocytosis during Synaptic Transmission

The prevalence of kiss-and-run endocytosis in central synapses is still an open question. This section discusses the evidence for kiss-and-run from five distinct modalities of measurement, commonly applied to the study of neurotransmission in central synapses.

Retention of Styryl Dyes upon Fusion

FM1-43 is a partially lipophilic dye, which fluorescence increases 100-fold when it partitions into membranes and thus it is virtually invisible in aqueous solution. The chemical structure of FM1-43 makes it difficult to cross lipid membranes, thus limiting the fluorescence labeling to outer membranes and recycling vesicles. Using this methodology, one can detect activity-dependent vesicular dye uptake and release in synaptic connections in multiple preparations including central neuronal cultures. Studies using FM dyes have revealed that activity-induced dye uptake and release operates with high fidelity. Specifically, the extent of fluorescent dye endocytosed during a particular stimulation matches the magnitude of fluorescence loss due to exocytosis in response to the same stimulation. This observation suggests that synaptic vesicles recycle without intermixing with endosomal compartments and thus the fluorescence probes do not get diluted.

The properties of styryl dyes also make them useful tools to reveal quantitative information on vesicle fusion within a presynaptic terminal. These dyes can be rapidly inserted into membranes (~3 ms); however, with the increasing lengths of their hydrocarbon chains, they have decreasing rates of dissociation from membranes. Measurements have shown that FM1-43 departitions from lipid to aqueous environment with a time constant of 2.5 s, whereas its analogs, FM2-10 and FM1-84, departition with time constants of 0.6 and 4.8 s, respectively. Since the introduction of FM dyes, several studies have reported partial release of FM1-43 upon synaptic vesicle fusion during multiple forms of stimulation. In some studies, destaining rates of synaptic boutons stained with FM2-10, FM1-43, and FM1-84 were slower in proportion to the increasing time constants of departitioning. These initial observations were later extended by experiments examining FM dye loss from single vesicle fusion events. The common interpretation of partial FM dye release is the presence of a fast endocytotic mechanism, which preferentially traps the slowly departitioning dyes, FM1-43 and FM1-84, in synaptic vesicles. Partial dye release is only possible if lateral diffusion of FM dye following the formation of the vesicle–plasma membrane interface is delimited by a barrier (presumably a protein-based fusion pore) between the two membranes. However, in other systems such as goldfish bipolar cells, all FM dyes have been reported to laterally diffuse out of fused vesicles, thus losing fluorescence irrespective of their departitioning rates in aqueous solution (Figure 3).

Rapid Changes in SynaptopHluorin Fluorescence

SynaptopHluorin (spH) is another fluorescent probe that is commonly used to monitor exocytosis and endocytosis of synaptic vesicles. spH is a fusion construct of the synaptic vesicle protein synaptobrevin (VAMP) with a pH-sensitive enhanced green fluorescent protein (EGFP) at its C-terminal (located in the synaptic vesicle lumen). The synaptic vesicle lumen normally has an acidic pH of approximately 5.5 at which spH fluorescence is quenched. When vesicles fuse, lumenal EGFP is exposed to the extracellular pH, resulting in a marked increase in its fluorescence. Studies using spH have provided valuable information on the tight coupling between exocytosis and endocytosis. One advantage of the spH probe is the molecular specificity of the fluorescence signal since the signal originates from a synaptic vesicle protein as opposed to nonspecific lipid-based fluorescence of FM dyes. Proton diffusion from a synaptic vesicle is not expected to be limited, and the time course of vesicle reacidification is thought to be fast without

Figure 3 Optical monitoring of kiss-and-run endocytosis using FM dyes. FM1-43 and its analogs are partially lipophilic dyes which fluorescence increases almost 100-fold when they partition into membranes. Therefore, they are virtually invisible in aqueous solution. The chemical structure of FM dyes makes it difficult for them to cross lipid membranes, thus limiting the fluorescence labeling to outer membranes and recycling vesicles. During a typical experiment, stimulation in the presence of extracellular dye leads to uptake of dye molecules into vesicles that have undergone exocytosis followed by endocytosis. Subsequent washout of extracellular dye uncovers fluorescent staining specific to actively recycling vesicles during the stimulation paradigm. Consequent stimulation results in fusion of dye-loaded vesicles and loss of fluorescence trapped in synapses. This fluorescence loss is due to departitioning of the dye into aqueous solution or lateral diffusion of dye in neuronal membrane. During kiss-and-run endocytosis, a protein barrier that makes up the fusion pore restricts FM dye lateral diffusion. If vesicle retrieval is faster than the dye departitioning rate, then the endocytosed synaptic vesicle may still contain residual dye.

Figure 4 Synaptophysin–pHluorin is a fusion construct of the synaptic vesicle protein synaptophysin (a four transmembrane domain synaptic vesicle protein) with a pH-sensitive EGFP at its C-terminal (located in the synaptic vesicle lumen). The synaptic vesicle lumen normally has an acidic pH of approximately 5.5 at which spH fluorescence is quenched. When vesicles fuse, lumenal EGFP is exposed to the extracellular pH, which results in a marked increase in its fluorescence. During endocytosis, pHluorin fluorescence is requenched as the vesicle lumen becomes acidic.

imposing a significant delay in the fluorescence signal during spH endocytosis. Although most studies have used synaptobrevin as a carrier for the pHluorin tag, some studies have taken advantage of other synaptic vesicle proteins as pHluorin attachments. As previously indicated, in these experiments, tagging synaptophysin (a four transmembrane domain synaptic vesicle protein) and the vesicular glutamate transporter with pHluorin revealed very little surface exposure (as fluorescence) (Figure 4).

Experiments have shown that once the surface fluorescence is quenched, it is possible to monitor single vesicle fusion events using spH as a probe. Gandhi and Stevens detected single vesicle fusion events with square pulse-like rapid alkalinization and reacidification behavior akin to single ion channel openings. These findings suggest that the number of spH molecules per vesicle is preserved during the exocytosis and endocytosis cycle in a manner consistent with the kiss-and-run hypothesis. However, the same results were not reproducible with a pHluorin fusion construct of synaptophysin, suggesting that rapid reversal of pHluorin signal may be due to lateral diffusion of synaptobrevin because synaptophysin–pHluorin does not laterally diffuse upon vesicle fusion.

Capacitance Measurements

Synaptic vesicles are membranous organelles which release their neurotransmitter content after fusion with the plasma membrane. This process can be directly monitored via capacitance measurements. Alteration in total membrane capacitance can be used as a reporter of membrane fusion or endocytosis as long as the magnitude of the capacitance change is above the background noise. A critical requirement for employment of this method is direct electrical access to the secretory cellular component. This requirement significantly impairs the applicability of this method to small synapses of the central nervous system, which typically cover a 1 μm^2 surface area. Therefore, most capacitance measurements have been limited to secretion from cell bodies of mast cells, adrenal chromaffin cells, or large pituitary nerve terminals. Studies by Ling-Gang Wu and colleagues on a large presynaptic terminal called the calyx of Held, located within the medial nucleus of the trapezoid body region of the brain stem, have employed capacitance measurements in examining the coupling between synaptic vesicle exocytosis and endocytosis.

Despite its limited applicability to synaptic vesicle fusion, the capacitance measurement method, when available, provides several advantages due to its ability to report the kinetics of exocytosis and endocytosis and, in some cases, the properties of fusion pore openings. Wu and colleagues extended their earlier work using the cell-attached configuration of the patch clamp technique on or near the active zones of the calyx of Held nerve terminals. This configuration has several advantages over traditional whole terminal recording configuration due to electrical isolation of a small membrane area, thus limiting background noise. This setting allowed resolution of single vesicle fusion events and revealed several rapidly reversible fusion events consistent with kiss-and-run fusion. These rapidly reversible fusion events were previously detected only in models of cellular secretion (e.g., chromaffin cells and mast cells). These findings are considered to be the most conclusive evidence for the occurrence of kiss-and-run fusion in central synapses albeit with limited information regarding the regulation and prevalence of this type of fusion.

Carbon Fiber Measurements

The chemical structures of catecholamine or monoamine transmitters make them susceptible to rapid oxidation. These oxidation current signals can be detected using carbon fiber electrodes held at DC voltage above the redox potential of these neurotransmitters. This method provides an accurate depiction of vesicular neurotransmitter content free of nonlinear properties of postsynaptic ionotropic receptors. Furthermore, detailed analysis of individual fusion event profiles can provide information regarding diffusion kinetics of neurotransmitters out of fused vesicles. For instance, initial application of this method to catecholamine secretion of adrenal chromaffin cells revealed prominent slowly rising 'foot' signals preceding the actual rapid rise of neurotransmitter concentration after fusion. The characteristics of this foot signal have been analyzed in multiple settings to examine mechanisms underlying fusion pore expansion. Sulzer and colleagues measured dopamine release from small synaptic vesicles of cultured ventral midbrain neurons using carbon fiber amperometry. Their data indicate that small synaptic vesicle fusion pores flicker either once or multiple times in rapid succession, with each flicker releasing approximately 25–30% of vesicular dopamine. Rapidly flickering fusion pore openings are consistent with kiss-and-run-type fusion events. However, limited applicability of the amperometric recording method restricts generalizations to other types of central synapses that use amino acid neurotransmitters.

Alterations in Postsynaptic Receptor Activation due to Kiss-and-Run Fusion Events

As previously indicated, a key aspect of the kiss-and-run hypothesis is its potential for leading to postfusion regulation of chemical substance diffusion from the vesicle lumen through regulation of fusion pore opening duration and diameter. Catecholamine or dopamine secretion detected via carbon fiber measurements clearly indicates that vesicle fusion events can be limited by the rate and size of fusion pore openings. In the case of glutamatergic synaptic transmission in the brain, however, this process has been more difficult to detect. Nevertheless, in the literature there are several lines of evidence that argue for a limitation in the fusion pore opening kinetics altering the extent of glutamate diffusion into the synaptic cleft. Glutamatergic synapses typically possess two types of ionotropic postsynaptic receptors. AMPA receptors have a low-affinity for glutamate, and they mediate most of the electrical signaling in response to glutamate release from presynaptic terminals. NMDA receptors, on the other hand, have a very high affinity for glutamate, although they require postsynaptic depolarization and glutamate binding to become active. Experiments performed in hippocampal synapses have shown that activation of postsynaptic AMPA or NMDA receptors can be determined by the kinetics of fusion pore opening and the release profile of glutamate. In young nerve terminals, glutamate diffusion occurs through a narrow fusion pore leading to exclusive activation of NMDA receptors because they have a higher affinity for glutamate. Synapse maturation, in turn, leads to an increase in the preponderance of full fusion events, thus activating NMDA and AMPA receptors.

Under these conditions, one can detect synaptic transmission with the same apparent features of an NMDA-only synapse (also referred to as a 'silent synapse'), but the NMDA-only nature of these synapses is explained by a presynaptic mechanism and not by lack of postsynaptic AMPA receptors. This model may explain some forms of synaptic plasticity; therefore, it has been proposed as an attractive presynaptic alternative to the more commonly observed postsynaptically silent synapses (i.e., synapses with no AMPA receptors).

Conclusion

In the past decade, an increasing number of studies using multiple tools have examined the synaptic vesicle fusion process and uncovered fusion events consistent with the kiss-and-run endocytosis mechanism. Nevertheless, none of these observations are without caveats; therefore, despite extensive research, the existence of kiss-and-run fusion in central synapses

is still in question. As stated previously, work on kiss-and-run endocytosis has been dominated by functional approaches without significant molecular insight. However, future molecular studies on the exact role of dynamin in synaptic vesicle endocytosis (since kiss-and-run is likely to be a dynamin-dependent process) as well as the role of SNARE complex components in synaptic vesicle endocytosis will inevitably lead to a more accurate picture of exocytosis–endocytosis coupling in synapses and help elucidate the mechanism of kiss-and-run.

Energy Homeostasis: Adiposity Signals

S C Woods, University of Cincinnati, Cincinnati, OH, USA

© 2009 Published by Elsevier Ltd.

Introduction

Two major categories of peripherally arising signals influence food intake. The first consists of peptides secreted from the gastrointestinal tract during meals in response to ingested food. These acutely acting signals contribute to the perception of fullness and the termination of an ongoing meal and are collectively called satiety signals. The prototypical example is cholecystokinin (CCK). Messages conveyed by satiety signals are either relayed to the hindbrain by sensory nerves or else stimulate the hindbrain directly. The second category of signals includes hormones, particularly insulin from the pancreatic islets and leptin from adipose tissue, stomach, and elsewhere; the secretion of these hormones is proportional to the amount of fat in the body. These adiposity signals are transported from the circulation into the hypothalamus in the forebrain. The actions of adiposity signals and their interactions with other controllers of food intake are the topic of this article.

Overview of the Controls over Food Intake

For body weight (body fat, actually) to remain stable over time, energy intake (food intake) must match energy expenditure (the sum of excreted energy, heat loss, and physical work). Any prolonged deviation from this balance will result in weight gain or loss. Humans and most mammals take in energy in discrete bouts or meals. For most of us, the impetus to begin a meal is rarely, if ever, based on a biological deficit or need, such as insufficient glucose or other energy source, in some critical tissue. Rather, evidence suggests that the timing of when meals are initiated is based on psychological factors such as habit, time of day, social situation, and convenience, among others. Thus, if body weight is indeed regulated via a linking of energy intake to energy expenditure, then the regulatory process must logically be manifest as a control over how many calories are consumed once a meal begins (i.e., meal size). Consistent with this hypothesis, many secretions of the gastrointestinal tract that are generated during meals are proportional to the number of calories consumed, and some of these secretions function as satiety signals to the central nervous system to help limit meal size.

In contrast to satiety signals that are secreted mainly during meals, adiposity signals are tonically active, providing an ongoing message to the brain proportional to total body fat. When an individual's weight changes, the amounts of insulin and leptin secreted into the blood change in parallel, and this is reflected as an altered adiposity signal reaching the brain. As discussed in detail in the following sections, the net effect is a change in the brain's sensitivity to satiety signals. For example, when an individual is food restricted or voluntarily reduces intake sufficiently to lose weight, the consequent reduction of leptin and insulin renders brain circuits that control meal size less sensitive to meal-generated satiety signals. This means that more calories than normal must be consumed before a sufficient signal is generated to stop a meal. This situation persists until body weight returns to normal. Conversely, when an individual gains excess weight, the increased insulin and leptin signal in the brain results in increased sensitivity to satiety signals. Smaller meals are consumed until the excess weight is lost.

Adiposity Signals
