Insulin and leptin are hormones that are secreted in direct proportion to the amount of white fat in the body, and each is transported via a receptor-mediated process through the blood–brain barrier into the hypothalamus and other brain areas (see Figure 1). Neurons sensitive to insulin and/or leptin thus receive a signal directly proportional to the amount of fat in the body. As discussed in the following sections, when exogenous insulin or leptin is added locally into the brain, food intake is reduced and body weight is lost. Conversely, when either the leptin or the insulin signal is reduced within the brain, more food is eaten and the individual gains weight. Consistent with their common actions, there is evidence that insulin and leptin, acting via their respective receptors, activate a common intracellular signaling cascade in neurons. In obesity, although circulating levels of both insulin and leptin are elevated, a disproportionately small amount of circulating insulin and leptin is transported into the brain. Analogously, the brain of obese individuals is also relatively insensitive to leptin and insulin.

To summarize, insulin and leptin provide an integrated signal to the brain regarding the amount of body fat. This signal influences the activity of integrative networks controlling energy homeostasis. When incremented locally in the brain, leptin and insulin have a net catabolic action, causing individuals to eat less and lose weight. Conversely, when

Figure 1 Diagram of the negative feedback control of body weight by insulin and leptin. Leptin from white fat and insulin from the pancreas are secreted in direct proportion to adiposity. Each penetrates through the blood–brain barrier by a receptor-mediated process. Receptors for insulin and leptin are expressed by two groups of hypothalamic arcuate (ARC) neurons. These in turn project to other brain areas to elicit net anabolic or catabolic actions. Catabolic transmitters in these circuits include α-melanocyte-stimulating hormone (α-MSH), corticotropin-releasing hormone (CRH), and oxytocin; anabolic transmitters include neuropeptide Y (NPY), agouti-related protein (AgRP), melanin-concentrating hormone (MCH), and the orexins.

the adiposity signal is reduced in the brain, food intake and body weight are increased (Figure 1).

Insulin as an Adiposity Signal

The best-known action of insulin is to increase glucose uptake in most peripheral tissues, consequently lowering blood glucose level. Diabetic patients take exogenous insulin to reduce their hyperglycemia, and a not uncommon side effect of this routine practice is to lower blood glucose to the point of hypoglycemia. However, because hypoglycemia *per se* can elicit hunger and induce eating, the best characterized behavioral effect of insulin administration is increased food intake, which is a consequence of insufficient glucose reaching the brain. This is not a direct effect of insulin, since administering glucose along with insulin does not result in eating, and since reducing the ability of the brain to utilize glucose for energy by administering nonmetabolizable glucose analogs also increases eating.

Insulin Acts within the Brain to Decrease Food Intake

Plasma insulin is low during fasting (basal condition) and increases during and immediately after meals (prandial condition) or after glucose administration (stimulated condition). Basal, prandial, and stimulated insulin levels are all directly proportional to the amount of white adipose tissue in the body, leaner individuals having lower levels and more obese individuals having higher levels. The amount of insulin in the plasma therefore conveys a signal indicating the degree of adiposity to any insulin-sensitive tissue. Insulin enters the brain via insulin receptor-facilitated transport through capillary endothelial cells. The process is saturable and selective for insulin. The transport of insulin into the brain is reduced in fasted animals, in animals maintained on a high-fat diet, and in genetic and dietary-induced obesity.

Insulin receptors are expressed in many areas of the brain, with high concentrations in the mediobasal hypothalamus, especially the arcuate nucleus, which also expresses the most active form of the leptin receptor. This region is thought to mediate most of insulin's catabolic action. When exogenous insulin is administered directly into the brain, near or directly within the mediobasal hypothalamus, animals behave as if they have excess fat in the body (i.e., they reduce their food intake and lose weight). The response is dose dependent, has been documented in numerous species including nonhuman primates, is not secondary to illness or incapacitation, and is more robust in males than in females. Animals fed a high-fat diet have central insulin resistance, perhaps contributing to the obesity that often develops. When insulin antibodies are administered in or near the mediobasal hypothalamus, animals overeat and gain weight.

Although insulin has not been administered directly into the brains of humans, certain formulations of insulin have been administered intranasally to humans, with a consequent increase of cerebrospinal fluid but not plasma insulin. Humans receiving insulin in this way eat less food and lose body fat.

To summarize, increased insulin in the mediobasal hypothalamus provides a signal that ample or excess energy is available in the body, and one consequence is a reduction of the amount of energy subsequently ingested. Simultaneously, the increased hypothalamic insulin signal also elicits a vagal reflex to the liver to suppress the production of glucose. Increased insulin (as well as leptin) is therefore analogous to other signals, indicating a surfeit of energy, such as an increase of certain lipids or glucose locally within the hypothalamus; there is evidence that overlapping intracellular signaling pathways mediate the overall catabolic response to these diverse metabolic signals.

Leptin as an Adiposity Signal

Since its discovery in 1994, the peptide hormone leptin has been identified as a key signal indicating the level of adiposity to the brain. Leptin is secreted primarily from adipocytes in direct proportion to adipose mass, although the actual stimulus is related to glucose metabolism within the fat cell. Analogous to the situation with insulin, leptin circulates in proportion to adiposity, is transported through the blood–brain barrier, and interacts with leptin receptors in the mediobasal hypothalamus and elsewhere in the brain. Once formed, the leptin receptor can be differentially spliced to yield fragments of different lengths. Only the complete or long form of the receptor, which is called ObRb, has intracellular signaling capacity, and it is localized in hypothalamic areas important in the regulation of energy homeostasis. Although ObRb are expressed in many tissues throughout the body, only those in the hypothalamus are necessary for the control of energy homeostasis.

Decades before leptin was discovered, both its action as a hormone and its receptor were inferred from a series of clever experiments on genetically obese mice with naturally occurring mutations. Douglas Coleman identified one strain of mouse that lacked a single gene and that was consequently hyperphagic and obese; he called them *obob* (obese) mice. He identified a second strain with a similar phenotype (hyperphagic and obese) that he called *dbdb* (diabetic) mice. He further discovered that normal control mice as well as *dbdb* mice had a factor in their blood that would cause *obob* mice to eat less and lose weight. He correctly concluded that *obob* mice lack the key hormone which was subsequently identified as leptin. He also discovered that blood from control mice, as well as blood from *obob* mice, had no effect on the eating or body weight of *dbdb* mice, and correctly concluded that *dbdb* mice, while producing the secreted hormone (leptin), lack the gene for the receptor for the hormone and are thus blind to its actions. The subsequent identification of leptin and its receptor verified Coleman's work and confirmed his prediction that administration of pure leptin (once it was discovered) would cure the obesity of *obob* but not *dbdb* mice.

Leptin is considered to be a gatekeeper signal with regard to activities controlled by the hypothalamus. Low leptin signaling, which typifies the lean state, attenuates activities not essential to acute survival such as reproduction. As body fat increases and leptin levels rise, a threshold is passed that disinhibits these activities, and further increments of leptin above the threshold appear to have little consequence.

Administration of leptin systemically or directly into the brain in or near the ventral hypothalamus of experimental animals causes reduced food intake and body weight. At the same time, leptin acts in the brain to increase energy expenditure by activating the sympathetic nervous system. Because of these actions, it was initially thought that exogenous leptin or other ligands for the leptin receptor could be used to treat human obesity. However, administering leptin systemically has not proved beneficial for weight loss in humans with frank obesity, although it might provide some benefit for individuals with type 2 diabetes. Because of this, the focus of trying to find therapeutic targets for leptin or for insulin to tackle body weight has shifted to circuits within the hypothalamus.

Central Neural Networks Influenced by Insulin and Leptin

Leptin receptors that are critical for leptin's catabolic actions are located mainly in the mediobasal hypothalamus and especially the arcuate nucleus (ARC), an area that contains parallel anabolic and catabolic circuits that are tonically active and influenced by adiposity as well as many other signals (**Figure 1**). The presence of these opposing hypothalamic circuits enables rapid and fine-tuned control over energy homeostasis, since the brain can simultaneously turn up one system (e.g., catabolic or anabolic) while turning down the other. Insulin and leptin cause a net reduction of activity in hypothalamic anabolic circuits and a net increase of activity in hypothalamic catabolic circuits.

Insulin and leptin interact with two specific populations of ARC neurons. Activity of neurons that synthesize proopiomelanocortin (POMC), the precursor molecule of the melanocortins, is stimulated by insulin and leptin, whereas activity of neurons that

synthesize neuropeptide Y (NPY) plus agouti-related protein (AgRP) is inhibited by insulin and leptin. α-Melanocyte-stimulating hormone (α-MSH) is a melanocortin that is derived from ARC POMC and is an agonist at melanocortin receptors (MC3R and MC4R) in several hypothalamic nuclei; AgRP is an endogenous antagonist of these same melanocortin receptors. Central administration of insulin or leptin, or the administration of α-MSH or synthetic agonists for melanocortin receptors, or the application of treatments that reduce ARC NPY (e.g., antisense oligonucleotides administered directly into the ARC), all result in reduced food intake and body weight. Conversely, the administration of NPY, AgRP, or synthetic melanocortin antagonists, or the absence of endogenous insulin or leptin signaling, all result in a net increase of food intake and body weight.

In sum, the ARC contains at least two types of neurons, the integrated activity of which determines body fat. ARC neurons respond directly to adiposity signals, as well as to local levels of energy-rich fuels, including glucose and long-chain fatty acids. The ARC also receives satiety information from the hindbrain. ARC neurons project to diverse brain areas, including several nearby regions of the hypothalamus. The paraventricular nuclei (PVN) expressing MC3R/MC4R and various Y receptors are targets for α-MSH, AgRP, and NPY. PVN neurons in turn secrete neuropeptides that exert a net catabolic action, including corticotropin-releasing hormone (CRH) and oxytocin. Central administration of CRH or oxytocin reduces food intake. Hence, excess body fat is signaled to the ARC via increased insulin and leptin activity, eliciting increased α-MSH and decreased NPY and AgRP activity. This in turn elicits increased activity in second-order neurons of the PVN, leading to reduced food intake and increased energy expenditure.

Lateral hypothalamic (LHA) neurons also receive axons from the ARC, and they secrete the anabolic peptides melanin-concentrating hormone (MCH) and the orexins. Central administration of either peptide increases food intake and body weight. The presence of opposing hypothalamic circuits for controlling energy homeostasis enables rapid and fine-tuned control over energy homeostasis, since the brain can simultaneously turn up one system (e.g., catabolic or anabolic) while turning down the other.

Central Resistance to Adiposity Signals

Obese individuals have high circulating insulin and leptin, yet they do not respond to these signals by reducing their caloric intake and losing weight. They are therefore said to be insulin and leptin resistant. Evidence suggests that the mechanism(s) underlying the resistance is manifest at several levels. First of all, as obesity increases, the proportionate amount of circulating insulin and leptin that is able to cross the blood–brain barrier decreases, such that the signal reaching key brain receptors is lower than is reflected in the blood. Second, the number of insulin receptors in the brain of several animal models of obesity is reduced. Finally, there is evidence that the intracellular signaling pathways linked to insulin and leptin receptors on brain neurons are compromised in obesity. Thus, in obesity, less insulin and less leptin arrive at brain neurons, the neurons have reduced numbers of insulin and leptin receptors, and when those receptors bind with insulin or leptin, the effect is reduced.

Recent evidence suggests that consumption of a diet containing relatively high amounts of saturated fats produces central insulin resistance independent of developing obesity *per se*. Finally, although the brains of both males and females respond to both insulin and leptin, there is an important sex difference. Females are relatively more sensitive to leptin whereas males are relatively more sensitive to insulin. One implication is that treatment strategies for obesity based on these adiposity signals might have to be gender specific.

Integration of Satiety and Adiposity Signals

Total daily food intake is the sum of intake in each individual bout or meal (including snacks). As discussed earlier, meal initiation is thought to be under the control of psychological as opposed to homeostatic signals. Regulatory control of energy intake based on homeostatic demands must therefore be exerted on how much is eaten during each meal, and meal size is at least partly under the influence of satiety signals. There is compelling evidence that the ability of satiety signals to terminate a meal varies with body fat, as signaled to the brain by leptin and insulin. When an individual has been calorie restricted (i.e., been on a diet) and loses weight, a reduced adiposity signal reaches the hypothalamus. This in turn reduces the sensitivity of the individual to satiety signals. The consequence is that larger meals are eaten. Conversely, individuals who have overeaten and gained weight have an increased adiposity signal, resulting in enhanced sensitivity to satiety signals.

Thus, a regulatory system exists in the brain that functions to maintain weight relatively stable over long periods of time. If circumstances dictate that body fat is reduced (or gained), the change is signaled to the brain with the result that more (or less) calories

are consumed at each meal. This situation persists until body fat is restored to its original level.

Conclusion

The brain – in particular the arcuate nucleus of the hypothalamus – receives and integrates diverse information pertinent to the maintenance of adequate stored energy as well as to the availability of ready-to-use energy in the blood in the form of glucose. The adiposity signals insulin and leptin provide a background tone in the hypothalamus, and this tone in turn determines the sensitivity of the individual to satiety signals, influencing how much food is eaten at any one time, as well as the sensitivity of the liver to signals that control glucose production. Malfunction of the signaling pathway for either leptin or insulin in the brain leads to increased fat deposition, peripheral insulin resistance and hyperglycemia, and/or other symptoms of the metabolic syndrome.

Introduction

Cannabis sativa preparations, such as marijuana, hashish, and dagga, have been used in medicine for many centuries. *Cannabis* derivatives have also been proposed for patients in whom it is necessary to promote feeding and to reduce vomiting. Furthermore, the orexigenic properties of *Cannabis* have been anecdotally noted for causing the 'munchies' after marijuana smoking. Following the discovery of Δ^9-tetrahydrocannabinol (THC) as the main component of *Cannabis*, it became clear that this compound was responsible for the food intake promotion induced by marijuana. THC, also known as dronabinol, has been largely and rather successfully used to stimulate appetite in human syndromes characterized by wasting diseases, such as cancer or acquired-immunodeficiency-syndrome-associated anorexia, or forms of dementia, including Alzheimer's disease. More recently, the pharmacological blockade of cannabinoid type 1 (CB1) receptors by CB1 antagonists has emerged as a key component of comprehensive treatment of abdominal obesity and its multiple cardiometabolic abnormalities.

In this context, two notions confirm the importance of the endocannabinoid system in the regulation of food intake and energy metabolism. On the one hand is the finding of a high degree of evolutionary conservation of the role of this system in the regulation of feeding responses. On the other hand, high levels of endocannabinoids in maternal milk are critically important for the initiation of the suckling response in newborns.

The Endocannabinoid System

Endocannabinoid Synthesis and Degradation

After the identification of the chemical structure of THC, cannabinoid research received a further important boost by the discovery of the CB1 receptor, the binding site of exogenous cannabinoids. In the early 1990s, together with the characterization of another cannabinoid receptor named CB2, the first endogenous ligands for CB1 and CB2 receptors, anandamide (*N*-arachidonoylethanolamine) (AEA) and 2-arachidonoylglycerol (2-AG), were identified. Both are nonoxidative derivatives of arachidonic acid. Over the past few years, several other derivatives of long-chain polyunsaturated fatty acids have been described; they appear to act, at least in part, through CB1 and CB2 receptors. Their functions are, however, less characterized as compared to AEA and 2-AG.

Endocannabinoids are lipophilic substances and their synthesis derives from phospholipid precursors. Unlike other neurotransmitters or hormones, they are not stored in vesicles but rather are released 'on demand.' This peculiar characteristic needs, therefore, a strict regulation of the different phases of their release, uptake, and degradation. In general, the synthesis of endocannabinoids is triggered by elevated intracellular concentrations of Ca^{2+}, such as during membrane depolarization. However, Ca^{2+}-independent processes have also been proposed to induce endocannabinoid synthesis.

The formation of AEA occurs in two steps. Initially, the precursor phosphatidylethanolamine, an abundant lipid present in the cell membrane, exchanges the ethanolamine moiety with an arachidonic acid moiety to yield *N*-arachidonoyl phosphatidylethanolamine using the enzyme *N*-acyltransferase. Thereafter, AEA is synthesized from this intermediate by the recently cloned *N*-acylphosphatidylethanolamine-selective phospholipase D. In addition, AEA can also be synthesized from *N*-arachidonoyl phosphatidylethanolamine via an additional intermediate, *N*-arachidonoyl phosphatidyl lysoethanolamine. The second major endocannabinoid, 2-AG, is synthesized in two steps from phosphatidylinositol, another lipid precursor abundantly present in membranes. Two different pathways have been described for the synthesis of 2-AG: 1,2-diacylglycerol and lysophosphatidylinositol were found to be intermediate products. A phospholipase C and a phospholipase A1, respectively, are involved in the generation of the two intermediate compounds. Two diacylglycerol lipase (DAGL) enzymes (DAGL-α and DAGL-β) catalyzing the synthesis of 2-AG from 1,2-diacylglycerol have recently been cloned. The other enzymes involved have not yet been clearly identified.

In a way similar to mechanisms involving 'classical' neurotransmitters, it is proposed that endocannabinoids – after exerting their effects in the extracellular space – are taken up into the cell by a transport mechanism. Transport is not driven by transmembrane ion gradients, but it does appear to be facilitated by membrane diffusion of these lipophilic compounds. The molecular identity of a putative endocannabinoid transporter(s) has not yet been

Figure 1 Continued.

ascertained. However, it has become clear that this process is complex and likely involves several proteins and mechanisms.

The degradation of endocannabinoids is better understood than is the biosynthesis. AEA is hydrolyzed to arachidonic acid and ethanolamine by the enzyme fatty acid amide hydrolase (FAAH). Degradation of 2-AG likely involves at least two enzymes. Monoacylglycerol lipase appears to be responsible for about half of the 2-AG-hydrolyzing activity, suggesting that additional 2-AG-hydrolyzing enzymes may exist.

Signal Transduction of the CB1 Receptor

In the central nervous system (CNS), endocannabinoids can act as neurotransmitters, transferring information from one neuron to the next. Here, postsynaptically released endocannabinoids travel to the presynaptic site where they activate CB1 receptors. They thus mediate a retrograde signal (Figure 1). The overall effect is a decrease in the presynaptic release of neurotransmitters such as glutamate and γ-aminobutyric acid (GABA). This phenomenon is present in synaptic connections of many brain regions, thus representing an important modulatory mechanism of neuronal transmission. The signal transduction of cannabinoid receptors might lead to the stimulation of different intracellular pathways, depending on the cell type involved and the experimental conditions. For instance, the CB1 receptor, which normally inhibits adenylate cyclase, can also stimulate the cyclic adenosine monophosphate (cAMP) pathway in some conditions. Moreover, recent results suggest the possibility of functional interactions of CB1 receptors with other receptors – for instance, with type 1 orexin receptors, 5-hydroxytryptamine (5-HT_2; serotonin) receptors, and dopamine D2 receptors. The possibility that such interactions depend on hetero-oligomerization processes might represent a very interesting novel aspect that will expand the view of the pharmacology and physiology of the endocannabinoid system. Activation of the CB1 receptor is also able to inhibit N- and P/Q-type voltage-activated inward Ca^{2+} channels in a $G_{i/o}$-dependent, but adenylate cyclase-independent, manner. CB1 receptor stimulation is also coupled to the opening of K^+ channels in a $G_{i/o}$-dependent manner. A-Type potassium ($K^+{}_A$) channels are activated by the CB1 receptor through dephosphorylation processes, probably mediated by the inhibition of adenylate cyclase, whereas inwardly rectifying K^+ (K_{ir}) channels are stimulated by direct coupling to the $G_{i/o}$ proteins. Cannabinoids acting at CB1 receptors are able to decrease the Ca^{2+} influx by inhibiting N- and P/Q-type Ca^{2+} channels and to increase the efflux of K^+ ions by activating K_{ir} and $K^+{}_A$ channels in neurons. Stimulation of K^+ and inhibition of Ca^{2+} currents are generally considered as the main effects of CB1 receptors on intracellular ion levels. However, contrary effects have also been described in certain neuronal systems. CB1 receptor stimulation activates extracellular signal-regulated kinases (ERKs), and the phosphorylation of ERKs in the hippocampus appears to physiologically depend on the 'on-demand' activation of the endocannabinoid system. Another important kinase pathway modulated by CB1 receptor is the phosphoinositol 3-kinase (PI3K) and its downstream effector protein kinase B (PKB; also known as Akt). Interestingly, at least in *in vitro* systems, the activation of the PI3K pathway appears to be upstream to the stimulation of ERK phosphorylation. Therefore, CB1 receptor stimulation might activate the PI3K pathway, which in turn activates Raf-1, and subsequently stimulates ERK phosphorylation. Thus, activation of ERKs might be linked to several intracellular effects, such as activation of Na^+/H^+ exchanger and activation of phospholipase A_2. Moreover, ERK stimulation might link CB1 receptor to the expression of immediate-early genes (IEGs). Several transcription factors, such as zif268, c-fos, and c-jun, were shown to be activated by exogenous CB1 receptor agonists. In analogy to the activation of ERKs, the endocannabinoid system has been proposed to control expression of zif268 and c-fos in pathophysiological conditions. Brain-derived neurotrophic factor (BDNF) is encoded by another immediate-early gene that is regulated *in vivo* and *in vitro* both by pharmacological treatment with CB1 receptor agonists and by endogenously produced cannabinoid. In summary, endocannabinoids appear to be very versatile signaling mediators.

Distribution of Cannabinoid Receptors in Tissues and Cells Controlling Energy Balance

Expression studies show that the CB1 receptor is one of the most abundant G-protein-coupled receptors in the mammalian brain. CB1 receptors have been found in all brain regions involved in the control of

Figure 1 Retrograde signaling mediated by endocannabinoids (ECs) and cannabinoid type 1 (CB1) receptors. (a) A presynaptic neuron is activated by an action potential, inducing an increase of intracellular Ca^{2+}, which, in turn, activates the machinery for the release of neurotransmitter – for example, glutamate or γ-aminobutyric acid (Glu/GABA; empty circles). (b) During synaptic neurotransmission, a stimulus in the postsynaptic neuron (e.g., depolarization) can induce the synthesis of ECs from the postsynaptic membrane. (c) Postsynaptically synthesized ECs are released into the synaptic cleft and activate presynaptic CB1 receptors. CB1 activation induces a decrease of presynaptic Ca^{2+} and, thereby, reduces the release of neurotransmitter. Note: This is a simplified representation of the retrograde signaling of ECs. Different mechanisms have been described to be involved in these events.

energy intake, including the nucleus accumbens, the paraventricular (PVN), and the ventromedial hypothalamic nuclei, in the lateral hypothalamus, the nodose ganglion, and the vagus nerve, and in the myenteric neurons and epithelial cells of the large intestine. In some regions of the brain, the ratio between the estimated amount of CB1 receptor and the level of G-protein activation is not always constant, thus indicating regional differences in receptor-coupling efficiencies. This is important to consider, because sometimes the endocannabinoid system seems to exert functions involving regions where the density of CB1 receptors is relatively low (e.g., in the hypothalamus, modulation of food intake). Therefore, the activity of cannabinoids on CB1 receptors cannot be predicted based solely on the relative receptor density, and other factors, such as receptor-coupling efficiency, should be taken into account. Finally, recent studies have highlighted CB1 receptor presence in various peripheral organs involved in metabolic control, including adipocytes, hepatocytes, endocrine pancreatic cells, and skeletal muscle cells.

Neuronal Endocannabinoid Control of Food Intake

Analogous to what has been described for THC, endocannabinoids also display orexigenic properties, and after the synthesis of specific CB1 receptor antagonists, the orexigenic properties of endocannabinoids have been definitively attributed to an activation of CB1 receptor.

Regulation of Rewarding Properties of Food by Endocannabinoids

As a general hypothesis, endocannabinoids gradually increase during intermeal intervals, reaching a critical level in order to trigger the motivation to eat. In favor of this possibility it should be borne in mind that AEA and 2-AG levels are increased in the fasting condition in the nucleus accumbens and are decreased after a meal. The endocannabinoid system is considered as a general stress recovery system and is overall 'silent.' The system exerts its modulatory actions only 'when' and 'where' it is needed to maintain the homeostasis after a stressful perturbation and its activation exhibits tightly regulated spatial and temporal selectivity. If this theory holds true, the elevation of endocannabinoids after fasting to promote food intake fits in this scenario. In fact, fasting remains one of the most challenging stressors for animals. In this view, the longer the time since the last meal, the greater the activity in relevant endocannabinoid circuits, and consequently the higher is the motivation to eat, driven by endocannabinoids. The endocannabinoid system is one of the key players in the modulation of 'reward/reinforcement' circuitry that is represented by an interconnection of brain nuclei associated with the medial forebrain bundle, linking the ventral tegmental area, the nucleus accumbens, and the ventral pallidum. The most relevant pathway of this circuitry is represented by the mesolimbic dopaminergic system. A relevant cross-talk between limbic endocannabinoid and dopaminergic systems to modulate the rewarding properties of tasty food is known to occur, as documented by the ability of a dopamine D1 antagonist to reduce the orexigenic stimulus induced by THC. Therefore, bearing in mind the anatomical distribution of CB1, which is highly expressed in the mesolimbic area, the initial leading hypothesis was in favor of a role of endocannabinoids as modulators of the appetitive value of ingested substances. Therefore, the first CB1 receptor antagonists were tested in many experimental settings aimed at monitoring their ability to reduce the intake of palatable food or alcohol. Whether the endocannabinoids increase the incentive value of the food, regardless of the quality of the macronutrients ('incentive hypothesis'), or, as also derived from experiments in humans with phytocannabinoids, whether endocannabinoids drive the search for highly palatable food ('orosensory reward hypothesis'), is still an unsolved issue. The opioid system is another important neuronal signaling system involved in the modulation of food intake. Endocannabinoids act in a synergistic manner with opioids to stimulate feeding behavior, and this interaction seems to occur not only at the mesolimbic system level but also at the level of the PVN of the hypothalamus.

The cross-talk between endocannabinoids and serotoninergic pathways in the modulation of feeding behavior has been less investigated as compared to the opioidergic one. Nonetheless, it seems that the two pathways stimulate food intake via independent mechanisms of action.

Endocannabinoids and the Neural Hypothalamic Network Controlling Food Intake

At the hypothalamic level, specific neuronal populations exert a strategic control over food intake. By interconnecting different hypothalamic nuclei, this network provides high levels of adaptability of feeding behavior to a multiplicity of central and peripheral signals. Signals coming from various peripheral organs, such as the liver, gastrointestinal tract, and adipose tissue, are conveyed at the hypothalamic level to constantly inform the brain about the state of nutrition via neural and humoral routes (see Figure 2). On the other hand, the hypothalamus appears to be sensitive to a wide range of metabolic perturbations associated with

Figure 2 Schematic representation of the putative role of endocannabinoids through cannabinoid type 1 (CB1) receptor activation in the hypothalamic circuits controlling food intake, depicting sites of action of hypothalamic endocannabinoids (black arrows) on corticotropin-releasing hormone (CRH) neurons in the paraventricular nucleus (PVN), on orexin (ORX) and melanin-concentrating hormone (MCH) neurons in the lateral hypothalamus (LH), and on proopiomelanocortin/cocaine- and amphetamine-regulated transcript (POMC/CART)-producing neurons (ARC, arcuate nucleus; AgRP, agouti-related protein; NPY, neuropeptide Y). In addition, the endocannabinoid system has been described to control glutamatergic and GABAergic transmission onto several hypothalamic nuclei.

fuel availability. In turn, this information is used to adjust both caloric intake and the deposition of fuels in the periphery.

Endocannabinoids are variably produced in the hypothalamus of rodents administered a standard diet. Analogous to the endocannabinoid changes at the level of mesolimbic system, 2-AG levels have been shown to increase during acute fasting, decline as the animals are re-fed, and return to normal values in satiated animals in the hypothalamus. Moreover, as demonstrated in adult rodents and in pups from undernourished dams, long-term food deprivation is known to reduce the amount of endocannabinoid production. Therefore, also at the hypothalamic levels endocannabinoids seem to display the ability to quickly respond to changes in nutritional states.

Leptin signaling interacts with endocannabinoids at the level of the hypothalamus. Animal models of impaired leptinergic signaling resulting in an obese and hyperphagic phenotype, such as that exhibited by *ob/ob* or *db/db* mice or *fa/fa* Zucker rats, are characterized by increased levels of endocannabinoids in the hypothalamus. Moreover, a single intravenous injection of leptin in *ob/ob* mice reduces the pathological overproduction of endocannabinoids. In these animals, CB1 antagonist treatment is able to reduce food intake, confirming the anorectic properties of this class of drugs. CB1 receptors present in the lateral hypothalamus co-localize with melanin-concentrating hormone (MCH) and prepro-orexin neurons. Populations of both orexin and MCH neurons have been implicated in the hedonic or motivational aspects of food intake by modulating projections to dopaminergic neurons in the ventral tegmental area. MCH neurons (promoting an increase in food intake) are tonically inhibited by GABAergic inputs coming from the limbic system. On one hand, by decreasing GABA release, endocannabinoids may enhance the excitability of MCH neurons, leading to increased feeding behavior, while on the other hand, by inhibiting the voltage-gated calcium currents in the same neurons, the leptin signal may result in less synthesis and release of endocannabinoids, leading to a reduced excitability of MCH neurons and to a decrease in appetite as a final effect. Therefore, the lateral hypothalamus may represent the site of converging signals between hypothalamic and mesolimbic structures to mediate the orexigenic activity of endocannabinoids.

An interaction between endocannabinoids and corticotropin-releasing hormone (CRH) has been hypothesized, based on the co-expression of CRH and CB1 mRNA in the PVN and the co-expression of CRH type 1 receptors and CB1 receptors in several brain regions. Accordingly, postsynaptically released endocannabinoids acting at presynaptic CB1 receptors are able to decrease glutaminergic transmission onto CRH-producing neurons, resulting in an inhibition of CRH release. This release of endocannabinoids from the parvocellular neurons is stimulated by a nongenomic effect of glucocorticoids. Therefore, it is conceivable that the well-known regulation of food intake by glucocorticoids may partly derive from a functional cross-talk with the endocannabinoid system.

The arcuate nucleus is the production site of neuropeptide Y (NPY), one of the most important hypothalamic orexigenic neuropeptides. NPY-positive neurons send projections to other feeding areas, including the PVN, the ventro- and dorsomedial hypothalamus, and the lateral hypothalamus. The presence of CB1 receptors in the arcuate nucleus is very limited if not absent, and the NPY/agouti-related protein system in the arcuate nucleus does not seem to be directly targeted by endocannabinoid action. However, endocannabinoids have been found to increase, and a CB1 receptor antagonist to decrease, depolarization-induced NPY release in a hypothalamic explant. This evidence does not mean that the effect of cannabinoids on NPY neurons is caused by a direct action, but it is more likely that cannabinoid agonists and antagonists are able to affect an intermediate factor, which in turn alters NPY release.

A functional cross-talk between CB1 receptors and melanocortin receptor type 4 (MCR4) receptors in the control of food intake has been recently highlighted by the finding of the synergistic action of subanorectic doses of a CB1 antagonist and of an MCR4 agonist administered together. Furthermore, CB1 receptor antagonists are able to inhibit the stimulation of food intake induced by MCR4 antagonists, whereas the orexigenic impulse initiated by the administration of CB1 receptor agonists is not blocked by co-stimulation with MCR4 agonists. These findings seem to suggest that melanocortin receptor signaling in the hypothalamic regulation of food intake is upstream of the activation of the endocannabinoid system and that CB1 receptors display an obligatory role in α-melanocortin-stimulating hormone (α-MSH) effects on food intake.

The interaction between cocaine- and amphetamine-related transcript (CART) and endocannabinoids remains controversial. $CB1^{-/-}$ (knockout) mice in basal conditions have reduced CART expression, suggesting that blocking the endocannabinoid signaling impacts negatively on CART expression. In contrast, mice with a genetic deletion of the anandamide-degrading enzyme FAAH, having consequently increased levels of endocannabinoids, exhibit reduced CART immunoreactivity in several hypothalamic regions involved in food intake. Moreover, in the same animals, treatment with CB1 antagonists is able to restore normal levels of CART expression, indicating that inhibition of CART signaling by CB1 receptor activation may be involved in the orexigenic effect of AEA. In conclusion, there is solid evidence confirming the presence of an interaction between endocannabinoids and CART, but the precise physiological significance deserves further study for complete elucidation. In analogy to the interaction with the CART system, cross-talk between endocannabinoids and ghrelin is undergoing intense scrutiny. Ghrelin is a hormone released by the stomach into the bloodstream during food deprivation, to signal to the hypothalamus the need for energy intake. Treatment with CB1 antagonists has been shown to strongly reduce the orexigenic effect stimulated by intracerebroventricular injection of ghrelin. Therefore, ghrelin might promote food intake by elevating endocannabinoid hypothalamic levels, but this hypothesis needs to be confirmed by further evidence.

A growing spectrum of data indicates that, like many peripheral cell types, some hypothalamic neurons integrate information about fuel sources other than glucose, to modulate food intake. An increasing body of evidence points to a critical role for both fatty acid production and utilization in regulating hypothalamic neurons implicated in the control of food intake. Consistent with this, it has recently been proposed that endocannabinoids may modulate the fatty acid synthetic (FAS) pathway in the hypothalamus via CB1 receptors and that the increase in food intake following food deprivation may involve a CB1 receptor modulation of the FAS pathway. CB1 receptor antagonist treatment has been demonstrated to inhibit the increase in FAS hypothalamic expression, and this may explain the anorexigenic properties of cannabinoid antagonists.

Endocannabinoids and the Enteric Nervous System

The CB1 receptor and endocannabinoids are highly expressed in neurons of the gastrointestinal tract. In the small intestine, starvation induces a sevenfold increase in AEA release, and this effect is reversed on re-feeding. Cholecystokinin (CCK) is known to have an important satiety role and the CCK type 1 receptor is expressed in the same vagal afferent neurons which also express the CB1 receptor. These neurons project from the stomach and duodenum to the brain stem. In addition, CB1 receptor expression

in the nodose ganglia is increased by food deprivation and is decreased after re-feeding; this effect has been shown to be blocked by CCK antagonists and mimicked by administration of CCK. Therefore, the endocannabinoid system could also affect food intake acting through CCK signaling.

Peripheral Endocannabinoid Control of Energy Metabolism

The Endocannabinoid System and Peripheral Organs Involved in Control of Metabolic Processes

The endocannabinoid system plays a central role in the neuronal control of food intake and energy balance. However, recent results have added important elements to the scenario of the mode of action of endocannabinoids in the regulation of food intake and energy metabolism, and they indicate that peripheral nonneuronal cell types also contribute to the overall functions of the endocannabinoid system. The advent of the $CB1^{-/-}$ mouse model has provided a step forward to substantiate the hypothesis of an additional effect of endocannabinoids in peripheral organs. Animals lacking CB1 receptors are hypophagic, leaner, and lighter as compared to wild-type littermates. Importantly, pair-feeding experiments show that in adult $CB1^{-/-}$ mice, metabolic factors appear to be the major cause of the lean phenotype. These differences in body weight regulation are amplified when a high-fat diet is administered to the same groups of animals, allowing the conclusion that the lack of CB1 receptors may confer resistance to diet-induced obesity (DIO). These observations converge to support the idea that additional peripheral food intake-independent metabolic functions may participate, or even predominate, in the control of energy balance exerted by the endocannabinoid system. Similar observations were reported in DIO mice using pharmacological CB1 receptor blockade. Long-term treatment with CB1 antagonists produced a transient reduction in food intake in DIO mice followed by the development of tolerance to the anorectic effect of the drug. However, the effect on body weight was sustained until the end of the 5-week experiment as compared to vehicle-treated DIO mice. It is now becoming clear that endocannabinoids interact with all of the organs involved in the control of metabolic functions. CB1 receptors are functionally active in white adipocytes stimulating lipogenesis. Importantly, CB1 antagonist treatment induces adiponectin release from adipocytes in culture, in animals and also in humans. Adiponectin is an adipose tissue-derived peptide known to possess antiatherogenic and antidiabetic properties. The circulating levels of adiponectin are directly correlated to increased insulin sensitivity. Moreover, the peptide is able to decrease hepatic glucose production and to regulate free fatty acid metabolism, via suppression of lipogenesis and activation of free fatty acid oxidation.

The CB1 receptor is also present in skeletal muscles. In *ob/ob* mice, treatment with a CB1 receptor antagonist generates considerable glucose uptake in soleus muscle in comparison with vehicle-treated animals.

Activation of the CB1 receptor in the liver increases gene expression of the lipogenic transcription factor sterol regulatory element binding protein-1c (SREBP-1c) and of its targets, FAS and acetyl-CoA carboxylase-1 (ACC-1), leading to a stimulation of *de novo* lipogenesis. Moreover, prolonged consumption of a high-fat diet in mice increases hepatic levels of AEA and induces an upregulation of CB1 receptor expression that may in turn promote the development of steatosis.

Summary

Energy balance and food intake control represent an extremely exciting area for studies on the regulatory functions of the endocannabinoid system. Strong evidence supports the idea of plasticity in endocannabinoid tone when shifting from conditions of normal to impaired energy balance. In fact, endocannabinoid levels are transiently upregulated in the CNS areas involved in control of food intake following short food deprivation and are relatively chronically downregulated following long-lasting food restriction. Moreover, it seems that a permanent and pathological overactivation of the hypothalamic endocannabinoid tone is associated with obesity, contributing to the hyperphagia often associated to this disorder. In addition to this central mode of action, endocannabinoids also appear to act at a peripheral level, by targeting a large variety of organs involved in metabolic processes. By reducing intestinal motility and energy expenditure and by optimizing nutrient assimilation and storage, the endocannabinoid system may be one of the most important players in the generation of our ancestral precursor, the 'thrifty genotype,' a human who was exceptionally efficient in the intake and/or utilization of food. Nowadays, considering the dramatic differences in ancestral and contemporary human lifestyles, the endocannabinoid system may be one of the key elements to explain the pandemic phenomenon of obesity.

Energy Homeostasis: Hypothalamic Development

Arcuate Neurons Are Key Homeostatic Feedback Regulators of Energy Balance

There are three major brain pathways that influence feeding and energy homoeostasis. (1) Hormonal homeostatic feedback from peripheral metabolic signals (including insulin, leptin, adiponectin, glucose, free fatty acids, glucagon-like peptide-1 (GLP-1), ghrelin, peptide YY, and pancreatic polypeptide). Within the brain, these signals primarily act in the hypothalamus and brain stem and can be involved in both stimulation and inhibition of food intake. (2) Vagal-gustatory sensory signals activate the dorsal vagal complex in response to increased gut distention to inhibit food intake. (3) Hedonic or 'reward' circuitry from the cortical/limbic system regulates food based on palatability or rewarding properties.

The arcuate nucleus (ARH) is located at the base of the hypothalamus and is generally considered the key conduit for sensing peripheral signals of energy balance. Although these neurons are within the blood–brain barrier, they do appear to have specialized access to circulating factors. The nature of this specialized access remains to be determined. The neurons in the ARH transmit these homeostatic signals to other hypothalamic sites that integrate the peripheral metabolic signals with incoming signals from the brain stem (vagal-gustatory sensory signals) and the cortical/limbic systems (hedonic or 'reward'-based information). In general, it is thought that all of these signals converge onto the paraventricular nucleus of the hypothalamus (PVH), which in turn generates neuronal signals to initiate appropriate responses to maintain body weight and energy homeostasis (i.e., modulate energy expenditure or initiate food foraging). The exact mechanism by which the hypothalamus initiates feeding behavior or food foraging is poorly understood. The modulation of energy expenditure is through activation of autonomic neurons in the parvocellular region of the PVH. These autonomic neurons project to the brain stem and spinal cord (intermediallateral cell column (IML)) to activate sympathetic and parasympatheic outputs to target organs (i.e., pancreas, adipose tissue, liver).

The two most-studied populations of neurons in the ARH involved in regulating homeostatic feedback circuits are the orexigenic neuropeptide Y/agouti-related peptide (NPY/AgRP) neurons and the anorexic α-melanocyte-stimulating hormone (αMSH – a peptide cleaved from pro-opiomelanocortin (POMC) prohormone) neurons. In the hypothalamus, NPY is thought to stimulate food intake and suppress energy expenditure primarily through the Y1 receptor, a G-protein-linked receptor; however, there is strong evidence that both the Y2 and Y5 receptor subtypes also play a role. Both AgRP and αMSH regulate food intake and energy expenditure through the melanocortin receptors MC3 and MC4; AgRP is an endogenous antagonist, whereas αMSH is an agonist for these G-protein-linked receptors. Thus, ARH-NPY/AgRP neurons provide a powerful orexigenic signal through activation of the Y receptors and through antagonism of the anorexic MC3/4 receptors.

The importance of the ARH-NPY/AgRP and αMSH neurons in the regulation of homeostatic feedback control is conserved in most species, including fish, worms, birds, sheep, rodents, and primates (both human and nonhuman). The most likely species difference in the regulation of food intake is the hedonic- or 'reward'-based feeding, which appears to be more prominent in higher species and is especially developed in humans. It is this hedonic-based feeding that likely contributes the most to the obesity epidemic in humans.

Regulation of Feeding during the Early Postnatal Period in the Rodent

At birth, rodents are relatively undeveloped compared to primates, including the hypothalamic circuitry that controls food intake and energy expenditure (discussed later). During the early postnatal period in the rodent, feeding behavior is thought to be primarily regulated by a combination of maternal behavior and gut distention. Rodent pups spend most of their time sleeping, but grooming stimulation from the dams rouses the pups and initiates nursing. The nursing stimulus initiates kyphosis (a trancelike state) in the dam that allows the pups to feed until their stomachs are full. The increased gut distention activates vagal-gustatory feedback into the dorsal vagal complex in the brain stem to terminate feeding. The brain stem circuitry to the hypothalamus transmits gustatory-vagal sensory information that develops very early in the postnatal period, as do the reciprocal autonomic efferent projections from the PVH to the brain stem that regulate energy expenditure. Rodents get their sole source of nutrients from the dam's milk until

around postnatal day 15–17, when pups initiate independent consumption. At around 21–23 days of age, most rodents in the laboratory setting are weaned from their dams.

Development of ARH Homeostatic Feedback Circuits in the Rodent

The NPY System

Throughout the brain there are numerous populations of NPY neurons that are involved in a variety of functions (reproductive neuroendocrine function, stress responses, fluid balance, learning and memory, etc.). However, NPY is primarily studied as one of the most abundant and potent orexigenic neuropeptides. While NPY neurons are present throughout the brain, the major source of NPY production within the hypothalamus of the normal adult rodent is the ARH-NPY neurons. In specific models of hyperphagia and obesity there is a second population of NPY neurons within the dorsomedial nucleus of the hypothalamus (DMH) that can become activated to play a role in energy homeostasis.

Rodents are born with NPY-expressing neurons within the ARH, with NPY expression in the ARH increasing throughout the postnatal period to peak around postnatal day 15–16. However, during the postnatal period (postnatal days 10–21) there is also expression of NPY in neurons in several other hypothalamic regions that are not present in the normal adult rodent. This includes NPY-expressing neurons in the DMH, both the compact and noncompact zones, PVH, perifornical region (a critical region for NPY-induced food intake), and the lateral hypothalamus. All of these regions are important energy homeostasis areas. The expression of NPY in these regions is low at birth and rapidly increases to peak around postnatal day 15–16 and subsequently decline or disappear before postnatal day 30. The physiological importance of these different populations of hypothalamic NPY neurons during postnatal development, and their role in the regulation of food intake, remains unexplored. It is of interest that the peak expression of NPY in all of these regions coincides with the initiation of independent ingestion. It is possible that NPY is an important signal for motivating maturing pups to search out additional food sources when milk from the dam can no longer provide the proper nutrients or the dam can no longer produce quantities sufficient to support the whole litter.

The role of NPY in the regulation of food intake during the early postnatal period is supported by evidence that central administration of NPY into the PVH as early as postnatal day 2 increases milk consumption in pups. Furthermore, there is an abundance of NPY Y1 receptor gene and protein expression throughout the hypothalamus at birth, including the critical 'feeding centers.' Thus, it makes sense that the NPY system may play an important role in providing the appetitive drive to meet the energy demands of growth and development. It is recognized that NPY is not the sole regulator of food intake during development or in the adult. In fact, mice with mutations of the NPY or NPY receptor genes display near normal growth and development. However, recent studies have shown that while destruction of ARH-NPY neurons early in development allows near normal development, destruction of these neurons in adult rodents causes a wasting disease. This indicates that the absence of NPY during the early postnatal period leads to compensation by other orexigenic systems, but that if present throughout development, the NPY system develops into a critical regulator of food intake in the adult rodent.

The Melanocortin System

The melanocortin system provides one of the most potent anorexigenic signals and is likely the key system for homeostatic feedback regulation of energy balance. Like the NPY system, the main populations of melanocortin neurons (αMSH and AgRP) are located within the ARH. Furthermore, it has been well documented in the adult rodent and primate that AgRP, the endogenous antagonist to the melanocortin system, is exclusively localized to ARH-NPY neurons.

Nearly all of the components of the melanocortin system (αMSH, AgRP, and MC4 receptors) are present in the hypothalamus at birth. However, while there are several populations of NPY neurons in the hypothalamus during postnatal development, only the ARH-NPY neurons co-localize AgRP. Likewise, within the hypothalamus, POMC neurons are also limited to the ARH. αMSH (POMC) neurons are also present in the solitary tract nucleus in the brain stem; however, very little is known about their function or projections. It is well recognized that the melanocortin system is one of the most important regulators of food intake and energy expenditure in adults; this appears to be true in all species from rodents to humans. Genetic deletion or mutations leading to inactivation of the melanocortin system (including the POMC, MC3 or MC4 genes, as well as prohormone converting enzymes) lead to obesity. In humans, mutations of the melanocortin system are the most common genetic cause of obesity. Overexpression of the endogenous melanocortin antagonists (AgRP or agouti) also leads to obesity.

In rodents, deletion of members of the melanocortin system causes a late-onset obesity that does not become evident until after 4 weeks of age. In contrast, in humans, mutations of the melanocortin system cause early-onset obesity, with children developing hyperphagia as infants. The reason for the different obesity ontogeny between rodents and humans likely has to do with the difference in the timing in the development of hypothalamic circuitry (discussed later).

Development of ARH Projections in Rodents

At birth, NPY fibers are present throughout the hypothalamus, but the source of this NPY is unknown. Recent studies have begun to track the sources of the NPY fibers using specific markers for ARH-NPY and brain stem–NPY projections. Prior to postnatal day 5, neither ARH nor brain stem NPY projections are developed, suggesting that local NPY-producing cells in the PVH, DMH, perifornical region, and lateral hypothalamus must be main sources of NPY during the neonatal period. Brain stem–NPY projections to the hypothalamus, which co-express norepinephrine, develop during the latter half of the first postnatal week and likely play a role in the regulation of food intake through modulation of vagal-gustatory feedback, but this remains to be confirmed.

ARH-NPY projections develop during the second and third postnatal week, with projections reaching the DMH around postnatal day 10 and the PVH around postnatal day 15. Other populations of ARH neurons appear to show a similar developmental pattern, but this has not been systematically worked out for all neurons in the ARH. This delayed development of ARH projections has several significant implications: (1) the lack of prominent anorexigenic ARH-αMSH projections to the PVH, combined with the abundance of local NPY, would promote an appetitive drive; (2) postnatal environmental cues, such as nutrition, likely have a significant impact on the development of ARH projections and could have long-term implications on body weight regulation (to be discussed later); and (3) there is not a functional homeostatic feedback circuit during this period.

Ontogeny of Homeostatic Feedback Control of Energy Balance in Rodents

Leptin is the most recognized and studied homeostatic feedback signal. This hormone is produced and secreted from adipose tissue in proportion to adipose mass as a signal to the brain. One of the major sites of action of leptin is the ARH, where leptin inhibits orexigenic NPY/AgRP neurons and activates anorexigenic αMSH neurons. Thus, when body fat stores are high, leptin signals the brain to reduce food intake and increase energy expenditure. When body fat stores are decreasing, such as during weight loss or in response to a fast, the decrease in leptin release is permissive for an increased appetitive drive. The importance of leptin feedback is highlighted by evidence that chronic leptin treatment results in sustained reductions in food intake and weight loss, while mutations of the leptin or leptin receptor genes result in severe obesity (in both rodents and humans).

In the adult rodent, leptin is a potent inhibitor of food intake and stimulator of energy expenditure. However, during the early postnatal period, prior to the development of ARH projections, leptin administration has no effect. What is surprising is that leptin treatment does not become effective at modulating food intake and energy expenditure until the fourth postnatal week, long after the development of ARH projections. This indicates that even though the ARH projections are intact, they are unable to transmit the homeostatic signal related to body fat.

Leptin and Insulin Are Key Signals for the Development of ARH Projections in the Rodent

While leptin does not play a role in the regulation of body weight homeostasis during the early postnatal period, it does play a critical role in the development of ARH projections. In rodents there is an endogenous surge of leptin that occurs during the second postnatal week. What causes this leptin surge is unknown. However, in mouse models that lack functional leptin or leptin receptor genes, ARH circuits fail to fully develop. Without the intact ARH projections the brain loses its major homeostatic feedback regulator and the result is hyperphagia and obesity. Leptin replacement specifically during the second postnatal week in leptin-deficient mice, mimicking the endogenous leptin surge, results in a normal development of ARH projections and partially reverses the obese phenotype in these animals.

While it is evident that the absence of leptin compromises the development of ARH projections, there is also evidence that too much leptin during the postnatal period can also cause abnormalities in hypothalamic function. In rodent models, chronic postnatal overfeeding results in early-onset obesity that persists into adulthood. Accompanying the early-onset obesity is a three- to fourfold increase in leptin levels during the early postnatal period. While there is no evidence to date to indicate that there are abnormalities in the development of ARH projections in animals with hyperleptinemia, there is

clear evidence that the responsiveness of neurons within the hypothalamus to homeostatic signals (leptin and insulin) is permanently altered. Thus, homeostatic feedback regulation of food intake and energy expenditure is likely blunted. Furthermore, in adult animals overfed during the early postnatal period, responsiveness of neurons within the PVH to NPY is dramatically increased, resulting in an increased orexigenic drive.

Insulin, produced from pancreatic β cells, is the key regulator of glucose homeostasis. Insulin receptors are highly expressed in the fetal brain in many species, including rodents and humans, and this expression declines during the postnatal period. Insulin is recognized as a potent neurotrophic factor; however, its role in brain development is not limited to the ARH or the hypothalamus. Both maternal hyperinsulinemia (induced by insulin treatment during pregnancy) and hypoinsulinemia (induced by streptozotocin destruction of the β cells) cause widespread abnormalities in brain development. However, it is difficult to determine what effects are due directly to the insulin, or lack thereof, and what is due to the changes in glucose levels. Genetic deletion of insulin receptors or any of its key downstream signaling components also causes severe abnormalities in overall brain development, such as reduction in neuronal proliferation. Because of the broad range and severity of the effects of knockout of components of the insulin system, it is difficult to discern a specific role in the development of ARH circuits.

Development of ARH Projections in Primates

Most of the neuropeptide and hormonal signals that are important for the regulation of food intake and energy balance in the rodent have also been shown to be important in primates (human and nonhuman), including NPY, AgRP, αMSH, leptin, and insulin. However, there are some basic differences in the neurocircuitry controlling food intake between the rodent and the primate. Within the hypothalamus of the normal adult nonhuman primate there are NPY neurons within the PVH, DMH, and ARH (also referred to as the infundibular nucleus in primates). The NPY neurons within the ARH likely play a role in homeostatic feedback regulation of energy balance similar to that in rodents. The role of NPY neurons in the PVH and DMH is less certain, yet mild metabolic challenges activate the NPY neurons in the PVH, suggesting that they are involved in the regulation of food intake and/or energy expenditure. Another significant difference between rodents and primates is the connections between the brain stem and hypothalamus. The GLP-1 neurons in the brain stem are activated by the vagus in response to gut distention and inhibit food intake through efferent projections to the hypothalamus. In rodents, the PVH and DMH are the major efferent targets of GLP-1 neurons. In contrast, the primary projection of GLP-1 neurons in the nonhuman primate is the ARH. The purpose of the direct interaction between the vagal-gustatory and homeostatic feedback circuits in the primate remains to be determined. Finally, there is a difference in the ontogeny of the brain, including the hypothalamus, between rodents and primates.

In nonhuman primates, NPY, AgRP, and αMSH neurons are evident in the ARH by the end of the second trimester. However, at this early age ARH projections to downstream target sites are sparse. The ARH projections to the DMH, PVH, and other hypothalamic centers develop during the third trimester and appear to be near fully developed by birth. While the development of ARH projections has not been studied in humans, NPY neurons are present in the ARH from the late second trimester fetal brain tissue, suggesting that the ontogeny of these neurons and their projections is likely similar to the nonhuman primate. The development of the ARH circuits during the third trimester suggests that maternal health and diet are likely critical environmental factors. Furthermore, perturbations in energy balance (i.e., over- or undernutrition) or poor maternal health, such as obesity and/or diabetes, during this 'critical period' of neuronal plasticity in the primate could cause abnormal development of this circuit, leading to permanent alterations in body weight management.

Energy Homeostasis: Paraventricular Nucleus (PVN) System

D Richard and E Timofeeva, Laval Hospital Research Center and Laval University, Quebec, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The paraventricular nucleus (PVN), which is located in the dorsorostral hypothalamus adjacent to the third ventricle, represents a major integratory region in the brain with recognized neuroendocrine, autonomic, and behavioral functions. The PVN controls the activity of key hypothalamic–pituitary–target organ systems that include the thyrotropic and corticotropic axes, which are also referred to as the hypothalamic–pituitary–thyroid (HPT) and the hypothalamic–pituitary–adrenal (HPA) axes. The controls exerted by the PVN on the HPT and HPA axes are in large part ensured by cells from the parvicellular neurosecretory system, including the thyrotropin-releasing hormone (TRH) and corticotropin-releasing factor (CRF) neurons. The parvicellular neurosecretory division together with the magnocellular neurosecretory system and the descending division constitute the three major functional parts of the PVN. The magnocellular neurosecretory system, which also has a major neuroendocrine function, hosts neurons that synthesize significant amounts of vasopressin and oxytocin, which are released into the circulation via neuron terminals ending in the posterior pituitary and which control water balance and blood pressure (vasopressin), as well as parturition and lactation (oxytocin). The descending division comprises neurons that innervate the brain stem and spinal cord and coordinates autonomic and behavioral responses.

The PVN, through the complex and integratory involvement of its neuroendocrine, autonomic, and behavioral functions, is in a key position to markedly influence energy homeostasis (or energy balance). Indeed, the parvicellular neurosecretory system, via its control over the HPA and HPT axes, modulates, together with the descending division, the regulation of energy homeostasis, which is achieved through fine-tuned controls exerted on energy intake (food intake) and energy expenditure (thermogenesis).

The PVN and Regulation of Energy Balance

The role played by the PVN in regulation of energy balance and hence of body weight and body fat stores has been acknowledged for years. Experimental lesions of the PVN, as well as *Sim1* haploinsufficiency, which provokes a hypodevelopment of the nucleus, lead to an excessive fat deposition in laboratory rodents. Sim1 is a basic helix–loop–helix Per–Arnt–Sim (bHLH-PAS) transcription factor that has proved to be necessary for the growth of several major cell types in the PVN, including oxytocin-, vasopressin-, TRH-, and CRF-containing neurons. These cells represent key players in the neuroendocrine, autonomic, and behavioral functions of the PVN. Additionally, the PVN is connected with numerous regions involved in the control of food intake and thermogenesis. Specifically, both the parvicellular neurosecretory system and the descending division receive major inputs: (1) those from the brain stem report on visceral signals and on the nutritional status, (2) those from the limbic system convey emotion/reward-related signals, and (3) those from the arcuate nucleus (ARC) plus the surrounding hypothalamic nuclei redirect to the rest of the brain information about the nutritional status and the state of energy stores. The PVN is rich in appetite- and thermogenesis-modifying neuropeptides/neurotransmitters, which exert their effect when directly microinjected within its major divisions. The list of these neuropeptides/neurotransmitters includes CRF, oxytocin, vasopressin, TRH, neuropeptide Y (NPY), melanocyte-stimulating hormone (α-MSH), galanin, cocaine- and amphetamine-regulated transcript (CART), opioid peptides, histamine, serotonin, and noradrenaline.

Data from studies carried out in PVN-lesioned laboratory rodents or in *Sim1* haploinsufficient ($Sim^{+/-}$) mice tend to suggest that the PVN participates in energy balance regulation mainly by controlling energy intake. PVN-lesioned and $Sim^{+/-}$ animals show hyperphagic behaviors without exhibiting marked changes in energy expenditure. However, one cannot exclude some role for the PVN in the control of energy expenditure. Selective excitation of the PVN and PVN microinjections of thermogenesis-inducing substances stimulate heat production in small laboratory animals. A role for the PVN in the control of energy expenditure is also supported by compelling neuroanatomical evidence associating the nucleus to the sympathetic innervation of brown adipose tissue (BAT), which represents an extraordinary thermogenic effector in small mammals. BAT thermogenesis is referred to as adaptive or facultative thermogenesis, as it may occur as a mechanism to increase energy expenditure in the sole purpose of regulating energy balance.

Figure 1 The neuroendocrine paraventricular nucleus and the regulation of energy balance. The paraventricular nucleus (a) corticotropin-releasing factor (CRF) and (b) thyrotropin-releasing hormone (TRH) cells project to the anterior pituitary, where they control the release of glucocorticoids and thyroid hormones. Glucocorticoids enhance visceral fat deposition by increasing food intake and reducing energy expenditure, whereas thyroid hormones reduce fat deposition by decreasing the food intake/thermogenesis ratio. The parvicellular neurosecretory division that contains the CRF and TRH cells is highly innervated by neurons originating from regions strategically positioned to relay signals informing about nutritional status and energy homeostasis. ACTH, adrenocorticotropic hormone; AGRP, agouti-related protein; AR, adrenergic receptor; ARC, arcuate nucleus; BST, bed nucleus of the stria terminalis; E, epinephrine; GABA, γ-aminobutyric acid; 5HT, 5-hydroxytryptamine; LH, lateral hypothalamus; MC4R, melanocortin receptor 4; MSH, melanocyte-stimulating hormone; NE, norepinephrine; NPY, neuropeptide Y; ORX, orexins; OXR, orexin receptors; T3, triiodothyronine; T4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; Y1, NPY receptor 1.

The Neuroendocrine PVN and Energy Balance Regulation

The parvicellular neurosecretory system of the PVN governs two major neuroendocrine entities, namely the HPA and the HPT axes, which are of particular importance in the regulation of energy balance (Figure 1). The HPA and HPT axes each comprise distinctive neuroendocrine cells located in the parvicellular division of the PVN; these cells control the activities of the axes. The PVN parvicellular CRF neurons, also called the hypophysiotropic CRF cells, govern the HPA axis by commanding the pituitary release of the adrenocorticotropic hormone (ACTH), which stimulates the secretion of corticosteroids from the adrenal cortex via the circulation. Similarly, a selective population of parvicellular TRH neurons controls the activity of the HPT axis and thereby the release into circulation of the thyroid hormones. The activation of the HPT axis is catabolic (decrease in energy/fat deposition), whereas that of the HPA axis generally increases energy/fat deposition.

The HPA axis activity is primarily stimulated by stressful conditions, which excite PVN CRF cells. When stimulated, the HPA axis, which is also referred to as the stress axis, causes the release of corticosteroids (cortisol in human and nonhuman primates; corticosterone in small mammals such as laboratory rodents). In humans as well as in laboratory rodents, excess in corticosteroids is generally associated with visceral/intra-abdominal fat retention. This phenotype is remarkable in patients with Cushing's syndrome, who are not only diagnosed with high circulating levels of corticosteroids but also are characterized by an excessive waist circumference and its associated deleterious health consequences.

The role played by the HPA axis in the regulation of energy balance has further been emphasized in several animal models of obesity, which include the Zucker *fa/fa* rat, a leptin-resistant rat due to a mutation in the gene encoding the long form of the leptin receptor (Ob-Rb), and the *ob/ob* mouse, a leptin-deficient mouse as a result of a mutated leptin gene. In both models, which display hyperactive HPA axes, disruption of the HPA axis through adrenalectomy prevents, blocks, or cures excessive fat deposition by removing corticosterone from the circulation. In laboratory rodents, corticosteroids enhance fat deposition by stimulating energy intake and inhibiting

BAT thermogenesis. Corticosterone is in fact a strong repressor of uncoupling protein 1 (UCP1). UCP1, the activity of which is largely dictated by the sympathetic nervous system (SNS), is a mitochondrial inner membrane protein that confers BAT with an immense thermogenic power. The SNS stimulation of UCP1 uncouples fuel oxidation from ATP synthesis by dissipating the proton gradient that builds up across the mitochondrial inner membrane during the transport of electrons through the mitochondrial respiratory chain during the process of oxidative phosphorylation. In uncoupled BAT adipocytes, ATP production is markedly reduced, which releases a major constraint on energy oxidation and therefore allows BAT mitochondria, upon SNS stimulation, to oxidize fat at an accelerated rate and to produce a considerable amount of heat.

The activity of the HPA axis is modulated by fluctuations in energy stores and by the nutritional status. In laboratory rodents, food restriction/deprivation is associated with high circulating corticosterone levels that result, in most circumstances, from a reduced plasma clearance of the hormone. In fact, in lean rats, food deprivation elevates corticosterone levels while it reduces CRF synthesis within the PVN CRF hypophysiotropic cells. However, in some models of obesity, elevation of corticosteroid levels associated with food restriction/deprivation appears centrally triggered. In the obese Zucker rat, for instance, acute food deprivation leads to a stimulation of the PVN CRF neurons, which readily increases the activity of the pituitary–adrenal complex and the release of corticosterone into the circulation. In this model, the pattern of brain activation elicited by food deprivation shows similarities with the pattern seen following neurogenic (interoceptive or psychological) stresses. In the Zucker rat, food deprivation seems to represent one of the most powerful stimulators of the PVN CRF cells of the HPA axis. This enhanced activity of the HPA axis is immediately suppressed upon eating, revealing the importance of the nutritional status in controlling the activity of the PVN CRF neurons, at least under certain circumstances. The nutritional status also appears to control the HPA axis activity in humans, in whom reductions in cortisol secretion and depressive mood after stress have been reported following the ingestion of a high-carbohydrate diet. There is evidence, in both humans and rodents, that stress may enhance the intake of specific palatable foods, which could be energetically beneficial, rewarding, and potentially 'comforting.'

Alternatively, severe stress has often been associated with anhedonia and anorectic effects. These effects have been attributed to an enhanced activation of the CRF system, which is incidentally not restricted to the population of hypophysiotropic cells found in the PVN, since CRF cells are widely distributed throughout the brain. CRF, through its two G-coupled receptor subtypes 1 and 2, which are also expressed in several brain regions, is capable of a very strong anorectic effect. The brain site for this effect does not appear to be the PVN and remains to be firmly determined. The CRF-mediated anorectic effect of stress does not therefore involve the PVN hypophysiotropic CRF neurons. These cells, which project to the external layer of the median eminence, where they release CRF through numerous terminal boutons into the proximal capillary plexus of the hypothalamic–hypophysial portal system, appear to fulfill a rather selective stimulatory role on corticotrophs. The action of the PVN CRF hypophysiotropic neurons on energy homeostasis is mainly mediated through the HPA axis and hence the release of corticosteroids. Yet, one should bear in mind that the control of the PVN CRF neurons is complex, being typically integrated into a stress response that superimposes over numerous neuronal circuitries that may individually influence food intake. The PVN receives major inputs from the brain stem and hypothalamic nuclei, which release peptides/neurotransmitters such as α-MSH, NPY, orexins, and catecholamines, whose action are mediated through various receptor types located on hypophysiotropic CRF cells, within the parvicellular neurosecretory system.

The HPT axis, which is also under the control of the neuroendocrine PVN, exerts nontrivial effects on energy homeostasis, most probably through the release of thyroid hormones. The activity of this axis is governed by TRH neurons found in the parvicellular neurosecretory division. These neurons, which seemingly also express other peptides, such as CART, project to the external zone of the median eminence, where they are ultimately responsible for the pituitary release of thyroid hormones. These hormones have proved to be of significant influence in the control of energy expenditure, generating up to 30% of the resting metabolic rate. The exact mechanism whereby thyroid hormones act to stimulate thermogenesis has yet to be fully elucidated. In small laboratory rodents, thyroid hormones modulate SNS-mediated BAT adaptive thermogenesis. There is also evidence that thyroid hormones enhance heat production through a regulated mitochondrial proton leak, which has yet to be described in terms of its functionality.

The PVN TRH cells receive major inputs from the brain stem and other hypothalamic nuclei, principally from the ARC. These inputs, as is the case for the CRF hypophysiotropic cells, are capable of

modulating the activity of the TRH cells, which are very sensitive to energy store oscillations. It has been acknowledged for years that a state of negative energy balance, such as that generated by fasting, strongly represses the activity of the TRH cells and downregulates TRH mRNA expression within the hypophysiotropic TRH neurons selectively. These effects lead to a significant reduction of HPT axis activity and hence to a reduction in TRH-mediated thermogenesis. Deprivation-induced hypothyroidism may be an important adaptive response that reduces energy expenditure in an attempt to minimize energy loss. This adaptation to energy shortage, which is achieved in concomitance with an increased activity of the HPA axis, further substantiates the significant implication of the neuroendocrine PVN in the regulation of energy balance.

The PVN Descending Division and Energy Balance Regulation

The descending division of the PVN consists of the dorsal and ventral medial parts of the structure that send projections to the brain stem dorsal vagal complex (DVC) and to the preganglionic autonomic neurons of the spinal cord. The DVC comprises the area postrema, nucleus of the tractus solitarius (NTS), dorsal motor nucleus of the vagus nerve. The descending division, which also innervates the parabrachial nucleus, periaqueductal gray, and ventral medulla, as well as nearby areas, receives, from the ARC and the brain stem, major inputs integrating signals informing about energy homeostasis. Other projections to the descending division include those from the dorsomedial hypothalamus (DMH), ventromedial hypothalamus (VMH), medial preoptic area (MPOA), and bed nucleus of the stria terminalis (BNST).

The PVN descending division consists of a heterogeneous population of cells with different morphology and physiological properties. It mainly comprises oxytocin and vasopressin neurons; the former are mostly located in the dorsal parvicellular subdivision, whereas the latter are predominantly found in the ventral part of the medial parvicellular subdivision. The subset of oxytocin neurons projecting to the brain stem is thought to be of particular significance in the role played by the PVN in the control of food intake and energy expenditure. This group extends to the DVC and to the intermediolateral (IML) column cells of the spinal cord and receives an important contingent of axons from the DVC capable of conveying visceral signals informing about energy stores and nutritional status. It is probable that oxytocin neurons can also influence thermogenesis, as they functionally connect to BAT. The use of retrograde transsynaptic tracers has indeed highlighted a functional anatomical link between the oxytocin neurons of the descending division and BAT. Oxytocin neurons connect to the IML in the spinal cord, which comprises preganglionic sympathetic neurons that project to the stellate ganglion, from which originates postganglionic SNS neurons innervating BAT adipocytes of the interscapular depot. It is noteworthy that the group of preganglionic autonomic PVN neurons includes cells that are also immunoreactive to CRF, TRH, somatostatin, met-enkephalin, and dynorphin. Some PVN CRF neurons projecting to the spinal cord have been identified both in the ventral part of the medial parvicellular subdivision and in the medial posterior parvicellular part of the PVN.

The ARC–PVN Pathway in Energy Balance Regulation

The PVN receives major inputs from the ARC, which currently is one of the most investigated hypothalamic nuclei in connection with energy homeostasis. The ARC is a tiny nucleus found in the basomedial hypothalamus just above the median eminence and adjacent to the third ventricle, in a position slightly caudal to the PVN. It comprises two populations of neurons strongly involved in the control of energy intake and energy expenditure, and capable of integrating peripheral signals that affect energy homeostasis. One population of neurons synthesizes proopiomelanocortin (POMC), whereas the other synthesizes NPY and agouti-related peptide (AGRP). Stimulation of POMC neurons, which also co-localize CART, is associated with a decrease in food intake and an increase in energy expenditure, whereas the activation of NPY/AGRP neurons leads to opposite effects. The POMC and NPY/AGRP neurons innervate both the descending division and the parvicellular neurosecretory area of the PVN, through which they mostly act to influence energy homeostasis (Figure 2).

POMC neurons exert their catabolic effect mainly via α-MSH, a peptidergic fragment resulting from POMC cleavage. Within the brain, α-MSH binds to melanocortin 3 and melanocortin 4 receptors (MC3R, MC4R), with which it forms, together with AGRP, the 'homeostatic' melanocortin system. The functional significance of both the MC3Rs and MC4Rs in energy homeostasis has been validated in *Mc3r* and *Mc4r* knockout mice. The ablation of the gene encoding MC3Rs enhances visceral fat deposition, whereas the targeted disruption of MC4Rs causes a massive and widespread body fat deposition. In

Figure 2 The arcuate nucleus–paraventricular nucleus pathway. The paraventricular nucleus receives an important contingent of fibers from the arcuate nucleus, which comprises two populations of neurons markedly involved in the regulation of energy balance. These neurons produce neuropeptide Y (NPY), agouti-related protein (AGRP), and proopiomelanocortin (POMC), three peptides capable of significantly modulating the effects of the neuroendocrine and autonomic/behavioral paraventricular nucleus on energy balance. The arcuate nucleus expresses receptors that mediate the effect of blood-borne hormones on energy balance. CRF, corticotropin-releasing factor; GHS-R, growth hormone secretagog receptor; IR, insulin receptor; LRb, leptin receptor, long form; m, magnocellular division of the paraventricular nucleus; OT, oxytocin; TRH, thyrotropin-releasing hormone.

humans, the MC4R deficiency represents the most commonly known monogenic form obesity; up to 2–3% of severely obese patients apparently have pathogenic MC4R mutations. The excessive fat deposition occurring in *Mc4r* knockout mice has been found to result from an increase in energy intake and a decrease in energy expenditure. AGRP is an endogenous antagonist of the melanocortin receptors that is solely expressed in the ARC neurons, where it is co-synthesized with NPY. AGRP is overexpressed in obese mice. When injected centrally, it increases food intake and reduces energy expenditure, similar to synthetic melanocortin receptor antagonists.

Unlike the MC3R, which is virtually absent from the PVN, the MC4R is expressed in the three major parts of the structure. Microinjections of MC4R ligands into the PVN reduce food intake, without apparently causing aversive effects. The role of the PVN in the anorectic effect mediated by the MC4R is well accepted. It has recently been demonstrated that the PVN reactivation by Cre-recombinase of the gene encoding the MC4R may correct the hyperphagia seen in *Mc4r* null allele mice (loxTB *Mc4r* mice). Reactivation of *Mc4r* in loxTB *Mc4r* mice was achieved by crossing these mice with Sim1–Cre transgenic mice to allocate the reexpression of *Mc4r* selectively in Sim1-expressing cells, which are mostly found in the PVN.

The neural circuitry involving the PVN MC4R in the control on food intake is currently largely unknown. Several MC4R mRNA-containing cells are located throughout the dorsal and ventral parvicellular parts of the PVN that constitute the descending division. It remains to be firmly established whether these neurons are clearly those that are responsible for the MC4R-mediated control of food intake. It is also not entirely clear whether the PVN MC4R plays a major role in controlling energy expenditure, even though a large proportion of the PVN neurons that are associated with the sympathetic outflow to white adipose tissue and BAT express the MC4R. The recent observation that the rather selective PVN reactivation of the *Mc4r* gene did not rescue the blunted thermogenesis observed in loxTB *Mc4r* mice cast doubts about the real influence of the PVN MC4R in the control of thermogenesis – this is despite the demonstration that microinjection of MC4R agonists within the PVN increases energy expenditure.

Alternatively, the PVN MC4R could influence energy homeostasis through the parvicellular neurosecretory division. There indeed exists a strong anatomical and functional relationship between the central melanocortin system and the PVN TRH neurons. A majority of the hypophysiotropic TRH neurons are dually innervated by POMC and NPY/AGRP neurons from the ARC. MC4R agonism activates the TRH system while it blocks fasting-induced repression of TRH synthesis in the PVN. Also, energy shortage is known to stimulate the expression of NPY and AGRP, which are strong inhibitors of the HPT axis. It is noteworthy that the number of AGRP fibers reaching the vicinity of the TRH neurons exceeds that of α-MSH-containing terminals, which is in line with the observation that AGRP accounts for the variations in HPT axis activity linked to oscillating energy stores.

The PVN also expresses Y1 and Y5 receptors, which are recognized as the main receptors mediating the action of NPY on energy balance. NPY represents a potent orexigenic peptide, the expression of which in the ARC is markedly stimulated in obese and food-deprived animals. In the PVN, Y1 and Y5 receptor mRNAs are expressed in a pattern very similar to that of the MC4R. NPY injected into the PVN not only stimulates food intake but also inhibits thermogenesis by BAT. The functional importance of NPY, as well as that of AGRP, in the regulation of energy balance has

recently finally found a genetic endorsement when mice genetically engineered for a selective ablation at the adult stage of the AGRP/NPY-expressing neurons were shown to exhibit an acute reduction in feeding. The selective ablation of these neurons leads to a significant reduction in the NPY-immunostained axons and terminals in the PVN, further emphasizing the relevance of ARC–PVN pathway in the regulation of energy balance. Ablation of the AGRP/NPY-expressing neurons is seemingly ineffective in neonates, in which compensatory adaptations may occur to rescue the lack of NPY/AGRP cells. It is noteworthy that conventional inactivation of *Npy*, *Npyr1*, *Npyr5*, and *Agrp* genes is largely inefficacious to influence body weight regulation in expected ways.

The neuronal pathways involved in the PVN Y1 and Y5 receptor-mediated effects on food intake and energy expenditure are not fully understood. These receptors are expressed in cells of the dorsal and ventral parvicellular parts of the PVN that host descending division neurons through which NPY may affect the control of food intake and energy expenditure. NPY could also exert a PVN-mediated effect on energy balance through its influence on the parvicellular neurosecretory division. NPY stimulates the HPA axis at the PVN level by stimulating CRF synthesis in hypophysiotropic CRF neurons. The elevated expression of NPY in obese and food-deprived animals has been associated with the stimulated HPA axis activity seen in those animals, which also exhibit a reduced HPT activity involving Y1 and Y5. This control exerted by NPY/AGRP neurons on the neurosecretory parvicellular system of the PVN further illustrates the importance of the neuroendocrine part of PVN in energy homeostasis.

The role played by the ARC–PVN pathway in the regulation of energy balance is modulated by adipostatic signals such as leptin and insulin, as well as by acute satiety/hunger signals such as PYY and ghrelin. These hormones most probably act at the level of the ARC to modify the PVN regulation of energy balance, even though direct actions at the levels of the PVN or indirect action through the brain stem cannot be excluded. The ARC NPY/AGRP and the POMC/CART neurons are sensitive to the action of leptin, insulin, ghrelin, and PYY.

The adipocyte-derived hormone leptin markedly decreases food intake and fat stores when injected in leptin-deficient humans or leptin-deficient *ob/ob* mice. Leptin acts in the brain, where it is actively transported and where it binds to its long-form receptor (Ob-Rb). It exerts its catabolic action mainly (not exclusively) at the level of the hypothalamus, where, through the STAT3 signaling cascade, it reduces the production of NPY and AGRP while stimulating synthesis of POMC. Importantly, leptin also acts early in life as a trophic signal that stimulates the ARC axon outgrowth to the PVN, lateral hypothalamus, and DMH. The effect of leptin on brain plasticity also translates into acute increases in the ratio of inhibitory synapses to the number of excitatory synapses on the ARC NPY and in the ratio of number of excitatory synapses to number of inhibitory synapses on the ARC POMC. Likewise, recent studies have highlighted the importance of adenosine monophosphate-activated protein kinase (AMPK) in the anorectic effect of leptin. AMPK is seen as a gauge for the cellular energy status and its activity is downregulated in the ARC and PVN following leptin administration; melanocortin receptor (MCR) agonism and MCR antagonism, respectively, decrease and increase AMPK activity in the PVN. Leptin also blunts the activity of the HPA axis in leptin-deficient *ob/ob* mice through a suppression of the activity of the PVN CRF hypophysiotropic neurons. Even though it is more and more certain that the effects of leptin on the PVN are mostly exerted through the ARC, the possibility nonetheless remains that the hormone can also act at the levels of the PVN as the nucleus synthesizes the Ob-Rb.

A central role for insulin in the regulation of energy balance has been advocated. Central administration of insulin reduces food intake and stimulates thermogenesis, and mice with a neuron-specific disruption of the insulin receptor gene develop diet-sensitive obesity. Similar to leptin, insulin has been reported to reduce the activity of NPY/AGRP neurons and to stimulate the POMC cells. The effect of insulin on the ARC–PVN pathway is in a certain way comparable to that of leptin.

The gastrointestinal hormones peptide tyrosine-tyrosine (PYY) and ghrelin also influence the activity of the ARC–PVN pathway. PYY, which has two endogenous forms, $PYY_{1–36}$ and $PYY_{3–36}$, acts at the level of the ARC to exert catabolic effects through the Y2 receptor via a mechanism that has yet to be fully delineated. $PYY_{3–36}$ reduces food intake in MC4R and POMC knockout mice, which suggests that the melanocortin system is not essential to the action of the peptide. This observation does not preclude an ARC-mediated action of PYY, since $PYY_{3–36}$ increases neuronal activity in the ARC and since the selective hypothalamic deletion of Y2 receptor, upon which acts PYY, alters the expression of both POMC and AGRP in the ARC. In contrast to PYY, ghrelin stimulates food intake. The orexigenic action of this peptide, which is abundantly produced in the

stomach, is mediated through the growth hormone secretagog receptor, which is found on the NPY/AGRP neurons that project to the PVN. Peripheral administration of ghrelin induces c-*fos*, a neuronal activity marker, in both the ARC in the PVN, suggesting that ghrelin, like leptin, insulin, and PYY, produces ARC effects that may ultimately influence the descending division and the parvicellular neurosecretory system of the PVN.

Conclusion

The PVN is an integratory region that plays a major role in the regulation of energy balance. Through its parvicellular neurosecretory system and through its descending division, this hypothalamic nucleus is indeed capable of significant controls on both energy intake and thermogenesis. The parvicellular neurosecretory system comprises the neuroendocrine TRH and CRF cells, the metabolic roles of which are exerted through the HPA and HPT axes. The activities of these axes in turn are highly coordinated with those of the neurons of the descending division that govern ingestive and other complex behaviors, as well as autonomic controls exerted on the cardiovascular, respiratory, and thermoregulatory/metabolic functions. The parvicellular neurosecretory system and the descending division are highly innervated by neurons originating from regions strategically positioned to relay signals informing about the nutritional status and energy homeostasis. Those regions received projections from the ARC, a prominent player in the regulation of energy balance. The ARC sends the PVN an important contingent of fibers, the terminals of which release in the PVN NPY, AGRP, and α-MSH, three peptides capable of significantly modulating the role of the neuroendocrine and autonomic/behavioral PVN on energy balance. The ARC harbors receptors, which mediate the effect of blood-borne hormones on energy balance.

Energy Homeostasis: Thermoregulation

K J Kaiyala, University of Washington, Seattle, WA, USA

Introduction

Mammalian and avian core body temperatures (T_{core}) are generally stabilized within impressively narrow limits by intricate and highly adaptive biobehavioral control systems. This stability occurs, often despite marked fluctuations in environmental and metabolic conditions, because powerful behavioral and autonomic effector responses are recruited in the face of anticipated or actual disruptions of T_{core} and/or skin temperature (T_{skin}).

Thermoregulatory strategies fall into two categories, behavioral responses and reflexive autonomic responses. Much of thermoregulation in higher mammals (almost all in humans) is accomplished via behavior, the neural control of which is barely understood. Reflexive autonomic thermoregulatory responses are generated in accordance with the principles of negative feedback control wherein sufficient disruptions of T_{core} and/or T_{skin} are sensed by the central nervous system (CNS) and translated into corrective responses via neuronal and peripheral effectors of body temperature. Accordingly, the recruitment of autonomic thermoeffector responses alters the balance between the rates of body heat production (HP) and heat loss (HL) so as to favor corrective changes of body temperature; to a reasonable approximation, the addition or subtraction of 1 cal of heat energy changes the temperature of 1 g of body mass by 1 °C.

Much progress has been made in understanding autonomic mechanisms of thermoregulation. This article is focused on autonomic effectors of HP and HL in terms of four simplified models designed to identify and synthesize some of the important concepts and anatomical substrates of modern thermoregulatory theory. Each model represents the efferent limb of a particular, relatively independent thermoregulatory control loop, one each for the control of nonshivering thermogenesis, shivering thermogenesis, cutaneous blood flow, and sweating. This organization reflects an overarching theoretical framework according to which multiple, relatively independent control loops govern each of the effector responses that promote HP and HL. The models trace their neuronal protocols to Jack Boulant and owe their inspiration and general architecture largely to Evelyn Satinoff, Shawn Morrison, Kazuyki Kanosue, and William Blessing, and their many fine colleagues. The models embrace the concept that thermoregulation is governed by a diverse set of relatively independent control loops, as opposed to a unitary central integrator which generates functionally coordinated efferent responses. The independence-of-control-circuits-hypothesis was initially propounded by Satinoff in the late 1970s and early 1980s, and is nicely compatible with the Boulant neuronal model. The independent-loops concept has been emphasized recently by Andrej Romanovsky, Kanosue, and other prominent thermoregulatory investigators.

The models emphasize a role for warm-sensitive neurons (which increase their firing rate with increasing temperature) as the thermal integrators involved in the establishment of both the lower and upper body temperature thresholds for the activation of corrective effector responses. The schema presented here invoke three classes of warm-sensitive neurons, one with a firing rate near the upper limit at normal T_{core}, one with a firing rate intermediate between the upper and lower limits at normal T_{core}, and one with a firing rate near the lower limit at normal T_{core}. All three classes have been observed experimentally. The concepts emphasized in this article are congruent with a wealth of experimental data and avoid some vexing theoretical problems faced by traditional set-point models and by models assuming a great deal of reciprocal inhibition between pathways for HP and HL.

Heat Production

Metabolic HP in homeotherms can be divided into obligative and facultative components. Obligative HP corresponds to the basal metabolic rate (BMR), a largely theoretical construct corresponding to the minimum metabolic rate obtained under ideal homeostatically benign conditions in unstressed, mildly fasted, and resting individuals. BMR is technically problematic, and is often replaced by resting metabolic rate (RMR), a slightly higher value measured under standardized conditions (in humans, RMR is the value obtained in a supine individual at rest in a thermoneutral environment, following an 8–12 h fast). BMR (and thus RMR) is sufficient for thermal homeostasis during exposure to ambient temperatures in the thermoneutral zone (TNZ), which, in fact, is often defined as the range of ambient temperatures in which metabolic rate remains at its minimal level (~28–32 °C in rats, ~25–27 °C in humans, corresponding to a BMR of ~70 and 17.5 cal kg^{-1} min^{-1}, respectively). In fact, in the TNZ, both HP

and evaporative heat loss (EHL) are at basal or resting values, and T_{core} is stabilized at the usual defended level (typically ~37 °C in advanced mammals) solely by vasomotor responses. Facultative thermogenesis refers to the increase of HP that occurs when ambient temperature decreases below the lower limit of the TNZ. Autonomic facultative thermogenic mechanisms include nonshivering thermogenesis (NST) and shivering thermogenesis (ST).

Homeotherms also employ behavioral means of increasing metabolic HP, exploiting the modest mechanical efficiency of muscular work (~10–20%) to obtain the heat. This strategy is certainly familiar to readers with outdoor experience, such as legions of hikers, campers, and skiers.

Nonshivering Thermogenesis

NST is an increase of metabolic rate that is not mediated by increased muscular contractile activity. It is customary to define NST as the increase in metabolic heat production above the normal basal level in response to cold exposure. In small mammalian species (e.g., mice and rats), NST involves a remarkable, specialized heat-producing organ, brown adipose tissue (BAT), while in larger species (e.g., adult humans) the role of BAT in NST is contentious. BAT is an organ both specialized to produce heat and vested with a substantial adaptive ability to increase its thermogenic capacity in the face of relevant homeostatic challenges, including cold exposure and chronic caloric excess. Indeed, BAT is a critical organ of survival in conditions of cold exposure in small mammals such as rats and mice, which have a 'dangerously' large surface area:volume ratio. BAT is also essential to thermal homeostasis for neonatal rodent species that are poorly insulated (lacking fur) and largely incapable of shivering at birth. It should be noted that BAT thermogenesis largely or completely replaces shivering as the major mode of heat production during cold acclimation in rodents. BAT is strategically located in the intrascapular, cervical, pericardial, intercostal, and perirenal regions. BAT is highly vascularized, and the vascular architecture is optimized to facilitate heat transfer from BAT to key anatomical areas, including the spinal cord and heart. BAT has an impressive thermogenic capacity, and can generate over 5500 cal kg^{-1} min^{-1} under experimental conditions. BAT is regarded as an important organ of thermoregulation in infant humans, but has been mostly dismissed as a meaningful participant in adult thermoregulation. More recently, however, the concept that BAT may play a meaningful role in adult human thermoregulation (and in body fat regulation) has come to be regarded more favorably by some investigators. It is interesting to note that BAT has been shown to be essential to obesity resistance in various rodent models of body fat regulation, including high-fat feeding in mice.

BAT achieves its remarkable thermogenic capability by way of a high density of large mitochondria which express in their inner membranes a unique guanosine diphosphate (GDP)-binding protein, uncoupling protein 1 (UCP1). This protein prevents the electrical potential energy in the mitochondrial proton gradient (generated by fuel oxidation and the electron transport chain) from being transferred (coupled) into the high-energy chemical phosphate bonds in adensosine triphosphate (ATP), the obligatory currency for most energy-requiring processes in the body. Instead, UCP1 allows protons to leak down their gradient into the mitochondrial matrix such that potential energy is transferred into heat energy rather than high-energy chemical bonds in ATP.

Resting energy expenditure and autonomic adaptive thermogenesis (activation of BAT and perhaps other UCP-expressing tissues, as well as ST) are regulated chiefly by the sympathetic nervous system (SNS). The SNS–BAT–UCP1 axis is relatively well understood in rats, mice, and rabbits, with many of the recent conceptual advances stemming from obesity-related research. NST is also proposed to occur to a lesser extent in other tissues, such as liver and muscle, but several aspects of this proposal await further data for clarification. In humans, NST appears to be chiefly dependent upon thyroid hormones. Interestingly, some neurons in the brain appear to be capable of releasing heat, and this phenomenon has been experimentally manipulated by generating mice that overexpress the putative mechanism for this neuronal heat production, an uncoupling protein analogous to the UCP isoform described for BAT.

Model for the Control of BAT Thermogenesis

Figure 1 illustrates a simplified scheme for the regulation of BAT thermogenesis by thermal and nonthermal factors. The scheme includes a parsimonious subset of the many brain areas implicated in BAT regulation, sufficient to be congruent with some important properties of thermoregulation, including alteration of thermogenic responses during fever, the fact that stress evokes a substantial increase in T_{core} (often called 'stress hyperthermia'), and the facts that feeding and adiposity significantly modulate T_{core} and thermogenic responses (e.g., states of caloric excess promote thermogenesis whereas states of caloric deficiency inhibit thermogenesis and decrease mean daily T_{core}). A key area is the preoptic anterior hypothalamus (POAH), a brain region critical to the

Figure 1 Model for the control of BAT thermogenesis by the sympathetic nervous system. Under thermoneutral conditions, intracapsular brown adipose tissue (IBAT) facultative thermogenesis is fully inhibited. This inhibition reflects a high level of inhibitory drive produced by preoptic anterior hypothalamic (POAH) warm-responsive (W) neurons acting on tonically excited neurons (++ and premotor (PM+)) in the dorsomedial hypothalamus (DMH) and rostral raphe pallidus (rRPa). POAH warm-sensitive neurons exhibit spontaneously high firing rates (FR) due both to an intrinsically high level of activity and strong excitatory input from peripheral warm-responsive (pW) sensors; a pW neuron is shown as providing excitatory input to both POAH neurons. With a lowering of hypothalamic temperature (assumed to correspond to T_{core}) and/or skin temperature, downstream DMH and rRPa neurons are disinhibited, thereby increasing noradrenergic input into IBAT brown adipocytes (A). The graphs depict the idealized effects of reducing pW input, as with skin cooling, illustrating that core and skin temperatures work together in producing IBAT effector responses. Ins, temperature-insensitive neuron; F, feeding-responsive neuron; S, stress-responsive neuron; IML, intermediolateral column of the thoracic spinal cord; PG, prostaglandin E subtype receptor-expressing neuron; SG, stellate ganglion; G, ganglionic neuron; solid lines drawn at normal core or skin temperatures (see text for further details).

precise regulation of T_{core} via autonomic means (effective behavioral regulation can survive ablation of the POAH and it should be noted that this is not the only region with temperature-sensitive neurons that are coupled to autonomic thermoeffector responses; such neurons are, in fact, found in all subdivisions of the neuraxis, including the spinal cord). A high percentage (perhaps ~30%) of the neurons in the POAH are warm-sensitive (W) neurons, meaning that their firing rate increases (by at least 0.8 Hz/°C) with increasing local temperature. Many of these are also responsive to skin and spinal temperature – note that Figure 1 depicts POAH W neurons receiving considerable excitatory input by peripheral warm sensors (pW). POAH W neurons also receive input from temperature-insensitive neurons (Ins), and Figure 1 depicts an inhibitory γ-aminobutyric acid (GABA)ergic prostaglandin (PG) E subtype receptor-expressing neuron, which enables a model for the upward setting of the temperature 'set point' (i.e., fever) during certain inflammatory states (described later). Note also in Figure 1 that the thermosensitivity of the POAH W neuron is such that its basal firing rate (FR) is nearly or fully maximal at the usual normothermic body temperature (37 °C). The high basal FR reflects the combination of a high intrinsic FR and strong excitatory drive provided by pW sensors; as indicated by the upper left-hand inset (in the POAH block), the W receptor FR at a given T_{core} (e.g., 37 °C) decreases when T_{skin} decreases from 32 °C (a thermally comfortable value) to 27 °C (which would usually be perceived as uncomfortably cold except perhaps in

cold-acclimated Aborigines, as described later). This schema agrees with experimental data and accounts for the fact that reflexive thermoeffector responses depend on a combination of core and skin temperatures. For simplicity, FR varies directly with temperature within a range bounded by particular hypothermic-to-normothermic values of core and skin temperature (here, the function for W receptor FR is given as % maximum FR $= 20 \times T_{core} + 10 \times T_{skin} - 960$, with the constraints that $0\% < \text{FR} < 100\%$); in reality, different central and peripheral thermosensors evince different FR functions, including quasilinear, sigmoidal, and quasi-Gaussian. It should be noted that warm sensors (as opposed to cold sensors, i.e., those that increase FR with a decrease in temperature) are hypothesized to fulfill the role of primary functional importance in thermoregulation, although by no means do all authorities agree with this. The % maximum FR equation is in general agreement with a long-accepted functional relationship originally described by Carl Gisolfi, a thermoregulatory and exercise physiologist, holding that a variety of thermoeffector responses can be described by the equation: $R - R_0 = B_1 \times T_{core} + B_2 \times T_{skin} - B_3$, where R is the effector response, R_0 is the basal effector response level, and the coefficients weight the importance of core and skin temperature in driving the change in response. In humans, the ratio of B_1:B_2 for thermoeffector responses ranges between about 9:1 and 5:1 (i.e., considerably higher than that for any of the models presented in this article).

Figure 1 depicts two POAH W neuronal projections that are inhibitory and which project caudally to synapse with tonically active neurons in other brain regions – the dorsal medial hypothalamic region (DMH, containing the neuron labeled ++) and the rostral raphe pallidus (rRPa, containing the premotor neuron labeled PM+) in the medulla oblongata. Neurons in the DMH and rRPa are coupled via additional excitatory relays to BAT. This type of connectivity comports with abundant data indicating that BAT (and also cutaneous vasoconstriction) are subject to considerable tonic excitatory drive that is normally restrained by inhibitory inputs. The DMH is a key region involved in integrating a variety of homeostatic responses, including 'emotional' stress, feeding/adiposity, and thermoregulation. Accordingly, the neuron labeled 'S,' a stress-activated neuron, and the neuron labeled 'F,' a feeding-activated neuron, are each capable of increasing excitatory drive to intrascapular BAT (IBAT). The rRPa region in the medulla oblongata has emerged as a major site of excitatory premotor neurons controlling IBAT in rodents. In addition to inputs from the DMH, there is evidence that some POAH W neurons project monosynaptically to rRPa neurons. An important functional consequence of both POAH-to-RPa circuit pathways is that RPa premotor neuronal firing is normally suppressed almost fully by the high level of POAH W neuron firing associated with normothermia, resulting in a low basal level of drive to IBAT, and this concept fits well with the experimental literature. With the occurrence of hypothalamic and/or skin cooling, the W receptor FR decreases, reducing the inhibitory drive to RPa IBAT premotor neurons, which stimulates HP via premotor neurons in the intermediolateral (IML) column of the spinal cord, ganglionic (G) cells in the stellate ganglion (SG), and, finally, brown adipocytes (A) in IBAT. Consider the genesis of fever, a phenomenon that behaves like a coordinately regulated increase of T_{core}. The temperature-insensitive neuron situated in the POAH represents a prostaglandin E subtype (EP3) receptor-expressing GABAergic cell. The EP3 receptor binds prostaglandin E_2 (PGE_2), a neurochemical product of inflammatory cascades such as that induced by the endotoxin lipopolysaccharide (LPS). LPS administration is a widely used experimental model of fever induction. It is now thought that LPS-induced PGE_2 binds to the EP3 receptor on POAH GABAergic neurons, thereby decreasing the FR of POAH W neurons and reducing the inhibitory drive to the tonically active RPa IBAT premotor neurons, so as to stimulate IBAT thermogenesis and precipitate a state of positive heat balance. Accordingly, this schema provides a putative mechanism for the genesis of fever, a state often ascribed to the upward resetting of the body temperature 'set point.' An important point emerges here: biology does not employ set points designed in the manner of the typical engineered device, although this fiction is still promulgated in myriad contemporary biomedical textbooks and scholarly publications (i.e., the set point equals the value of the reference input from which the value of negative is subtracted to generate the error signal). Starting with the classical neuronal model proposed by Hammel in the mid-1960s, a variety of models have been advanced to explain how the body implements set-point-like mechanisms that are consistent with the facts of neuronal signaling – particularly the fact that neurons do not generate outputs with negative values (e.g., -5 Hz), as would be necessary if the engineered set-point device were to be used – and the ability of many factors to modify the ultimate value of the regulated variable that is governed by the set point (e.g., the ability of LPS to elicit coordinated biobehavioral responses that increase the defended level of body temperature during fever). The reader should appreciate the existence of

biologically plausible schemes for what is variously called 'set point,' 'settling point,' 'set-level determinant,' 'interthreshold zone,' or 'null zone,' and is encouraged to consider the reports by Hammel, Bligh, Boulant, and Kanesoue.

Some additional details of sympathetically mediated BAT thermogenesis merit discussion. The SNS terminals innervating BAT release norepinephrine (NE), which binds to the β-3-adrenergic receptor on BAT adipocytes. This initiates a G-protein/cyclic adenosine monophosphate/protein kinase A (Gs/cAMP/PKA) signaling cascade that produces hormone-sensitive lipase (HSL). HSL increases lypolysis of triglyceride droplets. The resultant increase in free fatty acids both activates UCP1 and enters the β-oxidation cycle in mitochondria, serving as the thermogenic substrate. SNS activation increases UCP1 gene expression by phosphorylation of the transcription factor cAMP response element-binding protein (CREB), another cAMP/PKA-dependent signaling pathway. Chronic SNS stimulation of BAT induces mitochondrial biogenesis and brown adipocyte hyperplasia, and also induces hypertrophy in these cells via the β-1-adrenergic receptor. Conversely, a chronic decrease of SNS activity results in BAT atrophy.

Adaptive BAT thermogenesis also involves a critical role for thyroid hormones. Physiological increases of triiodothyronine (T3) increase oxygen consumption (heat production is proportional to oxygen consumption, and in nonexercising individuals can be estimated with minimal error as $4.85\,\mathrm{cal\,g^{-1}}$ of body mass). In fact, key steps in BAT thermogenesis are thyroid hormone dependent. Brown adipocytes express thyroid hormone receptors TRα-1 and TRβ; the latter mediates T3-induced UCP1 gene expression. In addition to the effects outlined earlier, NE-induced increases in cAMP also increase the conversion of intracellular thyroxine (T4) to T3 by activating type 2 iodothyronine deiodinase (D2), and this confers a thyroid–SNS synergism that is essential for the increase of thermogenesis required by small mammals in cold environments.

While BAT is the main source of thermoregulatory heat production in small mammals such as rats and mice, in human infants BAT may not be the only organ available for NST. Although UCP1 is expressed exclusively in BAT, other tissues, such as muscle and liver, express other variants of the UCP protein, which may confer the capability for NST (here defined, as is customary, as the metabolic heat produced above the basal level in response to cold exposure) in these tissues. The evidence for this proposal is not strong, however. What is clear is that NST in humans can be increased substantially by chronic cold exposure and, in some (lucky) individuals, by overfeeding, as indicated by an increase of resting energy expenditure (REE) during periods of overfeeding, conferring resistance to diet-induced weight gain. The roles of BAT and other tissues in this phenomenon remain unresolved.

A remarkable paradigm of increased NST in humans is provided by Hong's classic studies of traditional ama divers of Korea and Japan, women who harvest plant and animal life in waters reaching 10 °C during the winter. Before the adoption of wet suits, these women wore traditional cotton bathing suits. During winter months, these ama exhibited a ~25% increase of basal metabolic rate (which was associated with a ~50% increase of caloric intake, presumably reflecting additional energetic challenges of winter diving), as well as other adaptive heat-conserving responses, but not including an increase of adiposity.

Shivering Thermogenesis

Shivering thermogenesis occurs when practically all of the skeletal muscle groups are involuntarily driven to contract synchronously (at ~40 and 31 Hz in the mouse and rat, respectively), producing heat (the mechanical efficiency of shivering is 0%).

Heat production during cold exposure can be increased by nearly three- to fourfold by shivering. Skin and core temperatures act synergistically in the activation of shivering (but a simpler additive relationship is assumed in the model depicted in Figure 2). Although shivering can increase T_{core} by ~0.5 °C in humans, this thermogenic mode is inefficient because it increases the convective transfer of body heat away from the core by increasing muscle blood flow, and it increases convective heat loss to the environment via gross bodily movement (wind chill).

Model for the Control of Shivering Thermogenesis

The model depicted by Figure 2 shares several important structures and functional relationships with the model in Figure 1. Additional CNS areas include the posterior hypothalamic (PH) area, an area contiguous with the DMH which has long been implicated in thermoregulation; the midbrain red nucleus (RN) and reticular formation (RF), a diffuse complex of neurons and processes in the midbrain, pons, and medulla; and the ventral horn (VH) and dorsal horn (DH) of the spinal cord. The RN and RF give rise to descending motor pathways that innervate skeletal muscle fibers (SFs) as well as intrafusal muscle fibers (IFs) within muscle stretch receptors (also known as fusiform bodies). As with the model for BAT thermogenesis (Figure 1), reducing the FR of POAH

Figure 2 Model for the control of shivering thermogenesis. A decrease in preoptic anterior hypothalamic (POAH) warm-sensitive (W) neuronal activity disinhibits dorsomedial hypothalamus (DMH) and posterior hypothalamic (PH) stress-responsive (S) neurons that signal to premotor (PM) neurons in the red nucleus (RN) and reticular formation (RF). This allows increased excitatory drive to γ (and probably α) motor neurons in the ventral horn (VH) of the spinal cord (DH, dorsal horn of the spinal cord). Increased γ discharge to intrafusal fibers (IF) in skeletal muscle (SM) increases excitatory drive to the α motor neurons (analogous to the stretch reflex), causing involuntary contractions of skeletal muscle fibers (SF). FR, firing rate; HP, heat production; Ins, temperature-insensitive neuron; pW, peripheral warm-responsive sensor; rRP, rostral raphe pallidus; R, rostral raphe pallidus neuron.

W neurons by hypothalamic and/or skin cooling disinhibits tonically excited descending pathways. In this case (Figure 2), this 'excitation via the withdrawal of inhibition' activates γ motor neuronal input to IF muscle fibers. This, in turn, increases the afferent excitatory input from muscle spindles to the α motor neurons in the VH of the spinal cord, leading to increased contractile activity (i.e., shivering), with heat as a by-product. In essence, this mechanism exploits the classical stretch reflex by increasing the loop gain to the point that this subsystem exhibits sustained oscillations between states of contraction and relaxation. Note that Figure 2 includes a role for temperature-insensitive fever-promoting neurons in the POAH, as described for Figure 1, in keeping with the known involvement of shivering in thermogenesis during fever. Also depicted is a temperature-insensitive stress neuron in the DMH/PH, in keeping with the ability of nonthermal stressors to evoke a shivering-like state.

Heat Loss

Autonomic mechanisms of heat loss include pathways regulating cutaneous (skin) blood flow, a major determinant of the delivery of heat from the body core to the shell, and pathways regulating evaporative heat transfer to the environment via the secretion of sweat from skin (critical in humans), panting (critical in canines and other nonsweating homeotherms), or saliva spreading (critical in rodents).

Cutaneous Blood Flow

Sympathetically mediated regulation of cutaneous blood flow is vitally important for controlling the rate of body heat loss. In the rat, it is chiefly the cutaneous vascular bed of the tail that is involved in thermoregulation, while in rabbits the ear pinna is a major site of regulated cutaneous heat dissipation. Humans benefit from thermoregulatory control of the cutaneous vasculature of most of the body's

skin, comprising a surface area of ~1.7 m^2 for a 70 kg person. In humans, there are two branches of the SNS control of cutaneous blood flow, a noradrenergic vasoconstrictor system and a sympathetic cholinergic active vasodilation system (which is also involved in sweating, as described later). In rodents, cutaneous tail blood flow appears to be chiefly regulated by modulation of SNS vasoconstrictor tone, achieved by noradrenergic control of the smooth muscle in arteriolar precapillary sphincters and arteriovenous anastomoses (AVAs), which are both abundant in the rat tail. The tail dissipates ~20–25% of a rat's basal HP, which ranges between approximately 70 and 100 cal kg^{-1} min^{-1} (note: 'calories' as used here means gram-calories, or small calories – not kilocalories, or large calories). During heat stress, the ability to increase tail blood flow contributes to heat tolerance, but not nearly as much as does evaporative HL (see later); for example, in one classic study, rats whose tails were amputated exhibited an 8% reduction in heat tolerance as measured by the time required to reach a T_{core} of 40 °C at an ambient temperature of 40 °C.

In a 70 kg human, skin blood flow is ~0.25 l min^{-1} under resting normothermic conditions, whereas during severe heat stress skin blood flow rises to ~5 l min^{-1}, a 20-fold increase, representing nearly one-fourth of the cardiac output. During cold stress, skin blood flow can drop to ~0.05 l min^{-1}. It is worth noting that the rate of heat loss is proportional to the product of skin blood flow and the difference between core and mean skin temperatures. In addition to underscoring the importance of skin blood flow responses to thermal challenges, this quantitative relationship focuses attention on the importance of skin temperature in thermoregulation. In particular, one may note the value of keeping the skin relatively cool during exposure to hot environments and during exercise, where metabolic heat production can increase by nearly eight- to tenfold in healthy, fit individuals (roughly equivalent to the heat generated while jogging on a level track at 6 and 7.5 mph, respectively). Under such conditions, sweating provides an impressively powerful mechanism of skin cooling and hence of heat loss (see later). It is also of interest to note that one of the adaptations observed in some cold-dwelling humans is the ability to tolerate lower skin and core temperatures. For example, Hammel and his colleagues reported that during a night of controlled cold exposure, Australian Aborigines (who were acclimated to sleeping with little or no clothing in moderate cold, ~4–8 °C) readily tolerated core and skin temperatures that caused considerable discomfort and shivering in a group of Caucasian controls. Since HL is proportional to the difference between skin and ambient temperatures, lowering skin temperature reduces heat loss to the environment. In Hammel's Aboriginal subjects, the lowering of both core and skin temperatures reduced heat conductance to the environment by ~30% during sleep, a significant savings of body energy reserves. Therefore, being able to tolerate lower core and skin temperatures likely confers a significant survival advantage in settings of caloric scarcity. It should be noted that the adapted thermoregulatory state observed in Aborigines is apparently not found in humans living in extremely cold environments (e.g., Eskimos). Such peoples have survived by developing exceptionally effective clothing and shelter. (The traditional Eskimo cold-weather clothing ensemble is a marvel both of design and materials; the success of Roald Amundsen's pioneering expedition to the South Pole, reached on December 15, 1911, owed a great debt to Amundsen's adoption of Eskimo clothing and travel methods, as described in Roland Huntford's book, *The Last Place on Earth*. The interior of the Eskimo igloo rarely decreases below 10 °C.) The point is that if the environment is so severe that autonomic thermoregulatory adaptations are of little consequence to survival, humans simply eschew such adaptations in favor of largely avoiding the cold by way of a broad repertoire of behavioral options.

Model for the Noradrenergic Control of Cutaneous Blood Flow

Figure 3 depicts a model for the control of cutaneous blood flow by the noradrenergic vasoconstrictor system, based primarily on research in rats. Most of the structures depicted in Figure 3 have already been described for Figure 1; the new CNS region is the ventral tegmental area (VTA) of the midbrain, where an 'other' (O) neuron is situated to modulate the activity of a tonically active VTA neuron. Some of these likely are temperature-sensitive neurons. The ultimate peripheral target of this system is the smooth muscle controlling blood flow through the cutaneous vasculature (CV). The general functional scheme of Figure 3 follows that of Figures 1 and 2. Normally active POAH W inhibitory neurons project to tonically active neurons in the DMH and VTA, but in the present model there is room for upward shifts in the POAH W firing rate at normal hypothalamic temperature so as to permit an increase inhibitory drive to tonically active DMH and VTA neurons if skin temperature increases. Accordingly, an increase of pW input to POAH W neurons further inhibits DMH and VTA neuronal firing, leading to a withdrawal of sympathetic smooth muscle tone and a resultant increase in cutaneous blood flow. The function describing the POAH W FR is % maximum

Figure 3 Model for the control of cutaneous blood flow by the sympathetic nervous system. The pathways and control strategy are similar but not identical to those of **Figure 1**. Under thermoneutral conditions, the vasoconstrictor tone of the cutaneous vasculature (CV) is maintained at a fairly high level by tonically excited dorsomedial hypothalamus (DMH) and ventral tegmental area (VTA) neurons (O, other neuron) that are only partially inhibited by preoptic anterior hypothalamic (POAH) warm-sensitive (W) neurons. Increasing T_{core} and/or skin temperature causes an increase in POAH W neuronal activity, leading to greater inhibition of noradrenergic drive to the CV. This withdraws vasoconstrictor tone, allowing an increase of skin blood flow (BF), whereas decreases of POAH W neuronal activity decrease skin BF to very low levels via disinhibition of the tonically active DMH and VTA neurons. The question mark in the DMH block indicates that this area is not yet proved to be in this circuit (see text for further details). FR, firing rate; Ins, temperature-insensitive neuron; pW, peripheral warm-responsive sensor; S, stress-responsive neuron; rRPa, rostral raphe pallidus; IML, intermediolateral column of the thoracic spinal cord; SG, stellate ganglion; G, ganglionic neuron; V, vasoconstrictor neuron.

$FR = 12.5 \times T_{core} + 10 \times T_{skin} - 720$; the sigmoidal function describing skin blood flow is % maximum skin BF $= 100 \times [1 - 1/(1 + \exp(-1 \times (U))]$, where $U =$ (input FR $- 25)/5$ – that is, the response is half-maximal at an input FR of 25 and the width parameter is 5. This sigmoidal response is congruent with data indicating that rat tail blood flow increases exponentially by nearly tenfold from the basal values measured in a thermoneutral environment (e.g., ambient temperature = 30 °C) to the values measured in a hot environment (e.g., ambient temperature = 35 °C). The proportional increase in the rate of heat loss via the tail mirrors the proportional increase of tail blood flow.

Cholinergic Control of Cutaneous Blood Flow

Humans have both a sympathetic noradrenergic vasoconstrictor system and a sympathetic cholinergic active vasodilation system; the latter is responsible in humans for 80–95% of the increase in skin blood flow accompanying heat stress. Relatively little is known about the CNS areas that govern thermoregulation in humans, and it certainly remains to be established to what degree rodents, rabbits, and humans share common central substrates and pathways. (No model is presented in this article for cholinergic active vasodilation.)

Evaporative Heat Loss

Each liter of sweat evaporated from the skin surface requires ~580 kcal of heat energy, an impressive value. Most of this energy is derived from body heat, but thermal energy derived from the environment contributes to the evaporation of sweat, particularly in hot, dry environments where sweating keeps skin temperature below environmental temperature.

In humans, sweat rates can exceed $2\,l\,h^{-1}$, which would equate to $\sim 1200\,kcal\,h^{-1}$ of body heat removal if all of the sweat were to be vaporized by body heat. Normally, however, only about 50% of the sweat produced is evaporated, and the fraction that is not evaporated is of utterly no value in removing heat. The legendary marathoner Derek Clayton could produce sweat at $3.7\,l\,h^{-1}$, a vital factor in his ability to sustain a sub-5-min $mile^{-1}$ pace for 26.2 miles, a feat that typically requires sustaining a metabolic rate ~20-fold higher than resting. Anthropologists have proposed that the human capacity for evaporative heat loss (EHL) conferred a major selection advantage. EHL is so effective in preserving thermal homeostasis during prolonged walking and running in hot climates that early humans benefited greatly in terms of hunting, gathering, and other essential survival activities. In humans, sweating is controlled by sympathetic cholinergic nerve terminals that innervate the ~2 million eccrine ('thermoregulatory') sweat glands distributed in the skin. The cholinergic control of sweat glands is called 'sudomotor regulation.' Sweating and active vasodilation commence at nearly the same time in resting heat-stressed humans, and both processes are thought to involve cholinergic sudomotor activity, although the precise relationship between them remains unclear. It should be noted that much of the impressive human capacity for heat dissipation via sweating would be lost if it were not for the ability to achieve the marked increases in skin blood flow enabled by active cholinergic vasodilation.

Sweat glands are found almost exclusively in humans (the patas monkey has eccrine sweat glands). Lacking sweat glands, however, does not preclude the use of evaporative cooling for thermoregulation in the heat. Thermoregulatory EHL also occurs via panting and the application of saliva, urine, and other sources of moisture to the fur and skin. Panting, defined as a rapid respiratory frequency producing an increased minute volume but decreased tidal volume, is a critical avenue of EHL in canines, felines, and other mammals. Rodents also exhibit a panting-like phenomenon during heat stress, but the role of

Figure 4 Model for the control of sweating by the sympathetic nervous system. An increase in core and/or skin temperatures increases excitatory cholinergic drive to sweat glands (SwGL). This scheme postulates an important role for preoptic anterior hypothalamic (POAH) warm-sensitive (W) neurons that are excitatory to downstream neurons in other brain areas. FR, firing rate; CNS, central nervous system; O, other neuron capable of modulating sweat rate; pW, peripheral warm-responsive sensor.

panting in thermoregulation appears to differ among rodent species. What is clear is that rodents are very good at increasing EHL by spreading saliva on the fur and other surfaces of the body, such as the paws, scrotum, and base of the tail. Indeed, this mode of EHL is a vital component of maintaining thermal homeostasis in rats (and presumably other rodents), based on studies in which surgically desalivated rats were shown to be highly susceptible to heat stress (one study documented an 81% reduction in the time to reach a T_{core} of 40 °C). Interestingly, just as cholinergic blockade in humans abolishes EHL via sweating, it also prevents EHL via saliva spreading in rats.

Model for the Control of Evaporative Heat Loss

Figure 4 depicts a simple model for the control of EHL via sweating (with a few changes this model is also applicable to panting and saliva spreading). Uncertainties about the central pathways involved in EHL regulation oblige a scheme specifying few constituent parts (unfortunately, rats do not employ thermoregulatory sweating, or we would probably know a great deal more about this topic). The box labeled SwGL refers to sweat glands, and 'Other CNS' simply acknowledges that there must be important CNS areas downstream of the POAH. Note that the thermosensitivity of POAH W neurons is such that the threshold for increasing their firing rate is at the normal T_{core}. We also postulate that the threshold for increased skin (pW) firing is at the normal, preferred T_{skin}. Accordingly, an increase of hypothalamic temperature above 37 °C promptly drives an increase in sweating, and this response can be initiated at a lower T_{core} if skin temperature increases. (In fact, skin and core temperatures act synergistically in the sudomotor response. Here, the equation is % maximum FR = $50 \times T_{core} = 20 \times T_{skin} - 2490$.)

Concluding Remarks

The fact that the typical mammalian T_{core} of 37 °C is poised just 4–5 °C away from the limits of survival is often cited to underscore the vital survival importance of thermoregulation. But perhaps less widely appreciated is that all biobehavioral processes in health and disease depend – often critically – on T_{core}. Accordingly, the biobehavioral basis of thermoregulation has long fascinated students and scientists in a broad array of disciplines. However, much remains to be learned, and since the new knowledge will be of key importance in understanding many other physiological and pathophysiological phenomena, the reader is encouraged to learn more about, and perhaps even contribute, to the field of thermoregulation.

Energy Homeostasis: Visceral Control

T L Powley and R J Phillips, Purdue University, West Lafayette, IN, USA

Distributed Visceral Networks

The regulation of energy homeostasis is the product of neural networks that operate as physiological control systems. The networks span the central, peripheral, and enteric nervous systems (CNS, PNS, and ENS, respectively). The circuits extend over the entire visceral neuraxis, from the ENS in the walls of the viscera, through the autonomic or PNS pathways and the networks in both brain stem and spinal cord, to the rostral forebrain systems. These networks are interconnected and organized as feed-forward, feedback, and adaptive control loops. The pathways carrying afferent inflows and efferent outflows are dynamically cross-linked, and, importantly, integration of signals occurs at all levels of the visceral neuraxis.

Comparisons with earlier views of the neural mechanisms of energy balance bring this feature of this control-system concept into sharper relief: early views of the neural mechanisms of energy balance focused on the CNS. These older ideas employed hierarchical models of neural organization and construed the hypothalamus and a small number of CNS sites as integrative and executive centers. In such models, the peripheral nerves simply transmitted unintegrated signals from the periphery to diencephalic and forebrain centers and then carried motor commands back to the periphery. As more has been learned about the organization of the CNS, PNS, and ENS, however, such center-based hierarchical views of energy homeostasis have been replaced by a recognition that multiple distributed control loops integrate the regulatory adjustments of the CNS, PNS, and ENS.

Central Integrators and Visceral Networks Organize Short- and Long-Term Adjustments of Energy Homeostasis

Neural mechanisms that determine the energy economy of the body are typically distinguished as either short-term or long-term control loops. Short-term mechanisms execute adjustments that often occur in seconds or minutes. The responses occur so rapidly that they rely predominantly on neural pathways – there is relatively little time for paracrine, endocrine, and humoral responses to mobilize fully. Visceral afferents provide most of the fast, phasic short-term feedback associated with ingesting, digesting, and absorbing nutrients that provide energy.

Long-term mechanisms make adjustments that can often take hours (e.g., circadian fluctuations), days (e.g., estrus or menstrual cycles), or seasons (e.g., seasonal weight gain). Such adjustments are so protracted they can be, and typically are, orchestrated by endocrine and other humoral factors. These longer term signals operate directly on peripheral visceral afferents, but they also directly affect central stations of the visceral neuraxis, including notably the hypothalamus as well as the caudal brain stem, amygdala, hippocampus, and various other limbic regions.

The short-term/long-term distinction is useful in the discussions of function, but it is by no means hard and fast. Neural effects can occur over extended intervals, and paracrine and endocrine effects can occur in minutes, perhaps in seconds. Other factors also can blur the distinction. Energy control systems are cross-linked, the same controller can participate in both short-term and long-term adjustments, and circulating humoral factors modulate or change the gain of the neural elements in the networks. The present survey focuses on the neural elements of these networks.

Peripheral Inputs of the Energy Control Circuitry: Visceral Afferents

The first-order, or primary, visceral afferents that transmit sensory information from the gastrointestinal (GI) tract and organs of digestion to the CNS are organized into two pools of neurons. These two pools interconnect the CNS and the viscera and organize them into control networks. Neurites of one of the afferent pools travel with parasympathetic motor fibers, notably those of the vagus nerve, to innervate the different visceral organs involved in digestion and metabolism. Neurites of the other afferent pool travel with sympathetic nerves, notably the splanchnic nerves, to innervate the visceral organs (as well as adipose tissue depots).

The larger of the two populations of visceral afferent neurons constitutes the neurons of the nodose ganglion. Nodose neurons are pseudounipolar, distributing their peripheral processes through the vagus nerve to the organs of digestion and projecting their central processes into the brain stem nucleus of the solitary tract. Within the nucleus of the solitary tract, the visceral afferents synapse on second-order neurons that relay information rostrally throughout the central visceral neuraxis participating in energy

homeostasis. Some primary nodose neurites also synapse directly on dorsally directed dendrites of preganglionic neurons of the dorsal motor nucleus, thus establishing vago-vagal reflex arcs. Centrifugal outputs from more rostral CNS networks project onto these brain stem circuits to effect adjustments in their outflows and thus energy homeostasis. In addition to incorporating modulatory influences from more rostral mechanisms, the reflex circuits operate directly as mono- or oligosynaptic reflex arcs. Efferent outflows of these loops then reciprocally, in closed-loop fashion, affect or alter afferent inflows.

The second and smaller pool of visceral afferents constitutes a subset of the dorsal root ganglion (DRG) cells situated in association with the thoracic and higher lumbar spinal cord. Like nodose afferents, DRG primary afferent neurons projecting to the GI tract are pseudounipolar neurons, distributing their peripheral processes through the peripheral nerves projecting to the prevertebral autonomic ganglia that supply the viscera. The spinal afferent processes then course still more peripherally with postganglionic efferent axons to innervate the organs. These visceral afferents project their central neurites into laminae I and V of the spinal cord. Second-order neurons in the laminae of the cord project both rostrally into the more rostral visceral neuraxis and locally to sympathetic preganglionic motor neurons of the intromediolateral column.

Figure 1 Vagal afferent innervation of the stomach. A montage of a dorsal stomach whole mount from a rat that received a left nodose injection of wheat germ agglutinin–horseradish peroxidase. The pylorus is in the upper left, and the forestomach is at the right. Bundles of afferents enter from the lower esophageal sphincter (excised at the top) and radiate over the stomach to the greater curvature. In the antrum (upper left), bundles of axons can be seen traversing across the pylorus to innervate the small intestine. At this scale, fiber bundles are the most conspicuous elements; however, afferent terminals in the myenteric plexus and smooth muscle can be recognized. The organ measures approximately 40 mm on the long axis.

Vagal and Spinal Visceral Afferents Transduce Primary Energy Signals

The vagus nerve supplies the majority of the visceral afferents to the GI tract and liver. The nerve densely innervates the upper esophagus and larynx, as well as the more distal esophagus, the stomach, and the duodenum; it also innervates, though less densely, the remainder of the small and large intestines. As Figure 1 illustrates for the stomach, this innervation forms an extensive network distributing throughout the organs. These nodose ganglion afferents detect both the mechanical, chemical, and thermal properties of ingested nutrients and the chyme that is produced in the digestion and absorption of the energy.

Vagal afferents elaborate a heterogeneity of different ending types to transduce and analyze energy-related signals. Vagal mechanoreceptors, for example, are located both in the smooth muscle wall of the GI tract and in the mucosa and submucosal lining of the viscera. Different populations of mechanoreceptors are located in different tissues and sites, have different morphologies, and appear to transduce, depending on the specific population, forces of tension, or stretch. Figures 2 and 3 document two of the morphological specializations of vagal mechanoreceptors found in the stomach wall and illustrate that neurites of visceral afferents are differentiated into specialized terminals. Functional studies implicate the mechanoreceptors in monitoring the contents of the organs, particularly nutrient loads of the stomach.

Vagal chemoreceptors are situated to detect stimuli in the lumen of the organ system and, likely, paracrine factors in the lamina propria and adjacent tissues as well. The better studied of these chemoreceptors detect and respond selectively to carbohydrates, lipids, and proteins. Structural details of receptor location and morphology have not yet been fully established, but both electrophysiological and behavioral experiments indicate that the vagal chemoreceptors of the GI tract constitute the primary short-term negative feedback associated with nutrient ingestion and digestion.

The dorsal root ganglia also supply primary visceral afferents to the gastrointestinal organs. DRG afferent neurites are distributed through the esophagus,

Figure 2 Vagal afferents supply intraganglionic laminar endings to the myenteric plexus of the gastrointestinal tract. An individual vagal afferent that ends in multiple intraganglionic laminar endings is illustrated in a montage from the corpus of the rat stomach. A single afferent neurite labeled with the fluorescent tracer tetramethylrhodamine, which was injected into the nodose ganglion, can be seen entering the field from the bottom of the figure. As the neurite reaches its target area, it repeatedly divides into higher order processes that terminate in plates of laminar puncta that interdigitate with neurons and glia within the ganglia (neurons and glia are not stained in this image). Scale bar = 250 μm.

Figure 3 Vagal afferents supply intramuscular arrays (IMAs) to the smooth muscle layers of the GI tract. A single vagal afferent fiber terminating in a complex of IMAs is illustrated in this montage from the forestomach. In this example, a single afferent neurite labeled with the fluorescent tracer tetramethylrhodamine, which was injected into the nodose ganglion, can be seen entering from the bottom left and traveling to the upper right of the figure. As the neurite reaches the site of innervation of the smooth muscle, it gives off multiple collaterals that run in the same orientation as the muscle fibers in which the neurite terminates. The long rectilinear processes of IMAs are distributed parallel to each other and parallel to the muscle fibers. IMAs make contact with both smooth muscle fibers and the intercalated interstitial cells of Cajal (not stained). In the example illustrated, the arrays of neurite terminals that constitute the IMAs run in the circular muscle layer that can be seen running from the upper right of the figure to the lower left of the figure. Scale bar = 250 μm.

stomach, and intestines. These neurites are located in both muscle layers and in the mucosa and submucosa, where many of them associate with the vasculature. In comparison with the situation for vagal visceral afferents, even less is known about structural specializations of different DRG afferent neurites in the GI tract, but electrophysiological observations have established that DRG afferents are predominantly high-threshold receptors that are implicated in nociception associated with mechanical and chemical insults.

Ironically, given their importance in human health and disease processes, much less is known about the vagal and spinal visceral receptors and their transduction mechanisms than is known about the corresponding features of some exotic receptors (e.g., electroreceptors, magnetoreceptors) found in fish and birds. The situation results in the main from the inaccessibility of these receptors and other technical difficulties associated with studying the 'enteroreceptors' of energy homeostasis. The limited observations available suggest, and most investigators adopt the working assumption, that the mechanoreceptors located in the viscera share some, if not all, receptor molecules, channels, and sensory cascades with the mechanoreceptors found in skeletal muscle and skin. Similarly, the chemoreceptors located in the viscera presumably share at least some of the receptor molecules, channels, and molecular cascades found in the chemosenses of taste and possibly olfaction.

Hormones, Neuromodulators, and Metabolites Reflecting the Energy Economy Modulate the Gain of Visceral Afferents

Though the available information is still limited, visceral afferents have been shown to express extensive libraries of receptors for gut hormones, neuropeptides, and other signal factors as well as multiple species of ionotropic and metabotropic channels. Much of the transduction of the mechanical, chemical, and thermal

signals associated with the processing of nutrients apparently involves ionotropic membrane channels. In addition, however, many of the receptors and metabotropic channels are involved in detecting the local hormonal, paracrine, and cytokine milieu produced by the processes of digesting, absorbing, and metabolizing sources of energy. As has been detailed for load-sensitive vagal mechanoreceptors in the GI tract, the activity of many afferents appears to be potentiated or otherwise modulated locally by hormones and metabolites. The sensitivity or gain of gastric mechanoreceptors, for example, is affected by cholecystokinin (CCK), leptin, ghrelin, peptide tyrosine-tyrosine (PYY), and a number of other factors associated with processing and utilizing energy sources.

Fewer analyses have examined whether or to what extent the sensitivity or gain of DRG afferents may also be modulated by GI and metabolic factors, but the principle seems broadly instantiated: observations have recently established that not only vagal, but also gustatory, afferents express receptors for a variety of metabolic hormones.

Visceral Afferents Articulate with Motor Outflows

Visceral afferents elicit and also organize the CNS and autonomic motor outflows and the responses coordinated by central integrators in multiple ways. Depending upon the situation, an afferent input might simultaneously influence responses and integrator adjustments at several levels. Three organizing roles of the afferents are as (1) sources of axon responses or axon reflexes, (2) elements of mono- or oligosynaptic autonomic reflex arcs, and (3) input arms of polysynaptic central relays incorporated into more rostral control-system adjustments.

Visceral afferents appear to establish axon responses or reflexes that can locally modulate peripheral secretion and motility. Most of the evidence that visceral afferents can produce such effector-like responses, through the release of neuropeptides and other products at their peripheral terminals where they transduce visceral signals, comes from other organ systems (e.g., the respiratory system), but limited observations on GI physiology as well as the presence of secretory material in the peripheral terminals of afferents in the GI tract suggest that at least some of the visceral afferents participating in energy homeostasis may generate axon reflexes as well.

Visceral first- and second-order afferent projections in the brain stem and spinal cord establish mono- and oligosynaptic reflex arcs through which the inflows are translated into preganglionic motor outflows that produce or modulate many of the GI motor and secretory responses that orchestrate energy intake and expenditure (see earlier). Vago-vagal reflexes organized in the dorsal vagal complex of the brain stem participate in many responses that support and potentiate energy intake and metabolism. Spinal sympathetic reflexes influence energy expenditure as well as energy intake.

Visceral afferent projections in the CNS are organized not only to establish short-loop autonomic reflexes in the caudal brain stem and spinal cord; they are also organized to project heavily throughout the entire visceral neuraxis, including the more rostral limbic and cortical circuits that constitute the control systems of energy homeostasis. Such circuits in turn project caudally to modulate the autonomic as well as somatic outflows that produce, respectively, visceral and behavioral adjustments.

Visceral Pathways Participate in the Central Integration of Energy Homeostasis

The evolving understanding of visceral afferents and efferents, complemented by a developing appreciation that energy homeostasis can best be understood in terms of control-system networks, changes not only ideas about PNS and ENS roles in energy balance, but also revises perspectives on CNS mechanisms. Many of the early models of neural control of energy intake and expenditure assigned all integrative functions to the brain, with the different inputs (humoral, hormonal, etc.), including visceral afferent inputs as well, as so many static bits of information that were not processed and integrated until they were factored into a central or hypothalamic decision that then generated motor response commands and visceromotor programs. These models explicitly or implicitly emphasized a hierarchical view of neuraxis organization and executive decision-making model of homeostasis.

In contrast to the older view, the control-system view recognizes that the circuitry of energy balance consists of multiple neural loops organized as distributed, in-parallel networks. As energy-related inputs transduced by visceral afferents are relayed to the brain, these enteroceptive signals are modulated by gut hormones and other peripheral factors. Such modulation begins even at the level of the distal primary afferent processes. As the afferents carrying signals that integrate information about both the primary sensory events and the multiplicity of hormonal and humoral conditions in the peripheral milieu reach the brain, they articulate with the brain stem motor

and premotor areas and they also relay more rostrally where they are integrated with the processing occurring in other interconnected loops.

Perhaps most conspicuously, visceral afferent information is projected to hypothalamic sites, where it is integrated with the multiple humoral and endocrine factors, many of them signals of long-term energy regulation, that determine hypothalamic outflows to the somatomotor systems, the pituitary, and the descending autonomic efferent mechanisms. Incoming visceral afferent information is also relayed to visceral/gustatory cortical fields, where it presumably is then integrated with the myriad sensory representations of the external environment that are organized in the cortex. Centrifugal cortical efferents in turn project to the motor and autonomic networks found in the brain stem. Through other projections into multiple limbic sites as well as to cortex, the signals ascending in the visceral neuraxis are integrated with conditioned and learned contingencies that reflect the individual's experiences in procuring, ingesting, and utilizing energy. Additionally, through their proximity to the ventricular system and the circumventricular organs, many of the neuronal relays of the visceral neuraxis have access to the endocrine, metabolic and other factors that accumulate in cerebrospinal fluid.

As enteroceptive signals are relayed centripetally throughout the distributed networks that control energy homeostasis, and then again as the effector signals are distributed centrifugally to orchestrate motor and autonomic adjustments, the relay nuclei appear to serve as stations where reentrant collateral projections and humoral signals can adjust the processing of neural responses. Many of the neurons in the relevant neuronal relay stations of the visceral neuraxis in the brain stem, hypothalamus, and limbic system (e.g., the amygdala) express receptors for metabolic hormones, thus serving as additional nodes at which integration can occur.

In this system, inputs are as integral to the system operation as is any other element, and inputs can be as dynamic and as subject to changes in gain as any can other element of the control system. Though 'central' and 'peripheral' divisions have a logic in terms of descriptions of the nervous system, they have little significance in terms of control systems. Visceral afferents provide many of the key inputs or paths that constitute the feed-forward and feedback loops in the integrative control strategies that the nervous system uses to achieve homeostasis. Central integrators are controllers that adjust fluctuating feed-forward and feedback signals of the closed loops to reflect different targets, goals, and disturbances the system receives. Thus, these controllers operate on and through the feed-forward and feedback loops consisting of the visceral inputs and outputs or controlled variables.

Evolving Views of Visceral Circuits and Their Dynamic Roles in Energy Homeostasis

In summary, older views of the neural mechanisms involved in energy intake and expenditure traditionally adopted models that explained intake in terms of feeding and satiety centers in the hypothalamus and explained energy expenditure in terms of brain centers that controlled activity and the sympathetic efferent outflows to a variety of tissues. In the case of both intake and expenditure, the roles of afferent inputs were assumed to be limited. The afferents were taken to be relatively modest in number and distribution, the information they supplied was assumed to be unintegrated until it reached higher CNS stations, and the linkages of the inputs to the neural centers of execution were relatively tenuous.

Newer neuroscience views of regulation of energy homeostasis are more consonant with control-systems analyses in which the myriad responses that constitute intake and expenditure are the product of neural networks that operate as feed-forward, feedback, and adaptive controllers. These controllers are multiply interconnected or cross-linked by axon collaterals and projection pathways. The control loops are also functionally cross-coupled by shared mechanical, chemical, paracrine, hormonal, and humoral signals. The newer views include the recognition that visceral afferents are more extensive and more extensively distributed than previously assumed. These views also recognize that the visceral afferents dynamically integrate – even as distally as their peripheral neurites in the walls of the viscera – a much more complete array of energy-based signals than traditionally appreciated. And finally, newer perspectives see the visceral afferents participating in energy homeostasis not as remote neural channels conveying limited static information, but as integral components of the neural control systems that participate in the integrative processing of extensive arrays of nutritive and metabolic signals.

Engineering Viruses for CNS studies

R Lansford, California Institute of Technology, Pasadena, CA, USA

Introduction

The basic concept of gene therapy is to deliver specific therapeutic nucleic acid sequences to host cells, which results in a clinically relevant phenotypic change. Viruses, nanoassemblies of nucleic acid and protein, have been engineered by evolution to penetrate host cells and to usurp the host-cell cellular machinery to permit their own replication. The basic concept of a viral vector is to harness the highly honed virus infection pathway to deliver specific therapeutic nucleic acid sequences to host cells but to avoid the expression of viral genes that lead to replication, toxicity, and illness. Viral vectors have been found to be more efficient in delivering therapeutic genes than nonviral vectors. The ability to efficiently introduce specific genes into host cells makes viruses ideal tools for studying neural questions and combating neural diseases.

The life cycle of a typical virus involves its attachment to the cell surface, the uptake of the virions into the host-cell cytosol, the liberation of the genetic material from its protein casing, the expression of viral proteins, the replication of the viral genetic material, and the assembly of nascent virions and their egress from the host cells.

Recombinant viral vectors are generated from wild-type viruses by replacing genes that encode proteins necessary for their replication and packaging with foreign transgenes such as green fluorescent protein (GFP) or a therapeutic gene. The deleted viral genes can be stably expressed when integrated into the genome of a packaging cell line or transiently expressed from a plasmid or virus so that the viral gene products can be provided *in trans*. The recombinant viral vectors ideally maintain their ability to infect and transduce the same cell types they would normally have infected.

However, several hurdles still exist for using viral vectors for gene therapy and basic research. These hurdles include the preparation of large amounts of stable high-titer vectors, reducing immune reaction against viral vectors, and improving the ability to target the viral vectors to specific tissues and regulate transgene expression in a tissue-specific manner. The goal of this brief article is to introduce the reader to the value and diversity of viral vectors for gene therapy and basic research and to outline the exciting research currently going on in the field of engineering novel viral vectors.

Deciding on the Right Viral Vector for an Experiment

There are a many choices to consider when deciding the best viral vector to use for a particular experiment (Table 1). These involve determining what is preferred in terms of tissue tropism, tissue-specific gene expression, and the stability of viral genome within the host cell. Other considerations for choosing the best viral vectors are whether it induces an immune reaction within the human patient or animal model, the ease and cost of viral vector generation and purification, and the difficulty of the recombinant DNA techniques.

In general, viral vectors are designed to be replication defective for safety purposes to infect only a founder cell and its direct progeny for fate mapping studies, to introduce more transgenic DNA into their genomes, and to avoid recognition by their host's immune systems. It is vital for those using recombinant viral vectors to consider both the nature of the virus used as a vector and the effects of any transgene, introduced genetic elements, or other modification. For instance, there are distinct differences in working with viral vectors that express a gene that encodes GFP than in working with a gene that expresses a potentially hazardous transgene such as v-src or diphtheria toxin a. Placing a hazardous transgene in a viral vector that has been pseudotyped to efficiently infect a broad host range can be dangerous to investigators and their labmates.

Tissue Tropism

The typical surface of viruses includes numerous copies of an envelope protein that binds to specific receptor molecules on the plasma membrane of the host cell. Once bound to the receptor, viruses can either fuse with the plasma membrane or enter via the endocytic pathway. The tissue tropism or specific cell that a virus can infect is generally restricted to cells that express receptors that interact with the viral envelope glycoprotein. For instance, rabies virus is specific for motor neurons due to the affinity of gC in the virion envelope to heparin sulfate on the surface of the cell.

Table 1 Characteristics of viral vectors

Viral vector	*Genetic material*	*Packaging size (kb)*	*Tropism*	*Non-dividing*	*Integration*	*Titer (virions ml^{-1})*	*Advantages*	*Disadvantages*
Adenovirus	dsDNA	8–36	Broad	Yes	No	10^{11}–10^{12}	Efficient transduction of most tissues	Immune response; short-term expression
AAV	ssDNA	<5	Broad	Yes	Episomal (>90%) Integrated (<10%)		Long-term expression	Small packaging capacity; insertional mutagenesis
Alphavirus	RNA	2–5	Neurotropic	Yes	No		High expression	High expression
HSV-1	dsDNA	40; 152	Strong for neurons, broad	Yes	No	Low	Large transgene capacity	Immune response; short-term expression
Retrovirus	RNA	8.8	Broad	No	Yes	10^{8}–10^{9}	Long-term expression	Insertional mutagenesis
Lentivirus	RNA	9.6	Broad	Yes	Yes	10^{8}–10^{9}	Long-term expression	Insertional mutagenesis
AAV–HSV TN–HSV	DNA	152	Broad	Yes	Yes		Long-term	Insertional mutagenesis

AAV, adeno-associated virus; ds, double-stranded; HSV, herpes simplex virus; ss, single-stranded.

Pseudotyping alters the host range of a virus by exchanging the surface antigens between both DNA and RNA viruses, thus generating chimeric viral vectors. The glycoprotein from vesicular stomatitis virus (VSV-G), a rhabdovirus, is a popular choice for pseudotyping viruses because of its ability to confer a broad tropism and its ability to withstand the mechanical shearing stress present in ultracentrifuges, which permits viral vectors to be concentrated 1000-fold with minimal loss of biological activity. VSV-G can be incorporated into several different classes of viral vectors, including retroviruses, lentiviruses, and herpes viruses.

Murine central nervous system (CNS) transduction patterns of lentiviral vectors pseudotyped with envelope glycoproteins from murine leukemia virus (MuLV), lymphocytic choriomeningitis virus (LCMV), or the rabies-related Mokola virus were compared to a vector pseudotyped VSV-G. Mokola-, LCMV-, and VSV-G-pseudotyped vectors transduced similar populations, including the striatum, thalamus, and white matter, whereas MuLV efficiently transduced the striatum and hippocampal dentate gyrus. These results demonstrate that targeted transduction in the CNS can be achieved using specific envelope glycoproteins to pseudotype lentiviral vectors and offer Mokola-pseudotyped and MuLV-pseudotyped lentivectors as possible alternatives to VSV-G-pseudotyped lentivectors. The ability to biotinylate the adenovirus fiber allows researchers to modify the viral tropism by incorporating a myriad of targeting peptides/proteins into the structural context of the virion.

Genome versus Episome

Integration of the viral vector genome into the host genome guarantees that the genetic material is maintained during the lifetime of the cell and its daughter cells. This is ideal for long-term gene therapy in clinical settings or cellular fate mapping in researcher settings. A potential disadvantage of genomic integration is that the viral DNA may integrate near and possibly deregulate the normal expression pattern of an essential gene, inducing deleterious effects. Episomal vectors, however, are typically lost from the infected cells if they do not contain an origin of replication (ori)-permitted higher copy numbers. The Epstein–Barr virus (EBV) replicon elements (*oriP* and *EBNA-1*) help to stabilize episomal vectors by permitting up to 20 copies per cell.

Promoter Control

Transcriptional enhancers and silencers are typically distant from the promoter sequences that they regulate. Some of these regulatory elements do not operate correctly when they are abutted too close to one another. Undefined insulator elements within the human immunodeficiency virus (HIV)-based vectors appear to permit endogenous gene expression and persistence with certain tissue-specific transcription units; however, this seems to be the exception rather than the rule within small insert viral vectors. Promoters can be silenced due to positional effects related to their chromatin integration site, by the transcription complexes of genes that may have integrated into or adjacent to them, or by DNA methylation by the host cell of their transcription elements. Gene expression can also be downregulated at the level of mRNA stability. Viral promoters and some endogenous transcription units tend to be silenced in viral vectors, especially in cells that undergo cellular differentiation and during germ line passage in transgenic animals.

Herpes simplex virus (HSV)-1 amplicons can accommodate foreign DNA up to 150 kb, which is attractive for both basic and clinical research. Genomic sequences as well as large cDNAs, large transcriptional regulatory sequences for cell-type-specific expression, or multiple transgenes can be inserted in a modular fashion.

Targeted Gene Inactivation Using RNAi

Targeted gene inactivation in mice is a common and powerful technique that researchers use to determine the functional significance of genes. RNA interference (RNAi) has emerged as a powerful technique for generating loss-of-function phenotypes by downregulating the expression of specific genes in plants and animals. The basic concept is that the antisense sequence hybridizes with the normal mRNA in the cell and either blocks translation of the mRNA or increases the degradation of the host mRNA. RNAi typically regulates gene expression in cells via microRNAs, which are abundant in the nervous system.

Several of the ways that neuroscientists are currently using RNAi for both basic and therapeutic research have been recently well reviewed. Long-term RNAi may be efficaciously accomplished with adeno-associated viruses (AAVs), adenoviruses (Ads), and lentiviruses that have been engineered to deliver inhibitory RNAs (siRNAs) to the nervous system. siRNAs can be produced as short hairpin transcripts from RNA polymerase (RNAP) II and III promoters.

Engineering the Principal Viral Vectors

Adenovirus Vectors

Ad infections in humans leads to coldlike symptoms. Ad is a DNA virus containing a linear double-stranded

DNA genome of approximately 36 kb, of which up to 30 kb can be replaced with foreign DNA (Table 1). Neutralizing sera have been used to identify 49 different serotypes of Ad that are divided into six groups (A–F) on the basis of genome size, composition, homology, and organization. Cellular uptake of Ad involves binding of the Ad fiber coat protein with a cell surface receptor, including the major histocompatibility complex (MHC) class I molecule, the Coxsackie B viruses and Ad receptor, and the integrin family of cell surface heterodimers. The Ad fiber coat has been successfully modified using several ligands to alter the tissue tropism and specifically target the viral vector to desired cells and tissues.

The advantages of using Ad vectors include their broad host range, their ability to infect and deliver transgenes to both dividing and nondividing cells, and their ability to replicate episomally within the host nucleus. However, this also means that Ad expression is relatively short-lived (5–10 days) because the proportion of transduced cells decreases with each cell division or, possibly, due to immune intervention. Furthermore, they can be concentrated to high titers (10^{11}–10^{12} pfu ml^{-1}) and manufactured on a large scale.

Ad vectors are typically derived from subgroup C, serotypes 2 or 5. The first generation of Ad vectors contained deletions for one or two early (E) genes (E1 and E3). Deletion of the E1A and part of the E1B gene results in replication-deficient viruses that must be propagated in helper cell lines that provide the deleted E1 gene products *in trans*. The amount of DNA that can be inserted into Ad virions cannot exceed ~105% of the wild-type genome, which permits the insertion of only ~2 kb of foreign DNA into full-length Ad vectors, 5–6 kb of foreign DNA into E1A deleted vectors, or 7–8 kb of foreign DNA into E1- and E3-deleted vectors. Additional vectors have been generated that contain an E2a temperature-sensitive mutant or an E4 deletion. Recently, vectors have been produced that contain only the inverted terminal repeats (ITRs) and a packaging sequence around the transgene, with all the necessary viral genes being provided *in trans* by a helper virus to minimize recognition of the Ad vector by the immune system. Finally, high-capacity (hc) Ad vectors that permit gene transfer into dividing and nondividing cells but lack Ad viral genes that makes them more spacious, safer, and better suited for prolonged transgene expression have been reported.

Two disadvantages of many existing Ad vectors are caused by the induction of a T cell-mediated response against Ad proteins, which causes an inflammatory reaction, resulting in lysis of the transduced cells, and shortens the duration of transgene expression. The transient nature of gene expression and the induction of host immune responses limit the efficacy of Ad gene delivery and oblige new research to restore user confidence.

Adeno-Associated Virus

AAV vectors are promising therapeutic gene carriers because they can transduce nondividing cells, lack viral genes encoding immunogenic proteins, can be prepared at high titers, and achieve long-term transgene expression in animal models. AAV is classified as a separate genus in the family Parvoviridae, designated *Dependovirus* because it requires the presence of a wild-type Ad or herpes virus for productive infection; in the absence of a helper virus, AAV stably integrates into the host cell genome. There are more than 40 AAV serotypes. Although approximately 80% of humans are seropositive for AAV2 (serotype 2), the virus has not been linked to any human illness.

AAV is composed of a linear single-stranded DNA genome of approximately 4.7 kb and associated with a nonenveloped icosahedral capsid of approximately 22 nm (Table 1). Two open reading frames (ORFs), cap (which encodes the structural proteins that form the capsid) and rep (which encodes the regulatory proteins), are flanked by ITRs. The AAV site specifically integrates its DNA into chromosome 19q13-qter of the human genome via the interaction of AAV Rep78 or Rep68 proteins with Rep binding sites in the ITRs. Site-specific integration of AAV is unique among eukaryotic viruses, and its exploitation holds considerable promise for the targeted integration and stable expression of therapeutic DNA. Transduction does not appear to require cell division. The primary limitations of AAV vectors are their small cloning capacity and their elicitation of a humoral immune response.

AAV vectors exhibit a number of properties that have made this vector system an excellent choice for both CNS gene therapy and basic neurobiological investigations. *In vivo*, the preponderance of AAV vector transduction occurs in neurons, where it is possible to obtain long-term, stable gene expression with very little accompanying toxicity. Promoter selection, however, significantly influences the pattern and longevity of neuronal transduction distinct from the tropism inherent to AAV vectors.

AAV vectors have used to manipulate CNS function using a wide variety of approaches, including the expression of foreign genes, expression of endogenous genes, expression of antisense RNA, and expression of RNAi. For instance, AAV-mediated transduction of murine neurons has been seen as early as 7 days after stereotaxic injection of the virus into the hippocampus, striatum, and septum and reported

to last for at least 6 months. Interestingly, AAV can be retrogradely transported efficiently from muscle to the motor neurons of the spinal cord, permitting the long-term delivery of insulin-like growth factor 1 to a mouse model for amyotropic lateral sclerosis (ALS), which prolonged life and delayed disease progression. The different AAV serotypes increase the potential patterns of *in vivo* vector transduction, offering alternatives to the often-used AAV2 serotype that can be silenced by the immune system. These advantageous CNS properties of AAV vectors have fostered a wide range of clinically relevant applications, including Parkinson's disease, lysosomal storage diseases, Canavan's disease, epilepsy, Huntington's disease, and ALS.

Alphavirus Vectors

Alphavirus is a neurotropic positive linear single-stranded RNA virus that can cross the blood–brain barrier. Its plus-strand RNA genomes self-replicate within the cytosol and express high levels of protein. Viral vectors that express transgenes have been generated from the alphaviruses Semliki Forest virus (SFV) and Sindbis virus.

Cloning is straightforward with alphavirus genomes, and infectious RNA can be generated *in vivo* or *in vitro*. The virus releases positive-strand RNA into the host-cell cytosol, permitting rapid, high levels of gene expression, in dividing or nondividing cells (Table 1). Alphavirus replicons can express as much as 25% of the protein of a cell over a period of 72 h. That said, a potential disadvantage of these vectors is that they can induce cell death via apoptosis and inhibit macromolecular synthesis due to such high levels of protein synthesis. However, they may be useful as suicide vectors and may be desirable in certain experimental and clinical scenarios.

Alphaviruses efficaciously infect neuronal cells both *in vitro* and *in vivo* and express high levels of their transgene, such as GFP. The high levels of GFP expression in the cortical and hippocampal neurons permit dynamic imaging of delicate dendrites and neuronal tracing. In addition, new Sindbis-based vectors that delay the inhibition of protein synthesis due to a point mutation in a nonstructural protein delayed the onset of viral-induced cytotoxicity, and higher levels of enhanced GFP (eGFP) expression permit high-resolution dynamic imaging.

Herpes Simplex Virus Type 1

HSV-1 is a neurotropic double-stranded DNA virus that possesses several features suitable for application in the CNS. In an unmodified form, HSV-1 is a human pathogen, causing recurrent cold sores, keratitis, and, infrequently, severe encephalitis. Infection of wild-type HSV-1 on the epithelial cells of the skin or mucous membrane often results in a lytic viral replication cycle. Viruses released at the site of the primary infection may enter local sensory nerve terminals. Enveloped HSV virions can be actively transported anterogradely and retrogradely in neuronal axons. In the neuron, HSV-1 may enter into another lytic replication cycle that leads to neuronal cell death and egress of infectious particles, or the viral DNA may enter into a latent state in which the viral genome persists as stable episomal element.

HSV-1 is the prototype and best-studied virus of the a-herpes virus group. HSV-1 virions consist of four structural components: DNA, capsid, tegument, and envelope. The icosahedral capsid with a diameter of 125 nm surrounds a 153-kb double-stranded viral DNA that encodes over 70 genes (Table 1). The tegument is an amorphous coat of ~20 proteins that is localized between the capsid and the viral envelope, which contains ~12 membrane proteins.

After fusion of the viral envelope with the plasma membrane, HSV-1 capsids are propelled by dyenin along microtubules to the nuclear pore channel (NPC). The capsids of HSV-1 bind to the cytosolic side of the NPC, a vertex in the capsid is opened, and the DNA passes through the NPC, leaving behind an intact empty capsid that is liberated from the NPC. The mechanisms of how the HSV-1 genome is translocated through the NPC and even its genomic state (linear, circular, or concatemer) within the nucleus are poorly understood.

The HSV-1 amplicon vector is a plasmid-based expression system equipped with the full infection machinery of its parental virus. Advances of the helper virus-free packaging systems have eliminated many of the concerns over safety and toxicity. The HSV-1-based system, which rapidly and efficiently delivers and expresses bacterial artificial chromosome (BAC) library clones in human and mouse cells by converting them into infectious amplicon vectors, has been described. An HSV-1 amplicon is a bacterial plasmid that contains one or more transgene cassette (s) and two noncoding viral sequences: an origin of DNA replication (ori) and a DNA cleavage/packaging signal (pac). Homologous recombination methods in *Escherichia coli* permit genetic alterations with nucleotide precision to be carried out in BAC inserts. HSV-1 amplicon vectors possess several advantages as gene delivery vehicles, including (1) their large transgene capacity, up to 150 kb; (2) their ability to infect a wide variety of cell types across a broad range of species, both dividing and nondividing, without being infectious; (3) the ease of vector construction; and (4) their limited cytotoxicity and immunogenicity because of their lack of viral coding sequences. The presence of

prokaryotic DNA sequences within the packaged HSV amplicon triggers transcriptional silencing of the entire vector sequence, suggesting that generating amplicons devoid of bacterial sequences will improve long-term expression.

Wade-Martins and colleagues described a system to rapidly and efficiently deliver and express BAC library clones in human and mouse cells by converting them into infectious amplicon vectors. HSV-1-based amplicons were used to package and deliver into cells genomic inserts of >130 kb with efficiencies of up to 100%, as they demonstrated with a complete human hypoxanthine phosphoribosyltransferase (HPRT) locus contained within a 115 kb BAC insert. HSV-1-based amplicons were also exploited to deliver a complete genomic DNA locus encoding the human low-density lipoprotein receptor (LDLR) into mutant Chinese hamster ovary (CHO) cell lines and into human fibroblasts derived from patients with familial hypercholesterolemia (FH). These infectious genomic locus vectors appear to supply physiologically appropriate levels of the LDLR transgene product. The primary limitations of the HSV amplicon vector for human gene therapy are the transient nature of amplicon-mediated transgene expression and the absence of a scalable method to produce a high-titer vector. A comprehensive discourse that explores the several strategies that employ HSV amplicon vectors as tools for the dissection of neural network function and as therapeutics directed against a variety of neurological disorders has been published.

Lentivirus Vectors

HIV-1 is the etiological agent of acquired immunodeficiency syndrome. The ~9 kb HIV-1 RNA genome contains nine ORFs which encode 15 proteins. Lentiviruses, in contrast to most retroviruses, can infect dividing and nondividing cells when viral proteins guide the proviral complex through the nuclear pore.

After binding to its receptor, the viral capsid containing the diploid RNA genome enters the cell by membrane fusion. The viral RNA genome is next converted into a double-stranded proviral DNA by the viral enzyme reverse transcriptase. The proviral DNA is complexed with the nucleocapsid, reverse transcriptase, and integrase viral proteins. Dynamic imaging of HIV particles in living cells revealed that cytoplasmic dyenin and the microtubule network by HIV to migrate toward the nucleus. The HIV particles accumulate in the perinuclear region and access the nucleus during mitosis or by active transport through the NPC. The HIV-1 preintegration complex has karyophilic properties due to the presence of nuclear localization signals (NLSs) in the viral proteins matrix and integrase, which permit nuclear import in the absence of mitosis. After translocation into the nucleus, the viral enzyme integrase mediates the integration of the provirus into the host-cell genome.

Lentiviral vectors as gene delivery vehicles have been shown to confer efficient and long-lasting, *in vivo* gene transfer into a variety of cell types. What makes lentiviral vectors particularly useful is that they are able to stably express the delivered genes in a tissue-specific manner in differentiating cells and in the germ cells of transgenic animals. Lentiviral vectors have been used to generate transgenic mice, rats, quails, chickens, and monkeys very efficiently, with the vast majority of the animals expressing high levels of GFP. Lentiviral vectors injected into the mouse striatum may induce an immune response against the transgenic, but not viral, antigens. Current viral helper or packaging cell lines use separate plasmids for a pseudotyped *env* gene and for supplying the viral structural and regulatory genes *in trans*.

Several studies have used lentivectors to infect regions of the CNS. Lentiviral vectors have been used to infect cortical neurons *in vivo* with several neuron-specific promoters, including the α-calcium/calmodulin-dependent protein kinase II and the synapsin I promoters. This permitted the structural dynamics of dendritic spines and axonal projections in single cortical cells to be monitored using high-resolution two-photon time-lapsed imaging. In another study, lentivectors were injected into the subventricular zone of the adult mouse brain to mark and prove that neural precursor cells display self-renewal and multipotency, two essential characteristics of neural stem cells (NSCs). Thus, lentivectors may be an efficient way to introduce therapeutic genes into NSCs to ameliorate a broad range of CNS diseases.

Engineering Chimeric Viral Vectors

The pursuit for better viral vectors has led many researchers to combine the best features of different viruses into chimeric vectors. Chimeric viral vectors provide a system for the production of viral vectors whose genome is encoded within another virus with a different life cycle and distinct biological characteristics. Many intriguing chimeric viral vectors merge HSV vectors, due to their large insert capacity, and viral elements that permit genomic integration.

Chimeric HSV-1–AAV Amplicon Vectors

HSV–AAV-based chimeric vectors can mediate highly efficient and precise site-specific integration of large therapeutic transgenes into the human genome. HSV-1–AAV amplicon vectors contain the replication origin (OriS) and the packaging signal

(pac) of HSV-1, along with the integrative elements of AAV, including the rep gene and the ITRs. Vectors based on HSV-1 permit the delivery of transgenes of up to 150 kb while the ITRs and Rep of AAV can confer site-specific integration into the AAVS1 site chromosome 19 in human cells, which allows sustained expression of a transgene.

HSV–AAV chimeric vectors have been used for the infectious transfer of the human lysosomal β-galactosidase (β-gal) gene of 100 kb. Sustained expression of β-gal was reported in cells infected with rep-plus, but not rep-minus, HSV–AAV hybrid vectors. Approximately, 80% of the rep-plus clones displayed β-gal activity above normal levels for up to 4 months of constant growth, and ~33% of the clones were found to have undergone AAVS1-specific integration of the ITR-flanked transgene. These findings are promising in that HSV–AAV chimeric vectors neatly merge the site-specific integration capabilities of AAV elements with the large genome-carrying capacity of HSV1, although the percentage of AAVS1-specific integration needs to be higher to ensure a low probability of insertional mutagenesis.

One remaining hurdle of HSV–AAV chimeric vectors is that HSV-1 replication is inhibited by the rep genetic elements from AAV, resulting in low titers. The data suggest that high levels of Rep protein expression during vector packaging are responsible for the titer reduction. By changing the promoters that drive rep genes in or removing them altogether from HSV–AAV chimeric vectors, Fraefel's lab has obtained higher viral titers.

Chimeric TN–HSV Amplicon Vectors

Another approach taken to confer stable, long-term transgene expression on the HSV amplicon vector DNA has been to incorporate the *Sleeping Beauty* (SB) DNA transposon system into an HSV-1 amplicon vector. The chimeric SB–HSV amplicon vector comprises two separate amplicon vectors: one expressing the SB transposase and the other carrying an expression cassette flanked by an inverted repeat/direct repeat (IR/DR) from the SB transposon. A 25-fold increase in the frequency of stable transduction in cell lines was observed with integration-competent SB–HSV amplicons compared to typical episomal HSV amplicons. They also demonstrated that the vector system efficiently integrated the IR/DR-flanked expression cassette randomly into the genomes of nondividing primary mouse neurons in culture, thereby leading to sustained transgene expression. *In utero* injection of the SB–HSV amplicon vectors into the lateral ventricle of mouse brains on embryonic day (E)14.5 led to widespread neural transgene expression in postnatal-day-90 brains, including the hippocampus, dentate gyrus, subventricular zone, septofimbrial nucleus, and the motor cortices. The authors concluded that the target of vector transduction on E14.5 must have primarily been multipotent neural stem/progenitor cells residing along the ventricular zone.

Chimeric hcAd–AAV Vectors

The hcAd–AAV vector comprises linear monomeric DNA molecules consisting of the Ad origin of replication and packaging signal and the AAV ITRs and Rep; it can confer site-specific integration into the AAVS1 site chromosome 19 in human cells, which allows sustained expression of a transgene. Packaging cells are infected with a helper Ad vector to provide Ad DNA replication machinery, which along with AAV ITR-dependent dimerization leads to the assembly of vector genomes with a tail-to-tail configuration that are efficiently amplified and packaged into Ad capsids. Chimeric hcAd–AAV vectors have been used to express a 14 kb dystrophin cDNA in rat cardiomyocytes *in vitro* and to restore dystrophin synthesis in the muscle tissues of mdx mice *in vivo*.

Chimeric Lentivirus–Ad Vectors

Ad–retroviral chimeric vectors were developed first; however, their efficacy was limited because neighboring cells must be dividing for the second stage of infection by the retrovirus to occur. To overcome this limitation, lentiviral elements are often used instead of retroviral elements. The nonintegrative, high-titer, broad tropism Ad is able to deliver DNA that becomes integrated into neighboring cells by the lentivector intermediary in the current lentivirus–Ad chimeric vectors. Because both the Ad and lentivirus can infect dividing or nondividing cells, these chimeric vectors should permit the efficient integration of a transgene into nondividing neighboring cells *in vivo*.

Conclusion

Considerable progress has been made in generating novel viral vectors that may have profound therapeutic effects in the CNS in the years to come, but considerable advances still need to be made. The ability to temporally and spatially introduce therapeutic genes into a diseased CNS in a highly efficient manner indicates that viral vectors will play a vital role in future gene therapies. Although the highly efficient nature of viral-mediated gene delivery is alluring and intoxicating, the repercussions of a gene therapy experiment gone awry can be severe. A more comprehensive understanding of the basic biology of viruses will lead to better and safer viral

vectors in the future. A wide range of clinically relevant applications, including Parkinson's disease, lysosomal storage diseases, Canavan's disease, epilepsy, Huntington's disease, and ALS, are currently or will soon be in clinical trials. However, each individual treatment presents a unique set of difficulties that must be deciphered in order to attain clinically effective gene therapies.

Enteric Nervous System Development

M D Gershon, Columbia University, New York, NY, USA

Discovery of the Independent Function of the Enteric Nervous System

The discovery of the enteric nervous system (ENS) dates to the period of the American Civil War, when the presence of ganglia within the external muscle layers of the bowel (Auerbach's or myenteric plexus) and within the submucosa (Meissner's and Schabadasch's or submucosal plexuses) was described. Before the end of the nineteenth century, Bayliss and Starling had established that the 'local neural mechanism' (the ENS) mediates propulsive motility, which they called "the law of the intestine," independent of input from the central nervous system (CNS). While World War I raged, Trendelenburg emphatically confirmed this conclusion by eliciting "the law of the intestine," now renamed the peristaltic reflex, *in vitro*. Despite the clarity of this evidence, and the absence of its refutation, many biologists continue to believe that the ENS is an array of parasympathetic relay ganglia used by vagal and sacral nerves to control the gut. That they should do so is surprising because in his original definition of the autonomic nervous system, JN Langley clearly differentiated between the enteric and parasympathetic nervous systems. The parasympathetic and sympathetic systems were defined, respectively, by their craniosacral and thoracicolumbar outflows from the CNS, while the ENS, which can operate independently of CNS control, is a separate division that contains many neurons that lack a CNS innervation. The misapprehension of the independence of the ENS tends to trivialize its importance, decrease ENS research, and focus explanations of functional gastrointestinal disorders exclusively on the CNS.

Organization of the ENS

The ENS is comprised of myenteric and submucosal plexuses, which interconnect and innervate effectors, smooth muscle, blood vessels, and glands (Figure 1). Extrinsic motor and sensory nerves of vagal and spinal origin link the ENS and CNS. The number of enteric neurons ($>10^8$ in the human small intestine), which approximates that of the spinal cord, dwarfs the number of motor axons ($\sim 10^3$) in the vagus nerves. This disparity critically influenced Langley's view of the enteric innervation but does not mean that the CNS is unable to influence the ENS. It can, and does, with effects that often become all too disturbingly apparent when anxiety strikes. In fact, investigators who selectively visualize the efferent vagal innervation have marveled at its apparent extent. Vagal axons, however, are only a small proportion of the vast numbers of fibers in the ENS. When all axons are demonstrated, fibers can be distinguished individually only by electron microscopy. Intrinsic reflexes, their integration within the ENS, and their coordination with myogenic activity (muscle and interstitial cells of Cajal (ICCs)), not the CNS, are what determine the basic motile and secretory behaviors of the gut. ICCs are electrically coupled to smooth muscle and act as pacemakers and intermediaries, which transmit signals from nerve to smooth muscle.

The sensory component of the extrinsic enteric innervation is very much larger than the motor; about 90% of vagal fibers are afferent. Pain and discomfort are conveyed to the CNS primarily by spinal nerves, while information that the vagi convey to the brain does not necessarily reach consciousness. Vagal sensory fibers are responsible for nausea and, when highly stimulated, also convey pain, but mostly they are involved in 'homeostasis,' the ramifications of which are not completely understood but may be beneficial. Vagal stimulation is utilized to treat depression and epilepsy, and it improves learning and memory in humans and animals. Vagal motor fibers have been postulated to act on enteric command neurons, allowing the CNS to exert a powerful overall effect, despite the intrinsic control of motility and secretion. The CNS thus operates in a role analogous to that of a chief operating officer, who directs overall operations but does not micromanage.

The anatomy, physiology, and neurochemistry of the ENS are complex. The histological organization of the ENS, for example, resembles that of the CNS and lacks the connective tissue sheaths that normally surround peripheral nerves. Because the ENS thus lacks internal collagen, neurons are supported by enteric glia, which are rich in glial fibrillary acidic protein and resemble CNS astrocytes. Enteric neurons, moreover, are phenotypically diverse. Every class of neurotransmitter and neuromodulator that has been described in the CNS is also represented in the ENS. Enteric interneurons, furthermore, are arranged in microcircuits, which are not yet understood.

ENS Control of Motile and Secretory Behaviors

The basic pattern of the peristaltic reflex has been ascertained, but motility is more than just peristaltic reflexes. The gut sometimes propels its content and sometimes mixes them. The ENS contains a library of

Figure 1 A drawing showing the organization of enteric innervation. Extrinsic nerves are depicted at the top of the figure reaching the bowel as perivascular (sympathetic) and paravascular (sensory, parasympathetic) bundles in the mesentery. The submucosal and myenteric plexuses are indicated. The myenteric plexus lies between the circular and longitudinal layers of the muscularis externa. The submucosal plexus can be seen in the cutaway view and in profile in the cross-sectional view of the gut. Nerve fibers enter the mucosa but are limited to the connective tissue of the lamina propria, and none enter the lumen.

Figure 2 Enterochromaffin (EC) cells, which function as sensory transducers, can be demonstrated with silver (left) or immunocytochemically with antibodies to 5-HT (right). Silver stains depend on the ability of 5-HT to act as an agent that reduces silver salts to metallic silver, which precipitates to reveal the storage granules. Note that these granules (silver) and 5-HT are concentrated in the basolateral cytoplasm. This orientation reflects the basolateral secretion of 5-HT.

motor programs, from which it selects appropriate patterns. This library includes postprandial mixing to facilitate digestion and absorption, aborally directed power propulsion, orally directed power propulsion (associated with vomiting), and physiological ileus (in which motility stops). There is also an interdigestive, housecleaning program consisting of migrating motor complexes that sweep down the bowel. Choosing programs requires that the content of the lumen of the bowel be closely monitored.

No nerves actually enter the lumen (Figure 1); therefore, the ENS must be apprised of luminal conditions transepithelially. Enteroendocrine cells in the mucosal epithelium function as sensory transducers. The best known of these is the enterochromaffin (EC) cell, which contains serotonin, or 5-hydroxytryptamine (5-HT; Figure 2), which is secreted in response to increases in intraluminal pressure or, in the duodenum, applications of acid or glucose to their apical microvillous border. Also, 5-HT stimulates the mucosal processes of intrinsic primary afferent neurons (IPANs), subsets of which exist in the submucosal and myenteric plexuses. These cells do not project to the CNS but activate the intrinsic microcircuits that mediate peristaltic and secretory reflexes. IPANs thus allow the ENS to function independent of CNS input. Common motor neurons of the ENS relax or contract intestinal muscle, probably through the intermediation of ICCs. Excitatory motor neurons are cholinergic and also secrete a neurokinin; inhibitory motor neurons contain nitric oxide synthase but may also utilize adenosine 5′-triphosphate or vasoactive intestinal peptide (VIP) to exert relaxant effects. Additional enteric neurons are secretomotor and cause goblet cells to secrete mucous and crypt epithelial cells to secrete chloride and thus water, and they also regulate gastrointestinal peptide secretion by enteroendocrine cells. Secretomotor neurons are either cholinergic or VIP-secreting, without overlap. The IPANs of both plexuses are cholinergic and may also co-store peptides and a calcium binding protein, calbindin. In fact, about 70% of all enteric neurons are cholinergic; however, most of these neurons co-store additional peptides and/or small molecule neurotransmitters, such as 5-HT. Neurons of the ENS can be identified by a chemical code made up of the transmitter and other molecules that they co-express.

Serotonin Is Important in the Normal and Abnormal Behavior of the Bowel

Not only is 5-HT produced and secreted by EC cells to initiate reflexes, but it is also a neurotransmitter of long descending myenteric interneurons. Although

its CNS activity (seemingly related to everything that makes life worthwhile) is what made 5-HT famous, its concentration in the CNS pales beside that in the gut. The enteric epithelium, moreover, continually turns over. New cells are generated from stem cells in the necks of gastric glands and intestinal crypts, mature as they rise to the gastric surface and villus tips, and eventually die and slough into the lumen. The epithelial cells are thus constantly in motion. Because axons are not adapted to track moving targets, the axons of IPANs cannot make traditional synapses on EC cells but terminate as processes in the lamina propria of the mucosa. This type of paracrine junction is acceptable because the bowel is a gross and imprecise organ. Specificity of signaling is achieved, not by the close apposition of interacting elements, but by the ability of receptors to selectively respond to 5-HT. EC cells overcome the large and variable distance to the nerves they stimulate by secreting massive quantities of 5-HT. In fact, 95% of the body's 5-HT is located in the gut, and the EC cells represent a much larger store of it than do the neurons of the myenteric plexus. The overflow of 5-HT from EC cell secretion reaches the intestinal lumen and stocks platelets with 5-HT. Platelets do not synthesize 5-HT but take it up as they circulate through the bowel. The rate-limiting enzyme in 5-HT's biosynthesis is tryptophan hydroxylase (TpH). There are two TpH isoforms, TpH1 and TpH2. EC cells contain TpH1, and neurons of the ENS and the CNS contain TpH2.

The large quantities of constitutively secreted 5-HT, and its overflow, necessitate an efficient mechanism in the bowel for 5-HT inactivation. Inactivation is accomplished by 5-HT reuptake; this involves a plasmalemmal serotonin transporter (SERT), which is expressed in the gut by enterocytes and serotonergic neurons. Enteric SERT is identical to CNS SERT. Tricyclic antidepressants, serotonin selective reuptake inhibitors (SSRIs), and cocaine, which are in widespread use, and abuse, all inhibit SERT. These compounds potentiate 5-HT, but their enteric effects are limited by the presence of backup transporters, which include organic cation transporters (OCTs) and the dopamine transporter (DAT). The OCTs and DAT have a lower affinity than SERT does for 5-HT, but they have a high capacity, and they prevent catastrophe from occurring when SERT is knocked out. They do not, however, completely protect the bowel from SERT inhibition. Tricyclic antidepressants and SSRIs exert gastrointestinal 'side effects,' which are really direct effects. These include nausea, diarrhea, and perhaps as a result of the desensitization of 5-HT receptors, constipation. Diarrhea and constipation alternate in knockout mice, which lack SERT; these mice also lose water excessively in stool.

Major advances in the treatment of patients undergoing chemotherapy for cancer and in those suffering from irritable bowel syndrome (IBS) have highlighted the importance of enteric 5-HT. EC cells not only trigger intrinsic reflexes by secreting 5-HT and stimulating IPANs, but their 5-HT also activates extrinsic sensory nerves to initiate nausea and discomfort. Different subtypes of 5-HT receptor are utilized to activate, respectively, intrinsic and extrinsic nerve fibers. Submucosal IPANs, but are stimulated by 5-HT_{1P} receptors, which may be heteromultimers of other G-protein-coupled receptors. IPANs (as well as cholinergic motor neurons to smooth muscle) also express 5-HT_4 receptors at their terminals. The 5-HT_4 receptors enhance acetylcholine and calcitonin gene related peptide secretion and thus strengthen synaptic transmission in excitatory (prokinetic) pathways. Further, 5-HT activates extrinsic sensory nerves by stimulating 5-HT_3 receptors. Myenteric IPANs, which appear to drive the giant, sometimes painful contractions associated with the aboral power propulsion pattern of activity, are also stimulated by 5-HT_3 receptors.

The dichotomy of 5-HT receptor subtypes involved in intrinsic and extrinsic reflex stimulation makes therapy possible. Some 5-HT_3 antagonists, including ondansetron and granisetron, provide relief from the nausea that accompanies cancer chemotherapy without at the same time paralyzing the bowel by interfering with 5-HT-driven peristaltic and secretory reflexes, and some 5-HT_3 antagonists, particularly alosetron, also alleviate the discomfort associated with IBS. This is a major advance because the pain and discomfort of IBS are far more troubling to patients than the altered bowel habits that are another hallmark of that disease. Blockade of the giant contractions of power propulsion by 5-HT_3 antagonism may also contribute to the relief of pain and discomfort in IBS but may be counterproductive. Not only do 5-HT_3 antagonists block activation of the IPANs that initiate power propulsion; they also inhibit serotonergic fast excitatory neurotransmission within the ENS. Thus, 5-HT_3 antagonists are constipating and useful only to treat diarrhea-predominant IBS. It is possible that interference with the emergency aboral power propulsive pattern of activity contributes to the rare complication of ischemic colitis that has been linked to the use of 5-HT_3 antagonists in treating IBS.

In contrast to the slowing of motility associated with 5-HT_3 antagonists, the strengthening of neurotransmission in prokinetic pathways by 5-HT_4 agonists, such as tegaserod, is useful in the treatment of chronic constipation and constipation-predominant IBS. These compounds do not initiate reflexes and do not activate pain pathways but instead rely on

natural stimuli to get a refractory bowel moving again, and 5-HT_4 agonism strengthens propulsive motility. Therefore, 5-HT_4 agonists are effective when taken for their approved use.

The ENS Originates from Vagal, Truncal, and Sacral Regions of the Neural Crest

The complexity and unique nature of the ENS suggests that factors that drive its development will be different from those that govern development of the remainder of the autonomic nervous system. Meaningful research on ENS development dates from the demonstration by Yntema and Hammond that deletions of what they called the 'anterior neural crest' caused deficiencies to occur in enteric ganglia of chick embryos. Subsequently, Le Douarin deleted the crest from various regions of chick embryos, but she also replaced it with grafts of crest from quail embryos, creating interspecies chimeras. The grafted quail cells migrated seemingly normally in their new hosts. Quail cells express an identifying pattern of nucleolar-associated heterochromatin that enables them to be reproducibly identified in fields of chick cells (Figure 3). Quail cells can also be recognized immunocytochemically, as has been done in more recent studies, by using quail-selective antibodies. As a result, cells of neural crest origin can be identified in the target organs of chimeric embryos, which in combination with suitable grafts allows the sites of origin of crest-derived émigrés to be determined. The axial levels of origin of the crest-derived enteric neurons and glia have now definitively been mapped in avians through the study of interspecies chimeras. For some time, it was simply presumed that the origin of the mammalian ENS was more or less analogous to that of avians. More recently, vital dyes and genetic mapping techniques have been used to verify the correctness of that assumption. The ENS is derived from the postotic (vagal and rostral truncal axial levels equivalent to somites 1–7) and sacral (axial caudal to somite 28) regions of the crest (Figure 4).

Enteric Neurons and Glia Develop from a Multipotent Precursor Population

Along with knowledge of the sites of origin of crest-derived cells came the counterintuitive discovery that differences between enteric neurons in the neural crest origins of their predecessors do not explain the phenotypic diversity of the ENS. The developmental potential of various regions of the crest, at least with respect to the ENS, does not appear

Figure 3 Quail cells (arrows) from a graft of neural crest are demonstrated in the bowel of a chick embryo to which they have migrated. The nucleolar-associated heterochromatin that characterizes the quail cell nucleus has been demonstrated by staining DNA with the Feulgen reaction. Quail cells and thus cells of donor neural crest origin can be distinguished from the chick cells of the host.

Figure 4 Cells that migrate from the vagal, rostral truncal, and sacral levels of the neural crest colonize the bowel. Vagal crest-derived cells (red) colonize the entire bowel, truncal crest-derived cells (yellow) colonize only the esophagus and immediately adjacent stomach, and sacral crest-derived cells (blue) colonize the postumbilical gut, which thus contains cells of both vagal and sacral origin (purple).

to be preset. For example, crest which, if left unperturbed, would form the adrenal medulla will instead migrate to the gut and give rise to an ENS when it is transplanted to the vagal region of a recipient embryo. This interchangeability of developmental potential of populations of crest cells has led to the concepts that there are defined pathways in embryos along which crest-derived cells migrate and that populations of crest cells are pluripotent; nevertheless, despite the pluripotentiality of the population, individual premigratory crest cells may not be pluripotent. Some crest-derived cells may already be specified before they migrate. For example, crest-derived cells that form sensory neurons migrate away from the neuraxis before those that give rise to melanocytes. The evident pluripotency of populations of crest-derived cells may be due in part, therefore, to their heterogeneity. Even if individual stem cells are not able to give rise to all the derivatives of the crest, a population may contain a sufficient number of determined precursors to allow all these derivatives to develop. According to this idea, if cells migrate to the skin, those precursors that are capable of forming melanocytes will develop, but if the same population finds itself in the bowel, those precursors that are capable of developing as enteric neurons and glia will now differentiate. Actually, cells committed to be melanocytes (which leave the neuraxis late) do not normally migrate to the bowel; they preferentially migrate along the dorsolateral pathway that leads them to the skin. The small population of melanogenic crest-derived cells that do migrate ventrally are filtered out of the population that colonizes the bowel as it passes through the caudal branchial arches so that the gut is nonpigmented. On the other hand, melanocytes develop in the gut when melanogenic precursor cells are experimentally planted there; the gut is also pigmented in chicks with the Silkie Fowl mutation, in which migratory controls fail. The crest-derived precursors of the ENS are thus not normally pluripotent, in the sense of being able to give rise to every type of cell that can be generated by the neural crest. Crest-derived cells that have completed their migration to the bowel, for example, cannot give rise to melanocytes or mesectoderm. Examinations of clones of enteric crest-derived cells, however, have established that they are multipotent, in the sense that they can give rise to glia or any of the many types of neuron that are found in the ENS. In any case, the unique properties of the ENS are determined, not by the site of origin of committed precursors in the neural crest, but by epigenetic factors, especially microenvironmental cues these cells encounter within the gut or while migrating to it.

Development of the ENS Is a Progression of Interacting Cell Autologous and Nonautologous Events

The developmental potential of enteric crest-derived cells decreases progressively as these cells age; moreover, crest-derived cells cannot respond to growth factors or molecules of the extracellular matrix unless they first express the relevant receptors. Cell autologous and nonautologous events thus combine and interact to define differentiation of the ENS. Developmental progress in the formation of enteric neurons and glia is marked by a series of transcription factors that must be expressed, receptors that must be displayed on plasma membranes, and growth factors that must be encountered. The multipotent precursors of the ENS, which are capable of giving rise to both neurons and glia, obligatorily express the transcription factors Pax3 and Sox10, which drive expression of Phox2b and the receptor tyrosine kinase, Ret. Knockout of Sox10 or Phox2b prevents the formation of any enteric neurons or glia, while knockout of Ret blocks the formation of enteric neurons below the level of the esophagus and immediately adjacent stomach. To activate Ret, ligands must first bind to a member of the glial cell-derived neurotrophic factor (GDNF) family receptor alpha (GFRα) molecules. Two Ret ligands function in ENS development to stimulate Ret, GDNF, which binds to GFRα1, and nurturin, which binds to GFRα2. Of these, GDNF is required first and by almost all neural precursors. Nurturin appears to be necessary for the formation of restricted later-arising populations of neurons found mainly in the submucosal plexus. GDNF promotes proliferation of crest-derived precursors, which are extensive in fetal bowel, and is also chemoattractive for crest-derived cells. GDNF is produced by non-crest-derived elements of the enteric mesenchyme and is thought to assist in preventing crest-derived precursors from migrating out to the gut during its colonization. Recent evidence suggests that the basic helix–loop–helix transcription factor, Hand2, is also essential in allowing enteric crest-derived cells to complete the series of steps that take them from precursors to neurons. The gut is colonized, neuronal differentiation commences in the absence of Hand2, but when Hand2 is deleted, the precursors express early neuronal markers but then freeze without terminally differentiating. Perhaps because they begin neuronal differentiation, progenitors do not shift by default toward the glial lineage, nor do the unfinished precursors die. Thus far, animals lacking Hand2 have not survived long enough to determine the fates of the neuronal precursor cells that cannot complete differentiation.

Hirschsprung's Disease Is the Most Obvious Developmental Disorder of the ENS

Defects in the genes required early in ENS differentiation are associated in humans with Hirschsprung's disease, or congenital megacolon. Hirschsprung's disease occurs when a variable length (long segment or short segment) of terminal bowel is aganglionic. The affected region of the gut is not denervated, but when the ganglia, which mediate the complex behaviors of the bowel, are lacking, the gut is as effectively obstructed as if it had been tied off with a suture. The gut dilates proximal to the aganglionic segment. Extrinsic nerves and descending nerve fibers from the proximal ganglionated portion of the gut form coarse trunks in the aganglionic region. *RET*, which is mutated in 3–35% of cases in which a gene has been identified, and the endothelin B receptor (*EDNRB*), which is mutated in 5–15% of cases, are the most common genes found to be mutated in association with Hirschsprung's disease. Others include genes encoding the ligands GDNF, GFRα1, and nurturin for RET and EDN3 (endothelin3) for EDNRB, as well as the transcription factors SOX10, PAX3, PHOX2B, and SIF1.

Hirschsprung's disease is the most visible and highly investigated enteric neuromuscular birth defect. Hirschsprung's disease is not uncommon, occurring in about one per 5000 births, except among Mennonites, where the incidence is one per 500 births because of inbreeding. Because both the development of glia and all types of enteric neurons fail, albeit segmentally, it is not surprising that expression of each of the genes linked to Hirschsprung's disease is required early in ontogeny. If left untreated, Hirschsprung's disease is lethal, but surgical removal of the aganglionic bowel prevents death. Surgery is thus life-saving, but it may not leave patients with a fully functional, inconvenience-free gut. Defects in motility leading to constipation and/or soiling may remain, even after the aganglionic tissue has flawlessly been removed, suggesting that the remaining ostensibly 'normal' ENS is really abnormal. The presence of ganglia thus does not guarantee that the ENS is normal.

Subtle ENS Defects May Arise as a Result of Mutations in Genes Required Late in ENS Development

Because enteric behavior is complex, the presence or absence of enteric neurons, which has historically been used by pathologists to assess ENS function, is inadequate. Intestinal neuronal dysplasia, for example, is a Hirschsprung's-like condition, associated with abnormal ganglia rather than aganglionosis, in affected regions. Intestinal neuronal dysplasia has been somewhat controversial, and some have doubted its existence, but it has been documented by competent pathologists and is mimicked in mice lacking Hox 11L1 and in rats that with a heterozygous endothelin B deficiency, suggesting that intestinal neuronal dysplasia is a real condition. Chronic idiopathic intestinal pseudo-obstruction (CIIP) severe enough to require bowel transplantation can even occur despite the presence of ganglia in the nonfunctioning gut. The occurrence of functional abnormalities of gastrointestinal motility, despite the presence of enteric ganglia, supports a hypothesis that there is a spectrum of functional disorders, from CIIP to IBS, that are the result of defects in genes that are not required early in the development of the ENS but which are needed to complete the development of particular subsets of neurons or to regulate synaptogenesis. Gene products required late in ENS ontogeny include the neurotrophin NT3 and its high-affinity receptor, TrkC. During the period when GDNF is required to drive proliferation of enteric crest-derived cells, NT3 does nothing to them. Crest-derived cells do not acquire TrkC or become NT3-responsive until after these cells have colonized the bowel. NT3, furthermore, is not needed for the development of all enteric neurons but only for subsets. One such NT3-dependent subset is the submucosal IPAN, which initiates peristaltic and secretory reflexes. After the deletion of NT3 or TrkC, therefore, the ENS appears to be normal and ganglia are present; however, the bowel will not function normally because it lacks a critical subset of its neurons.

Late events are important in ENS development. Early crest-derived precursors have been visualized as they migrate through the murine bowel. These cells, of vagal origin, migrate proximodistally in long chains of seemingly attached cells in the outer gut mesenchyme. The driving force for migration appears to be the proliferation of precursors at the leading edge of the colonizing population; however, the evident contact of leaders with stragglers raises the possibility that population pressure from stragglers contributes to the forward movement of émigrés. The location of the migrating cells in the outer gut mesenchyme is appropriate for the formation of the myenteric plexus. Sacral crest-derived cells delay their arrival in the postumbilical bowel until the arrival of their vagal counterparts but then ascend in the bowel in a countercurrent fashion. The submucosal plexus forms after the myenteric. The formation of the submucosal plexus results from a secondary perpendicular migration of crest-derived cells from the outer gut mesenchyme toward the mucosa. This secondary migration occurs because

netrins, which are secreted by the endoderm, attract crest-derived cells. Netrins act on the netrin receptor called 'deleted in colorectal cancer' (DCC), which is expressed by migrating crest-derived cells. Netrins are also secreted by developing pancreatic acinar cells and attract DCC-expressing crest-derived cells from the bowel, which migrate out of the gut and into the developing pancreatic buds. These crest-derived cells ultimately give rise to intrapancreatic ganglia. It is interesting that the enteropancreatic migration of crest-derived cells is followed by the extension of enteropancreatic nerve fibers from neurons in gastric and duodenal myenteric ganglia. These nerves ultimately connect the bowel to the pancreas, where they terminate in ganglia.

Gastrointestinal dysmotility disorders are neither well understood nor rare. These conditions are believed to be congenital when they occur in children, but that belief has not clarified their pathogenesis or provided a means of treatment. Although similar gastrointestinal dysmotilities also occur in adults, the possibility that adult disorders might, like their pediatric counterparts, be congenital has not been tested. Much of the research on ENS development has focused on the pathogenesis of Hirschsprung's disease. This focus is understandable because the aganglionosis of Hirschsprung's disease is so obvious; moreover, the current treatment of Hirschsprung's disease, while life-saving, leaves much to be desired. Still, the paradigm that the presence of ganglia signifies a normally functioning ENS has proven to be false. It is thus possible that future research on the development of the ENS will be not only intellectually satisfying but fruitful in pointing the way toward understanding the pathogenesis of gastrointestinal conditions that are now mysterious, unpreventable, and poorly treated.

Introduction

The human enteric nervous system (ENS) contains an estimated 10^8 neurons in two major ganglionated plexuses that extend the entire length of the bowel: the myenteric plexus between the longitudinal and circular muscle and the submucosal plexuses associated with the mucosal epithelium. More than 16 phenotypically distinct neuronal populations have been identified and classified by their morphology, transmitter content, and electrophysiological properties into sensory neurons, ascending and descending interneurons, and excitatory and inhibitory motor neurons. These are organized into reflex circuits that control and coordinate motility, blood flow, and secretion to meet the digestion needs of the individual. While enteric reflexes operate independently of any connections to the central nervous system (CNS), extrinsic afferent and efferent fibers running in the parasympathetic and sympathetic connections to the brain stem and spinal cord are responsible for reflexes that help coordinate distant regions of the gastrointestinal (GI) tract, link digestive function to behavioral mechanism that control food intake, and mediate sensations such as pain. Disorders of the ENS are manifested as dysmotility and altered secretory function, which in turn lead to symptoms of dysphagia, diarrhea or constipation, nausea, discomfort, and pain. Disorders arise under a variety of circumstances, from congenital abnormalities in ENS development such as Hirschsprung disease (HSCR) to functional defects in reflexes brought about by inflammation or stress. Some are specific to the ENS, others are enteric manifestation of more widespread systemic disease. Understanding the ENS in health and disease has implications for advances in treatment options and the development of novel pharmaceuticals to treat GI symptoms.

Developmental Disorders

Developmental disorders of the ENS clinically present with signs of intestinal obstruction, usually in neonatal life or early childhood. In about 75% of patients the abnormal segment is restricted to the rectosigmoid of colon. In a small minority of cases (about 5%) the abnormality may involve the whole colon (total colonic aganglionosis) or may be even more widespread, affecting the entire length of the GI tract. Abnormalities extending into the esophagus are associated with difficulty in swallowing. Developmental defects may be familial, with a distinct pattern of inheritance, or sporadic. There is a familial tendency in about 7% of short-segment disease, increasing to about 21% in patients when the whole of the colon is affected. The most common developmental disorder was named after Hirschsprung, who first described the condition in the late nineteenth century. It occurs in about 1 in 4500 live births (3.8:1 males to female), and is characterized by a segment of bowel that is completely devoid of enteric ganglia. The aganglionic segment is constricted and unable to pass contents, leading to the normal bowel above becoming massively dilated. In many cases of HSCR the defect has been localized to chromosome 10q11.2, which specifies the *RET* gene that encodes a tyrosine kinase receptor (see later). Other genes have been linked to HSCR, including *SOX10*, *GFRα1*, and the gene for endothelin receptor type B (*EDNRB*), but, even so, for 50% of Hirschsprung cases the genetic cause has not been identified.

The neurons and glia that make up the ENS are derived from precursor cells in the vagal and sacral neural crest. Vagal crest-derived precursors are multipotent cells that migrate rostrocaudally through the gut before exiting the cell cycle and differentiating into the neuronal types that make up the unique features of the ENS. Sacral neural crest cells enter the gut after it has been colonized by vagal neural crest cells, but the molecular control of sacral neural crest cell development has not been extensively investigated. Migration, proliferation, and differentiation are all cued by the molecules that the crest-derived cells encounter on their journey along the bowel, acting on developmentally regulated receptors that these cells express. Some of the molecules and receptors that determine this process have already been well established. The *RET* knockout (RET −/−) shows a total absence of the ENS, suggesting that normal enteric development depends upon the functional integrity of this tyrosine kinase receptor signaling pathway. The ligand for *RET* receptor is glial-derived neurotrophic factor (GDNF), and knocking out the gene for this factor leads to a similar lack of expression of enteric neurons. GDNF acts as a chemoattractant for vagal neural crest cells (NCCs) expressing the RET/GFRα1 receptor complex. While RET and GFRα1 −/− mice have severe aganglionic phenotype, the heterozygotes have only mild reductions in neuronal counts. Nevertheless, these

animals have striking deficits in intestinal motility and transmitter release, demonstrating the importance of *RET* signaling for both ENS structure and function. Endothelin-3 (EDN3) and its G-protein-coupled EDNRB are another important component of the signaling process, particularly in the development of the distal colon. In the absence of EDNRB or EDN3 the spread of neural precursors from the small to the large bowel is severely impaired.

Neural crest-derived cells differentiate into glial cells and the various subsets of neurons that can be identified by morphology, projection pattern, neurotransmitter content, ion channels, and receptor expression. Intrinsic factors such as transcription factors and extrinsic cues, including molecules in the gut environment, combine to influence the neural fate and can be detected in various combinations during the course of development. Environmental cues appear to change over time while intrinsic cues vary with developmental age, such that enteric neural progenitors are only competent to differentiate at a particular time point in development. The transcription factor SOX10 is required for differentiation of enteric glial cells. SOX10 and EDNRB appear to interact to determine the penetrance and severity of aganglionosis, which is a feature of HSCR where there is phenotypic variability within and between family members. A potential site of action of SOX10 is on an enhancer element of the *EDNRB* locus that is spatiotemporally activated at the time that ENS precursors are populating the distal gut.

In addition to neurons acquiring the correct phenotype, they must assume their correct location within the myenteric and submucosal plexuses. Crest cells migrate predominantly in the outer gut mesenchyme. Recent evidence suggests that cells that form the submucosal ganglia turn away from their proximodistal migration in response to netrins secreted from the GI mucosa. Crest-derived cells acquire netrin receptors, including DCC ('deleted in colorectal cancer') at the time they make their turn. This migration can be abolished by DCC antibodies or in transgenic mice that lack DCC, and these animals lack a submucosal plexus. Neurotrophin-3 is required for development and survival of enteric neurons that express tyrosine kinase C receptor (TrkC), which includes a subset of submucosal neurons.

Sonic hedgehog (Shh) plays a pivotal role in the spatial development of the gut. Recent evidence indicates that Shh may regulate proliferation and differentiation of NCCs in the gut and modulate the responsiveness of NCCs to GDNF. Bone morphogenetic proteins (BMPs) influence many developmental processes under the influence of Shh. Transcripts of BMP-2 and BMP-4 can be detected in the bowel at the time of neuronal differentiation, and coinciding with the expression of their receptors BMPR-1a and BMPR-1b and their antagonists noggin, gremlin, chordin, and follistatin in both crest- and non-crest derived cells. Animals overexpressing noggin under neuron-specific enolase (NSE) control, as a means of avoiding earlier effects on differentiation and migration, had greatly increased numbers of both myenteric and submucosal neurons throughout the gut, suggesting that BMP signaling limits the size of the ENS. BMP also induced the precocious appearance of TrkC-expressing lineages in cultures of crest-derived cells, an observation that correlates with the decrease in TrkC-expressing neurons in the noggin-overexpressing animals. Thus, BMP signaling regulates both neuronal numbers and cell fate differentiation.

Clearly there are a multitude of factors that regulate proliferation, migration, and differentiation that are needed to enable NCCs to populate and subsequently innervate the entire bowel. Hirschsprung disease is typified by aganglionosis. However, it is clear that developmental abnormalities can lead to regions of bowel which have too few (hypoganglionosis) or too many (hyperganglionosis) enteric neurons. In addition, enteric neuronal survival and cell death may be influenced by extrinsic factors and, as such, may contribute to adult disease and alterations in GI function associated with age. One such factor may be as a consequence of inflammatory insult.

Inflammatory Neuropathies

Pathology and Major Clinical Features

The ENS *per se* may be a target of inflammatory/autoimmune reactions altering its structure and function. These forms of enteric neuropathies are referred to as 'enteric ganglionitis' or 'plexitis,' because they are characterized by a dense and composite inflammatory infiltrate of lymphocytes, plasma cells, monocytes, and other elements located within myenteric and/or submucosal ganglia and/or throughout the axonal processes supplying the alimentary tract. Myenteric ganglia, rather than submucosal ganglia, appear more commonly involved, raising the hypothesis that myenteric neurons may express certain constitutive antigens preferentially targeted by the immune system. Furthermore, the inflammatory/immune infiltrate within enteric ganglia is commonly associated with neuronal degeneration, up to complete loss of neurons in the most severe cases (i.e., acquired aganglionosis). As a result, the inflammatory/autoimmune injury of the enteric ganglionated plexuses and nerves causes gut dysfunction, including dysmotility and delayed transit, at any level of the GI tract. Depending on the segment

Table 1 Secondary forms of enteric ganglionitis: possible diseases responsible for enteric ganglia inflammatory changes

Disease	*Explanation*
Paraneoplastic	Small cell lung carcinoma, lung carcinoid, neuroblastoma, thymoma, gynecological tumors
Infectious	Chagas' disease, herpes virus infection
Autoimmune disorders of the CNS	Encephalomyeloneuropathy, multiple sclerosis
Connective tissue disorders	Scleroderma
Inflammatory bowel disorders	Ulcerative colitis and Crohn's disease

Figure 1 Inflammatory neuropathy characterized by dense infiltrate within the myenteric plexus (ganglionitis) in the colon of a patient with severe gut dysmotility. Lymphocytes are stained (pink) with a mouse monoclonal antibody targeting CD8 receptors. Note the close proximity between CD8 lymphocytes and enteric neurons. Blue staining identifies other components of the immune infiltrate. Anti-alkaline phosphatase immunohistochemistry technique. Original magnification is 100×.

involved in the inflammatory neuropathy, clinical manifestations include achalasia, gastroparesis, intestinal pseudoobstruction, and colonic inertia/megacolon.

Enteric ganglionitis can be classified into primary and secondary forms that show similar histopathological findings (e.g., inflammatory infiltrate within enteric ganglia) and clinical manifestations (e.g., severe dysmotility syndromes). The former are also termed idiopathic, as the search for underlying disorders responsible for inflammatory changes of the ENS is negative. The latter, in contrast, can occur in the context of a variety of diseases (Table 1). Enteric ganglionitis is a rare condition usually associated with severe gut disorders. However, recent findings raise the possibility that ENS inflammation could underlie a wide spectrum of gut sensorimotor abnormalities, including functional disorders such as irritable bowel syndrome (IBS). It is likely that the severity of immune response within myenteric ganglia is dependent upon genetic background influencing the immune system. Two major histopathological forms of enteric ganglionitis have been described – namely, lymphocytic type and eosinophilic type.

Lymphocytic ganglionitis This is characterized by CD3-positive T lymphocytes surrounding ganglion cell bodies mainly confined within the myenteric plexus. A vast majority of these T cells belong to T-helper (CD4) and T-cytotoxic/suppressor (CD8) subtypes (Figure 1). The T-cytotoxic activity likely targets constitutively proteins or *de novo*-expressed antigens on the surface of enteric neurons. This has been described in patients with achalasia and intestinal pseudoobstruction. Other components of the infiltration include CD79α-expressing cells, indicating the importance of mature B lymphocytes and circulating antineuronal antibodies in patients with enteric ganglionitis. The expression of *de novo* antigens and chemokines contributes to the loss of self-versus-nonself function, which in turn triggers an immune/inflammatory response within enteric ganglia (see later).

Further, regarding the activation of immunocytes, patients with inflammatory neuropathies develop a significant humoral response with a wide array of circulating antineuronal antibodies. These autoantibodies, which may be identified in cases of idiopathic and secondary (e.g., paraneoplastic syndrome) lymphocytic ganglionitis and dysautonomia, target different antigens expressed by enteric neurons, in particular the RNA-binding proteins of the Hu family. Yo protein (an antibody targeting a Purkinje cell cytoplasmic antigen), P/Q- and N-type Ca^{2+} channels, and ganglionic nicotinic acetylcholine receptors are also targets.

Eosinophilic ganglionitis This is characterized by a prominent infiltration of eosinophils in enteric ganglia. In contrast to lymphocytic ganglionitis, the eosinophilic forms do not appear to be associated with neuronal cell damage, indicating that eosinophils evoke neuronal dysfunction rather than degeneration. Animal models of gut inflammation confirm the general features of eosinophilic ganglionitis and provide a basis to better understand how eosinophils (and neutrophils) alter enteric neuron function. Mice infected with *Schistosoma mansoni*, a nematode known to evoke mucosal ileitis, granulomas, and diffuse inflammation of the neuromuscular layer, develop eosinophilic and neutrophilic ganglionitis of the myenteric plexus without significant neurodegeneration.

Putative Pathogenetic Mechanisms Leading to Enteric Ganglionitis

Several mechanisms play a role in the pathogenesis of enteric ganglionitis.

De novo Expression of Antigens in the ENS

A number of neurotropic viruses, such as herpes simplex type 1, Epstein–Barr virus, cytomegalovirus, and varicella-zoster, have been associated with gut dysmotility through an intraganglionic immune response secondary to the infection of enteric neurons. For example, varicella-zoster DNA was found within enteric ganglia in a proportion of achalasia patients and in animals infected with the same agent, suggesting a role in inflammatory neuropathies. This viral DNA leads to the expression of viral-related antigens on neurons and glial cells, thereby triggering immune activation. The ENS appears to be a target for scrapie-related prion protein (PrP^{sc}) and is involved in its transmission to the CNS.

Disruption of ENS Microenvironment

The ENS is protected by a blood–ganglion barrier. Glial cells are key players in the protection against noxae. Indeed, enteric glia exert a critical role in ENS maintenance and survival as well as in the cross-talk between ENS and the immune system. *In vitro*, enteric glial cells are stimulated by proinflammatory cytokines and in response release cytokines including interleukin (IL)-6. Mice deficient of enteric glia develop widespread enteritis associated with a progressive decrease in the neuronal population, which emphasizes a critical role for glia in enteric neuronal survival.

Molecular Mimicry

Classic paradigms, which apply to these mechanisms, are parasitic infection induced by *Trypanosoma cruzi*, which is responsible for Chagas' disease, and paraneoplastic syndromes. The GI tract is affected in cases of paraneoplastic syndrome related to neoplasms, including small cell lung carcinoma, thymoma, and gynecological and breast tumors. It is likely that onconeural antigens represent the trigger leading to both antineuronal antibody generation and enteric ganglionitis. Typical target molecules of paraneoplastic syndromes with GI involvement are the Hu and Yo (or cdr2) proteins, along with transmitter G-protein-coupled receptors and channels (see earlier).

Trypanosoma cruzi, a parasite transmitted to humans by Triatominae insects (the Reduviidae beetles), is responsible for Chagas' disease, which is an endemic disorder in South America, especially Brazil. In addition to cardiac and urinary system involvement, patients with Chagas' disease often demonstrate severe motor dysfunction of the GI tract – for example, achalasia (megaesophagus), megaduodenum and megacolon, and extrahepatic biliary tract. The underlying enteric ganglionitis is likely the result of a molecular mimicry leading to immune cross-reactivity between the parasite and enteric neurons. Particularly, the *T. cruzi* flagellar antigen Fl-160 (a 160 kDa surface protein) antigenically mimics a 48 kDa protein expressed by mammalian axons and myenteric neurons.

Postoperative Ileus

Postoperative ileus (POI) is a condition of impaired GI motility that is a frequent consequence of abdominal surgery. Contributory factors include anesthetic agent and postsurgery medication for managing pain. However, an inflammatory mechanism interacting with elements of the ENS and its extrinsic innervation is now considered to be relevant, particularly for the prolonged phase of POI. Resident macrophages play a pivotal role in the initiation of this enteric inflammatory response. Surgical manipulation triggers the release from macrophages of various mediators, including nitric oxide (NO) and prostaglandins, that can directly influence neuromuscular function, leading to inhibition of the entire GI tract. Macrophages also release proinflammatory cytokines, including tumor necrosis factor-α (TNF-α), IL-1β, IL-6, and monocyte chemotactic protein 1, all of which mediate cellular inflammation by recruiting circulating monocytes and neutrophils to the gut wall. These result in the further generation of neurogenic modulators, including NO and prostanoids. Cyclooxygenase-2 is considered to be crucial for activation of inhibitory motor reflexes and postoperative gut dysfunction. Mast cells may also contribute to POI and, like macrophages, can be triggered to release proinflammatory mediators and neuronal modulators, including histamine and proteases. POI may also involve hyperactivity of the sympathetic nervous system, which consequently results in strong inhibition of ENS circuits due to α_2-mediated presynaptic suppression of excitatory transmission as well as to direct postsynaptic inhibition of ENS activity.

Functional Disorders

The term 'functional bowel disease' was originally coined to indicate gut disorders without any detectible structural and biochemical abnormalities. Symptoms from the upper GI tract are referred to as functional dyspepsia (FD) and those in the lower GI tract as IBS. The hallmark of IBS is viscera hypersensitivity together with altered bowel habit (constipation, diarrhea, or alternating). FD is characterized by epigastric pain, nausea, and gastric motility and emptying disorder. Impairment of fundus relaxation associated with

early satiety is another hallmark of FD. Our current understanding is that the ENS, the brain–gut axis, and ENS–immune signaling are implicated in the pathophysiology of FD and IBS. Features include changes in serotonin signaling, altered gut microflora, genetic abnormalities, plasticity in receptor expression, and neuroinflammatory interactions.

Relevance of Immune Nerve Signaling in Functional Bowel Disease

Several studies have suggested a low-grade colonic inflammation as a pathophysiological factor in IBS. Patients with IBS exhibit an enhanced density of intraepithelial lymphocytes and an increased frequency of integrin $\beta 7^+$ T lymphocytes in the peripheral blood. Low-grade infiltration of lymphocytes in the myenteric plexus and neuronal degeneration have been described in patients with severe IBS. Pro- and anti-inflammatory mediators have powerful actions on the ENS.

Mast cell density and activity are significantly increased in biopsies taken from the large bowel of IBS patients. Increased numbers of mast cells in gastric biopsies have also been observed in patients with FD. An elevated mast cell number in IBS patients is associated with symptom severity and increased release of mast cell mediators, including histamine. Analysis of endoscopic biopsies from patients with food allergy and IBS has revealed significantly elevated H1- and H2-receptor mRNA levels. Both receptors are involved in histamine evoked enhanced excitability of enteric neurons, increases in secretion and motility, as well as altered sensory signaling in vagal and spinal afferents. The upregulated immune nerve signaling therefore contributes to symptom generation in IBS patients.

Gut infections may lead to functional bowel disease long after the acute infection has resolved. Some patients develop IBS symptoms after gastroenteritis, but it is not yet known what triggers plasticity in the ENS or chronic alterations in the immune nerve signaling. However, the outcome of such plasticity is observed as increased numbers of enterochromaffin (EC) cells and intraepithelial lymphocytes, altered cytokine profile, and increased gut permeability. The strong link between infectious gut diseases and the later occurrence of IBS and/or FD symptoms has led to a new patient definition, 'postinfectious' IBS (PI-IBS) or FD (PI-FD).

Serotonin and Functional Bowel Disease

Serotonin (5-hydroxytryptamine; 5-HT) is a key signaling molecule released from EC cells and ENS interneurons. It plays a critical role in reflex responses to chemical and mechanical stimuli. 5-HT acts through various receptor subtypes on enteric nerves, muscle, and epithelial cells. The ligand-gated 5-HT_3 receptor and metabotropic 5-HT receptors evoke excitatory responses in the ENS. The 5-HT_4 receptor is localized presynaptically on enteric nerves to facilitate fast synaptic transmission, but is also present on smooth muscle cells, where it seems to have a relaxing effect. In general, 5-HT_4 agonists are clinically used as prokinetic drugs whereas 5-HT_3 antagonists act to reduce neural activity. Thus, 5-HT_3 receptor antagonists improve symptoms in patients with diarrhea-predominant irritable bowel syndrome (D-IBS), whereas 5-HT_4 agonists are beneficial in patients with constipation-predominant IBS (C-IBS). Individuals with PI-IBS are a clinically distinct subgroup characterized by diarrheal symptoms and increased serotonin-containing EC cells, compared to those with non-PI-IBS.

Relaxation of the fundus is important for gastric accommodation during meal ingestion. There is evidence that PI-FD patients have impaired fundus accommodation attributable to dysfunction of enteric inhibitory neurons. Reflex relaxation is also important for coordinated gastric emptying. Activation of serotonin receptors by sumatriptan leads to release of NO from inhibitory motor neurons and as a consequence improves fundic accommodation in FD patients.

Microflora, ENS, and Functional Bowel Disease

There is compelling evidence for the importance of the gut microflora for the maintenance of normal gut functions. Some of theses effects may involve direct or indirect interactions with the ENS. Changes in the gut microflora in IBS patients have been observed and alterations of gut microflora associated with probiotic treatment improve some IBS symptoms. What we know so far is that probiotic treatment is associated with alterations of ENS phenotype, specifically reduced expression of the calcium-binding protein, calbindin, and the neuromediator, substance P (SP). In contrast, antibiotic treatment has been reported to increase SP expression in the ENS. How altered expressions of calbindin and SP are induced remains unknown, but interactions of the microflora with the enteric immune system are likely to be important, possibly by an action of cytokines on neurochemical coding. In this respect, the probiotic bacterium *Bifidobacterium infantis* 35624 alleviates symptoms in IBS patients by normalizing the ratio of anti- and proinflammatory cytokines.

CNS and ENS Interactions

Brain–gut interactions are important in IBS, especially in the context of stress and its effect on the hypothalamic–pituitary–adrenal axis and autonomic outflow, the latter being influenced by hypothalamic mediators such as corticotropin-releasing factor

(CRF). CRF and its receptors are also present within the ENS, and peripheral mechanisms play an important role in stress responses. Basal CRF levels are lower in IBS patients and increase significantly during stress. CRF1 receptor activation leads to acetylcholine release from excitatory motor neurons, and this contributes to alterations in gut function associated with stress.

Conclusion

Enteric disorders range from the rare and relatively rare life-threatening inflammatory and congenital neuropathies to common functional disorders including IBS and FD. Similarly, treatment options vary, from extreme measures of surgical intervention to pharmaceutical approaches that accelerate or delay transit to treat symptoms of constipation or diarrhea. However, with recent advances in understanding comes the prospect for novel treatments – for example, neural stem cells transplants to repopulate the aganglionic bowel in HSCR, or new generations of drugs that normalize the altered enteric reflexes that cause GI motor and secretory dysfunction and visceral hypersensitivity.

Introduction

The enteric nervous system (ENS) is a complex neuronal network which extends along the entire axis of the gastrointestinal tract and controls vital functions, such as motility, secretion, nutrient uptake, blood flow, as well as immune and inflammatory processes.

The gastrointestinal tract constitutes a unique environment for neuronal structures in that it is made up of a large variety of nonneuronal cell types, including enteric glial cells (EGCs), epithelial cells, enteroendocrine cells, smooth muscle cells, interstitial cells of Cajal (ICCs), and fibroblasts as well as fibroblast-like cells, all of which are highly heterogeneous in their ontogenetic origin and functions. In addition, the healthy intestine is in constant and immediate contact with bacterial microbiota and food antigens from the gut lumen and therefore contains a resident population of inflammatory cells contributing to a physiological state of basal, low-level inflammation. Due to this distinct environment, the ENS contains some cellular phenotypes which differ substantially from other parts of the autonomic or peripheral nervous system (PNS).

Neural elements in the gut wall are ensheathed by astrocyte-like EGCs rather than Schwann cells, which are the typical glial cells elsewhere in the PNS. Of all cells, EGCs have the closest contact with neural structures in the gut wall.

However, there is another cell type in a number of different locations in the gastrointestinal tract which also forms close associations with nerve terminals, namely the ICC. ICCs are nonneurectodermal cells which receive neuronal input and at the same time are electrically coupled to intestinal smooth muscle cells (ISMCs).

Both EGCs and ICCs can be conceived as cellular interfaces between the neuronal elements of the ENS and the various nonneuronal cell types in the gut wall.

Enteric Glial Cells

Structure, Growth, and Development

Morphology and anatomy The ENS is formed of two major cell populations – neurons and EGCs. Since their first description by Dogiel in 1899, EGCs have been recognized as the most abundant cell type in the ENS, but quantitative data on EGC numbers are still limited.

EGCs form a widespread network at all levels and throughout all layers of the gastrointestinal tract: they lie adjacent to neuronal cell bodies in the enteric ganglia and accompany the extraganglionic nerve strands in which they are the only cellular elements; they form a dense network around the epithelial crypt bases in the intestinal mucosa, where they come into close contact with the epithelial cell layer; and they are also present in the mesenterium, where they accompany the extrinsic nerves to the gut.

Morphologically, EGCs resemble central nervous system (CNS) astrocytes: both cell types are small, stellate, and express similar antigens, such as the intermediate filaments glial fibrillary acidic protein (GFAP) and vimentin, the calcium-binding protein S-100β, the enzyme glutamine synthetase, and Ran-2. Additionally, EGCs transiently express the intermediate filament nestin during development. In contrast to astrocytes, EGCs are mostly regarded as a relatively homogeneous cell population. However, there is evidence to suggest regional heterogeneity of EGCs even though distinct subsets have not been consistently identified, and the functional significance of this is currently unclear.

EGCs have unique ultrastructural features that differentiate them from the satellite cells of autonomic ganglia and Schwann cells: they envelop neuronal cell bodies and axon bundles without producing myelin; they do not form basal laminae; they ensheathe axons not individually but, rather, in groups; they are extensively coupled by gap junctions; and they make numerous synaptoid contacts with vesicle-containing nerve varicosities.

Development, differentiation, and growth factors acting on EGCs Akin to enteric neurons, glial cells in the gut arise from a population of multipotent neural crest precursor cells whose terminal differentiation occurs in the bowel. Most EGCs evolve from vagal neural crest cells which colonize the entire length of the gut in a proximodistal direction, but some evolve from sacral neural crest cells which migrate in a distal–proximal direction. Although the vast majority of EGCs thus originate from early waves of crest-derived cells, a few of them are derived from precursors that enter the gut along with the extrinsic innervation later in development.

Proliferation and differentiation of the early ENS precursor cells is tightly controlled by microenvironmental factors. Early in the ontogeny of the ENS, nestin-immunoreactive neural crest cells emerge

which are capable of giving rise to both EGC and neurons. These cells proliferate in response to the neurotrophic factors glial cell line-derived neurotrophic factor (GDNF) – most likely from mesenchymal cells in the developing gut wall – and neurturin, but not persephin or endothelin-3.

Subsequently, nestin-positive precursors are replaced by separate lineages of neuronal and glial progenitors which express type-specific cytosolic and intermediate filament proteins. At this stage, the glial precursors are no longer supported by GDNF but, rather, by neurotrophin-3 (NT-3) through the high-affinity tyrosine kinase receptor TrkC. This is modulated by bone morphogenetic protein-2 (BMP-2) and BMP-4, both of which are members of the transforming growth factor-β (TGF-β) superfamily, and promoted by the neuropoietic cytokines ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor through the α and β subunits of the CNTF receptor.

Neuregulins (NRGs) from the epidermal growth factor superfamily constitute crucial factors for further EGC growth and differentiation: the NRG1 family members are neuronally derived molecules that interact with the transmembrane tyrosine kinase receptor erbB3 and its erbB2 coreceptor. Glial growth factor is a soluble NRG1 isoform which strongly suppresses neuronal differentiation while promoting differentiation of peripheral glia, including EGCs. Mice with a targeted deletion of *erbB3* lack enteric glia, whereas CNS astrocytes are unaffected, indicating that NRGs are critically important for EGC development and that there are fundamental differences between astrocytes and EGCs.

Finally, the transcription factors Sox10 and Sox8 have a vital role for the proper differentiation of enteric glia: *Sox10*-deficient mice lack peripheral glial cells including EGCs, and the effects of *Sox10* heterozygosity are aggravated by *Sox8* mutations in *Sox10/Sox8* double-mutant mice, suggesting that *Sox8* acts as a modifier gene for Sox10. Because Sox10 controls the expression of ErbB3 in neural crest cells, *Sox10* ablation phenotypically mimics the deletion of NRG1/ErbB3.

Function

Physiological conditions *Enteric glia and neurons.* Historically, EGCs have been viewed as packing material holding the ENS together ('glia' derives from the Greek word for 'glue'). This concept is challenged by evidence for a role of EGCs in the maintenance of gut functions: loss or defunctionalization of EGCs is associated with changes in neurochemical coding and function of enteric neurons, or neuronal degeneration.

It is unknown if EGCs maintain neuronal integrity via provision of structural support, release of neurotrophic or neuroprotective factors, or creation of a protective local microenvironment by buffering the extracellular milieu (e.g., via uptake of excess cations).

EGCs express voltage-activated inward and outward K^+ channels which are related to the astrocytic K^+ channels, confirming that EGCs could play a role in the prevention of extracellular K^+ accumulation in the ENS.

Morphological data suggest that EGCs structurally stabilize the ENS because they are anchored to the surface of enteric ganglia and nerve strands through GFAP-positive filaments. Whether the production of GDNF, nerve growth factor, or NT-3 by EGCs contributes to the maintenance of enteric neurons is unknown. Akin to astrocytes, EGCs may have an active role in information transfer and may modulate neuronal communication and synaptic plasticity.

Evidence for EGC contribution to neurotransmitter synthesis and inactivation comes from, for example, immunohistochemical findings that in the ENS, glutamine synthetase is exclusively expressed by EGCs. EGCs may thus have a pivotal role in glutamatergic signaling through detoxification of waste ammonia and glutamate and also as a source of glutamine for neuronal glutamate and γ-aminobutyric acid (GABA) (re-)synthesis. Intriguingly, immunohistochemical evidence further supports a role for EGCs in GABAergic neurotransmission: the high-affinity GABA transporter GAT2 appears to be predominantly expressed in EGCs, implicating them in GABA detoxification via rapid removal from the extracellular space.

EGCs could also be involved in neuropeptidergic transmission via inactivation and removal of enteric neuropeptide transmitters. In the gut wall, the oligopeptide transporter PEPT2 is almost exclusively expressed by EGCs, which are thus able to rapidly take up di- or tripeptide neuropeptide degradation products.

Evidence for a role of EGCs in nitrergic neurotransmission comes from the observation that enteric L-arginine immunoreactivity is almost exclusively in EGCs, suggesting that EGCs are the main reservoir of L-arginine – an essential precursor for nitric oxide (NO) – so that neuronal NO synthesis may depend on glial L-arginine delivery.

In an animal model of partial EGC ablation, glial loss is accompanied by a decrease in neuronal vasoactive intestinal polypeptide (VIP) and NO expression levels, confirming the role of EGCs in peptidergic and nitrergic neurotransmission. EGCs are further involved in nucleotide signaling: in the ENS, expression

of the ectonucleotidase NTPDase2 is restricted to EGCs, suggesting that they control extracellular ATP and ADP concentrations. EGCs further express purinoceptors of the $P2X_7$ and $P2Y_2$ subtypes and respond to the purinergic agonists ATP and UTP. An exciting study has provided indirect evidence that EGCs are also a source of ATP, which in turn participates in the intercellular propagation of Ca^{2+} waves between EGCs. Because Ca^{2+} wave-induced glial ATP release could elicit neuronal responses, nucleotide signaling may be instrumental for information transfer between enteric neurons and glia and serves to illustrate that enteric glia do not only participate in neurotransmitter synthesis and inactivation but also, akin to astrocytes, may play an active role in neurotransmission via a bidirectional glia–neuron axis. The demonstration of propagated intercellular Ca^{2+} waves adds to the evidence for functional networks between EGCs via gap junctions, allowing for concerted glial activity in the gut.

EGCs are activated by numerous neurotransmitters and neuroligands, such as epinephrine, serotonin, endothelin family members (through an ET_B receptor linked to phospholipase C and intracellular inositol 1,4,5-triphosphate (IP_3) receptors), and vasopressin, as well as by molecules implicated in neuroimmune cross-talk, such as histamine, prostaglandins, and the protease-activated receptors-1 and -2. Central vagal efferent stimulation of the ENS induces glial expression of the immediate early gene Fos through nicotinic acetylcholine receptors, and α_{2a}-adrenoceptors are present on a subset of EGCs. Bioactive lipid mediators such as sphingosine-1-phosphate and lysophosphatidic acid activate EGCs through a G-protein-coupled receptor system. Finally, EGCs respond to stimulation of primary afferent nerves by intraluminal capsaicin and inflammation.

Enteric glia and endothelial/epithelial permeability. In murine models, ablation of EGCs induces vascular lesions (e.g., a submucosal vasculitis), indicating a breakdown of the vascular endothelial barrier, and mucosal disruption, implicating EGCs in the regulation of endothelial and epithelial permeability. However, the interactions between EGCs and intestinal blood vessels that modulate microvascular functions, particularly endothelial permeability, are unclear, and the debate regarding whether an equivalent of the 'blood–brain barrier' exists in the ENS is unresolved.

In contrast, glial interactions with the intestinal epithelium are more thoroughly investigated. The epithelial lining of the gastrointestinal tract is formed by a continuous monolayer of polarized cells which are held together by tight junctions and constitute a first-line defense system against noxious contents of the gut lumen. Soluble factors released from EGC (e.g., TGF-β) appear to enhance the intestinal epithelial seal (e.g., by acting on the epithelial cytoskeleton and tight junction proteins). Furthermore, EGCs are a potential source of neurotrophins such as GDNF which modulate intestinal epithelial cell apoptosis.

Thus, EGCs seem to be crucial components of the mucosal defense system via sustainment of the intestinal epithelial barrier. Furthermore, EGC have been observed to inhibit intestinal epithelial cell proliferation, implicating them in the prevention of epithelial barrier disorganization and hyperproliferation during early inflammatory processes, bacterial infection, or epithelial dys- and neoplasia.

Pathophysiological conditions *(Neuro-)inflammation.* Intestinal inflammation is associated with functional and structural alterations of the ENS, the majority of which are secondary to the inflammatory process. However, in animals with compromised EGC networks, glial alterations occur very early in the course of intestinal inflammation, which causally implicates these cells in intestinal inflammation.

In animal models, EGCs vigorously respond to inflammatory insults, and glial proliferation rate as well as GFAP expression levels are consistently upregulated. In some models, this is associated with signs of neuronal disintegration or decreased neuronal cell counts.

Interestingly, a diminished EGC network with reduced GFAP expression was described in the non-inflamed ileum of Crohn's disease patients and implicated in disease etiopathogenesis. However, this finding was subsequently challenged by another study reporting increased EGC counts in the inflamed human intestine. It is not clear which mechanisms determine EGC proliferation in the inflamed intestine, but published evidence suggests it is differentially modulated by the various cytokines expressed in the inflamed intestine.

Inflammation-induced EGC activation is not restricted to enhanced cell proliferation. Expression of major histocompatibility complex class II (MHC II) antigen on EGCs has been demonstrated in patients with Crohn's disease, accompanied by lymphocytic infiltration and neuronal damage in the ENS, suggesting that EGCs may direct immunologically mediated damage to the ENS.

The concept of functional EGC–immune cell interactions is endorsed by a series of *in vitro* experiments that have ascertained the capacity of purified EGCs for phagocytosis and cytokine-inducible MHC II and intercellular adhesion molecule-1 expression which is fully functional for antigen-specific, MHC-restricted T cell activation. Additionally, EGCs appear to produce and be regulated by cytokines, for example, via functional receptors for the

proinflammatory cytokines interleukin (IL)-1β and IL-6. Also, EGCs from normal mouse mucosa express the neuropeptides neurokinin (NK) A and substance P, both of which have the potential to act on both immune and epithelial cells.

Overall, EGCs actively respond to inflammation. Also, because they interact with enteric neurons, endothelial cells, and the intestinal epithelium, all of which participate in intestinal inflammation, EGCs may act as an integral part of an enteric neuroimmune network that contributes to and regulates inflammatory processes in the intestine.

Neurodegeneration. A substantial loss of EGCs has been described in the aged ENS and in patients with various functional and/or inflammatory disorders, including intractable slow transit constipation and diverticulitis. It is unclear if EGC decay precedes or follows neuronal loss. EGCs could contribute to neurodegeneration by attracting immune cells to the ENS. Alternatively, impaired glial functions could result in insufficient support of enteric neurons and thus cause neurodegeneration, even in the absence of inflammation.

Malign proliferation. Notably, in contrast to astrocytomas and glioblastomas, cancerous proliferation of EGCs is unknown. The reason for this difference is not understood.

Interstitial Cells of Cajal

Structure, Growth, and Development

Morphology and anatomy In the gut wall, ICCs are present as networks associated with ENS plexuses and dispersed inside most circular muscle layers, including the sphincters. ICCs can be recognized by their unique ultrastructure and expression of the proto-oncogene *c-kit* that encodes for the receptor tyrosine kinase Kit. ICCs typically have fusiform cell bodies and multiple long processes, and they express a variety of gap junction proteins, including connexins 40, 43, and 45. ICCs are electrically coupled with each other as well as with the ISMC syncytium via gap junctions, and their intricate networks extend along and around the gastrointestinal organs to all points involved in phasic contractions.

Based on topographical and functional evidence, the following groups of ICCs have been defined: ICC-MY (also called ICC-MP or ICC-AP) are located in the plane of the myenteric plexus between the circular and longitudinal muscle layers; ICC-DMP are located in the small intestine in close association with the nerve terminals of the deep muscular plexus and close to the submucosal surface of the circular muscle layer; ICC-IM, also called intramuscular ICCs, are distributed within the muscle layers of the gastrointestinal tract, where they are interposed between varicose nerve terminals and ISMC and receive input from enteric motor neurons; and ICC-SM are the pacemaker cells along the submucosal surface of the circular muscle layer in the colon. ICC-SM also occur in the gastric antrum and pylorus, but the physiological roles of these ICCs have not been identified. Finally, ICCs can be found in the septa between intestinal smooth muscle bundles; these cells are called ICC-SEP.

ICC-MY and ICC-SM have membrane caveolae that may serve in cellular signaling processes and provide a scaffold for transport and signaling proteins. L-type Ca^{2+} channels, plasma membrane Ca^{2+} pump protein, and Na^{+}/Ca^{2+} exchanger type 1 were found co-localized with caveolin-1 in ICCs. ICCs express an abundance of mitochondria and prominent smooth endoplasmic reticulum (SER), which are often closely associated with each other and lie in close proximity (within 10–20 nm) to the plasma membrane.

Development and differentiation The ontogeny of ICCs was settled in the 1990s when it was eventually consented that ICCs and ISMC arise from common mesenchymal progenitors. From midembryonic stages, ICC precursors express the receptor tyrosine kinase Kit. Both ICCs and many ISMC precursors initially express Kit, and then the cells destined to become ISMC downregulate Kit and upregulate the synthesis of myofilament proteins, whereas cells destined to differentiate into ICCs maintain Kit expression.

In adults, ICCs are dependent on the ligand for the Kit-receptor – namely Kit ligand, stem cell factor, or Steel factor – and disappear in its absence, whereas in mutant mice with blocked Kit activity, normal ICCs are present until soon after birth, suggesting that the Kit signaling pathway is not necessary for the embryonic development of ICCs but, rather, for their postnatal development and maintenance.

Insulin and insulin-like growth factor type-1 have also been implicated as essential growth factors for ICCs.

Function

Physiological conditions ICCs provide several important functions in the gastrointestinal tract: (1) generation of electrical slow wave activity, (2) coordination of pacemaker activity and active propagation of slow waves, (3) transduction of the motor output from the ENS to the ISMC syncytium, and (4) mechanosensation to stretch of gastrointestinal muscles.

Slow waves are rhythmical oscillations of the membrane potential which spread, without decrement, through the ICC network. Release of Ca^{2+} from

IP_3 receptor-operated stores is the fundamental cellular event that initiates pacemaker current. Uptake of Ca^{2+} and cycle-to-cycle maintenance of Ca^{2+} levels in IP_3 receptor-operated stores, mediated by SERCA Ca^{2+} pumps, is critical for Ca^{2+} release events in ICCs. The contribution of additional ionic conductance(s) to pacemaker activity and the steps between Ca^{2+} release and activation of pacemaker currents is currently under investigation.

Because ICCs are electrically coupled to ISMC, their activity is conducted into the ISMC syncytium which responds to slow wave depolarizations with activation of a variety of voltage-dependent ion channels to generate contractions. Thus, ICC electrical slow wave activity organizes excitation–contraction coupling into a pattern of phasic contractions in the gut.

Unlike the heart, the intestinal smooth muscle layers do not have point sources, or nodes, with specialized electrical pacemaker cells but, rather, continuous networks consisting of thousands of spontaneously active, electrically coupled ICCs that function as a unit with the dominant pacing frequency provided by the cells with the most rapid pacing frequency.

In the stomach and small intestine, there are proximal-to-distal pacemaker frequency gradients which are the basis for oral to aboral peristaltic waves. Slow waves do not propagate from the stomach into the small intestine because these regions are separated by an isolating region of electrically quiescent ISMC.

In the small bowel, pacemaker frequencies and propagation properties of slow waves organize motility into segmental contractions which are typical for the postprandial motor pattern in this region of the gut.

The colon displays two pacemaker regions, one at the submucosal surface of the circular muscle layer and the other between the circular and longitudinal muscle layers, and a distal-to-proximal slow wave frequency gradient has been suggested.

The ENS can regulate the excitability of the ISMC syncytium to slow wave depolarizations. However, motor neurotransmission in the gut does not occur through loosely defined synaptic structures between nerves and ISMC but, rather, via synaptic-like connections between varicose nerve terminals and ICC-IM. Since ICC-IM are coupled to ISMC, the electrical responses elicited in ICCs are conducted to ISMC. Thus, the mechanical response of phasic muscles to the ongoing slow wave activity is strongly modulated by the ENS through regulation of ISMC excitability.

ICCs express functional receptors to receive ENS motor input, such as NK-1 and -3, and somatostatin 2A receptors. After exposure to substance P, NK1 receptors on ICCs are internalized and receptor immunoreactivity aggregates in the cytoplasm, indicating receptor-mediated ICC activation. In addition, ICCs express the muscarinic receptors M2 and M3 for cholinergic input and also VIP receptors (VIP-1). They have also been demonstrated to receive nitrergic input.

Morphological evidence also supports a role for ICC-IM as possible integrators for in-series stretch-dependent changes: vagal afferent nerve endings can terminate as intramuscular arrays within the muscle wall of the stomach. These endings form close appositions with ICC-IM, upon which they appear to form multiple spiny appositions or varicosities that may provide a role in stretch perception. Thus, ICCs could play a role as mechanosensitive transducers.

Pathophysiological conditions ICC damage has been implicated in a variety of gastrointestinal motility disorders, such as gastroparesis, pseudo-obstruction, chronic constipation, and posttraumatic or postinfectious dysfunction. Disruption of ICC networks will abolish synchronization of electrical pacemaker activity and allow for localized increase in slow wave frequency as well as the appearance of ectopic pacemaker sites, resulting in disorganized motor patterns.

ICCs are among the first cells that are injured during an inflammatory insult, and maintenance of ICC health or promotion of their regeneration may be crucial in recovery after injury. In humans, there is evidence of injury to the processes of ICCs and nerves of the colonic submuscular plexus in patients with active ulcerative colitis. Therefore, ICCs may be a major factor in inflammation-induced gastrointestinal motility disorders.

Finally, a pathological condition has been described in which pacemaker frequency in the distal stomach – the antrum – is augmented so that the more proximal gastric regions can no longer drive antral activity. This condition is termed tachygastria, and it is associated with delayed gastric emptying.

Enteric Nervous System: Neural Circuits and Chemical Coding

J B Furness, University of Melbourne, Parkville, VIC, Australia

Introduction

The enteric nervous system (ENS) contains the integrating nerve circuitry for control of the movements of the gastrointestinal tract, for transfer of fluids across the mucosal surface in the small intestine and colon, for local blood flow control, and for control of secretion of gut hormones. Enteric neurons also influence the gut immune system. The intrinsic nerve circuits contain 14–20 types of neurons, depending on region and species. In the small intestine of the guinea pig, in which all types of neurons have been identified, 15 neuron types occur. In addition to the intrinsic neurons, the endings of extrinsic neurons (vagal, pelvic, and sympathetic efferent and vagal and spinal afferent neurons) intermingle with the processes of enteric neurons. Along with the fact that the cell bodies of intrinsic primary afferent neurons, interneurons, and motor neurons are not segregated in enteric ganglia, this large number of participating neurons presented a major problem to scientists who tried to unravel the enteric neural circuitry. Part of the solution to this problem came when it was discovered in the late 1970s and the early 1980s that there were a range of chemical markers of enteric neurons. From this discovery arose the chemical coding hypothesis. The hypothesis in its simplest form proposes that neurons of every functional class can be distinguished from neurons of other classes by chemical attributes that constitute a chemical code. In the ENS, the code is contributed to by neuropeptides, which is fortunate because peptides are very suitable for the generation of highly effective antibodies for immunohistochemical studies. Once chemical identities that could be exploited histochemically were established, it became possible to determine the projections and synaptic relations of each class of neuron.

Chemical Coding in the ENS

Table 1 provides a listing of the chemical codes for enteric neurons in the guinea pig small intestine. This reinforces the observation that the chemical codes provide very useful distinctions between neurons of different functional types (Figure 1). Similar, but less extensive, investigations have been made in human, mouse, rat, pig, and sheep ENS. These show that some aspects of the chemical codes are highly consistent between species. This includes codes for excitatory muscle motor neurons that all contain tachykinins and the synthesizing enzyme (choline acetyltransferase) for the transmitter acetylcholine (ACh). Inhibitory muscle motor neurons contain nitric oxide synthase (NOS), implying that NO is a transmitter of these neurons, vasoactive intestinal polypeptide (VIP) and pituitary adenylyl cyclase activating polypeptide (PACAP). These neurons also use adenosine 5′-triphosphate (ATP) as a transmitter. In all species, there are secretomotor neurons that contain VIP. Intrinsic primary afferent neurons (IPANs) contain one or both of the calcium-binding proteins, calbindin and calretinin, and either or both substance P (SP) and calcitonin gene-related peptide (CGRP). They are also characterized by binding the lectin, IB4, which is also a marker of some vagal and spinal primary afferent neurons.

The aspects of codes that are highly conserved are those that relate to essential functions of the neurons – for example, primary transmitters, postsynaptic receptors, and associated enzyme systems. Thus, when a substance is a primary neurotransmitter, it appears to be present in all neurons that have equivalent roles in different species and regions of the gastrointestinal tract. For example, extensive studies in many species indicate that all inhibitory neurons to the muscle contain the synthesizing enzyme for NO, NOS, and the peptide VIP. Beyond this, the codes can vary considerably between species, by the inclusion of chemical markers that do not seem to have significant roles. These have been termed superfluous transmitters, although some of the substances are not transmitters. In relation to enteric neurons, their significance has been discussed elsewhere. It has been postulated that some substances may have no role (they could be considered developmental or evolutionary leftovers) or that some substances may have roles other than a participation in neurotransmission.

Some of the coding is related to subtle differences within enteric neuron populations; for example, in the guinea pig small intestine, inhibitory neurons with short projection have the code NOS/VIP/ENK/GABA/NPY/PACAP, whereas the long-projecting neurons have the code NOS/VIP/BN/DYN/NFP/PACAP. Some of the long neurons are also neuropeptide Y (NPY) immunoreactive. Also in human, a proportion of the VIP-containing neurons that innervate the circular muscle are NPY immunoreactive. No differences in the pharmacology of transmission that relate to these chemical coding differences are known. Another example of species difference is that the noncholinergic

Table 1 Chemical coding of functionally defined neurons in the ENS

Functional definition	*Chemical coding*	*Transmitter/comments*	*Comments on species differences*
Myenteric neurons			
Excitatory circular muscle motor neurons (6)	Short: ChAT/TK/ENK/GABA Long: ChAT/TK/ENK/NFP	To all regions, primary transmitter ACh, cotransmitter TK	Excitatory neurons in all species contain ACh and TKs, which subserve transmitter roles
Inhibitory circular muscle motor neurons (7)	Short: NOS/VIP/PACAP/ENK/NPY/GABA Long: NOS/VIP/PACAP/Dynorphin/BN/NFP	Several cotransmitters with varying prominence: NO, ATP, VIP, PACAP	Inhibitory neurons in all species contain NOS and VIP family peptides. Other markers, such as NPY, differ between species
Excitatory longitudinal muscle motor neurons (4)	ChAT/Calretinin/TK	Primary transmitter ACh, cotransmitter TK	In all species these contain ACh and TKs, but calretinin is not always present
Inhibitory longitudinal muscle motor neurons (5)	NOS/VIP/GABA	Several cotransmitters with varying prominence: NO, ATP, VIP, PACAP	In all species these contain NOS and VIP family peptides
Ascending interneurons (1)	ChAT/Calretinin/TK/ENK	Primary transmitter ACh	Not identified in other species
Descending interneurons (local reflex) (8)	ChAT/NOS/VIP $\pm$ BN $\pm$ NPY	Primary transmitter ACh, ATP probably a cotransmitter	Not identified in other species, but commonly contain VIP
Descending interneurons (secretomotor and motility reflex) (9)	ChAT/5-HT	Primary transmitters ACh, 5-HT (at 5-HT_3 receptors)	In all species there appears to be descending interneurons that contain 5-HT
Descending interneurons (migrating myoelectric complex) (10)	ChAT/SOM	Primary transmitter ACh	Not identified in other species
Myenteric intrinsic primary afferent neurons (2)	ChAT/TK/orexin/IB4/NeuNcyt/NK_3 receptor, most calbindin	Primary transmitters TK and ACh	Calbindin is a good marker in guinea pigs, but calretinin is a better marker in rats, mice, and human. These neurons contain CGRP in many species
Intestinofugal neurons (3)	ChAT/BN/VIP/NOS/CCK/ENK	Primary transmitter ACh, cotransmitter VIP	ACh is primary transmitter in all species. VIP seems to be a reliable across-species marker
Motor neurons to gastrin cells[a]	GRP	Primary transmitter GRP	Same marker (GRP) in all mammals investigated
Submucosal neurons			
Noncholinergic secretomotor/vasodilator neurons (12)	VIP/CART/CRF/GAL/PACAP/NMU	Primary transmitter VIP; a small proportion of these have cell bodies in myenteric ganglia	In all species In human, these neurons may be cholinergic
Cholinergic secretomotor/vasodilator neuron (13)	ChAT/Calretinin/Dynorphin	Primary transmitter ACh	Not specifically identified in other species
Cholinergic secretomotor (nonvasodilator) neurons (14)	ChAT/NPY/CCK/SOM/CGRP/Dynorphin/GAL/NMU	Primary transmitter ACh; a small proportion of these have cell bodies in myenteric ganglia	Not specifically identified in other species
Uni-axonal neurons projecting to the myenteric plexus (15)	VIP (NOS?)	Possibly displaced myenteric interneurons	Neurons projecting to the myenteric plexus also identified in the pig. They probably occur in other species
Submucosal intrinsic primary afferent neurons (11)	ChAT/TK/orexin/IB4/NeuNcyt/calbindin	Calbindin-IR, seen with some antisera only. Primary transmitter ACh, may be TK contribution	Appear to be present in all species. CGRP and calretinin are generally markers of these neurons

Table 1 Continued

Functional definition	*Chemical coding*	*Transmitter/comments*	*Comments on species differences*
Excitatory motor neurons to the muscularis mucosae[a]	ChAT/TK	Primary transmitter ACh	In all species these contain ACh and TKs
Inhibitory motor neurons to the muscularis mucosae[a]	NOS/VIP	Pharmacology of transmission appears to be similar to other enteric inhibitory muscle motor neurons	Inhibitory neurons in all species contain NOS and VIP family peptides

[a]Motor neurons that are found in other parts of the tubular digestive tract.
ACh, acetylcholine; ATP, adenosine 5′-triphosphate; BN, bombesin (the mammalian form is sometimes referred to as GRP); CCK, cholecystokinin; ChAT, choline acetyltransferase; CART, cocaine and amphetamine-regulated transcript peptide; CGRP, calcitonin gene-related peptide; CRF, corticotrophin-releasing factor; ENK, enkephalin; GABA, gamma aminobutyric acid; GAL, galanin; GRP, gastrin-releasing peptide (mammalian bombesin); 5-HT, 5-hydroxytryptamine; IB4, isolectin B4; MMC, migrating myoelectric complex; NeuNcyt, cytoplasmic immunoreactivity for the neuronal nuclear protein, NeuN; NFP, neurofilament protein; NK, neurokinin; NOS, nitric oxide synthase; NPY, neuropeptide Y; NeuNcyt, cytoplasmic NeuN; PACAP, pituitary adenylyl cyclase activating peptide; SOM, somatostatin; TK, tachykinin; VIP, vasoactive intestinal peptide.
This table lists the neuron types that are found in the guinea pig small intestine and some of their defining characteristics. The numbers in brackets are the identifying numbers for the neurons in Figure 1.

Figure 1 The types of neurons in the small intestine of the guinea pig, all of which have been defined by chemical coding, cell body morphology, key transmitters, projections to targets, and functions. The numbers adjacent to the neurons correspond to the numbers in Table 1, which lists each of the neuron types by their functions and provides data on their chemical coding and transmitters. Projection directions (to oral or to anal) are indicated. Note that the muscularis mucosae (MM) is very thin in the guinea pig small intestine and the neurons that innervate this muscle are not depicted. Motor neurons to the muscularis mucosae are in the submucosal ganglia and are prominent in other species. LM, longitudinal muscle; MP, myenteric plexus; CM, circular muscle; SM, submucosal plexus; Muc, mucosa.

secretomotor neurons in guinea pig do not contain NPY, whereas they do in rats.

Peptide Immunoreactivity

Many of the substances that form the chemical codes are peptides. In most cases, peptides belong to families of similar molecules, not all of which were known when the immunoreactivity or mode of transmission of enteric neurons was first discovered. For example, antibodies raised against SP revealed enteric neurons, and antagonists for SP's actions reduced transmission. Thus, the earlier literature refers to SP as the marker and transmitter of enteric neurons. Later, it

was found that the same gene that gives rise to SP codes for the closely related peptide neurokinin A (NKA), that most anti-SP antibodies recognize NKA, and that both contribute to excitatory transmission from the same neurons. The collective name for these peptides, tachykinins, is now used to describe the contents and transmitters of these neurons. Similarly, immunoreactivity for VIP could also include immunoreactivity for the closely related peptides of the VIP family, PHI and PHM. These problems of exact definition of the peptide contained in and released from enteric neurons extend to enkephalins and the different molecular forms of CCK, and most likely to other peptides.

Chemical Coding and Plurichemical Transmission

Pharmacological studies between the 1960s and 1980s (and even more recent studies) indicated that there were multiple substances that contributed to transmission in the gastrointestinal tract. One of the outcomes of investigations of chemical coding was that investigators were obliged to conclude that the same neuron releases several transmitters. This appears to be the rule in the ENS. Several potential neurotransmitters have been identified in almost all neurons, and there is direct evidence of several neurotransmitters for some of the neurons. Examples of neurons that release several transmitters are included in Figure 2. The type of transmission that occurs in the ENS, which involves several transmitter substances derived from the same neuron, has been called plurichemical transmission. Among the transmitter substances that are released from a single neuron, one usually has a dominant role. This has been called the primary transmitter.

Excitatory Muscle Motor Neurons

These neurons have as their primary transmitter ACh, which acts on muscarinic receptors on the muscle (the dominant receptor subtypes being M_2 and M_3 receptors). Thus, transmission from the neurons is effectively abolished by muscarinic receptor block. However, in all species and regions, these neurons contain tachykinins (SP, NKA, and some related peptides), and if transmission is carefully analyzed, it is found that a small component of transmission is contributed by tachykinins, which act through NK1 and NK2 receptors. The method of choice to locate the nerve terminals of excitatory neurons in the muscle is using tachykinin immunoreactivity. These neurons also contain opiate (enkephalin-related) peptides that act presynaptically on the nerve endings from which they are released to reduce transmitter output.

Inhibitory Muscle Motor Neurons

There was a period of difficulty and substantial debate associated with the identification of the transmitter of inhibitory neurons. It is now recognized that these neurons utilize cotransmitters, including ATP, NO, and peptides of the VIP family.

The primary transmitter is generally NO. NO is an unusual chemical messenger because it is not stored but, rather, created on demand when the synthesizing enzyme, NOS, is activated. NO is membrane permeable, and it crosses the membrane to interact with its receptor, soluble guanylyl cyclase, in the cytoplasm. NOS is readily revealed in tissue, either by enzyme histochemistry or by immunohistochemistry, and it is a very good marker of inhibitory neurons supplying gut muscle, although VIP immunoreactivity is also an excellent label for these neurons.

ATP, which is also released as a transmitter from these neurons, acts on both P2X and P2Y receptors on the muscle. The effect of ATP on the muscle is mediated by the opening of apamin-sensitive K^+ channels (SK channels), and apamin is in many cases an effective antagonist of the ATP-mediated component of inhibitory transmission. It is clear that there must be a link between purine receptor activation and SK channel opening. The other transmitter type of these neurons is the VIP peptide family. There is good evidence that two family members, VIP and PACAP, are both released, but there may be other related peptides, such as PHI. These peptides both act through VPAC receptors. The relative roles of the three transmitters differ between species and gut region, even within the same species. There is also evidence that carbon monoxide could contribute to inhibitory transmission.

One consequence of there being multiple transmitters of the inhibitory neurons may be that a deficiency in one transmitter can be partly compensated. There is little in the way of functional deficit in mice in which neuronal NOS is eliminated by gene knockout. The mice have gastric outlet obstruction, which is due to a failure of the pyloric sphincter to adequately relax, but motility control in the remainder of the bowel is close to normal.

Chemical Coding and Transmission from Secretomotor and Vasodilator Neurons

In the small intestine and colon, there are neurons that have both secretomotor and vasomotor functions (secretomotor/vasodilator neurons). These neurons have axons that branch to supply both the mucosal epithelium and the arterioles in the mucosa. Most prominent among these are neurons that contain the VIP family peptides, VIP and PACAP; these

Figure 2 Transmitters of ascending and descending reflex pathways supplying the muscle. Transmitters are indicated adjacent to the synapses where they act. Information flows from the intrinsic primary afferent neurons to motor neurons directly or through one or more interneurons. Primary transmitters and their receptors are indicated (e.g., ACh: Nic, primary transmitter, acetylcholine, acting at nicotinic receptors). In cases in which roles are minor or uncertain, the information is in brackets. See **Table 1** for transmitter abbreviations. Receptors: Nic, nicotinic; m, muscarinic; M2, M3, muscarinic 2, 3; NK1 (2, 3), neurokinin 1 (2, 3); P2X, purine 2X; P2Y, purine 2Y.

are noncholinergic secretomotor/vasodilator neurons. In cats, rats, guinea pigs, and humans (and probably all mammals), they use VIP/PACAP as the principal transmitter, and in humans and rats at least, the peptides act on the mucosal epithelium at VPAC1 receptors. The chemical coding of these neurons has not been worked out in all species; in guinea pig they are coded by VIP/PACAP/CART/CRF/GAL/NMU, in rat by VIP/PACAP/NPY/calbindin (and maybe more substances), and in human by VIP/PACAP/NPY (there are probably other contributors to this code that are yet to be discovered).

Cholinergic secretomotor/vasodilator neurons also occur, but it is the noncholinergic neurons that appear to dominate physiological responses. In guinea pigs, the cholinergic secretomotor/vasodilator neurons are best revealed by their content of calretinin. These neurons have not been adequately characterized in other species.

In addition, there is a population of cholinergic vasodilator neurons that have one of the most extensive neuropeptide codes discovered to date. The code in the guinea pig is ChAT/NPY/CCK/SOM/CGRP/Dynorphin/GAL/NMU (seven different neuropeptides).

Gastrin-releasing peptide (GRP; also known as mammalian bombesin) is a primary transmitter from motor neurons to gastrin-containing endocrine cells of the antral mucosa. Analysis of chemical codes indicates that these neurons also express a cholinergic phenotype (they are ChAT immunoreactive). Moreover, pharmacological analysis indicates that there is also a cholinergic contribution to transmission. This is quite an unusual situation. A dominant idea is that when co-localization of a neuropeptide and a classical transmitter such as ACh occurs, the major transmitter role is taken by the classical transmitter and a minor role is taken by the peptide. Here, that is reversed.

Chemical Coding of Sympathetic, Noradrenergic Neurons That Supply the Gut

The coding of the sympathetic innervation of the gastrointestinal tract has been very useful in the analysis of

the circuitry. The cell bodies of the sympathetic neurons that supply the gastrointestinal tract are in sympathetic chain (paravertebral) ganglia and in the large prevertebral ganglia of the abdominal and pelvic cavities (the coeliac, superior mesenteric, inferior mesenteric, and pelvic ganglia). Although indirect evidence had suggested that three neuron types, controlling three functions (motility, secretion of fluid, and vasoconstriction in the intestine) were separate, this was made much more obvious when it was discovered that the three classes of neuron had different chemical coding. The vasoconstrictor neurons innervate the arteries directly and cause constriction through the release of noradrenaline and ATP; these have the code NA/NPY in guinea pigs (and probably in most other mammals). Secretomotor inhibitory neurons have the code NA/SOM, with the primary transmitter role being taken by noradrenaline. The motility-controlling neurons may also have a neuropeptide code in the guinea pig, but the accompanying peptide is not known.

Enteric Nerve Circuits

The chemical codes that have been uncovered have provided a major impetus to solving the problem of the organization of neural circuits in the intestine (Figure 3). Histochemical identification of neurons according to their chemistry has been combined with intracellular injection of dye, nerve lesion studies, and retrograde tracing to identify the morphologies and projections. To this has been added information of the synaptic connections that are made, which has been determined by electron microscopy, electrophysiological analysis of synaptic transmission, and pharmacological investigation of enteric reflexes. A concurrence between results obtained with each of the methods has led to a very robust depiction of the circuitry for motility control in the small intestine (Figure 3) and also for control of water and electrolyte secretion and local blood flow.

In response to suitable stimuli, the motility-controlling circuits in the small intestine can switch between different functional roles, including propulsive movements, mixing, retropulsion, and the migrating myoelectric complex. How this switching occurs is not known.

The functions and general circuit organization in the large intestine are similar to those in the small intestine, and although the circuits have not been studied in the meticulous detail that they have been in the small intestine, they are presumed to be quite similar. The ENSs of the esophagus and stomach are quite different.

In the esophagus, the lining is protective, not fluid transporting, and there is no submucosal plexus in this part of the gastrointestinal tract and no secretomotor or local vasomotor reflexes. In addition, motor control of the external muscle, where it is composed of striated muscle (which is the majority of the esophagus in most species of mammal), is through circuits in the central nervous system (specifically, in the medulla oblongata) via vagal nerve pathways. Control of gastric motility and acid secretion (its major nerve-controlled functions) is also primarily through the brain stem nuclei, although there is a small degree of regulation by enteric circuits.

Figure 3 The circuitry for motility reflexes in the small intestine (simplified). Reflex pathways are depicted in a short segment of intestine to illustrate circumferential projections of neurons. The first parts of descending inhibitory and ascending excitatory reflex pathways for propulsive reflexes are depicted. Intrinsic primary afferent neurons (IPANs) are circumferentially oriented and form self-reinforcing networks. They provide outputs to ascending and descending interneurons and monosynaptic connections to motor neurons. One type of descending interneuron (bottom), which is involved in conducting the migrating myoelectric complex along the small intestine, receives few inputs from IPANs but connects with motor neurons.

The brain stem circuits exert their effects through axons that run in the vagus nerve and synapse on enteric neurons.

Enteric Nervous System: Neurotrophic Factors

M J Saffrey, Open University, Milton Keynes, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Our understanding of the roles of neurotrophic factors in the enteric nervous system (ENS) has lagged behind that in other parts of the peripheral nervous system, largely because of the complexity of enteric neuronal circuitry. Neurons of the ENS are located within the gut wall, in numerous small, irregular-sized ganglia located along the entire length of the gastrointestinal tract. The circuitry of the ENS is difficult to analyze experimentally, because, unlike many parts of the nervous system, where well-identified neurons make clearly defined connections with their target tissues, enteric ganglia, particularly the myenteric ganglia, are composed of a mixture of different neuronal types in varying proportions, with diverse projections to a range of target cell types.

When the prototypic neurotrophic factor, nerve growth factor (NGF), was first identified and its effects on sensory and sympathetic neurons characterized, its possible effects on the ENS were not studied. In the early 1990s, however, when other members of the neurotrophin family, notably brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) and their receptors, were identified and their properties and actions began to be elucidated, it was found that several of these proteins were expressed in the gut. At that stage, their localization within the gut wall had not been fully characterized, but analysis of the effects of NT-3 on neural precursors isolated from the embryonic gut indicated that NT-3 promoted differentiation of both enteric neurons and enteric glial cells. These studies provided the first indication that neurotrophins may play a role in the ENS. More recently, supporting evidence for this hypothesis has come from transgenic mice in which NT-3 expression is disrupted; these mice exhibit abnormalities in the ENS (see later).

Soon after identification of the neurotrophins, two major discoveries provided a breakthrough in the study of neurotrophic factors and the ENS. First, in the early 1990s, was the discovery that a mutation in the c-ret gene was associated with Hirshsprung disease, a congenital condition in which varying lengths of the terminal colon are aganglionic, and have no enteric neurons. At this time, although the c-ret gene was known to encode a tyrosine kinase receptor, its ligand was unknown. c-ret −/− knockout mice were found to die shortly after birth, and among other abnormalities were found to lack enteric neurons (and glia) from all regions of the gut except for the esophagus. Soon after this finding, in 1996, transgenic animals lacking the newly discovered neurotrophic factor, glial cell line-derived neurotrophic factor (GDNF), were found to display an identical phenotype to the c-ret −/− mice, and it was discovered that c-ret was the signaling receptor for GDNF. c-ret forms part of a receptor complex, together with a glycosyl phosphatidylinositol (GPI)-linked GDNF binding receptor, now known as GFRα1. GFRα1 knockout mice also display the aganglionic phenotype. Since the discovery of GDNF, three related proteins were discovered, at least one of which, neurturin (NTN), is also active in the ENS.

Since these first seminal studies suggesting roles for GDNF and NT-3 in the developing ENS, much more work has been carried out on the expression and actions of neurotrophic factors in the gut. Most detailed studies have focused on establishing the roles of neurotrophic factors in the development of enteric neurons, a process which is not described in detail here. Increasing efforts, however, are now being put into investigating the patterns of expression and actions of neurotrophic factors in the gut after birth and in maturity, with the aim of determining if these factors are involved in neural plasticity in the adult ENS and if disruption of neurotrophic factor support may be involved in some pathological changes that take place in the ENS, or in ENS aging.

Neurotrophic Factors and Their Receptors in the Gut

The main neurotrophic factors and/or their receptors that have been shown to be present in the gut, or active on enteric neurons, and hence implicated in the development and/or the maintenance of the ENS, are shown in Table 1. It is important to note, however, that in addition to factors classified as neurotrophic factors, other secreted proteins, peptides, and molecules play important roles in the survival, differentiation, and maintenance of the ENS. Examples of such proteins that act on the developing ENS before birth include the hedgehog family members, Indian and Sonic hedgehog, which may be involved in the patterning of the ENS; the bone morphogenetic proteins, BMP-2 and -4, which are involved in early specification of enteric neurons; and endothelins, which inhibit neuronal differentiation and may thus prevent precocious neuronal differentiation in the

Table 1 Neurotrophic factors and neurotrophic factor receptors involved in ENS development and/or maintenance[a]

Neurotrophic factor family	*Receptors*	*Comments*
Neurotrophins	Common low-affinity p75 receptor; high-affinity tyrosine kinase receptors (Trks), with preferential specificity:	NGF, NT-3, and BDNF all expressed in the gut; varied reports of receptor expression by enteric neurons (see text)
Nerve growth factor (NGF)	TrkA	
Brain-derived neurotrophic factor (BDNF)	TrkB	
Neurotrophin-3 (NT-3)	TrkC	Evidence for roles of NT-3 in ENS both pre- and postnatally; some evidence for roles of other factors (see text); no evidence for NT-4/5 expression in the gut, but extrinsic sensory innervation of intestine severely affected in NT-4 −/− mice
Neurotrophin-4/5 (NT-4/5)		
Glial cell line-derived neurotrophic factor (GDNF) family	Common signaling tyrosine kinase receptor c-ret; glycosyl phosphatidylinositol (GPI)-linked binding GFRα family, with preferential specificity:	
GDNF	GFRα1	GDNF and NTN and their receptors expressed in the gut; established roles for GDNF in early ENS development; NTN has later actions
NTN	GFRα2	
Artemin	GFRα3	Some evidence for artemin expression in gut and action on enteric neurons (see text)
Persephin	GFRα4	No evidence for expression or actions of persephin in the gut
Neuropoietic cytokines	Tripartite receptor, comprising:	Evidence that an as yet unknown factor, probably related to CNTF or LIF, acts at a neuropoietic cytokine receptor complex in the ENS; activation of receptor complex implicated in prenatal development, but roles uncertain; some actions postnatally
Ciliary neurotrophic factor (CNTF)	CNTFRα	
Leukemia inhibitory factor (LIF)	Gp130	
Oncostatin M	LIFRβ	
Cardiotrophin-1		

[a]Note: this is not an exhaustive list of all factors/receptors in these families.

developing gut. In several cases these proteins act by influencing the responsiveness of neural precursors to neurotrophic factors such as GDNF.

Other growth factors, proteins, peptides, and even molecules traditionally associated with processes such as neurotransmission may also have neurotrophic actions in the ENS. Examples include fibroblast growth factor 2, which may be expressed by enteric neurons and which promotes neurite outgrowth from postnatal myenteric neurons *in vitro*; adenosine; serotonin, which promotes differentiation of fetal neuronal precursors in culture; and also vasoactive intestinal peptide (VIP) and nitric oxide, which have been found to promote survival of adult myenteric neurons in culture. These molecules are not further considered here.

Roles of Neurotrophic Factors in Early (Prenatal) ENS Development

The most detailed understanding of neurotrophic factor action in the gut is that of GDNF, in particular its roles during early development of the cells of the ENS, which arise from specific regions of the neural crest. Since this topic is covered in detail elsewhere, only an outline is provided here.

Glial Cell Line-Derived Neurotrophic Factor

GDNF is essential for development of the ENS. It is expressed in the early intestinal mesenchyme, just after the arrival of migrating neural crest-derived progenitors in the developing gut; these progenitors express the signaling receptor for GDNF, c-ret, as or just before they arrive in the gut. In cell culture models, GDNF has been found to promote survival, proliferation, and differentiation of ENS progenitor cells as well as their migration along the growing gut. As already mentioned, transgenic mice in which the GDNF gene is disrupted have an aganglionic gut distal to the esophagus and are not viable. Targeted disruption of either the c-ret or the GFRα1 genes produces animals with a similar ENS phenotype.

Neurturin

NTN is also expressed in the developing gut mesenchyme, and GFRα2 is expressed by developing enteric ganglion cells. Both NTN and GFRα2, however, are first detected slightly later than GDNF and GFRα1 in

the developing mouse gut. *In vitro*, NTN promotes the survival and proliferation of enteric neural progenitors; *in vivo*, targeted disruption of the NTN or GFRα2 genes results in mice which exhibit abnormalities of the ENS. The enteric abnormality in NTN and GFRα2 knockout animals results in a reduction in neuronal perikaryon size, a small but consistent reduction in myenteric neuronal numbers, and a reduction in the density of cholinergic nerve fibers in adult animals. GFRα2 knockout mice also display a reduction in the density of substance P-immunopositive fibers. Both NTN −/− and GFRα2 −/− transgenic animals also exhibit abnormalities in gut function, including reduced smooth muscle contractility and reduced responses to electrical stimulation and carbachol. These changes may contribute to the poor growth of NTN −/− and GFRα2 −/− mice seen after birth.

Artemin

A recent study has shown that overexpression of artemin in mice results in hyperplasia of myenteric ganglion cells, and that artemin has a small effect on enteric neurons *in vitro*. Clear evidence for expression of GFRα3 by enteric neuronal precursors or differentiated enteric neurons, however, is lacking, and it is possible that the effects observed in this study were due to an action of artemin binding to GFRα1 or GFRα2.

Neurotrophin-3

NT-3 is expressed in the developing intestinal mesenchyme, and TrkC receptors are expressed by enteric neural progenitors. *In vitro*, NT-3 promotes survival of progenitors and differentiation of enteric neurons and glia. *In vivo*, NT-3 −/− and TrkC −/− transgenic mice have enteric ganglia, although recent evidence has shown that NT-3 null mice have reduced numbers of myenteric and submucosal neurons. Conversely, transgenic mice in which overexpression of NT-3 is targeted to the myenteric plexus have increased numbers of myenteric neurons, of a larger size than those in wild-type mice. Evidence also indicates that NT-3 acts together with other factors, and may be important in later stages of fetal ENS development.

Nerve Growth Factor and Brain-Derived Neurotrophic Factor

Although NGF, BDNF, TrkA, and TrkB transcripts have all been detected in the developing gut, there is no evidence that they have a role in early ENS development.

Neuropoietic Cytokines

The neuropoietic cytokines ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF) are expressed in the gut; CNTF has been detected in the fetal mouse gut, and LIF is expressed in postnatal rat gut. Neural crest-derived neural precursors immunoselected from embryonic day 14 (E14) fetal rat gut express the receptor, CNTFRα, as do developing neurons in the E16 and E18 rat ENS. Although CNTF and LIF knockout mice appear to have a normal ENS, transgenic mice in which either the CNTF receptor α or LIF receptor β are disrupted die at birth and have reduced numbers of enteric neurons; in particular, they exhibit a loss of substance P-immunoreactive and nitric oxide synthase (NOS)-immunoreactive neurons that innervate smooth muscle.

Although the actions of all these different types of neurotrophic factors have been summarized separately here, evidence suggest that they are likely to interact; ENS development is dependent upon a range of neurotrophic and other factors.

Developmental Disorders of the ENS That Involve Neurotrophic Factors

The main developmental disorder of the ENS, Hirschprung disease, has been much studied, and disruption of the GDNF/c-ret signaling pathway as a major cause of Hirschprung disease is well established. The involvement of disruption to the endothelin signaling pathway in Hirschprung disease has also been well described. The possible involvement of other neurotrophic factors in developmental disorders of the ENS, however, has been little studied. Deficiency in neurotrophin expression has been described in the transitional zone of some Hirschprung disease patients. Dysregulation of neurotrophic signaling may also be involved in the etiology of infantile pyloric stenosis, a condition in which infants have hypertrophic pyloric muscle associated with abnormal innervation.

Neurotrophic Factors and Postnatal Changes in the ENS

The mammalian ENS undergoes a number of changes after birth, during the periods of gut growth and dietary change. Although most enteric neurons differentiate during fetal development and enteric ganglia are formed before birth, neural crest-derived stem cells have been identified in the postnatal gut and a small population of neural precursors has been shown to withdraw from the cell cycle postnatally. The relative proportions of different types of enteric neuron in newborn animals have been found to be different from those in adults. The cholinergic population, in particular, is not fully established at birth, and in rodents, the numbers of neurons expressing VIP, pituitary adenylyl cyclase-activating peptide (PACAP),

and neuronal NOS (nNOS) in the myenteric plexus have been shown to increase during the first few weeks of life. The morphological properties of enteric neurons also change; in addition to an increase in cell soma size, neuronal processes must grow appropriately in parallel with their target tissues and it is likely that 'fine tuning' takes place, to fully establish enteric circuitry at a structural level and also at the neurochemical level – for example, in the expression of neurotransmitter receptors. Neurotrophic factors are likely to play a role in these changes. Evidence in support of a postnatal role for neurotrophic factors and their receptors comes from studies of their expression and actions in the postnatal gut.

Expression of Neurotrophic Factors and Their Receptors in the Postnatal Gut

The neurotrophic factors that are active in the fetal ENS – GDNF, NTN, and NT-3 – continue to be expressed in the postnatal rodent gut. Evidence from immunohistochemical studies of human tissues indicates that BDNF and LIF are also expressed in the gut during the postnatal period. Semiquantitative reverse transcription polymerase chain reaction (RT-PCR) of mRNA extracted from whole gut has been used to analyze possible changes in expression levels of GDNF and NTN and their specific GPI-linked receptors postnatally. This work indicates that there may be a decline in the level of expression of GDNF in the first few postnatal weeks, while that of NTN may increase, reaching a maximum at postnatal day 14 in mice. These changes in expression are mirrored by possible decreases in the levels of GFRα1 and increase in GFRα2 during the same time period. Interpretation of such analysis of mRNA levels in whole gut, which contains a mixture of cell types, however, does not determine if local expression levels of proteins change, and is further complicated by the rapid postnatal growth of the different gut layers. In this context it is worth noting that other studies have reported continued high levels of expression of both GDNF and NTN into adult life. Possible changes in expression levels are nevertheless potentially of importance, since data from both NTN and GFRα2 null transgenic mice indicate that NTN may play a role in the later development of the ENS, particularly of cholinergic neurons, some of which have been reported in other studies to differentiate postnatally.

The expression of other neurotrophic factors and their receptors during postnatal development has been studied using immunohistochemical techniques. In human infants, TrkA and TrkB receptors have been found to be expressed by both enteric neurons and glia, while TrkC receptors are expressed only by enteric neurons. BDNF and NT-3 are also expressed by enteric ganglion cells. Detailed analysis to localize neurotrophic factor and receptor expression to particular neuronal subpopulations, however, has not been performed during the postnatal period. It should also be noted that a different pattern of expression of TrkB has been described in adult rodent gut (see later). Nevertheless, expression of neurotrophic factors by enteric neurons in postnatal animals suggests that these factors could be involved in establishing interneuronal connections within the developing ENS circuitry.

Actions of Neurotrophic Factors on Postnatal Enteric Neurons and Glia

In vitro work supports the hypothesis that neurotrophic factors play a role in the postnatal development of the ENS. Studies of isolated myenteric ganglion cells in dissociated cell culture show that myenteric neurons from postnatal rats respond to exogenously applied GDNF, NGF, NT-3, and CNTF. GDNF and NT-3 promote neuronal survival and neurite extension, NGF promotes neuritogenesis, and CNTF has been reported to also promote neurite sprouting *in vitro*. There is also evidence that GDNF and NT-3 may have effects on the neurochemical properties of cultured myenteric neurons, possibly promoting expression of VIP. Study of the effects of GDNF on neurons at different postnatal ages indicates that older (postnatal day 14) myenteric neurons may be less responsive to GDNF than are those from younger (postnatal day 7) animals, an observation that is consistent with the molecular data on GFRα1 and GFRα2 mRNA levels in postnatal mice.

Neurotrophic Factors and the Adult ENS: Roles in Intestinal Neurophysiology and Neuroprotection?

Expression of Neurotrophic Factors and Their Receptors in the Adult Gut

Expression of neurotrophic factors and their receptors in the gut continues into adult life. GDNF and NTN mRNA expression in the adult rat gut has been confirmed by molecular techniques, and GDNF protein has also been shown by immunoassay to be present at high levels in the adult gut. Analysis of mRNA indicates that GDNF and NTN expression continues even in aged (24 months old) rats. Although relatively few studies have been performed, immunohistochemical evidence indicates that some, but not all, enteric neurons in adult humans, rats, mice, and other vertebrates express NGF, BDNF, or NT-3. Co-expression of the three neurotrophins by enteric neurons has not been examined to date. In rat intestine, NT-3-immunoreactive neurons were found to be abundant in the

submucous plexus, but sparse in the myenteric plexus, and most NT-3-immunopositive neurons also expressed the peptide VIP.

Analysis of receptor expression indicates that adult enteric neurons express c-ret, GFRα1, GFRα2, TrkA, and TrkC, while TrkB expression seems to be confined to glial cells. Recent immunohistochemical analysis in adult rat colon showed that 71% of myenteric neurons are immunopositive for TrkA, and 78% express the low-affinity neurotrophic receptor, p75. More than 60% of myenteric neurons express both receptors. The functional significance of this widespread expression of NGF receptors was demonstrated by application of exogenous NGF, which resulted in TrkA phosphorylation. Double labeling demonstrated that TrkA was expressed by different types of enteric neurons, including choline acetyltransferase-immunopositive and nNOS-immunopositive neurons. Whether or not the level or pattern of receptor expression by individual neurons changes during the life span remains to be determined, although there is evidence that responsiveness of myenteric neurons to NGF, NT-3, and GDNF is maintained throughout life.

Roles of Neurotrophic Factors in the Adult and Aging Gut

What is the role of neurotrophic factors in the mature and aging ENS? Recent evidence shows that there may be both a neuromodulatory action, affecting gut function, and a neuroprotective role, promoting neuronal survival.

Effects of neurotrophic factors on gastrointestinal motility The acute effects of BDNF in the central nervous system have been well documented. The observation that BDNF and other neurotrophins are expressed by enteric neurons therefore led to the suggestion that they may also have rapid and short-lived actions in the gut, as well as, or instead of, longer term neurotrophic effects.

Evidence that neurotrophins may have effects on intestinal physiology came indirectly, when it was noted that patients in clinical trials involving treatment with recombinant BDNF or NT-3 for neurological disorders had an increased frequency of bowel movements and diarrhea. Subsequent trials of the possible therapeutic use of NT-3, administered three times a week subcutaneously, for treatment of patients with idiopathic constipation also resulted in a dose-dependent enhancement of colonic transit and improved passage of stools. Gastric emptying and both intestinal and colonic transit were accelerated in these patients. Studies of the effects of NGF, recombinant BDNF, and recombinant NT-3 infused into the tail vein of rats showed that these factors had similar effects on colonic motility: an increase in the spike frequency, amplitude, and duration. Recombinant NT-3 (but not the other factors) also promoted myoelectrical activity in the stomach and small intestine. The mechanisms by which the neurotrophins exert these effects, however, are unclear. The effect in humans began 24–48 h after onset of treatment, so could possibly be due to a relatively rapid trophic effect, perhaps on the efficacy of particular nerve types or neurotransmitter systems. To date, analysis of the effects of these factors *in vitro* has not provided clear evidence on their mode of action *in vivo*.

Protective roles of neurotrophic factors in the ENS Recent evidence indicates that neurotrophic factors may have protective roles in the ENS during maturity and in aging. Effects of neurotrophic factors in model systems in which enteric neuronal damage was induced either by hyperglycemia or by reactive oxygen species (ROS) have been investigated.

Enteric neuropathy is a well-documented complication of diabetes, and loss of enteric neurons has been demonstrated in humans and in animal models. The causes of enteric nerve damage in diabetes have not been established, although hyperglycemia is likely to be involved. In recent work, the effects of elevated glucose levels on cultured fetal enteric neurons were examined. Glucose produced a dose-dependent increase in apoptosis in these cultures, an effect that was significantly reduced in the presence of GDNF. Importantly, *in vivo*, overexpression of GDNF also protected against apoptosis, specific neuronal loss, and motility changes seen in streptozotocin-induced diabetic transgenic mice.

GDNF and NT-3 have also been shown to reduce generation of ROS and protect against ROS-induced apoptosis *in vitro*. When isolated segments of the muscularis externa containing the myenteric plexus are incubated in the presence of dihydrorhodamine, which fluoresces when exposed to ROS, addition of GDNF and NT-3, but not NGF, reduces the fluorescent signal. Furthermore, when myenteric ganglia are incubated in the presence of the ROS generator menadione, some myenteric neurons undergo apoptosis. More do so in samples from aged animals, fed an *ad libitum* diet. Incubation in the presence of GDNF or NT-3, but not NGF, reduced the number of apoptotic neurons detected in this model. Interestingly, this protective effect was lost in the aged *ad libitum*-fed animals, but not in rats fed a calorically restricted diet.

Are Neurotrophic Factors Involved in Clinical Conditions Affecting the ENS?

The continued expression of neurotrophic factors in the adult gut and their receptors by enteric neurons

also leads to the question of whether disruption of neurotrophic factor signaling is involved in clinical conditions that affect the ENS. Enteric neurons innervate all cell types in the gut, so neurotrophic factors may directly or indirectly influence all types of intestinal pathophysiology. One area in which neurotrophins have been implicated is that of the inflammatory bowel diseases, where, in addition to the inflammatory damage to nonneuronal gut tissues, abnormalities of the ENS have been described.

In experimental colitis, pretreatment with neutralizing antibodies to NGF or NT-3 resulted in exacerbation of the inflammatory response, implying that these factors normally exert a protective effect in this model of inflammatory disease. In humans with either Crohn's disease or ulcerative colitis, increased expression of NGF and NT-3 was seen, at both the mRNA and the protein levels. Selective losses of NGF-sensitive enteric neurons in experimental colitis, however, have also been described, and intestinal mast cells have also been shown to express both NGF and TrkA. Enteric neurons have also been shown to cause mast cell degranulation. Neuroimmune interactions in the gut are therefore complex, and although neurotrophic factors are likely to play a role in inflammatory conditions, much remains to be learned about this and other aspects of their actions in the gut.

Introduction

The enteric nervous system (ENS) is a subdivision of the autonomic nervous system (Figure 1). Neural control of the digestive tract is by the autonomic nervous system. Three subdivisions of the autonomic nervous system, known as the sympathetic, parasympathetic, and enteric divisions, make up the autonomic innervation of the alimentary tract. The enteric division, which is also called the ENS, functions like a brain in the gut. It is an independent integrative nervous system which has its neural networks placed in close apposition to the effector systems it controls in the stomach, in the approximately 30 ft of small intestine and in the 8 ft of large intestine as well as the esophagus, gallbladder, and pancreas. The effector systems are the musculature, secretory glands, and blood vasculature. There are approximately 100 million neurons in the ENS, which is about the same number as in the spinal cord. Rather than packing the 100 million neurons required for control of gut functions into the skull as part of the brain and relying on signal transmission over long, unreliable pathways to the gut, evolutionary natural selection distributed the integrative neural networks of the ENS along the gut in immediate proximity to the effector systems.

In a manner similar to the central nervous system, the networks at the effector sites have evolved as an organized array of different kinds of neurons interconnected by chemical synapses. Function in the networks is determined by generation of action potentials within single neurons and chemical transmission of information at synaptic points of contact between individual neuronal elements. Coded information is transmitted from one region of the neuron to another by action potentials. The action potential codes are transformed into chemical codes at synapses with other neural elements within a given network. Action potential codes arriving in presynaptic neuronal terminals are transformed to chemical signals for transmission across the synapse to receptors on postsynaptic neural elements where reconversion into action potential codes occurs in the postsynaptic neurons. Postsynaptic neurons integrate large numbers of synaptic inputs, which may be excitatory or inhibitory. Postsynaptic integration is fundamental for computation and processing of neural information.

The enteric microcircuits in the various specialized compartments of the digestive tract are wired with large numbers of neurons and synaptic sites where information processing occurs. Multisite computation generates output behavior from the integrated circuits that could not be predicted from properties of their individual neurons and synapses. Emergence of complex behaviors is a fundamental property of the neural networks of the ENS, in the same way as in the brain and spinal cord.

In much the same manner as in the brain and spinal cord, the enteric microcircuitry processes information and generates patterns of signals that determine the timing and sequencing of behavior of the muscle groups and secretory glands and the distribution and dynamics of blood flow within the gut wall. Processing of information in the circuits is a function whereby computation of input signals results in output to the effectors that is a meaningful transform of the input. Like electronic calculators, which receive numbers as input and calculate outputs according to specific equations preprogrammed into the circuits, the neural circuits receive sensory signals and compute outputs that control behavior of the effectors in ways adapted for overall performance of the specialized regions of gut.

Processing of sensory signals is among the major functions of the microcircuits in the ENS. The sensory signals are generated by sensory nerve endings and coded in the form of action potentials. The code may represent the status of an effector system (e.g., tension in a muscle) or may signal a change in parameters, such as acidity and osmolarity, in the environment of the lumen of a specialized compartment. Sensory signals are deciphered by the neural networks to generate output signals that initiate homeostatic adjustments in the behavior of each individual effector system and the integrated behavior of the whole organ.

Myenteric and Submucosal Plexuses

The ENS consists of ganglia, primary interganglionic fiber tracts, and secondary and tertiary fiber projections to the effector systems (i.e., musculature, glands, and blood vessels). Two ganglionated plexuses are the most obvious structures of the ENS (Figure 2). The myenteric plexus, also known as Auerbach's plexus, is located between the longitudinal and circular muscle layers of the esophagus, stomach, and small and large intestine. The submucosal plexus, also known as Meissner's plexus, is situated in the submucosal region between the circular muscle and

mucosa. The submucosal plexus is most prominent as a ganglionated network in the small and large intestine. It does not exist as a ganglionated plexus in the esophagus and is sparse in the submucosal space of the stomach. In larger mammals (e.g., humans), the intestinal submucosal plexus consists of an inner submucosal network (Meissner's plexus) located at the serosal side of the muscularis mucosae and an outer plexus (Schabadasch's plexus) adjacent to the luminal side of the circular muscle coat. In human small and large intestine, a third intermediate plexus lies between Meissner's and Schabadasch's plexus.

Most motor innervation of the intestinal circular and longitudinal muscle coats originates from motor neurons that have their cell bodies in the myenteric plexus. Motor innervation of the intestinal secretory glands (i.e., Brunner's glands in the duodenum and crypts of Lieberkühn in both small and large intestines) originates in the submucosal plexus. Neurons in submucosal ganglia send fibers to the myenteric plexus and also receive synaptic input from axons projecting from the myenteric plexus. The interconnections link the two networks into a functionally integrated nervous system.

Structure, function, and neurochemistry of ganglia in the ENS are reminiscent of those in the central nervous system but differ considerable from ganglia of the sympathetic and parasympathetic autonomic divisions. Unlike most sympathetic or parasympathetic autonomic ganglia, where function is mainly as relay-distribution centers for signals transmitted from the brain and spinal cord, enteric ganglia are interconnected to form a nervous system with mechanisms for integration and processing of information like those found in the brain and spinal cord. This is the justification for referring to the ENS as the brain in the gut.

Figure 1 The digestive tract is innervated by three divisions of the autonomic nervous system: the sympathetic, parasympathetic, and enteric divisions. The parasympathetic division is subdivided into cranial and sacral divisions based on the anatomical location of the preganglionic cell bodies in the brain stem and spinal cord. Preganglionic cell bodies of the sympathetic division are in the thoracolumbar regions of the spinal cord. Cell bodies of the enteric division are in its myenteric and submucosal divisions.

Heuristic Model for the ENS

The heuristic model for the ENS is the same as for the brain and spinal cord and, for that matter, any other independent integrative nervous systems, such as those in invertebrate animals (Figure 3). As in any independent integrative nervous system, sensory neurons, interneurons, and motor neurons in the ENS are connected synaptically for flow of information from sensory neurons to interneuronal integrative networks to motor neurons to effector systems. The job of the ENS is to organize and coordinate the activity of each effector system into meaningful behavior of the integrated organ. It is integrated with sympathetic and parasympathetic autonomic centers in the central

Figure 2 Structural relations of the intestinal musculature and the ENS. Longitudinal and circular muscle coats are the main components of the musculature involved in propulsive motility; secretory glands are in the mucosa. Ganglia and interganglionic fiber tracts of the myenteric and submucosal plexuses are main constituents of the ENS. The myenteric plexus is situated between the circular and longitudinal muscle coats; the submucous plexus is between the mucosa and circular muscle coat.

Figure 3 Sensory neurons, interneurons, and motor neurons are synaptically interconnected to form the integrated microcircuits of the ENS. Like the central nervous system, sensory neurons, interneurons, and motor neurons are connected synaptically for flow of information from sensory neurons to interneuronal integrative networks to motor neurons to effector systems. The ENS organizes and coordinates the activity of each effector system into meaningful behavior of the whole organ. Bidirectional communication occurs between the central and the ENS.

nervous system and bidirectional communication occurs between the centers in the central nervous system and the ENS.

Neuronal Types

Dogiel types I and II are the principal morphological classes of neurons in the ENS. The German neuroanatomist, AS Dogiel, described these two morphological types of enteric ganglion cells that were named after him. Dogiel types I and II are distributed in both myenteric and submucosal plexuses. Both types of neurons are distributed in a two-dimensional plane (i.e., the cell bodies are not stacked one on the other). Cell bodies are flat, coin-like disks with multiple neurites exiting around the perimeter, which may adapt the ENS for the changing forces within the gut wall experienced during contraction of the musculature or stretching of the wall as the hollow organs fill.

Dogiel type I neurons have cell bodies with many short processes and a single long process (Figure 4). These are flat neurons with the processes extending from the cell body in the circumferential and longitudinal planes of the wall. The short processes are dendrites, which receive synaptic input; the long process is an axon. The axon of Dogiel type I neurons projects for relatively long distances through interganglionic fiber tracts and many rows of ganglia. Still, the projections are not long in absolute length; the longest known projections of any enteric ganglion cell are only approximately 2–3 cm. Dogiel I neurons projecting in a specific direction often express a specific neurotransmitter. Aborally projecting Dogiel I axons release nitric oxide and vasoactive intestinal polypeptide as neurotransmitters; those projecting in the oral direction release substance P and acetylcholine. Some of the Dogiel type I neurons are motor neurons to the musculature and secretory epithelium; others are interneurons.

The cell bodies of ENS neurons with Dogiel type II morphology have smooth surfaces with long and short processes arising in a variety of configurations (Figure 4). The long processes may extend through interganglionic fiber tracts across several rows of ganglia in the circumferential direction, the oral direction, or aborally. Shorter processes may only project within the home ganglion. Almost all Dogiel II neurons in the myenteric plexus project a process to the submucosa/mucosa. Dogiel II processes in the mucosal regions express the 5-HT_3 serotonergic receptor subtype and are fired by serotonin that is released from mucosal enterochromaffin cells during mechanical and chemical stimulation of the mucosa. Dogiel II neurons express the neurotransmitters substance P and acetylcholine.

A population of Dogiel II neurons, which electrophysiologically are characterized by long-lasting afterhyperpolarization following generation of an action potential, have been proposed to be intrinsic primary afferent neurons referred to by the acronym IPAN. Nevertheless, these neurons behave quite differently from spinal or vagal primary sensory afferent neurons, which faithfully encode changes in stimulus energy into the firing of action potentials. Instead, variability in excitability of enteric afterhyperpolarization (AH)-type neurons and their synaptic interconnections

Figure 4 Histoanatomy of Dogiel morphologic types I and II in the ENS. (a_1, a_2) Dogiel morphologic type II neurons in the myenteric plexus of the guinea pig small intestine. Dogiel II neurons have multiple long processes with variable lengths and shapes that ramify throughout the ganglion and into interganglionic fiber tracts. (b_1, b_2) Dogiel morphologic type I neurons in the submucosal plexus of the small intestine of the guinea pig. Dogiel I neurons have multiple short dendrites at the edges of the cell body and a single axon. The neurons were marked by the injection of biocytin from micropipettes that also served as recording microelectrodes.

suggest that they may be multifunctional interneurons and play an important role in determining the output of, as well as the input to, enteric reflex circuits.

Electrical Behavior

Intracellular microelectrodes are used to record the electrical and synaptic behavior of enteric neurons in preparations removed from the various organs of the digestive tract. Differences in electrical and synaptic behavior provide a basis for classification of enteric neurons into two main subgroups termed AH type and submucosal (S) type.

S-type neurons were first identified on the basis of nearly universal occurrence of fast excitatory postsynaptic potentials (Figure 5) and AH-type neurons were identified based on the occurrence of long-lasting AH associated with the action potential (Figure 6). AH-type electrophysiological behavior is found mainly in enteric neurons with Dogiel type II morphology and S-type behavior is found mainly in Dogiel type I neurons.

Repetitive action potential discharge can occur in S-type neurons; repetitive discharge generally does not occur in AH-type enteric neurons (Figure 6). Membrane excitability is higher in S-type enteric neurons than in AH-type neurons. S-type neurons fire repetitively during the intraneuronal injection of long-duration depolarizing current pulses through the recording microelectrode. The frequency of the repetitive spike discharge increases in proportion to the amplitude of the depolarization produced by the injected pulses. AH-type neurons do not fire repetitively during sustained membrane depolarization when they are in a resting state. Irrespective of the strength of a depolarizing pulse, these neurons fire only one or two spikes at the onset of the pulse. During slow synaptic excitation (Figure 5), AH neurons become hyperexcitable and fire repetitively like S-type neurons.

In the guinea pig, which is the most commonly studied model, the occurrence of AH-type neurons is limited to the gastric antrum and small and large intestine. S-type neurons are found throughout the digestive tract, including gastric corpus and antrum, gallbladder, esophagus, and pancreas.

Neurotransmission

Synaptic events in the ENS are generally the same as in the brain and spinal cord. Excitatory postsynaptic potentials, inhibitory postsynaptic potentials, and presynaptic inhibition and facilitation are the principal synaptic events in the enteric microcircuitry. Both slow and fast synaptic mechanisms are expressed in neurons with AH-type electrophysiological behavior and Dogiel II morphology and S-type electrophysiological behavior and uniaxonal Dogiel I morphology. Fast synaptic potentials have durations in the millisecond range; slow synaptic potentials last for several seconds or minutes. Fast synaptic potentials are usually excitatory postsynaptic potentials. The slow synaptic events may be either excitatory postsynaptic potentials or inhibitory postsynaptic potentials.

Fast Excitatory Postsynaptic Potentials

Fast excitatory postsynaptic potentials are membrane depolarizations with durations less than 50 ms

Figure 5 Fast and slow excitatory postsynaptic potentials (EPSPs) and slow inhibitory postsynaptic potentials (IPSPs) are the primary kinds of synaptic potentials in enteric neurons. (a) Two fast EPSPs were evoked by successive stimuli and are shown as superimposed records. Only one of the EPSPs reached threshold for discharge of an action potential. The time course of the EPSPs is in the millisecond range. The fast EPSPs were evoked by single electrical shocks applied to the axon that formed the synapse with the recorded neuron. (b) Slow IPSP evoked by stimulation of an inhibitory input to the neuron. This is a hyperpolarizing synaptic potential that will suppress excitability (i.e., decrease probability of action potential discharge) compared with enhanced excitability during slow EPSPs. (c) Slow EPSP evoked by repetitive electrical stimulation of the synaptic input to the neuron. Slowly activating depolarization of the membrane potential continues for more than 2 min after termination of the stimulus. Repetitive discharge of action potentials reflects enhanced neuronal excitability during the slow EPSP.

Figure 6 Enteric neurons are classified as S type 1 or AH type 2 based on their electrophysiological behavior. (a) AH type 2 neuron had low excitability reflected by discharge of only a single action potential during intraneuronal injection of a 200 ms depolarizing current pulse. (b) S type 1 neuron had relatively high excitability reflected by repetitive discharge of action potentials during intraneuronal injection of a 200 ms depolarizing current pulse. The bottom traces in (a) and (b) show the current pulses and the top traces show the neuronal responses to the depolarizing current pulses. (c) AH type 2 neurons are characterized by long-lasting membrane hyperpolarization (i.e., afterhyperpolarization) following the discharge of an action potential.

(Figure 5). They are found at synapses in both myenteric and submucosal plexuses, where they appear most prominent in neurons with S-type electrophysiological behavior in all of the specialized organs of the digestive tract. Most of the fast excitatory postsynaptic potentials are mediated by acetylcholine at nicotinic postsynaptic receptors. The actions of serotonin at the serotonergic 5-HT_3 receptor subtype and purine nucleotides at P_{2X} purinergic receptors behave much like fast excitatory postsynaptic potentials.

Slow Excitatory Postsynaptic Potentials

Slow excitatory postsynaptic potentials are involved in neurotransmission in both myenteric and submucosal plexuses and in both AH- and S-type neurons. They are most pronounced in Dogiel morphologic type II neurons with AH-type electrophysiologic behavior where conversion from hypo- to hyperexcitability is involved. Neurons with slow excitatory synaptic inputs are found in the small and large intestine and gastric antrum but not the gastric corpus or gallbladder. They seem to be associated with specialized regions in which propulsive motility is a significant function.

Slowly activating membrane depolarization continuing for several seconds to minutes after termination of release of the neurotransmitter from the presynaptic terminal identifies slow excitatory postsynaptic potentials (Figure 5). Enhanced excitability, reflected by long-lasting trains of impulses, is the hallmark of slow excitatory postsynaptic neurotransmission. Enhanced excitability is apparent experimentally as repetitive spike discharge during depolarizing current pulses. AH-type neurons, which fire only a single spike at the beginning of a depolarizing current pulse in the inactivated state, will fire repetitively in response to depolarizing pulses when the slow excitatory postsynaptic potential is in effect. When activated by slow synaptic inputs, behavior of AH-type neurons is much like that of S-type neurons and may be confused as such if they happen to be in an activated state due to ongoing release of the transmitter or a paracrine mediator that mimics slow synaptic excitation. Postspike hyperpolarization in AH-type neurons is suppressed during slow excitatory neurotransmission. Suppression of the AH is part of the mechanism that permits repetitive spike discharge at increased frequencies during the enhanced state of excitability.

Slow excitatory postsynaptic potentials are a mechanism for long-lasting activation or inhibition of gastrointestinal effector systems. The prolonged neuronal firing during a slow excitatory postsynaptic potential drives the release of neurotransmitter from the neuron's axon for the duration of the spike discharge.

Table 1 Mimetics of slow excitatory postsynaptic potentials

Mimetic (receptor)	*Mimetic (receptor)*
Acetylcholine (muscarinic M_1)	Vasoactive intestinal peptide
Cholecystokinin (A)	Caerulein
Thyrotropin-releasing hormone	Gastrin-releasing peptide
Calcitonin gene-related peptide	Tachykinins (NK_1/NK_3)
Bombesin	γ-Aminobutyric acid
5-Hydroxytryptamine (5-HT_{1P}/5-HT_2)	Motilin
Interleukin-1β	Glutamate
Histamine (H_2)	Interleukin-6
Adenosine (A_2)	Platelet-activating factor
Corticotropin-releasing factor (CRF_1)	Bradykinin (B_2)
ATP ($P2Y_1$)	Proteases ($PARS_{1,\ 2,\ \text{and}\ 4}$)
Pituitary acenylate cyclase Activating peptide	Prostaglandin E
	Leukotrienes C_4, D_4, and E_4

Prolonged inhibition, or excitation at neuronal synapses in the processing circuits and at neuroeffector junctions, is the functional outcome of slow synaptic excitation. This governs the functional behavior of the effector systems. Compared to twitches of skeletal muscles, contractile responses of the gut musculature and glandular secretion are sluggish events that last for several seconds from start to completion. The prolonged trainlike firing during slow excitatory postsynaptic potentials is the neural correlate of long-lasting excitatory or inhibitory responses of the muscle groups in the functioning gastrointestinal tract. Prolonged secretory responses in the intestinal crypts are also related to the sustained firing during slow synaptic excitation.

Several messenger substances found in neurons or endocrine or immune cells of the gut mimic slow synaptic excitation when applied experimentally to enteric neurons (Table 1). Receptors for more than one of the messenger substances may be present on the same neuron.

Slow Inhibitory Postsynaptic Potentials

Slow inhibitory postsynaptic potentials are hyperpolarizing synaptic potentials found in neurons in both myenteric and submucosal plexuses of the small and large intestine and in myenteric neurons of the gastric antrum. Slow inhibitory postsynaptic potentials activate relatively slowly and continue for several seconds after termination of the stimulation (Figure 5). The characteristics of slow synaptic inhibition are the inverse of slow synaptic excitation in that hyperpolarization instead of depolarization of the membrane potential occurs (e.g., a change from -50 to -75 mV). Hyperpolarization of the membrane potential reduces excitability and the

Table 2 Mimetics of slow inhibitory postsynaptic potentials

Mimetic (receptor)	*Mimetic (receptor)*
Acetylcholine	Opioid peptides (μ, δ)
5-Hydroxytryptamine (5-HT_{1A})	Norepinephrine (α_2)
Neurotensin	Cholecystokinin
Somatostatin	ATP
Adenosine (A_1)	Galanin (GAL-1)
Nociceptin	

probability that the neuron will fire impulses. Inhibitory postsynaptic potentials are more readily demonstrated in the submucous than in the myenteric plexus of animal preparations.

Several putative neurotransmitters or paracrine mediators evoke responses similar to slow inhibitory postsynaptic potentials when experimentally applied to enteric neurons (Table 2). Some of these substances are peptides, others are purine compounds, and another is norepinephrine. Receptors for two or more of these substances may be localized to the cell body of the same neuron.

Peristaltic Reflex

The peristaltic reflex is a polysynaptic reflex circuit in the ENS that underlies all of the propulsive motility patterns found in the small and large intestine and esophagus. It is the intestinal analog of spinal motor reflexes (e.g., monosynaptic patellar and Achilles tendon reflexes and polysynaptic withdrawal reflexes). The peristaltic reflex is much the same in that it is a fixed response evoked by investigational stretching of the intestinal wall or stroking of the mucosa. It is like a polysynaptic spinal reflex in that it is a motor response to sensory stimulation that is repeated the same way each time the hardwired reflex circuit is activated. The peristaltic reflex circuit is synaptically connected to evoke relaxation of the circumferentially oriented muscle layer and contraction of the longitudinal muscle below the point of stimulation and contraction of the circumferentially oriented muscle layer above the point of stimulation.

Like spinal reflexes, the peristaltic reflex is positioned at the lowest level of the hierarchical organization of neural control of intestinal motility and undoubtedly underlies each of the various patterns of propulsive motility that impart functionality to the intestine during daily life. As with a spinal motor reflex, the sequencing of the pattern of behavior of the intestinal longitudinal and circular muscles is hardwired into the circuitry, whereas the strength of each motor component of the pattern and the repetition rate of the pattern are adjusted by sensory feedback or other commands to automatically compensate for local loads and higher functional demands on the intestine as a whole. The distance over which propulsion occurs and the direction in which it occurs in the specific patterns of motility, which characterize the various digestive states, are additional factors requiring a higher order of neural control. Short-distance propulsion in the postprandial digestive state, propulsion over intermediate distances during interdigestive motility (i.e., migrating motor complex) and long-distance power propulsion, all in the orthograde direction, and long-distance retropulsion during emesis are neural control requirements that are met by the integrative microcircuitry of the ENS.

The muscle layers of the intestine contract and relax in a stereotypic pattern during peristaltic propulsion (Figure 7). This pattern is determined by the sequence in which the peristaltic polysynaptic reflex circuit activates excitatory and inhibitory motor neurons to the longitudinal and circular muscle layers. During propulsion, the longitudinal muscle layer in the segment ahead of the advancing intraluminal contents contracts in response to activation of its excitatory motor innervation while at the same time the circular muscle layer relaxes in response to activation of its inhibitory motor innervation. The intestinal tube behaves geometrically like a cylinder with constant surface area. Shortening of the longitudinal axis of the cylinder during contraction of the longitudinal muscle is accompanied by a widening of the cross-sectional diameter. The simultaneous shortening of the longitudinal axis and relaxation of the circular muscle results in expansion of the lumen, which prepares a receiving segment (Figure 7) for the forward-moving intraluminal contents during peristaltic propulsion.

Organization of a receiving segment constitutes one-half of propulsive peristaltic reflex behavior. The second half is contraction of the circular muscle in the segment behind the advancing intraluminal contents. The longitudinal muscle layer in this segment relaxes at the same time that the circular muscle contracts, resulting in the conversion of this region to a propulsive segment that propels the luminal contents ahead into the receiving segment (Figure 7). The propulsive segment is formed when neural connections in the reflex circuit shut off the excitatory innervation to the longitudinal muscle and the inhibitory innervation to the circular muscle while activating excitatory motor neurons to the circular muscle.

The heuristic model for peristaltic intestinal propulsion assumes blocks of the basic polysynaptic reflex circuit connected in series along the length of small intestine and large intestine (Figure 8). A block of the basic polysynaptic circuit is formed by synaptic

Figure 7 Intestinal peristaltic propulsive motility. (a) The circumferential and longitudinal muscle layers of the intestine behave in a stereotypical pattern during peristaltic propulsion. A hardwired reflex circuit in the ENS determines the pattern of behavior of the two muscle layers. During peristaltic propulsion, the longitudinal muscle layer in the segment ahead of the advancing intraluminal contents contracts while the circumferential muscle layer relaxes simultaneously. Simultaneous shortening of the longitudinal intestinal axis and relaxation of the circumferential muscle in the same segment results in expansion of the lumen, which becomes a receiving segment for the forward-moving contents. The second component of the reflex is contraction of the circular muscle in the segment behind the advancing intraluminal contents. The longitudinal muscle layer in the same segment relaxes simultaneously with contraction of the circular muscle, which results in conversion of this region to a propulsive segment that propels the luminal contents ahead into the receiving segment. (b) Motor behavior of the intestinal wall during the peristaltic reflex in a segment of guinea pig ileum in response to distension by infusion of saline at time = xs. Shortening of the longitudinal axis and expansion of the lumen is seen in the receiving segment and contraction of the circular muscle and reduction in the diameter of the receiving segment is apparent at time = 3xs as propulsion proceeds to empty the lumen through the outlet. Wall behavior was redrawn from photographic images provided by Prof. M Takaki, Department of Physiology, Nara Medical University, Japan.

connections between interneurons and motor neurons (Figure 8). Propulsion occurs over extended lengths of intestine as blocks of the basic circuit are recruited to activity in consecutive segments. In this respect, the intestine is like the spinal cord, in which connections for polysynaptic reflexes remain irrespective of the destruction of adjacent regions of the spinal cord. Resection of an intestinal segment does not alter the reflex circuitry in the two segments remaining on either side of the resection. Consequently, organized propulsion is not impaired after resection of various lengths of bowel.

Central Pattern Generation

Independent integrative nervous systems in vertebrates and invertebrates contain neural networks that are programmed to generate timing and phasing signals for repetitive, rhythmic movements. Walking, swimming, flying, and copulation are examples of repetitive movements controlled by neural networks that have central pattern generators. In the small intestine, repetitive activation of peristalsis within the activity front of the migrating motor complex during the fasting state, mixing movements occurring rhythmically at multiple sites along the small intestine during the digestive state, and rhythmic cycles of secretion from the mucosa in response to food allergens all reflect rhythmic output from pattern generators in neural networks of the ENS.

Earlier concepts of neural networks taught that each kind of somatomotor behavior generated by an integrated muscle group required a different hardwired circuit for each specific behavior. Current concepts hold that a neural network can be polymorphic with the same circuit being capable of generating a variety of different motor behavioral patterns. Circuits of this nature are present in the ENS and can be described as anatomical networks, which hold a library of components that can be reconfigured in different ways to form a variety of different functional circuits. Overlays of neuromodulatory signals select the configuration and thereby determine the output of the network. This is accomplished through selective release of neuromodulatory chemicals that blanket the circuit and act to alter the electrical and

Figure 8 A hardwired polysynaptic peristaltic reflex circuit in the ENS underlies intestinal propulsive motility. (a) Two kinds of input activate the basic peristaltic reflex circuit. One is distension of the intestinal wall and activation of intramural mechanoreceptors. Second is the release of 5-hydroxytryptamine (5-HT) from enterochromaffin cells by mechanical stimulation of the mucosa. When the reflex circuit is functioning, excitatory motor neurons to the longitudinal muscle coat and inhibitory motor neurons to the circular muscle coat are activated to form the receiving segment below the point of stimulation (see Figure 7). At the same time, activation of excitatory motor neurons to the circular muscle coat and inactivation of inhibitory motor neurons to the circular muscle coat occur in the propulsive segment above the point of stimulation. (b) Blocks of the basic polysynaptic peristaltic reflex circuit are continuous along the intestine. Propulsion over extended distances is accomplished when synaptically connected blocks of circuitry are sequentially activated in a specific direction. Activation of sequential blocks generally travels in the aboral direction in the normally functioning bowel; it travels in the oral direction in the upper small intestine during emesis.

synaptic behavior of the neural elements that make up the circuit. Reconfiguration of ENS microcircuits and the resulting output to the effector systems occurs in response to neuromodulatory messenger substances released in paracrine manner from endocrine cells and immune/inflammatory cells within the intestinal wall.

The ENS contains a library of programs for specific patterns of intestinal motor behavior (Figure 9). Each program, when running, adapts the bowel for a specific digestive state or, in some cases, for adverse condition in the intestinal lumen (e.g., inflammation, infectious agents, or food allergens). One or the other program may be called up by endocrine or paracrine release of a neuromodulator that floods over the circuit or by neuromodulatory inputs from the central nervous system.

Neuroimmune Modulation

Histamine release from enteric mast cells in response to a food allergen and the resulting overlay of histamine on the ENS is an example of how a neuromodulator reconfigures the network to generate a rhythmic pattern of coordinated secretion and muscle contraction. Experimental application of histamine, which simulates degranulation of mast cells and mimics antigen-evoked degranulation of mast cells in the intestine of sensitized animal models, evokes cyclical bursts of glandular secretion with each of the secretory bursts linked to contraction of the musculature. The secretory behavior is activated for approximately 1 min and then inactivated for a few minutes prior to the next cycle (Figure 10). As each secretory cycle peaks, contraction of the intestinal muscularis externa occurs.

Figure 9 The ENS stores a library of programs for specific patterns of intestinal motor behavior that are adaptive for one or the other of the intestinal digestive states. In the postprandial state, the ENS runs the motor program for mixing movements while other programs are inoperative. At the completion of digestion and absorption of the nutrients of a meal, the postprandial program is terminated and the system calls up the interdigestive program, which, when running, programs for motor behavior described as the migrating motor complex. The ENS runs defensive programs characterized by powerful propulsive motility when threatening agents (toxins, infective agents, and food allergens) find their way into the intestinal lumen.

Figure 10 Activation of an ENS program for coordinated mucosal secretion and muscular contraction in the guinea pig colon. An overlay of histamine on the microcircuits of the submucosal plexus evokes repetitive cycles of mucosal secretion and coordinated contractions of the muscularis externa. The full-thickness preparation of intestinal wall was placed in an Ussing flux chamber with a small strain gauge attached to the serosal surface. The upper trace records mucosal secretion reflected as increases in transmucosal short-circuit chloride current; the lower trace is muscle contraction recorded by the strain gauge.

Only two neuromodulatory actions of histamine at the single neuron level of organization account for the emergent pattern of enteric network output that is subsequently transformed into a rhythmic pattern of integrated behavior at the level of the secretory glands and musculature. One neuromodulatory action is an intense increase in excitability, which mimics slow synaptic excitation in the cell bodies of neurons that make up the circuit (Figure 5). This excitatory action of histamine is mediated by histamine H_2 receptors expressed at the surfaces of the enteric neuronal cell bodies in the guinea pig intestine. The second neuromodulatory action of histamine is at synaptic connections between the neurons that form the integrative networks. Histamine acts at inhibitory receptors on the presynaptic terminals to suppress the release of neurotransmitter and thereby suppress transmission at the synapses. The presynaptic inhibitory action of histamine is mediated by the histamine H_3 receptor subtype in the guinea pig. These two actions of an overlay of histamine on two different histaminergic receptor subtypes at the single neuronal level are transformed into reconfigured rhythmic output at the integrated circuit level of organization.

Nature of the Enteric Nervous System

The enteric nervous system (ENS) is involved in many physiological and pathophysiological processes in the gastrointestinal tract. It is essential to normal life, as indicated by the high morbidity or mortality associated with congenital or acquired deficiencies of this system. It generates motility, secretomotor, and vasomotor reflexes triggered by stimuli that indicate the mechanical state of the gastrointestinal tract and the presence, the consistency, and the chemical nature of the luminal contents. The ENS contains all the basic components of polysynaptic reflex arcs – that is, primary afferent neurons, interneurons, and motor neurons. Several types of interneurons (one ascending type and three descending types) and motor neurons (excitatory and inhibitory motor neurons innervating the longitudinal or circular muscle, secretomotor neurons, and vasomotor neurons) have been identified. In the case of the guinea pig, the animal model that has been most extensively used for studying the ENS, 14 functional neuron types, which are distinguished by their shapes, projections, neurochemistry, and cell physiological properties, have been progressively discriminated in the small intestine.

Enteric Primary Afferent and Motor Neurons Are Not Segregated, Unlike Neurons Controlling Other Organs

Remarkably, the primary afferent limbs of the ENS reflex arcs are still not well defined and the identity of the primary afferent neuron(s) is still the object of new investigations. This is due to the fact that the afferent and efferent limbs of the reflex arcs are not topographically and functionally compartmented, with a defined integrative center that would group the interneurons similarly to the dorsal horn, the medulla, or the midbrain. On the contrary, they are integrally embedded in the gut wall that is both the source of the stimuli to be detected by primary afferent neurons and the effector that receives commands elaborated by the motor neurons. The absence of functional topography is also a rule within each myenteric ganglion, although there is a limited topography in submucosal ganglia. These ganglia are organized in two interconnected networks, the myenteric and the submucosal plexuses, with the myenteric ganglia occurring all along the gastrointestinal tract. In total, the ganglia contain as many neurons as the spinal cord.

Different Types of Primary Afferent Neurons in the ENS

In this unique system, five different neuron types are known to act as primary afferent neurons. Two are entirely included in the ENS circuitry within the wall of the gastrointestinal tract: these neurons, which are ENS neurons *sensu stricto*, correspond to the Dogiel type II and some filamentous neurons. Although suggested by experimental studies as early as the beginning of the twentieth century, the fact that enteric neurons could act as primary afferent neurons was established definitively only in the 1990s. This function was attributed exclusively to the Dogiel type II neurons, called intrinsic primary afferent neurons (IPANs), until strong arguments were provided in 2004 showing that some filamentous neurons also subserve a primary afferent role.

A third neuron type has been called an intestinofugal afferent neuron (IFAN). As indicated by this terminology, the cell body of this neurons is located within the ENS, whereas the axon projects to sympathetic ganglia in order to activate sympathetic motor neurons innervating the gut (thus forming enteroenteric reflex circuits). These neurons have been described as being mainly Dogiel type I neurons, although some Dogiel type II neurons also seem to be IFANs.

The other primary afferent neurons that innervate the gastrointestinal tract are the vagal and spinal primary afferent neurons, whose central processes project respectively to the medulla and the dorsal horn. Much less numerous than the ENS primary afferent neurons, they innervate extensive areas of the gastrointestinal tract, compared to the intrinsic primary afferent neurons, because of the broad distribution of their collateral processes. Here, we focus exclusively on ENS primary afferent neurons.

Criteria for the Identification of Enteric Primary Afferent Neurons

Morphological Criteria

The first criterion in the literature is morphological. It needs to be placed in historical context (the end of the nineteenth century) because morphology is not convincing by itself. On the basis of functional

arguments indicating that the enteric reflex arcs were totally included in the gastrointestinal tract, Dogiel sought a presumptive enteric primary afferent neuron and intuitively attributed this function to the neurons that are now called Dogiel type II. These neurons have round or oval smooth cell bodies with several long smooth processes that seem to be axons. Their cell bodies are found in both the myenteric and the submucosal plexuses. In each case, one process innervates the mucosa or muscle, whereas other processes connect with some myenteric neurons.

Functional Criteria

Experiments directed at the functional identification of enteric primary afferent neurons were first successfully conducted in the 1990s using *in vitro* preparations. The first criterion that was advanced was the persistence of neuron activity elicited by mechanical or chemical stimuli in the absence of synaptic input (which was blocked by hexamethonium or lowering the Ca^{2+} concentration of the saline). Such identification was first provided using activity-induced expression of the immediate early gene c-*fos*. A mild mechanical stimulus (puffs of N_2), applied to the mucosa when synaptic transmission had been blocked, activated submucosal Dogiel type II neurons of the small intestine. Further functional studies were performed using intracellular micropipettes to record non-synapse-dependent electrical activity evoked in myenteric Dogiel type II neurons of the small intestine by physiological stimuli. Brief bursts of action potentials were induced when the mucosal endings of the myenteric Dogiel type II neurons were stimulated by acetate. In these neurons, ongoing firing of action potentials was evoked by circumferentially stretching nonparalyzed preparations. The colonic myenteric filamentous neurons were also activated by circumferential stretching that induced an ongoing firing of action potentials in paralyzed preparations.

A second criterion was to demonstrate that action potentials are not generated at the level of the soma but in distal processes. This was demonstrated by recording proximal process potentials (PPPs, also referred to as electrotonic potentials). PPPs are recorded when action potentials are initiated in a process, and conducted to the cell body, but do not invade the cell body. Thus, a PPP in response to a mechanical or chemical stimulus indicates that the terminal of the process was a 'sensory' receptor (directly or indirectly) for the stimulus. PPPs were recorded from ileum myenteric Dogiel type II neurons when 5-hydroxytryptamine (5-HT) was applied on the mucosal endings of these neurons. 5-HT, likely to be released by enterochromafin cells activated by mechanical or chemical stimuli, is a possible intermediate in the sensory transduction process. PPPs were also recorded from ileum myenteric Dogiel type II neurons when actively contracting preparations were stretched circumferentially. They were also recorded from colonic filamentous neurons in paralyzed preparations stretched circumferentially. The fact that action potentials can be generated at the level of the mucosal processes of Dogiel type II neurons in the ileum was confirmed by collision experiments in which the soma and the mucosa were stimulated sequentially.

The initial change in membrane potential of a receptor when it is stimulated, the receptor potential, is a local and nonpropagated event that decreases in amplitude with increasing distance of the recording site from the receptor. For this reason, it cannot be recorded when it is generated far from the cell body. However, in one case such events could be recorded from myenteric Dogiel type II neurons in the small intestine. This was done in paralyzed ileum preparations by focal deformation of the neuronal processes within ganglia in which recordings were made. Depolarizing potentials that could reach the threshold for generating action potentials were recorded.

Mediators of Transduction of Physiological Stimuli

The endings of both intrinsic and extrinsic primary afferent neurons are in the lamina propria, on the opposite side of the mucosal epithelium exposed to chemicals in the lumen. Thus, to signal to the afferent nerve endings, the luminal chemical must either cross the epithelium or cause a chemical messenger to be released, most likely from mucosal endocrine cells. Two mediators have been identified, 5-HT and ATP, both of which can be released from the stimulated mucosa. There are many other products of mucosal endocrine cells that may also have roles.

Additional Functions of Dogiel Type II and Filamentous Neurons

Dogiel type II neurons, like many neurons (e.g., motor (efferent) neurons to skeletal muscle) that, through their collaterals, can act as interneurons, have dual functions. Like some spinal primary afferent neurons that have additional motor effects through transmitter release from their peripheral endings, Dogiel type II neurons probably have motor effects when they release transmitter onto the mucosal epithelium. In addition, it is remarkable that the somas of these neurons receive slow excitatory postsynaptic inputs, and in this context they can be considered to be interneurons.

Filamentous neurons are classically described as being ascending or descending interneurons. Which type of descending interneurons are the mechanosensitive filamentous neurons remains to be established.

Enteric primary afferent neurons also act as nociceptors, whose activation by noxious stimuli triggers protective responses. In the small intestine and colon, protective responses are initiated by irritants that are included in enemas, by bacterial products that cause diarrhea, and by parasitic infestations that induce expulsion of the parasites.

Enteric Primary Afferents and Integrative Functions

The enteric primary afferent neurons detect several aspects of the physiological condition of the intestine, including wall tension (representing the bulk of material in the lumen and the contractile state of the intestine), mechanical forces on the mucosa, and the chemical nature of the luminal contents. This information is integrated (although the details of how the integration is accomplished are unknown) to determine the output of the ENS, which includes mixing and propulsive activity of the musculature, secretion of water and electrolytes, and adjustment of mucosal blood flow. These local enteric controls are in turn integrated with signals from other gut regions and from the central nervous system (CNS).

The fact that the enteric neurons that have been demonstrated to function as primary afferent neurons (the Dogiel type II neurons and the filamentous neurons) are also both interneurons is striking. The Dogiel type II neurons connect with each other in order to communicate circumferentially, whereas the filamentous neurons propagate the messages distally (oral to anal). As stated previously, the ENS contains reflex arcs with no topographically individualized integrative center. We can speculate that this particular condition predestines the interneurons to fulfill the primary afferent function. It is possible that specific 'sensory' signals have to be driven circumferentially or distally in order to produce coordinated reflexes, which would be performed in an 'economic' way if the interneurons transduce the mechanical stimuli.

Terminology: 'Primary Afferent Neuron' and 'Sensory Neuron'

It is necessary to conceptually distinguish between the primary afferent innervation of tissues and organs and their sensory innervation: The activation of visceral receptors (e.g., stretch receptors in the lung and osmoreceptors in the liver) evokes no sensation, and therefore the term primary afferent is most appropriate to designate the neurons that carry this information. On the other hand, some neurons innervating the viscera do give rise to sensation, such as pain and warmth, and these are properly called sensory neurons. The important difference between visceral primary afferent neurons in general and the subset that mediate conscious sensation of the state of the viscera extends to the primary afferent neurons that reside within the intestine.

Ionic Basis of the Excitability of the Enteric Primary Afferent Neurons

The electrophysiology of the Dogiel type II neurons has been studied in detail in the guinea pig small intestine. As yet, comparable investigations of the filamentous neurons have not been undertaken. The Dogiel type II neurons of the small intestine exhibit a suite of channels through which their excitability and patterns of firing are controlled. The patterns of firing and the excitability influence the nature (e.g., propulsion or mixing) and intensity of reflexes. Because of their critical position in the circuits (being the first neurons of enteric reflex pathways), the ion channels of enteric primary afferent neurons are potential targets for therapeutic drugs. The distinctive features of the electrophysiology of Dogiel type II neurons are a large action potential with a hump on the falling phase, a large and prolonged after-hyperpolarizing potential (the slow AHP) that can last 4 to approximately 20 s, a low-input resistance, and a prominent hyperpolarization-activated cation current.

Two inward currents underlie the action potential in the soma, a tetrodotoxin (TTX)-sensitive Na^+ current (I_{NaV}) and a Ca^{2+} current (I_{CaV}). A TTX-resistant Na^+ current (TTX-R I_{NaV}), carried by $Na_v1.9$ channels, also occurs in Dogiel type II neurons, but there is no evidence that this contributes in any significant way to the action potential. I_{CaV} during the action potential is carried by N channels with a small contribution of R and P/Q-type channels.

Under conditions in which background synaptic transmission is suppressed, the Dogiel type II neurons exhibit the slow AHP that identifies them as the so-called AH neurons, but when they are acted upon by neurotransmitters or hormones, the slow AHP can be suppressed. The AHP current (I_{AHP}) is also active at rest. This current is blocked by charybdotoxin and clotrimazole, both of which depolarize the neurons. When AH/Dogiel type II neurons are in a state of low excitability, they fire only one to three action potentials to a 500 ms intracellular depolarizing pulse and they have a resting membrane potential of approximately −60 to −65 mV. Some contribution to the

background conductance is made by the hyperpolarization-activated cation current (I_h) and Cl^- currents. AH/Dogiel type II neurons also have an A-type K^+ current (I_A) that may have a low level of activation at rest.

An early AHP is continuous with the falling phase of the action potential and lasts approximately 50–100 ms. The currents that cause this AHP include a contribution from large conductance potassium channels (BK channels). This early AHP is followed by a depolarization that precedes the slow AHP and is due to a Ca^{2+}-activated depolarizing cation current.

The slow AHP is the result of two opposite currents: the slow AHP current itself (I_{AHP}) and the I_h current that generates a sustained depolarization and that is increased by the I_{AHP}-induced hyperpolarization. I_{AHP} is carried by IK channels whose opening probability is reduced by phosphorylation by protein kinase A (PKA) or protein kinase C (PKC). Consistent with this, the PKC stimulant, phorbol dibutyrate (PDBu), causes excitability increases, membrane depolarization, and increases input resistance. The IK channels are activated by dephosphorylation, particularly via calcineurin.

Synaptically Mediated Changes in Excitability

As previously indicated, AH/Dogiel type II neurons receive slow synaptic inputs that have an important influence on their excitability and pattern of firing. Synaptic inputs arise from other AH/Dogiel type II neurons, from serotoninergic descending interneurons, and from neurons that are still not identified.

In AH/Dogiel type II neurons, slow excitatory postsynaptic potentials (EPSPs), which can be elicited by stimulation of the interganglionic connectives at 10–20 Hz for 1s, are characterized by a depolarization of membrane potential and a transient increase in somatic excitability, accompanied by a reduction of the slow AHP. The effects commonly peak in a few seconds, last for several minutes, and are primarily due to a reduction in resting K^+ conductance, including inhibition of I_{AHP}. This is reported to be combined in some neurons with activation of a Cl^- conductance. The change in the slow AHP is not caused by reduced Ca^{2+} entry. One possible intermediate in causing this change is the activation of protein kinases and subsequent inactivation of the IK channels, as described previously.

Slow EPSPs induced in AH/Dogiel type II neurons by stimulating circumferential pathways (which preferentially stimulates the synaptic inputs arising from other AH/Dogiel type II neurons) are mimicked by neurokinin-1 receptor (NK_1R) and neurokinin-3 receptor (NK_3R) agonists. The activation of each receptor triggers two different types of slow EPSPs, which can be discriminated by the fact that the slow EPSPs mediated by NK_1R have significantly shorter latencies than those due to activation of NK_3R. NK_3R appears to be the predominant mediator of the slow EPSPs evoked by stimulation of circumferential inputs.

Slow EPSPs are also induced in AH/Dogiel type II neurons when the descending pathways, included serotonergic pathways, are activated. These slow EPSPs, with longer time to peak and duration than the neurokinin-mediated slow EPSPs, are mediated via receptors that have the properties of 5-HT7 receptors (they are blocked by SB 269970); 5-HT1P-mediated slow EPSPs have also been described. The 5-HT7 receptor has an impressive similarity with the 5-HT1P receptor, a G-protein-coupled receptor that acts through G_o, PKC, and finally accumulation of cAMP and activation of PKA. Whether 5-HT7 and 5-HT1P are the same entity remains to be established.

Other potential enteric neurotransmitters also cause slow excitation of enteric neurons. These include acetylcholine, acting via muscarinic receptors; cholecystokinin; gastrin-releasing peptide; pituitary adenylyl cyclase-activating peptide; and vasoactive intestinal peptide.

Another synaptic event, more prolonged than slow EPSPs, is also observed in AH/Dogiel type II neurons. This synaptic event, called sustained slow postsynaptic excitation (SSPE), outlasts nerve stimulation by many minutes, and successive SSPEs show substantial facilitation. The increased excitation during a facilitated SSPE can be maintained after stimulation for as long as 4 h.

The SSPE is induced by repeated, low-frequency (0.5–2 Hz) trains of stimulation of synaptic inputs. It involves increased somatic excitability that is facilitated by successive stimuli. During stimulation, the soma excitability of the AH/Dogiel type II neurons slowly increases, they depolarize, and their input resistance increases markedly, often by more than twofold. This magnitude of increase, accompanied by depolarization, implies that K^+ currents are inhibited. During the SSPE, the slow AHP is reduced in amplitude and duration and can eventually be blocked. With sufficient depolarization of the neurons, invasion by antidromic action potentials is suppressed. Spontaneous action potentials are rare and the occurrence of fast EPSPs is not reported during the heightened excitability caused by the SSPE. The suppression of the slow AHP results from IK channels being targeted by phosphorylating enzymes during the SSPE. Consistent with this, the PKC stimulant PDBu suppresses the slow AHP in a manner identical to that seen during the SSPE. In addition, PDBu causes

somatic excitability increases, membrane depolarization, and increased input resistance in a concentration-dependent manner, mimicking the SSPE. In a converging way, PKC inhibitors Ro31–8220 and calphostin C prevent the SSPE. On the contrary, the SSPE is maintained in the presence of the PKA inhibitor H89.

An obvious candidate neurotransmitter for the SSPE could be a tachykinin. However, this is unlikely because the SSPE persists after block of NK_1 and NK_3 tachykinin receptors on enteric neurons.

Influence of Inflammation on the Excitability of Enteric Primary Afferent Neurons

Inflammation of the small intestine or colon causes marked changes in motility and secretion. Effects can long outlast the period of inflammation and cause ongoing pathology (e.g., irritable bowel syndrome). Because of these observations, there has been considerable interest in the reactions of IPANs to inflammation.

Synaptic changes have been described in a neuron population that should include the filamentous neurons; however, this neuron type was not discriminated from the rest of the population. On the contrary, the changes that affect the AH/Dogiel type II neurons have been specifically analyzed following inflammation. Infection with *Trichinella spiralis* in the jejunum and administration of trinitrobenzene sulfonic acid (TNBS) into the lumen of the distal colon both increase the excitability of the AH/Dogiel type II neurons. In these models, in addition to inhibition of the I_{AHP}, different ionic currents were affected. In the *T. spiralis* infection model, the increase of excitability was reversibly suppressed by H_2 histamine receptor blockers and might thus reflect an endogenous release of histamine. Activation of H_2 histamine receptors probably suppresses the I_A current, which not only contributes to the resting potential but also modulates the firing frequency of neurons. Histamine also activates a Cl^- conductance via H_2 receptors. Thus, I_A blockade and Cl^- conductance activation could explain the firing increase, the membrane depolarization, and the increase in input resistance described in this model. The abolition of the slow AHP was accompanied by a decrease in the action potential duration, indicating a decrease of Ca^{2+} entry that can explain the reduction of the amplitude and the duration of the slow AHP. All these changes were accompanied by the presence of fast EPSPs that routinely reached suprathreshold depolarization and caused action potential discharge. In the TNBS model, the increased neuronal excitability and the reduction in the slow AHP was proposed to be principally due to an increased activation of I_h rather than alterations in gK_{Ca}. Action potential shape, and therefore Ca^{2+} entry into the cell, appeared to be unaffected. In this model, the changes of excitability were shown to be mediated by cyclooxygenase-2 (COX-2) because they were abolished in TNBS-treated animals in which COX-2 was inhibited by colony-forming units.

The excitability of these neurons is increased by the inflammatory mediators histamine, prostaglandins, leukotrienes, and interleukins and by activation of proteinase activated receptors and 5-HT. Each of these inhibits the slow AHP current, I_{AHP}, thus causing an increase in somatic excitability, and in most cases they depolarize the membrane potential and increase Rin. The mechanisms leading to a decrease of I_{AHP} differ according to the mediator and also differ from the actions of the SSPE in some respects. The inflammatory mediators may also act on other targets to affect excitability of AH/Dogiel type II neurons.

Are There IPANS in the Esophagus and Stomach?

There is a lack of knowledge about the existence and possible identities of IPANs in the esophagus and stomach. In these regions, many of the controlling reflexes pass through the CNS, notably through vagal control centers in the medulla oblongata. Efforts to identify AH/Dogiel type II neurons by their morphology or electrophysiological properties have led to the conclusion that this type of neuron is rare or absent from the esophagus, is not found in the proximal stomach, and is rare in the gastric antrum. Whether another type of neuron plays the role of IPANs, or whether intrinsic afferent neurons are indeed rare in these regions, has not been resolved.

Entorhinal Cortex

A Solodkin and G W Van Hoesen, University of Iowa, Iowa City, IA, USA

© 2009 Published by Elsevier Ltd.

This article is reproduced from the previous edition © 2004, Elsevier B.V.

The term entorhinal cortex (Brodmann's area 28) is derived from the fact that it lies 'within' the rhinal sulcus, and this is the case in all species including the great apes. However, in humans the rhinal sulcus is often small and anteriorly placed and it is the collateral sulcus instead, that aids in delimiting this cortex laterally. In carnivores and rodents it constitutes the largest part of the piriform lobe, whereas in nonhuman primates it forms the anterior portion of the parahippocampal gyrus. In humans, the anterior and medial portion of the parahippocampal gyrus is called the gyrus ambiens, but this is merely a bulge of entorhinal cortex that sits in the tentorial aperture medial to the point where the free edge of the tentorium cerebelli cuts or grooves the parahippocampal surface (Figure 1(a)).

The entorhinal cortex is a type of periallocortical cortex and is atypical when compared to isocortical areas or for that matter, to any other cortex. For example, the size of the cells composing its layers appears involuted compared to isocortical areas. In area 28, the largest cells are located superficially, whereas in the isocortex they are found more deeply. Additionally, it resembles a hybrid, where the superficial layers are related more to the proisocortices, and the deeper layers to the allocortices. Additionally, an acellular layer IV, or lamina dissecans, formed by tangentially oriented myelinated fibers is readily apparent.

There is variability among species in entorhinal cytoarchitecture, and this seems most apparent in layers II and III. In the rat, the neurons found in these layers have a horizontal or laminar organization, forming a continuous and somewhat homogeneous band at variable distances from the pia. In monkeys, however, these cells are sometimes clumped together forming islands of cells. This discrete organization reaches its maximal expression in the human brain producing clear anatomical modularity within the superficial layers of the entorhinal cortex. This is highly suggestive of a vertical pattern of organization coexisting with the more conventional horizontal multilayered one. Entorhinal modules in the human brain are suggested even in the level of the gross specimen because this cortex can be delimited by the presence of superficial bumps easily detected with the unaided eye (Figure 1(a)). Near the turn of the century the Swedish anatomist Retzius named these verrucae to call attention to their resemblance to skin or epidermal diseases of viral origin. Thus, the entorhinal cortex in humans appears formed by a mosaic of components whose most conspicuous elements are the cell islands of layer II and the myelinated fibers associated with them (Figure 1(b)). Additionally, the distribution and disposition of local circuit neurons as well as cholinergic and dopaminergic afferent fibers, cytochrome oxidase patches and the distribution of its vasculature, highlights and supports the notion of modularity (Figure 1(c)).

In terms of connections, the entorhinal cortex is remarkable since it can be conceptualized as an interface between the hippocampal formation on the one hand and a large variety of association and limbic cortices on the other. In fact, the entorhinal cortex, via the perforant pathway (which originates in cells of layers II and III), is the main source of extrinsic afferent input to the hippocampal formation, targeting the ammonic fields CA1, CA2, and CA3 in addition to the subiculum and dentate gyrus. Nonhippocampal efferents of the entorhinal cortex project to neighboring areas such as perirhinal cortex (Brodmann's area 35), posterior parahippocampal gyrus (areas TH and TF) and inferior and polar temporal cortices. Other efferents from the entorhinal cortex are widely distributed to several association and limbic cortices such as prefrontal and orbitofrontal (areas 9, 25, and 46), retrosplenial (area 29), cingulate (area 24) and posterior parietal cortices (area 7) as well as superior temporal gyrus (area 22). These are of great interest since they arise from the deep layers of the entorhinal cortex, from neurons known to receive powerful hippocampal output.

Afferents to the entorhinal cortex arise from a large variety of cortical and subcortical areas including adjoining areas such as TF and TH in the posterior parahippocampal gyrus, subiculum, perirhinal cortex (area 35), the temporal polar cortex (area 38), periamygdaloid cortex, and the superior temporal gyrus. Other areas sending afferent fibers to the entorhinal cortex are the prefrontal and orbitofrontal cortices (areas 25 and 32); limbic cortices send important afferent input from cingulate (areas 24 and 23), retrosplenial (area 29), piriform (in rodents), and agranular insular cortices. Among the subcortical areas sending afferent projections to the entorhinal cortex are the septal nuclei, anterior and medial thalamus, raphe nuclei, amygdala, locus coeruleus, basal nucleus of Meynert, and anterior olfactory nucleus.

Figure 1 (a) Gross view of the ventral medial temporal lobe in the normal human brain after dissection of the brain stem and cerebellum. Note the position of the parahippocampal gyrus (pg) medial to the collateral sulcus (cs) and posterior to the temporal pole (tp). The anterior part of the parahippocampal gyrus contains the entorhinal cortex (ec) which also covers the gyrus ambiens (ga). Note the corrugated appearance of the entorhinal cortex created by the verrucae or wartlike bumps that demarcate its extent. (b) Cross-section through the entorhinal cortex of the normal human brain stained with the Gallyas fiber stain. The modular appearance of the fiber distribution outlines the verrucae. (c) Parvalbumin immunostaining for this calcium-binding protein in the entorhinal cortex of the normal human brain. The sharply defined patches of neuropil and cellular staining in the superficial layers are coexistent with the verrucae and layer II islands of the entorhinal cortex. The more dense laminar immunostaining for parvalbumin in deeper layers corresponds to layer III. am, amygdala; hp, hippocampus; ot, olfactory tract.

Figure 2 (a) Thioflavine-S fluorochrome staining for neuritic plaques, diffuse plaques, and neurofibrillary tangles in the entorhinal cortex in Alzheimer's disease. Note the islands of neurofibrillary tangles in the superficial layers of the entorhinal cortex and their coincidence with the verrucae as seen along the pial surface (marked by the arrow). The large circular images in the deeper layers of entorhinal cortex are largely neuritic and diffuse plaques. (b) Alz-50 immunostaining for the abnormally phosphorylated tau protein A68 in the entorhinal cortex in Alzheimer's disease. The modules of immunostaining in the superficial layers correspond to the islands of neurons that form layer II and the distribution of their dendrites.

In summary, the entorhinal cortex receives direct inputs from a large number of association and limbic cortices, and in turn, sends widespread neural systems to other parts of the cortex. It is in a unique position to provide input to the hippocampus and then disseminate hippocampal output to other parts of the cortical mantle. Thus, it is not surprising that it is thought to play a role in memory consolidation related to all sensory modalities. The close and two-way relationship established between the entorhinal cortex and hippocampal formation on the one hand and the entorhinal cortex and association and limbic cortices on the other makes its role in memory processing highly plausible.

Clinical and behavioral observations support the above. For example, the entorhinal cortex in humans is the most affected cortical area in Alzheimer's

disease. In this disorder, pathology targets the entorhinal cortex early in the illness and destroys at least three of its five cell layers if the duration of the illness is long. The modules are always targeted (**Figures 2(a) and 2(b)**). Due to the modular organization of this cortex, these changes in all likelihood do not have to be complete to disrupt the functions modules are designed to subserve.

Entrainment of Circadian Rhythms by Light

A M Rosenwasser, University of Maine, Orono, ME, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In general, the endogenous, inherited period of the circadian pacemaker is close to – but not exactly equal to – 24 h. Indeed, the term *circadian* ('approximately daily') was coined to emphasize this fundamental feature of biological timing. Thus, endogenous circadian pacemakers depend upon signals derived from exogenous daily cycles in order to synchronize, or entrain, to the exact 24 h periodicity of the environment. It is only through this entrainment process that circadian pacemakers acquire their adaptive utility as biological 'clocks,' responsible for coordinating behavior and physiology with local time. While several periodic environmental factors may contribute to or modulate the entrainment of the circadian pacemaker, the most prominent, widespread, and fundamental source of circadian entrainment is the daily alternation of environmental light and darkness. In nature, light intensity and spectral composition change in a complex manner as a function of time of day, and depend not only on solar illumination but also on lunar phase, starlight, latitude, and local climatic conditions. Further, actual exposure to available environmental light depends dramatically on an animal's ecological niche and lifestyle (e.g., time spent in burrows, caves, or deep in the ocean). Nevertheless, simple square-wave ('on–off') light–dark cycles have proved to exert effective circadian entrainment in the laboratory, and much has been learned about the formal, physiological, and molecular bases of light entrainment from studies conducted under such simplified environmental conditions.

Formal Analysis of Light Entrainment

Parametric and Nonparametric Entrainment

Brief light pulses can evoke rapid and permanent changes in the phase of the free-running circadian pacemaker. The response of the circadian pacemaker to a light pulse is phase dependent, such that photic stimulation near 'subjective, dusk' or early in the subjective night results in phase delays (i.e., shifts to relatively later timing in subsequent cycles), while photic stimulation late in the subjective night or near dawn results in phase advances (i.e., shifts to relatively earlier timing in subsequent cycles, see Figure 1). In contrast, the circadian pacemaker is relatively refractory to photic stimulation during the circadian daytime, indicating that the critical phases of light exposure for entrainment occur near dusk and dawn. The function relating the magnitude and direction of circadian phase shifting to the phase of stimulation for any given stimulus is referred to as the 'phase–response curve' (PRC) for that stimulus (see Figure 2). Extensive research has shown that the general shape of the light-pulse PRC, as just described, is seen consistently across species, and indeed, across orders, and in both nocturnal and diurnal life-forms. Thus, while the seminal vertebrate PRC experiments were done mainly in nocturnal rodents, more recent analyses have shown that the 'typical' diurnal mammalian PRC very closely resembles that of nocturnal mammals in both amplitude and waveform.

Colin Pittendrigh systematized these observations in the highly influential and extensively validated nonparametric theory of light entrainment, which proposed that phasic responses to brief light exposures occurring at specific critical circadian phases (i.e., near dusk and dawn) are responsible for entrainment of the circadian pacemaker, even under more natural light–dark schedules with 'complete' photoperiods (see Figure 3). This model may be contrasted conceptually with the parametric entrainment theory, associated with the work of Jurgen Aschoff, and based on extensive observations indicating that the period of a free-running circadian pacemaker changes systematically (either lengthening or shortening, depending on the species) as a function of continuous light intensity. Thus, parametric entrainment theory proposes that the tonic effects of temporally extended light exposure alter the underlying period of the circadian pacemaker, causing it to match the periodicity of the entraining environment.

Although nonparametric entrainment has proved to be a powerful descriptive and predictive model, recent analyses indicate that both phasic, nonparametric effects and tonic, parametric effects may contribute to circadian entrainment, especially under field conditions, or during exposure to more realistic laboratory simulations of the natural light–dark cycle. Thus, some species appear to entrain successfully in the natural environment without ever being exposed to abrupt, dawn- and dusk-related light transitions, while in laboratory experiments, both brief and extended light exposures result in long-term changes in free-running period as measured in continuous darkness (i.e., 'after-effects' of prior entrainment). Further, quantitative simulations incorporating both nonparametric (phase-shifting) and parametric (period-adjusting) effects

Figure 1 Examples of phase shifting of free-running circadian activity rhythms by brief light pulses. Left panel: Circadian rhythm of wheel running recorded from a hamster in constant darkness. On the day indicated by the arrow, the animal was exposed to light for 30 min (open circle) beginning at circadian time 20. (By convention, the onset of activity in a nocturnal animal is defined as circadian time 12; thus, circadian time 20 is 8 circadian h after activity onset; where 1 circadian hour = circadian period/24.) On circadian cycles following the light pulse, activity onset occurs earlier than would be predicted by extrapolating from the phase of the preceding free-running rhythm. After several days of 'transient' cycles, as is typical for advancing phase shifts, a stable phase advance of several hours is revealed. Right panel: In this experiment, a similar light pulse was presented at circadian time 14, resulting in a phase delay shift of approximately 1 h, which was complete within one circadian cycle. Phase resetting without transients is typical of light-induced phase delays. Reproduced from Mistlberger RE and Rusak B (2005) Circadian rhythms in mammals: Formal properties and environmental influences. In: Kryger MH, Roth T, and Dement WC (eds.) *Principles and Practice of Sleep Medicine*, 4th edn., pp. 1–30. Philadelphia: Elsevier-Saunders, with permission from Elsevier.

result in more stable entrainment than do models based solely on nonparametric effects.

Toward Naturalistic Light–Dark Cycles

The importance of parametric effects for natural entrainment is also highlighted by laboratory experiments utilizing simulated gradual twilight transitions, rather than the more typical square-wave light–dark cycles. Acute exposure to brief twilight-like light pulses and brief square-wave light pulses yields identical phase shifts when the two pulse types are equated for photon numbers, indicating that the nonparametric effects of light pulses are independent of pulse 'shape.' In contrast, inclusion of simulated twilight transitions during steady-state entrainment to extended photoperiods alters dramatically the pattern of circadian entrainment relative to standard square-wave light–dark cycles. In addition to altering the timing of daily activity onsets and offsets, exposure to twilights results in more stable and more effective entrainment, and alters the free-running period as measured during subsequent exposure to constant darkness. Together, these studies strongly suggest that parametric effects of twilight exposure on the underlying free-running period increase the entraining efficacy of a light–dark cycle.

Figure 2 Phase–response curves describing the phase-dependent sensitivity of the hamster circadian pacemaker to photic (top) and nonphotic (bottom) stimulation. (Top) As seen in Figure 1, brief (here, 15 min) light pulses result in phase delays when presented near subjective dusk or early in the subjective night, while similar light pulses evoke phase advances when presented late in the subjective night. While the exact timing and relative amplitude of the delay and advance zones of the phase–response curve differ across species, these general features characterize all known photic phase–response curves in both nocturnal and diurnal animals. (Bottom) Phase advances during mid-subjective day and small phase delays during late subjective night are the result of 2 h of exposure of free-running hamsters to a novel environment containing a running wheel. Such nonphotic phase shifting is typically seen only in animals displaying signs of behavioral arousal or activation during the novelty stimulus. Reprinted from Rosenwasser AM (2003) Neurobiology of the mammalian circadian system: Oscillators, pacemakers, and pathways. In: Fluharty SJ and Grill HJ (eds.) *Progress in Psychobiology and Physiological Psychology*, vol. 18, pp. 1–38. San Diego: Elsevier Academic Press, with permission from Elsevier. Original data replotted from (top) Daan S and Pittendrigh CS (1976) A functional analysis of circadian pacemakers in nocturnal rodents. II. The variability of phase response curves. *Journal of Comparative Physiology A* 106: 253–256 and (bottom) Mrosovsky N, Salmon PA, Menaker M, et al. (1992) Non-photic phase shifting in hamster clock mutants. *Journal of Biological Rhythms* 7: 35–41.

Figure 3 Light entrainment of a free-running circadian pacemaker according to the nonparametric model. In these panels, the phase of the circadian pacemaker is represented by its phase–response curve (PRC) and by the expected timing of locomotor activity. The examples shown in this figure assume a circadian pacemaker of a nocturnal organism that free-runs in constant darkness with a free-running period (FRP) of 21 h. (a) Free-running of PRC and overt rhythm with a period of 21 h. Note that the PRC and activity rhythm recur earlier each day relative to the 24 h objective day. (b) 'One-pulse' entrainment. A brief light pulse is administered to the same organism once every 24 h. During stable entrainment, the light pulse will recur at a circadian phase that results in a daily phase delay of 3 h (in this case, at approximately circadian time 13). (c) Two-pulse entrainment by a 'skeleton' photoperiod (PPs 12:12) in which a brief light pulse is administered once every 12 h. During stable entrainment, the light pulses will occur at circadian phases such that the net steady-state phase (i.e., advance plus delay) will result in a daily 3 h delay (in this case, the net 3 h delay is achieved by a daily 1 h advance combined with a daily 4 h delay). (d) Entrainment to a complete 12 h light–dark photoperiod (LD 12:12). In this case, the dawn transition results in a daily 1 h phase advance, while the dusk transition results in a daily 4 h delay, similar to the effects of the skeleton photoperiod shown in panel (c). According to this model, light occurring between dawn and dusk (i.e., in the daytime) is largely irrelevant for circadian entrainment. From Johnson CH, Elliott JA, and Foster R (2003) Entrainment of circadian programs. *Chronobiology International* 20: 741–774.

Another difference between typical laboratory light–dark cycles and natural light–dark cycles is that the natural nighttime environment includes variable amounts of starlight and moonlight, while the night phase of laboratory light–dark cycles is typically characterized by total darkness. While field studies have frequently concluded that animal activity patterns are altered by such very dim nocturnal illumination, the relevance of these studies for entrainment of the circadian pacemaker is uncertain. Recent laboratory studies have begun to compare circadian entrainment under square-wave light–dark cycles, with or without very dim nocturnal illumination approximating that of starlight or dim moonlight. Even at intensities that fail to evoke circadian phase shifting, dim nocturnal illumination, like twilight transitions, appears to increase the effectiveness of the light–dark cycle, possibly by increasing the pacemaker's sensitivity to daytime light intensities. The possible contribution of parametric modification of the underlying period of the circadian pacemaker to these effects has not been tested directly.

Physiology of Light Entrainment

Circadian Photoreception

In invertebrates and in nonmammalian vertebrates, both ocular and extraocular photoreceptors typically contribute to circadian entrainment. Vertebrate extraocular photoreceptors include both light-sensitive pinealocytes, as well as deep-brain or encephalic photoreceptors. While a number of novel and retinal photopigments have been identified within the vertebrate brain, the functional and anatomical couplings of encephalic photoreceptors to the circadian pacemaker have not been described in any vertebrate model system. In contrast, mammalian circadian photoreception appears to be entirely dependent on retinal mechanisms. Nevertheless, the photoreceptors and the central neural pathways mediating mammalian circadian entrainment comprise a distinct biological system, separate from those mediating visuoperceptual functions.

Studies with mice bearing genetic mutations leading to the progressive loss of nearly all classical rod and cone photoreceptors showed that some strains of retinally degenerate mice continue to display normal circadian photosensitivity. Eventually, similar results were obtained in genetically engineered mice completely lacking rods and cones throughout development, demonstrating unequivocally that nonclassical retinal photoreceptors are sufficient to mediate circadian entrainment. Physiological and biochemical experiments identified a novel retinal photopigment, melanopsin, and showed that this protein was specifically expressed within the small and scattered subpopulation of retinal ganglion cells giving rise to the retinohypothalamic tract (RHT), thus conferring intrinsic photosensitivity on these neurons. The term retinohypothalamic tract has been used traditionally to refer to the near-bilaterally symmetrical retinal projection to the hypothalamic suprachiasmatic nucleus (SCN), site of the primary vertebrate circadian pacemaker. Nevertheless, melanopsin-positive retinal ganglion cells also project to other diencephalic and mesencephalic targets, including other identified components of the circadian timing system (e.g., the intergeniculate leaflet), as well as neural structures mediating oculomotor reflexes and other 'nonvisual' (some authors prefer 'non-image-forming') retinal functions.

While melanopsin-positive photosensitive retinal ganglion cells are sufficient to mediate circadian light entrainment, genetic deletion of melanopsin impairs, but does not fully abolish, photic control of the circadian pacemaker. Indeed, light entrainment is abolished only when both melanopsin and classical photoreceptors are deleted, indicating a degree of redundancy in circadian photoreception. Thus, very recent studies show that photosensitive retinal ganglion cells can also respond to light via rod- and cone-mediated neural signals, and that melanopsin expression levels depend on the integrity of the classical photoreceptors. Further, genetic deletion of RPE65, a protein required for the maintenance of rod and cone photosensitivity, results in much more dramatic disruption of circadian entrainment than does elimination of the classical photoreceptors. Together, these findings indicate that classical retinal photoreceptors, while not necessary, do normally contribute significantly to circadian entrainment.

Entrainment Pathways, Neurotransmitters, and Intracellular Signaling

As mentioned earlier, the RHT projects to the SCN, intergeniculate leaflet (IGL), and other 'nonvisual' brain regions. The terminals of this projection release glutamate as the primary neurotransmitter, as well as specific peptide cotransmitters, including pituitary adenylyl cyclase-activating peptide (PACAP) and possibly substance P. Indeed, double-labeling studies of the retina demonstrate that melanopsin and PACAP provide essentially redundant markers for RHT cell bodies. Light-evoked glutamate release from RHT terminals acts through both *N*-methyl-D-aspartate (NMDA) and non-NMDA glutamate receptors to activate a number of second-messenger systems and downstream signaling pathways, leading eventually to the transcriptional changes underlying

Figure 4 Cellular and molecular bases of light entrainment. Light is transduced into a neural signal by melanopsin-positive intrinsically photoreceptive ganglion cells (IPGCs) in the retina and conveyed to the suprachiasmatic nucleus (SCN) core along the retinohypothalamic tract (RHT), resulting in the release of the neurotransmitter glutamate and the neuromodulators pituitary adenylyl cyclase-activating peptide (PACAP) and substance P (SP) onto retinorecipient cells in the SCN core. Glutamate activates *N*-methyl-D-aspartate (NMDA) receptors, leading to calcium influx and activation of several known calcium-dependent signaling pathways (e.g., mitogen-activated protein kinase; MAPK), resulting in phosphorylation of cyclic AMP (cAMP) response element-binding protein (CREB). Activated CREB binds to the calcium/cAMP response element (CRE) in the promoter regions of both *Per1* and *Per2*, thus activating their transcription. Neurons in the photoresponsive SCN core then communicate with the spontaneously rhythmic SCN shell (and with SCN efferent targets) using a variety of neurotransmitters, including vasoactive intestinal polypeptide (VIP), gastrin-releasing peptide (GRP), SP, and γ-aminobutyric acid (GABA). Cells in the rhythmic SCN shell contain molecular clocks driven by a set of interlocking positive and negative autoregulatory transcription–translation feedback loops (e.g., *Per*, *Cry*, *Rev-Erba*, *BMAL1*). SCN shell neurons communicate with SCN efferent targets using vasopressin (VP) and GABA as neurotransmitters. Additionally, the SCN communicates with some target sites using a diffusible signal. Reprinted from Antle MC and Silver R (2005) Orchestrating time: Arrangements of the brain circadian clock. *Trends in Neurosciences* 28: 145–151, with permission from Elsevier.

phase shifting of the circadian pacemaker (see Figure 4). Analysis of these mechanisms is complicated, however, by the fact that the pacemaker autoregulates its own entrainment by establishing time-limited windows of sensitivity to environmental entrainment stimuli and to activation of neurotransmitter receptors and second-messenger systems. For example, the circadian pacemaker is sensitive to light-induced phase shifting mainly during the subjective night, as described by the photic PRC. Thus, light entrainment is based on a circadian rhythm in the photic sensitivity of the pacemaker, and like other circadian rhythms, rhythmic light sensitivity is controlled by mechanisms intrinsic to the pacemaker. In addition, while photic stimuli evoke similar changes in gene transcription during early and late subjective night, the signaling pathways coupling glutamate receptor activation to transcriptional activation during these two circadian time windows appear to be at least partially nonoverlapping.

Both *in vivo* and *in vitro* studies have demonstrated that light, glutamate, and/or NMDA evoke alterations in gene expression and circadian phase shifting only at night. These night-active phase-shifting stimuli appear to access the molecular clock via multiple calcium-dependent and cyclic GMP (cGMP)-dependent signaling pathways, leading to (1) phosphorylation of the transcription factor calcium and cyclic AMP response element-binding protein (CREB), (2) transcription of specific immediate-early genes (IEGs), including *c-fos*, and (3) alterations in the transcription of specific 'clock' genes such as the *period* genes (*Per1*, *Per2*), the protein products of which represent state variables encoding the oscillation phase of the circadian pacemaker. While not a primary focus of the present discussion, the circadian pacemaker can also be phase shifted and entrained by nonphotic stimuli linked to behavioral arousal and wakefulness (see Figure 2), and by agonists at specific subtypes of serotonin, γ-aminobutyric acid (GABA), and neuropeptide Y (NPY) receptors. In contrast to photic entrainment, the circadian pacemaker is sensitive to

these stimuli primarily during the subjective day, and day-active phase shifting stimuli access the molecular clock via cyclic AMP (cAMP)-dependent signaling pathways. Further, night-active and day-active phase-shifting stimuli are mutually antagonistic. Thus, while the circadian pacemaker is refractory to phase shifting by serotonin, GABA, and NPY agonists during the subjective night, these stimuli effectively block nighttime phase shifting by light and glutamate agonists, while in turn, photic stimulation during the subjective day antagonizes nonphotic phase shifting.

In addition to glutamate, RHT neurons also synthesize and co-localize the neuropeptide PACAP. Numerous studies indicate that PACAP plays a significant role in light entrainment of the circadian pacemaker, in part via modulation of glutamatergic signaling. PACAP–glutamate interactions appear to be rather complex, however, and depend on both circadian phase and PACAP levels. Early studies using the *in vitro* SCN slice preparation suggested that PACAP functions mainly as a daytime entrainment signal; despite its retinal origin, PACAP stimulation of the SCN mimicked the effects of nonphotic stimuli, producing cAMP-mediated phase advances during subjective day. While subsequent studies confirmed these observations at relatively high (micromolar) concentrations, PACAP was also shown to mimic the nighttime effects of light and glutamate on circadian phase shifting and clock gene expression at lower (nanomolar) concentrations. Further, at the higher concentrations that evoke daytime phase shifting, nighttime PACAP administration exerts complex modulation of glutamate-induced phase shifting and gene expression. Thus co-application of PACAP is reported to block glutamate-induced phase advances and *period* expression during late subjective night, but to potentiate glutamate-induced phase delays during early subjective night. Similarly, in behavioral experiments, intra-SCN PACAP mimicked – and a PACAP receptor antagonist blocked – the phase shifting effects of light during early subjective night, but PACAP was without effect during late subjective night. The role of PACAP in light entrainment has also been examined using both PACAP-deficient and PACAP receptor (PAC1)-deficient mice, but the effects of genetic deletion of the peptide and the receptor were different. Thus, PACAP-knockout mice showed decreased light-induced phase delays while PAC1-knockout mice showed increased phase delays during early subjective night. Further, while PACAP-knockout mice also showed reduced light-induced phase advances, PAC1-knockout mice actually showed abnormal light-induced phase delays during late subjective night. Finally, the PAC1-knockout mice also displayed surprising dissociation between light-induced phase shifting and gene expression, in that the potentiated early-night phase delays were accompanied by blunted light-induced *c-fos* and *period* expression.

Processing of Entrainment Signals by the SCN

The initial evidence for the anatomical heterogeneity of the SCN emerged from tract-tracing studies showing that retinal afferents to the rat SCN are generally segregated within the ventral aspect of the nucleus, especially in its more caudal aspects. Subsequently, chemoanatomical studies revealed marked regional heterogeneity in the expression and distribution of specific neuropeptides within the nucleus. Based on the distribution of retinal (and other) SCN afferents, as well as on neuropeptide expression, the rat SCN has been typically characterized as comprising two distinct regions: (1) a ventrolateral zone, defined in part by the presence of retinal terminals along with vasoactive intestinal peptide (VIP)-immunopositive and gastrin-releasing peptide (GRP)-immunopositive cells and (2) a dorsomedial zone, defined mainly by the presence of arginine–vasopressin (AVP)-positive cells. More recent studies, however, have revealed extensive species differences in the intranuclear arrangement of both afferent terminals and neuronal phenotypes, even among nocturnal rodents. In one particularly striking example, Silver and co-workers have identified a small, densely packed and centrally located cluster of calbindin (CB)-positive neurons in the hamster SCN that is not readily apparent in other species. In attempting to better accommodate such species differences, Moore has proposed an alternate view in which the SCN is composed of functionally distinct 'core' and 'shell' subnuclei, which differ across species in their exact extent and placement. Nevertheless, a two-component core and shell scheme may eventually prove insufficiently complex to account for the full range of species-related variation, or even for the functional compartmentalization of the SCN within a species. Thus, retinal, thalamic, and brain stem SCN afferents, generally described as overlapping in the ventral SCN, may exhibit somewhat different terminal fields within the SCN core, while different SCN peptides clearly display more than two distinct intranuclear distribution patterns. On the other hand, given that the SCN appears to mediate two primary circadian functions (rhythm generation and entrainment), it is appealing to hypothesize the existence of two discrete subnuclei, each associated mainly or exclusively with one of these functions.

Since retinal projections to the SCN are generally coextensive with the core subnucleus, it has frequently

been suggested that this SCN region may play a preeminent role in the photic entrainment of the circadian pacemaker (see Figure 4). Indeed, retinal afferents form direct synaptic connections with VIP-, GRP-, and CB-positive SCN core neurons. In addition, both *in vivo* and *in vitro* studies show that direct application of SCN core peptides such as VIP and GRP can mimic the cellular and phase shifting effects of light on the circadian pacemaker, but that similar effects are not seen for direct application of SCN shell peptides. Two other major SCN afferent systems converge within the SCN core to form terminal fields that overlap at least partially with the RHT: (1) a projection arising from retinorecipient neurons of the thalamic IGL, and co-localizing NPY and GABA, and (2) a projection consisting of serotonergic (and possibly nonserotonergic) axons of the midbrain raphe. Projections from the IGL to the SCN provide an indirect route for retinal signals to reach the SCN, and while disruption of this pathway fails to abolish photic entrainment of the circadian pacemaker, it does alter the effects of light on circadian period, phase, and coherence. Further, IGL lesions broadly disrupt the ability of arousal-related nonphotic cues to phase shift the circadian pacemaker, indicating that the IGL plays a major role in the integration of photic and nonphotic entrainment signals. Similarly, an important function of serotonergic raphe projections to the SCN involves arousal-dependent modulation of photic input to the circadian pacemaker, via both pre- and postsynaptic interactions with the photic signaling pathway(s).

In accord with the apparent convergence of both photic and photomodulatory signals, acute light exposure increases the expression of the immediate-early gene, *c-fos*, and of the identified clock genes, *Per1* and *Per2*, specifically within the SCN core (see Figure 4), including in VIP-, GRP-, and CB-containing cells. While some studies have also shown light-induced IEG and *period* expression in the SCN shell, such effects appear to reflect indirect signaling pathways by which photic information is relayed from light-sensitive SCN core neurons to light-insensitive SCN shell neurons. Remarkably, light evoked phase shifts of gene expression in the SCN core appear to occur almost immediately (within hours), while resynchronization of gene expression in the SCN shell tracks closely with the gradual reestablishment of a new steady-state phase at the behavioral level. Both pharmacological evidence and studies with genetically modified mice indicate that VIP and GABA signaling within the SCN are critical for conveying such signals from core to shell, and, further, for maintaining synchrony among individual SCN pacemaker neurons, probably located in both core and shell.

In contrast to the evidence supporting a preeminent role for the SCN core in processing photic entrainment signals, other studies have revealed that the spontaneous expression of cellular and molecular rhythmicity is more widespread and more robust within the SCN shell relative to the core. For example, SCN shell peptides exhibit persisting *in vivo* circadian rhythms at both mRNA and protein levels under constant darkness, while SCN core peptides do not (both core and shell peptides are consistently rhythmic under light–dark cycles). Similarly, the SCN shell displays spontaneous circadian rhythmicity in both *c-fos* and *period* gene expression while the SCN core does not. Surprisingly, however, spontaneous rhythms in normally nonrhythmic SCN core peptides can be 'unmasked' by depletion of other SCN neuromodulators, including somatostatin (generally a shell-associated peptide) and serotonin. In the SCN slice preparation, dorsal (presumably shell) SCN neurons are more likely than ventral (presumably core) SCN neurons to exhibit spontaneous circadian rhythms in firing rate, while SCN slices are more likely to display rhythmic AVP release than VIP release. It is important, however, that circadian firing rhythms may in fact be detected throughout the SCN, and that both shell and core peptides may be released rhythmically by SCN slices. Indeed, cultured SCN slices may display simultaneous circadian rhythms in both AVP and VIP release, with different free-running periods, demonstrating that both core and shell subnuclei must contain potentially autonomous oscillatory networks.

Early studies indicated that microsurgical separation of the dorsomedial (shell) and ventrolateral (core) SCN in a hypothalamic slice preparation spared electrophysiological rhythms in the ventrolateral aspect while abolishing rhythmicity in the dorsomedial aspect of the nucleus. Similarly, fetal tissue transplants appear to restore rhythmicity in SCN-lesioned arrhythmic hosts only when the transplants include surviving core-related peptides, such as VIP and/or CB. While these studies may seem to suggest that critical circadian pacemaker cells are located in the SCN core, they are probably better interpreted as confirming the necessary role for SCN core peptides in coordination and synchronization of critical pacemaker cells within the SCN core and shell. Thus, a reasonable hypothesis for photic information processing within the SCN is that retinorecipient light-entrainable cellular oscillators in the SCN core provide neural signals that are necessary for the entrainment and synchronization of light-insensitive cellular oscillators in the SCN shell. According to this view, much of the dynamic complexity of circadian light entrainment revealed

by formal analysis at the behavioral level can be accounted for by interactions among functionally distinct SCN subnuclei.

Conclusion

Analysis of the mechanisms by which photic signals entrain the circadian pacemaker has provided a rich model system in chronobiology, and more generally, in behavioral neuroscience. Classic and contemporary behavioral analyses have revealed several general quantitative principles, the most powerful of which is the phase-response curve, a complex yet predictable function that characterizes the phase-dependent responsiveness of the circadian pacemaker to light. Recently, an integrative, multidisciplinary approach incorporating physiological, pharmacological, anatomical, and molecular approaches has successfully pried open the 'black box' formalism of PRC analysis and has provided a robust biological understanding of the photic entrainment pathway. These basic scientific studies await further exploitation as applied chronobiologists develop practical interventions that may be effectively deployed in the service of public health and safety.

Introduction

As early as 1837 Valentin and Purkinje visualized the lining of the inner cavities of the brain, the brain ventricle system, by the observation of striking cilia on its surface. This lining was called 'ependyma' (Greek meaning 'upon garment'), and its constituent cells are termed ependymal cells. The ependymal cells belong to the family of neuroglial cells (glia) and are thus also called ependymoglial cells or ependymal glia. After its early discovery, it required many decades of research to elucidate this cellular layer(s) as an extremely important component of the developing and mature brain.

During ontogenetic development, the ventricular lining is composed of proliferating cells termed the 'matrix zone,' which generates all types of neuroectodermal brain cells, including neurons and their 'local successors,' the ependymoglial cells. In the adult central nervous system (CNS), the ependymoglial cells contribute to the secretion of the cerebrospinal fluid (CSF) and are an essential component of an important biological barrier system segregating different compartments such as blood, CSF, and CNS interstitial space (blood–brain and blood–CSF barriers; Figure 1). Originally, Paul Ehrlich found that a blood-infused dye failed to stain the brain tissue, and his pupil, Ernst Goldmann, observed complementarily that the very same dye, if applied into the CSF, did stain the brain tissue. This led to the concept of a biological barrier between blood and brain. Due to the free access of the dye from brain ventricle to brain tissue, they concluded that there is no CSF–brain barrier. However, the staining of circumventricular organs and the choroid plexus in Goldmann's experiment applying the dye into the general circulation (Goldmann-I experiment) and the avoidance of staining of these organs in the experiment applying the dye into the CSF (Goldmann-II experiment) suggested the existence of a barrier between the CSF and the blood (Figure 1). The cellular basis of these barriers has been located within the endothelium (endothelial blood–brain barrier in most vertebrates; only in elasmobranchs (sharks and rays) is the blood–brain barrier located in astrocytes), in the epithelial choroid plexus cells, and in the tanycytes of the circumventricular organs (glial blood–CSF barrier).

Definition of Ependymoglial Cells

Macroglial cells, including oligodendrocytes, astrocytes, and ependymoglial cells, may be classified according to the shapes and contacts of their cell processes. Distinctively, only ependymoglial cells establish contact with the ventricular surface (or, in the case of Müller glial cells, with the subretinal space, a remnant of the embryonic ventricle system). Astroglial cells are consistently characterized by the fact that at least one of their processes bears endfeet contacting a basal lamina around blood vessels (glia limitans perivascularis), the pia mater (glia limitans superficialis), or both. Ependymoglial cells share this property; opposite to their ventricular processes, these bipolar cells establish endfeet at a basal lamina (the majority of the subependymal blood vessels become obliterated in later stages of embryogenesis and most of the ependymocytes contact the remaining 'basement membrane labyrinths' rather than true blood vessels or the pia). Generally, we have to distinguish between these 'normal' cilia-bearing ependymocytes lining the major part of the ventricular surface and the choroid plexus epithelial cells and the tanycytes (Figure 1). Both of the latter cell types form the blood–CSF barrier to avoid free diffusion between blood and CSF. This is essentially due to the absence of an endothelial barrier: in the choroid plexus, the endothelium has to be permeable in order to allow the formation of the CSF from the blood by the plexus epithelial cells (Figures 1–3). In the circumventricular organs and in the hypothalamus–hypophyseal system, the vessels are permeabilized in order to receive neurosecretory input from the neurons and to deliver signal compounds from the blood to the neurons (Figures 2 and 3).

Morphology of Ependymoglial Cell Types

The morphology of ependymoglia is diverse (Figure 4). Much of this diversity is related to structural and functional interactions of a given cell with its microenvironment, which includes blood vessels, the pia mater, and/or the ventricular space. Where macroglial cells form a 'border sheath' against the ventricular space, pia, or blood vessels, they form epitheloid aggregates. This is observed in ependymocytes, choroid plexus cells, and retinal pigment epithelial cells which also belong to ependymoglial cells. The term 'radial glia' should be restricted to bipolar ependymoglial

Figure 1 Schematic drawing of the topology of the compartments within the central nervous system (CNS). Within the CNS, there is the neural compartment containing neurons and the neuropil, glial cells, and the vasculature consisting of endothelial cells surrounded by a basal lamina, pericytes, and astroglial endfeet. At the outer surface of the CNS, superficial astroglial endfeet interconnected by gap junctions form the glial limiting membrane, a border toward the meningeal cells which, however, is no physiological barrier. The blood vessels within the pia mater have blood–brain barrier properties. At the inner surface of the CNS, ependymal cells line the ventricular space. Here as well, they have no barrier properties but are interconnected by gap junctions and poorly developed, leaky tight junctions. Due to the fact that the cerebrospinal fluid (CSF) is produced by the plexus epithelium from the blood, there is no barrier between blood and choroid plexus epithelium; however, between blood and cerebrospinal fluid, there is the so-called blood–cerebrospinal fluid barrier. This barrier is formed by tight junctions between choroid plexus epithelial cells and tanycytes in the circumventricular organs. The endothelial cells in these organs and in the choroid plexus are highly permeable and fenestrated.

Figure 2 Highly schematic view of the equipment of a choroid plexus epithelial cell with transporter molecules and the Na^+, K^+-ATPase. Prerequisite for cerebrospinal fluid (CSF) production is the fenestration of the choroid plexus blood vessels.

cells that extend long processes throughout the thickness of the tissue. Early in embryonic development, the immature brain (i.e., the wall of the ventricular system) is spanned by a scaffold of many fetal radial glial cells. In the mature CNS, the descendants of these cells are further differentiated into multipolar astrocytes, or they are maintained as tanycytes in the circumventricular organs or as Müller cells in the retina (Figure 4).

Tanycytes

Tanycytes are a common type of macroglia in the CNS of lower vertebrates (and even deuterostomic invertebrates). In adult mammals, they are restricted to certain brain regions where the tissue is thin, such as some circumventricular organs (e.g., the subcommissural organ), the stalk of the pituitary, and the velum medullare, and to the raphe region of the spinal cord. In the circumventricular organs of all vertebrates except sharks, the capillaries are fenestrated; in these regions, the tanycytes (as well as the choroid plexus cells) constitute the blood–CSF barrier by expressing an extensive apical tight junctional network (Figure 3(f)). Some of these tanycytes are specialized for the secretion of signaling molecules and the material constituting the Reissner's fiber.

Ependymocytes, Choroid Plexus Cells, and Retinal Pigment Epithelial Cells

Ependymocytes, choroid plexus cells, and retinal pigment epithelial cells are specialized glial cells lining the ventricle (or the subretinal space, respectively; Figure 4). At their basal pole, most mature ependymocytes contact remnants of embryonic blood vessels (so-called basement membrane labyrinths; Figure 4)

Figure 3 Electron micrographs of the ependyma and choroid plexus. (a) Ultrathin section through a mitotic ependymal cell of a prenatal mouse brain showing the proliferative property of this periventricular matrix zone. To the left of this mitotic cell, a differentiated ependymal cell already has developed a cilium. The framed box is shown in b, showing the cilium with the basal apparatus and the tight and adhesion junctions interconnecting this cell with its neighbors. (c) Ultrathin section of choroid plexus with epithelial cells (top) and a blood vessel (bottom). The framed box of the apical region of the epithelial cell is magnified in d, showing the microvilli and the junctional domain between two cells. (e) Ultrathin section through the basal labyrinth of a choroid plexus epithelial cell underlined by a basal lamina. Below this basal lamina, the fenestrated endothelium of a blood vessel can clearly be recognized. Arrows indicate fenestrations. (f) Freeze-fracture replica of the apical tight junction of a choroid plexus epithelial cell constituting the blood–cerebrospinal fluid barrier and consisting of parallel strands mainly associated with the inner (protoplasmic) leaflet of the membrane (P-face (PF)). EF, E-face, the outer (external) leaflet of the membrane.

rather than intact blood vessels. At their other pole (i.e., the ventricular pole), they possess, in addition to microvilli, kinocilia to support the movement of CSF (Figures 3(a), 4, and 5(c)). The latter is mainly secreted by the choroid plexus cells, characterized by a high density of Na^+, K^+-ATPase molecules at their microvillous membrane and a high concentration of the water channel protein aquaporin-1 (Figures 2 and 5(d)). This secretion requires a high permeability of the fenestrated plexus endothelial cells (Figure 3(e)), which is now known to be induced by the delivery of the vascular endothelial growth factor (VEGF). VEGF is recognized by the endothelial VEGF receptor followed by a signal cascade leading to the formation of fenestrations. To prevent the diffusion of blood-borne substances into the ventricle, the plexus epithelium is equipped with a densely meshed tight junctional apparatus (Figure 3(f)) constituted by the zonula occludens protein 1 (ZO-1), occludin, and claudin family members 1, 2, and 11 (Figure 5) and also probably by unknown molecules.

Retinal pigment epithelial (RPE) cells reveal features which are related to those of choroid plexus epithelial cells. They line the subretinal space opposite to the neuroretina. Their apical surface forms two types of microvilli: (1) long (5–7 µm) thin microvilli maximizing the membrane area available for transepithelial transport and (2) specially arranged shorter microvilli termed photoreceptor sheaths. The basal surface of RPE cells contains numerous invaginations to increase the surface area. Like the choroid plexus cells, RPE cells are in close apposition to many blood vessels, secrete VEGF in order to induce fenestrations in the choroid vessels, are specialized for transmembrane transport, and form the blood–CSF (or, in this case, –subretinal) fluid barrier by their tight junctions. However, there is an important difference between RPE and plexus epithelial cells (and all other ependymoglial cells): RPE cells do not secrete fluid across their apical microvillous membrane but, rather, perform a net fluid uptake from the subretinal space. This water resorption is mediated via Na^+/bicarbonate$^-$ exchange and prevents (together with the intraocular pressure and with cellular adhesion molecules) a detachment of the neuroretina from the pigment epithelium.

Figure 4 Semischematic survey of the main types of ependymoglial cells and their localization in different regions of the central nervous system. The situation shown at left is also true for the pigment epithelial cells of the eye. The left tanycyte can also be called radial glial cell due to contact to both the pial surface of the brain and the brain ventricle. Another example of this type of tanycyte is the retinal Müller (glial) cell: in this case, the basal lamina corresponds to the inner limiting membrane of the retina. The microvilli-bearing lower part is oriented toward the pigment epithelial microvilli within the subretinal space which is equivalent to the ventricle of the early eye cup. The right tanycyte is the vascular tanycyte, which is the site of the blood–cerebrospinal fluid barrier in the circumventricular organs. The classical ependymocytes line the ventricle and bear cilia on their surface which provide for the steady movement of the cerebrospinal fluid.

Marker Molecules of Ependymoglial Cells

Ependymoglial cells can be visualized by immunocytochemical labeling of certain antigens that are, at least within the CNS, restricted to these cells. The expression of these molecules by certain cell types may change with differentiation or during pathological processes (Table 1). Furthermore, not all members of a given cell population (otherwise considered homogeneous) must express the same antigen (at detectable levels). Table 1 provides an overview of antigens commonly identified by immunolabeling procedures on specific types of astro- and ependymoglial cells.

Ultrastructural Features of Ependymoglial Cells

The somata of some types of ependymoglial cells contain conspicuous melanin pigment granula (RPE cells and choroid epithelial cells). In most of these epitheloid glial cells (including the ependymocytes), the lateral membranes of the somata are interconnected by zonulae adherentes and tight junctions, thus forming the blood–brain (or –retina) barrier (Figures 3 and 5).

In ependymoglial cell nuclei, the nucleoplasm is rather evenly distributed compared to that in oligodendrocytes and microglial cells. In some ependymoglial cells, such as in many tanycytes, the cell nuclei are very irregularly shaped and may display deep incisions. The nuclei (and somata) of Müller cells seem to be 'indented' by neighboring neurons; atomic force microscopy has shown that Müller cell somata are 'more soft' (i.e., possess a lower module of elasticity) than the somata of the neighboring bipolar neurons.

Stem processes are those cellular processes which directly arise from the soma. Typically, they contain bundles of intermediate filaments. Particularly high densities of intermediate filaments are found in the basal (i.e., endfoot-bearing) processes of tanycytes and Müller cells. The stem processes usually contain numerous mitochondria. An interesting exception is Müller cell processes in species with avascular retinae which contain mitochondria only at their apical pole (i.e., close to the choroid, which is the only source of oxygen supply), whereas their stem processes are devoid of these organelles. It has been argued that due to their dominant glycolytic energy metabolism, Müller cells are free to move and place their mitochondria toward sites of high pO_2 rather than toward sites of high energy demand as observed in the neurons with their dominant aerobic metabolism.

The stem processes of tanycytes and Müller cells do not show the regular dichotomic branching pattern characteristic of neuronal dendrites but, rather, are the origins of specialized endings or side branches described in the following sections.

Ependymoglial and astrocytic endfeet cover almost all basal laminae within the CNS (along the blood vessels, the pia mater, and the vitreous body in the eye). In the case of tanycytes and Müller cells, the endfeet are densely filled with smooth endoplasmic reticulum. Bundles of intermediate filaments extend into the endfeet but fail to occupy the cytoplasm close to the basal lamina-contacting endfoot membrane. These filaments consist primarily of vimentin when the endfoot is in contact with CSF or vitreous humor and of glial fibrillary acidic protein (GFAP) when a blood vessel is contacted; however, this rule may be modified in some cases. With the exception of Müller

Figure 5 Confocal laser scanning images of the ependyma and the choroid plexus. (a) Occludin was the first known tight junctional component within the membrane. It is very well expressed in the epithelial cells of the choroid plexus. (b) Transitional zone between ependyma and choroid plexus. GFAP (red) is present in astrocytes and ependymal cells but not in choroid plexus epithelial cells, whereas the tight junctional protein occludin (green) is expressed in choroid plexus epithelial cells only and not in astrocytes. However, as shown in (c), occludin is expressed in both ependymal cells (as recognized by cilia) and plexus epithelial cells (top). (d) The choroid plexus epithelium specifically expresses the water channel protein aquaporin-1 (AQP1), which is not found in ependymal cells. (e) Ependymal cells, together with astrocytes, synthesize AQP4, which in turn is not found in the choroid plexus (top). (f) Glucose transporter-1 isoform (GLUT-1) immunostaining. Where the paracellular route is occluded by highly resistant tight junctions as in plexus epithelial cells, glucose has to be transported by specific transporter molecules such as the sodium-independent GLUT-1. Because the ependymal cells have only leaky (occludin-positive) tight junctions (c), the glucose transporter is not needed in ependymal cells (not shown). (g and h) Within the choroid plexus, the endothelial tight junction molecule claudin-5 is restricted to blood vessels, whereas the tight junctions of epithelial cells contain, besides claudin-2 and -11 (not shown), claudin-3 (h). (i) The epithelial and endothelial basal laminae of the choroid plexus can be recognized by antibodies against fibronectin. The epithelial tight junctions can be visualized not only by classical tight junctional components such as occludin and claudins but also by the coxsackievirus–adenovirus receptor (CAR). Scale bar = 20 μm.

cells in species with completely avascular retinae (i.e., missing both intra- and supraretinal blood vessels), the endfeet are rich in mitochondria. The occurrence of caveolae, coated pits, and vesicles concerned with endo-, exo-, or pinocytosis indicates active material exchange with the compartment on the other side of the basal lamina (i.e., blood plasma, vitreous body, or subarachnoidal fluid). A secretory function has been ascribed to the tanycytes of some circumventricular organs.

Enigmatic membrane structures of ependymoglial cells are the so-called orthogonal arrays of intramembranous particles (OAPs), which have been most extensively described in astrocytes. There, they are concentrated in membrane domains that directly contact a basal lamina, particularly the perivascular basal lamina. In periventricular ependymocytes which do not possess a basal lamina, OAPs occur across the whole cellular surface with the preference of the basolateral membrane. Interestingly, the existence of OAPs and tight junctions is inversely correlated: the ependymoglial cells have OAPs but no or less developed tight junctions, whereas the choroid plexus epithelial cells have well-developed tight junctions but no OAPs. It is known that OAPs are mainly composed of the water channel protein aquaporin-4

Table 1 'Marker antigens' suitable to visualize and/or to identify the various types of ependymoglial cells during ontogenetic development, in the normal mature CNS, and during reactive changes in cases of pathology

Cell type	*Antigen*	*Developing*	*Adult*	*Reactive*
Ependymoglia	GFAP	(+)	++	
	Vimentin		++	
	Cytokeratin		+++	
	RAN-2		++	
	Occludin		++	
	AQP4		++	
RPE	Vimentin		++	
	CRALBP		+++	
	R-cadherin[C]	++	–	
	Occludin	+	+++	
	GLUT-1		+++	
Choroid plexus epithelium	Cytokeratin		++	
	GFAP		–	++
	Vimentin		++	
	Neurofilament*		++	
	Occludin		+++	
	Claudin-2,-3,-11		+++	
	CAR		+++	
	AQP1		+++	
	GLUT-1		+++	

Whereas the table basically reflects the situation in mammals, many of the antigens can also be found in the corresponding cell types of other vertebrates. In cases in which an antigen is only found in nonmammalian cells, it is labeled by an exposed letter: C, chicken. An asterisk indicates that the listed antigen (or antibody, respectively) does not label selectively glial cells but (in other regions of the CNS) also labels neurons. Antigens expressed in the cytoplasmic membranes, such as ion channels, receptors, or adhesion molecules, are excluded since immunocytochemistry for these antigens usually results in 'diffuse' labeling of the neuropil at the light microscopical level. However, tight junctional molecules are included (**Figure 4**).
AQP1/4, water channel proteins aquaporin-1 and -4; BLBP, brain lipid-binding protein; CAR coxsackievirus–adenovirus receptor; CRALBP, cellular retinaldehyde-binding protein; GFAP, glial fibrillary acidic protein; GLUT-1, sodium-independent glucose transporter isoform 1; RAN-2, rat neural antigen-2.

(AQP4). In astrocytes, the role of OAP/AQP4 for water homeostasis of the brain and for maintenance of the blood–brain barrier has been widely discussed; in periventricular cells, the role of OAP/AQP4 may be connected to osmotic regulation as well.

The development of the OAP/AQP4-related polarity of astrocytes seems to correlate with the time of agrin expression. Agrin is a heparan sulfate proteoglycan of the extracellular matrix present on ependymoglial endfeet. It has been shown to be essential for the clustering of acetylcholine receptors in the postsynaptic membrane of the motor endplate. Agrin also binds to α-dystroglycan, a member of the dystrophin–dystroglycan complex which localizes at glial endfoot membranes in a similar manner as OAP/AQP4. In mice with an induced deletion of the gene encoding Dp71 (i.e., the Müller cell-specific member of the dystrophins), a redistribution of AQP4 and Kir4.1 in the Müller cell membrane was observed. Kir4.1 is a weakly inward rectifying potassium channel involved in the glial buffering capacity of extracellular K^+ ions. These and other data support the hypothesis that agrin and dystrophins cooperate in modulating the OAP/AQP4- (and Kir4.1-) related polarity of astrocytes and ependymoglial cells, such as retinal Müller cells and tanycytes.

When, under pathological or experimental conditions, apicolateral membranes of RPE cells, Müller cells, or ependymocytes are confronted with mesenchyma, they lose their original features and develop an endfoot-like structure. This response suggests that mesenchymal contact (i.e., collagen/laminin/agrin and/or other molecules) stimulates the insertion of Kir4.1 K^+ channels and the production of a basal lamina by adjacent mesenchymal cells.

Ventricular Contacts

Cell processes contacting the ventricular (or subretinal) space occur in ependymoglial cells such as tanycytes and Müller cells (but not in astrocytes). They always display an enlarged surface area by extending microvilli into the fluid volume; furthermore, the apical pole contains abundant mitochondria. Both features are indicative of a high metabolic activity that is presumably related to active exchange of substances with the luminal fluid.

Neighboring glial ventricular contact processes (and adjacent neuronal cell processes, if present) are connected by various types of apicolateral junctions. These (particularly desmosomes) are general 'markers' of virtually all epithelial cells and occur very early in development. However, their nature varies considerably depending on the local microenvironment. In regions where no endothelial blood–brain barrier exists (e.g., in most circumventricular organs and in the RPE), ependymoglial cells form a CSF–brain barrier by expressing tight junctions. Apicolateral gap junctions normally occur between retinal Müller cells in frogs but not in mammals. However, when rabbit Müller cells form homogeneous cultures *in vitro*, gap and even tight junctions can be observed, suggesting that the retinal microenvironment *in situ* inhibits the establishment of such intercellular contacts. RPE cells proliferating in areas of retinal detachment may lose their basal lamina contact (Bruch's membrane) and face the subretinal fluid around their entire surface. In these cases, they lose their membrane polarity.

The apical surface of typical ependymocytes is characterized by the presence of 12–60 kinocilia, which vary in number according to the species. The cilia are 10–20 μm long and are of the $9+2$ type. This term means that the cilia contain an axoneme structure consisting of two centrally arranged single microtubules and nine circularly arranged doublets of microtubules. These cilia beat rhythmically at a frequency of approximately 200 beats per minute, and they appear to assist the rostrocaudad flow of CSF.

Choroid Plexus and Tanycytes as the Site of the Blood–Cerebrospinal Fluid Barrier and Immunological Aspects of It

As mentioned previously, the choroid plexus epithelium and the tanycytes of the circumventricular organs form a physiologically important barrier between the CSF and the blood. This is necessarily a consequence of the facts that (1) the CSF has free access to the brain parenchyma through the leaky lining of ependymocytes and (2) the neurosecretory cells of the circumventricular organs and the tuberohypophyseal system need the direct contact with leaky blood vessels in order to release their hormones into the vasculature. Likewise, plexus epithelial cells need the direct contact with leaky blood vessels to produce the CSF from the blood. The intense interplay between neurons, ependymoglial cells, and blood vessels may be demonstrated by the observation that hormonal or osmotic stimulation of neurons in the tuberohypophyseal system leads to changes in the covering of blood vessels by tanycytic endfeet, the ultrastructure of which changes with the physiological state. These changes modify the interface area available for neurohumoral secretion. In rhesus monkeys, the structure of hypothalamic tanycytes differs between males and females; moreover, the apical protrusions of tanycytes in females change their size and number depending on the estrous cycle.

Much of the morphological diversity of astrocytes and ependymoglial cells results from the different local microenvironments into which a given cell is born (or migrating). Inevitably, mesenchymal contact will induce the formation of endfeet with OAP-rich membranes, whereas contact with CSF will induce the outgrowth of microvilli and the formation of stabilizing cell–cell junctions. Where neuronal elements are contacted, the glial cells form delicate side branches that end in lamellar sheaths or fingerlike branchlets. The number, size, and shape of these glial 'end structures' are precisely adjusted to the morphological and functional features of the adjacent neuronal elements. This adjustment continues after ontogeny as a lifelong process of plasticity.

A role of the choroid plexus in the pathogenesis of multiple sclerosis (MS) or its animal model experimental allergic encephalomyelitis (EAE) – that is, as an alternative entry site for circulating lymphocytes directly into CSF – has not been seriously considered. The morphological correlate of the blood–CSF barrier is the tight junctions of choroid plexus epithelium. Interestingly, in EAE the adhesion molecules intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) are upregulated on the choroid plexus epithelium in parallel with their upregulation on blood–brain barrier endothelium. Ultrastructural studies have revealed a polar localization of ICAM-1, VCAM-1, and mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on the apical surface of choroid plexus epithelial cells and their complete absence on the fenestrated endothelial cells within the choroid plexus parenchyma. Furthermore, ICAM-1, VCAM-1, and MAdCAM-1, expressed in choroid plexus epithelium, mediate the binding of lymphocytes via their known ligands.

Massive ultrastructural changes can be observed during EAE within the choroid plexus; however, at the ultrastructural level the tight junctions seem to remain intact. Choroid plexus epithelial tight junctions are morphologically unique (resembling only those of the central myelin sheaths) because they are characterized by their parallel and poorly anastomosing strands (**Figure 3(f)**). This specific type of tight junctions of CNS myelin sheaths was found to be exclusively constituted by oligodendrocyte-specific protein (OSP), which has been identified as a member of the claudin family (claudin-11). A possible role for OSP/claudin-11 in the development of EAE was

demonstrated by the induction of the disease in susceptible mice after immunization with OSP/claudin-11 and by the demonstration of antibodies directed against OSP/claudin-11 in the CSF of patients with MS. Although the presence of anti-claudin-11 antibodies in the CSF of MS patients is still taken as a measure for myelin degradation, it might well reflect a modulation of the blood–CSF barrier localized at the choroid plexus epithelium.

In addition, because choroid plexus epithelial cells have been found to express major histocompatibility complex class I and II molecules on their surface, it will be interesting to determine the contribution of this barrier to autoimmune inflammation within the CNS.

Developmental Aspects of the Ependymoglial Cells

Since the nineteenth century, it has been recognized that the periventricular zone is a matrix zone of growth and differentiation. There was a long-standing debate on whether this matrix contains segregated pools of glial and neuronal progenitors or common progenitors for macroglial cells and neurons. Data suggest that even in adult mammals neural stem cells in the matrix zone generate precursor cells of both the neuronal and the glial lineage, and that the determination of the cleavage plane during mitosis may also determine the fate of the stem cells. Considerable effort is being spent to understand the extremely complex molecular mechanisms that control the differentiation processes. Apparently, there is a complex balance between neurogenic and gliogenic factors and their receptors, such as neurogenin, notch receptor, bone morphogenetic proteins, or leukemia inhibitory factor receptor, which decide together (and/or under the control of the transcription factor Pax6) which one eventually determines the cell fate for a given postmitotic cell. Similarly, the radial glial (Müller) cells in the retina are considered as a potential source of neural regeneration after damage of retinal neurons, at least in the chicken. Again, Pax6 and other transcription factors play an important role in this glio-neuronal transdifferentiation process.

Eph Receptor Signaling and Spine Morphology

F Irie and Y Yamaguchi, Burnham Institute for Medical Research, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Dendritic spines are small protrusions that are present in large numbers on the surface of dendrites. For example, a single pyramidal neuron in the hippocampal CA1 region possesses as many as 30 000 dendritic spines. A majority of excitatory synapses are formed on the surface of these dendritic spines. Dendritic spines typically have a mushroom-like morphology, with a spherical head that contains the postsynaptic density and a stalk that connects the head to the dendritic shaft. Spines exhibit remarkable morphological plasticity during development as well as in the adult brain. It has been speculated that the morphological plasticity of dendritic spines is important for learning and memory, and spine morphological abnormalities characterize neurological disorders such as mental retardation and schizophrenia. The molecular mechanisms underlying the morphological plasticity of spines have been intensively investigated, and recent studies have uncovered a critical role for Eph receptor signaling in the regulation of spine plasticity.

Dendritic Spine Formation

Young, immature neurons do not have dendritic spines. Instead, the dendrites of these neurons are covered with a large number of thin, filopodia-like protrusions. As neurons mature, these dendritic filopodia are replaced by dendritic spines. It is still not entirely clear how the transition from filopodia to mature spines occurs. In one model, highly motile dendritic filopodia make contact with nearby axons, and these initial contacts evolve into mature synapses as the tips of the filopodia expand to become spine heads. In another model, spines are formed directly from the dendritic shaft as new membrane appendages, independent of the filopodia that initiated the axonal contact. While there is still no consensus as to how dendritic spines develop, it is nevertheless clear that a cell surface recognition event between an axon and a dendrite is involved in initiating spine formation. This surface recognition event likely transduces signals into the postsynaptic neuron to induce the structural changes that lead to dendritic spine formation. As a cell contact-dependent signal transduction system that regulates the actin cytoskeleton, Eph receptors and their ephrin ligands possess the necessary properties for carrying out such a role (see Figure 1).

The Eph Receptor Family

The Eph receptors are transmembrane tyrosine kinases and are classified into two groups. The ten EphA receptors preferentially bind the glycosyl phosphatidylinositol (GPI)-anchored ephrin-A ligands, whereas the six EphB receptors preferentially bind the transmembrane ephrin-B ligands. Binding of ephrin ligands activates the tyrosine kinase activity of the Eph receptors through receptor clustering. Activated Eph receptors phosphorylate themselves (autophosphorylation) and other cytoplasmic proteins. Some of the phosphorylated tyrosine residues within the Eph receptor serve as binding sites for SH2 domain-containing proteins, such as Src, Fyn, and Abl. In addition to these classical signaling mechanisms, the C-terminal tail of the Eph receptors can bind postsynaptic density/disc/zonula occludens-1 (PDZ) domain-containing proteins, many of which have been implicated in synaptic function.

Binding of Eph receptors to ephrins also sends signals into the cells expressing the ephrins. The B-ephrins, which do not have a kinase domain, can be phosphorylated by cytosolic Src family kinases. Phosphorylated B-ephrins interact with SH2 domain-containing adaptor proteins, which may help transduce reverse signals. Furthermore, interaction of the cytoplasmic tail of the B-ephrins with PDZ domain-containing proteins has also been reported to play a role in reverse signaling. Thus, ephrin–Eph receptor signaling is bidirectional and can induce a reciprocal exchange of signals between two cells upon physical contacts.

Eph receptors and ephrins are most highly expressed in the developing nervous system. During development, the main function of these molecules is to regulate axon pathfinding and morphogenesis. For instance, Eph receptors and ephrins show remarkable gradient expression patterns in the retina and optic tectum, which is essential for establishing correct topographic connections between retinal axons and neurons in the tectum. While the roles of Eph receptors and ephrins in the developing nervous system are undeniably large, these proteins are also present in the adult brain. Strong expression of Eph receptor proteins in the adult brain is observed in regions such as the cortex, hippocampus, cerebellum, and olfactory bulbs, where remodeling of neuronal connectivity continues in the adult. Importantly, Eph receptors and ephrins are concentrated in the synaptic regions.

Figure 1 Ephrin ligands contact the Eph receptors, inducing intracellular signaling that controls multiple tissue morphogenic processes. See text for discussion.

Earlier studies suggest a pattern in which Eph receptors are present in the postsynaptic region, whereas ephrins are in axons and presynaptic sites. However, recent data indicate that the actual expression patterns are more complex, depending on the type of synapse. For instance, B-ephrins are presynaptic in the CA3 region of the hippocampus but postsynaptic in the CA1 region. In addition, ephrins and Eph receptors are also expressed at sites of contact between neurons and glial cells (see later).

Eph Receptors Promote Spine Formation during Development

It is well established that Eph receptor signaling plays a physiological role in the morphological maturation of dendritic spines during development. Initial observations were made in cultures of primary neurons in which EphB receptor signaling was perturbed. Transfection of a kinase-inactive EphB2 receptor mutant, which acts on all types of EphB receptors in a dominant-negative manner, inhibits spine formation in hippocampal neurons. Perturbed neurons continue to have immature, filopodia-like protrusions even after 3 weeks in culture. In contrast, treatment with exogenous B-ephrins induces premature spine formation in immature neurons, which usually have only filopodia-like protrusions.

A physiological requirement of EphB receptor signaling in spine development *in vivo* has been demonstrated by the analysis of EphB receptor mutant mice. In *EphB1/EphB2/EphB3* triple-null mice, a significant reduction in spine density and a prevalence of spines with no heads or with abnormally small sizes have been identified. Abnormal spine development was also observed in knockin mice expressing an *EphB2* mutant, in which its kinase domain is replaced with lacZ, on an *EphB1* null background. These results indicate that EphB receptor forward signaling is required for normal dendritic spine formation, a conclusion consistent with the observations from *in vitro* experiments.

In neurons expressing the kinase-inactive EphB2 receptor, the number of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) glutamate receptor clusters is markedly reduced, whereas the number of γ-aminobutyric acid (GABA) receptors, which form directly on the dendritic shaft, remains unchanged. It is not known whether the loss of AMPA receptor clusters is the consequence of the absence of spine formation *per se* or whether EphB receptor signaling is directly involved in AMPA receptor clustering. As for the latter possibility, it is interesting to note that the AMPA receptor-binding protein, glutamate receptor-interacting protein 1 (GRIP), binds to the C-terminal tail of EphB2 receptor.

While EphB receptor forward signaling is required for spine formation, it is not known which ephrin(s) acts as physiological ligands in this context. In the mouse hippocampus, ephrin-B3 is expressed in dentate gyrus granule neurons that project to CA3 neurons. This ephrin is an obvious candidate as the physiological ligand for EphB receptors on dendritic spines of CA3 neurons. Increasing evidence demonstrates that the spatiotemporal expression patterns of ephrins and Eph receptors are complex. It is therefore likely that different ephrin–Eph receptor combinations are involved in spine development in different brain regions.

Although a physiological role for EphB receptors in spine development is supported by both *in vitro* and *in vivo* data, much less is known about the role of EphA receptors. There is evidence that ephrin-A–EphA receptor signaling plays a role in the morphological plasticity of spines through neuron–glia communication. Astrocytes are an integral component of synapses, with their fine membrane processes making contact with extrasynaptic surfaces of dendritic spines. Ephrin-A3 and EphA4 receptor are expressed at sites of neuron–astrocyte contact (ephrin-A3 on astrocyte processes, and EphA4 receptor on dendritic spines). An interesting observation in this regard is that treatment of hippocampal slices with ephrin-A3 induces shortening of dendritic spines, and spines in *EphA4* null neurons are longer than in wild-type neurons, suggesting that ephrin-A3 on astrocytes may regulate spine morphology through activation of EphA4 receptor signaling in dendritic spines.

Molecular Mechanisms of Spine Morphogenesis and the Role of Eph Signaling

The cytoskeleton of dendritic spines is composed mainly of actin filaments. Dynamic reorganization of the actin cytoskeleton is essential for the motility of dendritic spines, as shown by a number of perturbation experiments. In contrast, blocking myosin motors does not inhibit spine motility. These results suggest that reorganization of the actin cytoskeleton is the key molecular event underlying spine formation. Consistent with this notion, recent studies have revealed the essential role of Rho family guanine triphosphate hydrolases (GTPases) in dendritic spine formation. For example, expression of constitutively active Rac1 in transgenic mice causes an increase in number of smaller spines in cerebellar Purkinje cells, whereas expression of dominant-negative Rac1 causes a progressive elimination of spines in hippocampal slices. In a *Drosophila* Cdc42 mutant, spine density is reduced in a subset of neurons (the vertical system neurons). Perturbation of another Rho family GTPase, Rnd1, causes reduction in the spine number and width and shortens the length of headless protrusions.

There is a wealth of data indicating that ephrin–Eph receptor signaling regulates spine formation and other morphological changes in neurons via reorganization of the actin cytoskeleton (see **Figure 1**). The main targets of EphB receptor signaling appear to be Rho family GTPases and their regulators, guanine nucleotide exchange factors (GEFs). A pioneering study on this regard was the identification of the Rho GEF ephexin as an effector for ephrin-A-mediated growth cone collapse. Ephexin binds EphA receptors and the association activates the GEF activity of ephexin, which leads to RhoA activation and growth cone collapse. The role of EphB receptors in spine development appears to involve a similar modulation of GEFs and Rho family GTPases. Treatment of cultured neurons with ephrin-B2 ligand causes activation of Cdc42. The association of EphB2 receptor and the actin-binding neural Wiskott–Aldrich syndrome protein (N-WASP) with the GEF intersectin-l enhances the activity of intersectin toward Cdc42. It is well established that Cdc42 and N-WASP coordinately activate the actin polymerization machinery through the actin-related protein (Arp2/3) complex, leading to the formation of branched actin filaments. Thus, EphB receptor activation on the surface of presumptive spines may cause the expansion of spine heads through the polymerization of branched actin filaments. EphB receptor–intersectin signaling may be modulated by Numb, an adaptor protein that interacts with intersectin-l and Cdc42. Numb promotes the GEF activity of intersectin, and small interfering RNA (siRNA)-mediated Numb knockdown suppresses ephrin-B-dependent spine formation in cultured hippocampal neurons.

Another GEF regulated by EphB receptors is kalirin. Kalirin-7, one of the kalirin isoforms, catalyzes nucleotide exchange on Rac1 and is enriched in the postsynaptic density. Expression of a GEF-inactive

mutant of kalirin-7 reduces the number of dendritic spines in cortical neurons. Ephrin-B2-mediated activation of EphB receptors induces tyrosine phosphorylation and translocation of kalirin to synapses, which in turn activates p21-activated kinase (PAK). PAK is a Cdc42/Rac-activated serine–threonine kinase that promotes actin reorganization. This pathway is also likely to be involved in spine formation, since perturbation of PAK inhibits ephrin-B-induced spine formation.

EphB receptor signaling leading to spine formation has also been recently reported to activate a pathway involving focal adhesion kinase (FAK) and paxillin. Stimulation with ephrin-B activates RhoA through the association of EphB receptors with FAK, Src, Grb2, and paxillin, which is induced by tyrosine phosphorylation of these proteins. Knockout of FAK or dominant-negative perturbation of RhoA blocks dendritic filopodia shortening induced by ephrin-B stimulation in young neurons. These data suggest that RhoA also plays a role in dendritic spine formation.

As described earlier, both *in vitro* and *in vivo* experiments indicate that kinase activity is required for EphB receptors to induce spine formation. This suggests that proteins that are phosphorylated by EphB receptors play a role in the process. Besides kalirin, one of the phosphorylation targets of EphB receptors is the cell surface proteoglycan syndecan-2. Upon transfection into young neurons, syndecan-2 induces spine formation. Although the molecular mechanism underlying syndecan-2-mediated spine formation remains unclear, phosphorylation of its cytoplasmic domain by EphB receptors is necessary for this activity. Other example of EphB receptor phosphorylation targets that are likely to be involved in spine formation are the nonreceptor tyrosine kinase Abl and the Abl-related kinase Arg. These kinases affect actin polymerization via enabled/vasodilator-stimulated phosphoproteins (Ena/VASPs), which associate with the barbed ends of actin filaments and promote continued actin polymerization. In *Drosophila*, Ena promotes branching of dendrites and the formation of spine-like protrusions.

The formation of mature dendritic spines requires not only the reorganization of the actin cytoskeleton but also a supply of membranes to accommodate the increase in surface area. Dendritic spines contain endosomal compartments, which serve as a store of recycling membranes. Manipulating the levels of an endocytic protein (CPG2) has been shown to affect spine size. It is also interesting that ephrin-B–EphB receptor signaling regulates clathrin-mediated endocytosis of AMPA-type glutamate receptors through tyrosine phosphorylation of the endocytic accessory protein synaptojanin 1. Although not yet investigated, activation of EphB receptor signaling may therefore alter the supply of membranes available for enlargement of dendritic spines. Thus, ephrin-B–EphB receptor signaling could regulate dendritic spine formation and plasticity by influencing not only the actin cytoskeleton but also membrane trafficking.

Concluding Remarks

While originally identified as axonal guidance cues operating during embryonic development, the ephrin–Eph receptor system has emerged as an important regulator of synaptic function. As summarized in this article, studies done during the past 5 years have largely established the functional significance of these signaling molecules in dendritic spine morphogenesis. There remain important unanswered questions, though. For instance, our understanding of the role of ephrins and Eph receptors in activity-dependent spine plasticity is still limited. Is morphological plasticity of spines in the adult brain also regulated by ephrins and Eph receptors? We do not know how the function of Eph receptors in *N*-methyl-D-aspartate (NMDA)-dependent synaptic plasticity, which is mediated by their extracellular domains, is related to their function in spine formation. Finally, it will be important to investigate whether dysfunction of the ephrin–Eph receptor system may underlie some human mental disorders. Abnormal spines have been reported in various mental disorders and psychiatric conditions, including mental retardation, autism, schizophrenia, and drug addiction. Although the association of null mutations of Eph receptor and ephrin genes with mental disorders has not been identified, Eph receptor signaling impairment may be caused by other genetic, epigenetic, or pharmacological mechanisms, which would be one of the major focuses in ephrin–Eph receptor research in the brain.

Epilepsy

P Kandula and C Harden, Weill Medical College at Cornell University, New York, NY, USA

Published by Elsevier Ltd.

Introduction

Epilepsy is a chronic neurologic condition marked by the recurrence of unprovoked seizures. Seizures in turn, are paroxysmal events that result from abnormal neuronal discharges. Both the terms seizure disorder and epilepsy are interchangeable and refer to recurrent, unprovoked seizures. Although terminology is a more recent advancement, epilepsy itself is not a newly recognized condition. In fact, mention of epilepsy dates back to the writings of Hippocrates around 700 BC. Nationwide, epilepsy affects anywhere from 0.5% to 3% of the population. The highest incidence occurs in young children and the elderly.

Etiology

As previously mentioned, only recurrent, unprovoked seizures constitute epilepsy. Seizures can also occur in certain 'provoked' settings. Metabolic derangements such as hypoglycemia, hyponatremia, and hypocalcemia could provoke self-limited seizures. In addition, acute alcohol withdrawal, certain medications that lower seizure threshold, and high fevers in young children, can also cause a seizure.

Any condition that alters the structure or function of the central nervous system (CNS) can predispose an individual toward epilepsy. In the elderly, vascular disease (ischemic strokes, hemorrhage, malformations) accounts for a large number of epilepsy cases. Primary CNS tumors, as well as metastatic tumors to the brain, account for epilepsy in mid-life. Infectious (encephalitis) and degenerative disorders (Alzheimer's dementia) are additional causes of epilepsy. Congenital malformations (cortical dysplasias, migrational defects) are more common in children. A few epilepsy syndromes have a known underlying genetic cause. Many of these syndromes occur in children and young adolescents, with an autosomal dominant inheritance, with incomplete penetrance. In reality, however, in approximately 50% of cases, a definitive underlying etiology cannot be found.

Pathophysiology

Epilepsy is a reflection of abnormal firing of neurons that produces an electrophysiologic change, as well as variable clinical symptoms. Simplistically, epilepsy is a mismatch between neuronal excitatory and inhibitory processes. In the CNS, the neurotransmitter that mediates excitation at most synapses is glutamate. However, glutaminergic expression of excitation depends on the specific receptor stimulated. Neuronal glutamate receptors include AMPA (alpha amino-3-hydroxyl-5-methyl-4-isoxale propionic acid), kainic acid, and NMDA (*N*-methyl-D-aspartate). AMPA receptors are responsible for fast excitatory neurotransmission via the sodium-potassium channel. NMDA receptors are found with AMPA receptors but are physiologically blocked by magnesium ions. However, when the AMPA channels are open (with glutamate action), the magnesium blockade is released, and the NMDA channels are open. Calcium can then enter, and the slow, sustained phase of excitatory neurotransmission takes place. On the other hand, GABA (γ-aminobutyric acid) is the main inhibitory neurotransmitter found in the CNS. Activation of the GABA-A receptor subtype is responsible for neuronal inhibition. There is also evidence to suggest that impaired GABA-A receptor function can lead to certain inherited or acquired epilepsies. Thus, lack of GABA-mediated inhibition along with excessive neuronal excitation are the critical mechanisms of epileptogenicity.

Classification and Clinical Features

Over the years, a concerted effort has been made to classify epilepsy syndromes. Today, classification is primarily based on the combination of the 1981 Classification of Epileptic Seizures and the 1989 Classification of Epilepsies and Epileptic Syndromes by the ILAE (International League Against Epilepsy). In large part, however, these distinctions are primarily academic, and the classification of seizures in practical terms is based on clinical symptoms and region of onset on the electroencephalogram (EEG).

Partial seizures are divided into complex partial and simple partial. Complex partial seizures involve altered awareness or impaired consciousness. Complex partial seizures can vary clinically. In the classical complex partial seizures of temporal lobe origin, for example, prominent lip smacking (oral movements) and automatic behavior consisting of nonvoluntary movements of fumbling and picking at objects can occur in the setting of altered consciousness. Patients may often be confused, tired, and unable to follow commands immediately after clinical symptoms cease, constituting a 'post-ictal' phase. In contrast, during simple partial seizures, patients are conscious and awareness is not altered. Most often, focal motor seizures are seen with simple partial seizures. These

movements consist of jerking of the contralateral leg, arm, face, or any combination of the three. Both simple and complex partial seizures have a focal onset on the EEG. However, either seizure type can start focally, but can spread to other regions of the brain and become secondarily generalized. Once a seizure becomes secondarily generalized, there is always associated loss of consciousness.

Generalized tonic-clonic convulsive seizures are the most common pattern in clinical practice. Seizures can be primarily generalized at onset, or instead start off as a complex partial seizure with subsequent tonic-clonic movements of all extremities. Clinically, associated cyanosis, increased salivary secretions, changes in the blood pressure or heart rate, bladder incontinence, or tongue biting can occur. Unlike a partial seizure, there is no preceding aura (symptoms preceding the onset of a seizure). Individuals are usually difficult to arouse for several minutes to hours after the convulsion. In fact, individuals may report complete amnesia for the entire event upon awakening. With regard to the EEG, generalized seizures start with rhythmic ictal discharges in both cerebral hemispheres at the same time. Currently, there are seven types of generalized seizures recognized by the ILAE, consisting of generalized tonic-clonic, tonic, clonic, myoclonic, absence, atypical absence, and atonic seizures.

Generalized tonic-clonic seizures (grand mal) were described earlier. Tonic seizures consist of only the stiffening (tonic) phase of a grand mal seizure. Similarly, clonic seizures consist of only the clonic (jerking) phase of a grand mal seizure. Myoclonic seizures are quick, sudden jerks of the entire body, or predominantly the upper extremities. At times, the movement is profound and patients may fall to the ground or alternatively drop an object out of their hand during the seizure. Absence, or petit mal, seizures are again brief episodes of behavioral arrest, with clinical unresponsiveness, staring, and eyelid fluttering or automatic type activity. Individuals immediately resume prior activity after the absence seizure is over. However, patients are generally amnestic to the event. Absence seizures are more common in childhood and can be mistaken by family and educational providers as attention-deficit disorders. Classically, the EEG shows bihemispheric three cycle per second spike-and-wave discharges during the seizure. Atypical absence seizures are generally longer in duration and include more complicated motor manifestations. In addition, the EEG does not show the classical three cycle per second spike-and-wave discharges, but rather a slower variant, referred to as slow spike and waves. Atonic seizures consist of a sudden loss of muscle tone. Clinical manifestations range from falling to the side while sitting to dropping to the ground, if standing. Patients can injure themselves if not protected. Atonic seizures are usually associated with a complex of other seizure types, seen in severe epilepsies. If atonic seizures are frequent, individuals may wear a helmet to protect themselves during an event.

Evaluation and Treatment

When a patient presents with a new onset paroxysmal event(s), particularly with alteration or loss of consciousness, seizures should be entertained as a possible diagnosis. Careful history and physical can help in distinguishing a seizure from other paroxysmal events. A clinical description from an observer can provide additional clinical information. Detailed questioning regarding the presence or absence of a warning sign (aura), alteration of consciousness, focal movements, automatic behavior, urinary or fecal incontinence, and post-event confusion should be obtained. Duration of the event is also important, as most seizures are typically less than 1.5 min in duration. Potential risk factors for seizures should be identified, such as a history of head trauma, prior history of encephalitis/meningitis, childhood febrile seizures, and family history of seizures. General medical history regarding use of new medications that may lower the seizure threshold (bupropion, lithium, levofloxacin) or cause metabolic derangements (diuretics causing hyponatremia, insulin causing hypoglycemia) that can lead to subsequent seizures should be questioned.

During the physical exam, focal neurologic signs (focal weakness, etc.) as well as systemic signs (fever, altered mental status) should be investigated. Laboratory investigation including electrolyte counts (sodium, calcium, magnesium, serum glucose), liver and renal function test, toxicology screen, and complete blood cell count should be performed. Further testing may include urinalysis, urine cultures, chest X-ray, blood cultures, and lumbar puncture if a source of infection is likely. If encephalitis is suspected, cerebrospinal fluid should be sent for herpes simplex virus polymerase chain reaction (PCR). Empiric treatment with antibiotics should be started in suspected cases of meningitis/encephalitis. Imaging should be performed in all patients, particularly when focal findings are suspected based on neurological examination and/or clinical history. Magnetic resonance imaging (MRI) is the imaging modality of choice. MRI sequences should include adequate sequences to visualize in particular the temporal lobes and mesial structures to identify common conditions such as mesial temporal sclerosis (atrophy of medial temporal lobe structures). Imaging with intravenous contrast should be

performed if a tumor is suspected. Finally, EEG should always be performed in addition to the above serologic and imaging tests. Neuroimaging is a test of structural integrity, while EEG is a test of cortical function. The purpose of the EEG is threefold. First, epileptiform discharges in the form of spikes, sharps, or spike-and-wave complexes may be identified, suggesting potential origin sites for seizures. Second, epileptiform discharges with specific patterns may help to identify epilepsy syndromes, such as the characteristic spike-and-wave discharges seen in childhood absence epilepsy. Finally, stratification of seizures into focal versus generalized onset can help select an appropriate anti-epileptic medication. Although epileptiform discharges are highly suggestive of epilepsy, they are not pathognomonic. The gold standard for localization of seizure onset would be to record an actual ictal (seizure) event. Thus, if further localizing information is needed, a prolonged EEG with video should be performed.

Treatment with an anti-epileptic agent is then based on EEG findings and clinical correlation. Technically, recurrent seizures constitute epilepsy. Thus, a patient with two or more unprovoked seizures should be treated. For some persons, it may be appropriate to treat after only one seizure has occurred, for example, high functioning adults for whom a seizure recurrence could have severe consequences, or those patients who have a structural lesion on brain MRI. The risk of seizure recurrence after one seizure is reduced with anti-epileptic drug treatment; therefore, the decision to treat should take into account the risk of seizure recurrence versus the risk of treatment.

Some individuals will continue to have seizures despite an adequate trial of at least two anti-epileptic agents and fall under the category of refractory epilepsy. Individuals with a focal onset of seizures in noneloquent cortex may be potential candidates for resective epilepsy surgery. In other cases, refractory patients may be considered for vagus nerve stimulation implantation or, more recently, implantable devices for deep brain stimulation for epilepsy.

Prognosis

Ultimate prognosis is dependent on the epilepsy syndrome, underlying etiology, and response to anti-epileptic agents. Some generalized epilepsies, such as childhood absence epilepsy, have a good prognosis. In some cases, children may eventually stop having seizures as adulthood approaches. In others in whom a baseline neurologic deficit exists, seizures may be more difficult to control. In general, patients who do not have a favorable response to a first anti-epileptic agent, unless it was for drug allergy, have a lower chance (around 15%) of completely responding to a subsequent second or third agent. The overall cumulative success rate of controlling epilepsy is on the order of 70%. Thus, 30% of patients would be considered medically refractory. In cases where patients are candidates for temporal lobectomy for mesial temporal sclerosis, epilepsy treatment success rate is nearly 70%.

After several years of complete seizure control on medication, the decision as to whether to stop antiseizure medications is often discussed. While there is no clear point after which discontinuing antiseizure medications is appropriate, most neurologists would not do so unless the patient was seizure-free for at least 2 years. Risk factors for seizure recurrence include the presence of a structural brain lesion, a persistently abnormal EEG, and frequent seizures prior to seizure control with medication.

Conclusions

As in any chronic illness, a multidisciplinary approach including neurologists, epileptologists, and psychiatrists is required for the management of epilepsy. Coexisting mood disorders such as depression, bipolar disorder, and dysthymia are not uncommon in the epilepsy population. There are also studies suggesting that people with epilepsy attempt suicides at higher rates than the general population. Lastly, many patients suffer from the psychosocial aspects of the condition, including cumulative medication side effects, the loss of control with recurrent seizures, and the ongoing cultural and societal stigma associated with the condition.

Introduction

Epilepsy can arise from a complex interplay between multiple genes and various environmental factors, but the recent discovery that some idiopathic epilepsies result from specific single gene mutations (monogenetic epilepsies) enhances our understanding of the genetics and molecular mechanisms of the these disorders. That most of these mutations directly affect ion channel function is not surprising, since ion channels are important in the brain for the maintenance of the delicate electrical equilibrium between neuronal networks.

Ion channels are important in a wide variety of cellular functions in the brain and other electrically excitable tissues, such as the heart muscle and the peripheral nerves, and there are numerous examples of neurological diseases that are caused by dysfunctional ion channels (e.g., periodic paralysis, episodic ataxia, hereditary deafness, inherited arrhythmia with congenital long QT syndrome, and migraine). Diseases arising from ion channel dysfunction are termed channelopathies, and to these can now be added several forms of genetically mediated epilepsy.

Function of Ion Channels

In the brain, ion channels are necessary for the generation and propagation of signals between neurons. Alteration in their function could produce a reduction in seizure threshold, causing different epilepsy syndromes. Ion channels typically result from cell membrane proteins that form selective pores so as to allow the passage of sodium (Na^+), potassium (K^+), chloride (Cl^-), or calcium (Ca^{2+}) ions across their respective electrochemical gradients. Basically, there are two types of ion channels:

1. Voltage gated (these are opened and closed by changes in membrane potential).
2. Ligand gated (a transmitter molecule opens and closes the gate by binding to a receptor site).

The gene mutations underlying the different genetic epilepsy syndromes can affect either the voltage- or the ligand-gated ion channels. Each type of ion channel is briefly described in the following sections, after which the clinical features and genetic bases of the epilepsy syndromes caused by mutations affecting ion channels are discussed (see Table 1 and Figure 1).

Voltage-Gated Cation Channels

Voltage-gated Na^+, K^+, Cl^-, or Ca^{2+} channels are formed by several subunits. Four pore-forming homologous subunits (the α subunits) determine the ion gating and permeation in the channel. One or more smaller accessory subunits (identified as β, γ, or δ) have other modifying functions. These ion channels are normally closed at the resting potential but are readily activated once the membrane is depolarized. Activation gates are opened within milliseconds of depolarization, and with sustained depolarization, closure of inactivation gates leads to channel inactivation (i.e., repolarization). The inactivated channel remains refractory to further openings till it recovers. The smaller accessory β, γ, or δ subunits regulate functional proteins in the membrane, thus affecting the kinetics of channel gating.

Na^+ and K^+ channels are mostly involved in the process of depolarization and repolarization. Depolarization occurs with inward Na^+ currents, while repolarization occurs with rapid inactivation of these Na^+ currents and activation of outward K^+ current. Alteration in these channel functions can lead to hyperexcitability and fast repetitive action potentials. Ca^{2+} channels regulate presynaptic neurotransmitter release at the nerve terminals.

Ligand-Gated Ion Channels

Ion channels that are activated by neurotransmitters are called ligand-gated channels. The transmitters activating these channels include acetylcholine (ACh), γ-aminobutyric acid (GABA), glycine, glutamate, and nucleotides. Neurotransmitters can either be excitatory (e.g., ACh and glutamate) or inhibitory (e.g., GABA and glycine). Ligand-gated channels are typically composed of four or five main subunits. The channel opens with transmitter binding and remains desensitized until removal of the transmitter, which leads to closure of the channel, allowing it to be available again for further openings.

Generalized Epilepsy with Febrile Seizures Plus

Febrile seizures are a common childhood seizure disorder affecting from 2% to 5% of children from 6 months to 5 years of age. Febrile seizures are not considered epilepsy, since they are, by definition, associated with an increase in body temperature. Although genetic factors play a role in febrile seizures,

Table 1 Genetic epilepsy syndromes and associated gene mutations

Epilepsy syndrome	*Chromosomal location*	*Gene*	*Channel, subunit*
GEFS+	19q13	*SCN1B*	Na, β1

GEEA	19p13	*CACNA1A*	Ca, α1A subunit

Abbreviations (syndromes and genes): GEFS+, generalized epilepsy with febrile seizures plus; SMEI, severe myoclonic encephalopathy of infancy; BFNS, benign familial neonatal seizures; BFIS, benign familial infantile seizures; BFNIS, benign familial neonatal–infantile seizures; ADNFLE, autosomal dominant nocturnal frontal lobe epilepsy; CAE, childhood absence epilepsy; JAE, juvenile absence epilepsy; JME, juvenile myoclonic epilepsy; EGMA, epilepsy with grand mal on awakening; GEEA, generalized epilepsy with episodic ataxia; SCN, sodium channel; GABR, GABA A receptor; KCN, potassium channel; CHRN, neuronal nicotinic acetylcholine receptor; CLCN, chloride channel; CACN, calcium channel. The different gene mutations encoding ion channels and their respective involved subunits are given (Na, sodium; K, potassium; GABA A, γ-aminobutyric acid; ACh, acetylcholine; Cl, chloride; Cav, calcium channel, voltage dependent; Ca, calcium).

the likelihood of a child with typical febrile seizures developing epilepsy (about 2%) is little different from the epilepsy risk in the general population. In 1997, a dominantly inherited epileptic syndrome was described in a large Anglo-Australian family; this led for the first time to joining febrile and afebrile seizures as part of the same clinical phenotype. Affected individuals frequently have afebrile seizures as well as simple febrile seizures that occur beyond 4 or 5 years of age. This pedigree shows a mild overall phenotype. The term generalized epilepsy with febrile seizures 'plus' (GEFS+) was coined, and many affected families have now been identified.

Clinical Features

GEFS+ is transmitted as an autosomal-dominant trait with reduced penetrance and a highly variable phenotype, even within the same pedigree. The manifestations include (1) febrile seizures, (2) febrile seizures 'plus' (initially used to describe febrile seizures after 5 years of age, but later, to include afebrile generalized tonic–clonic seizures occurring in addition to febrile seizures), (3) afebrile generalized seizures, including generalized tonic–clonic, myoclonic, atonic, absence (when absence occurs, seizures usually occur less frequently than with typical 'childhood absence epilepsy' in the sense that they are less frequent), and myoclonic–astatic epilepsy, and (4) partial seizures (frontal and temporal lobe epilepsy).

The most common seizure patterns within the different pedigrees are febrile seizures (FS) and febrile seizures plus (FS+). Different seizure types can be associated with FS or FS+, but the most common are generalized tonic–clonic. As mentioned earlier, the phenotype can be widely variable even within the same family with an identical mutation. Affected family members may manifest with GEFS+, only FS, or even isolated afebrile generalized tonic–clonic (GTC) or partial temporal seizures, suggesting that isolated afebrile seizures may represent a 'GEFS+

Figure 1 This diagram depicts the complex genotype–phenotype relationship in epilepsy. While a variety of mutations can produce similar phenotypes, a single mutation can produce a range of phenotypes. Abbreviations (syndromes, blue; genes, purple; gene subunits, green): BFNS, benign familial neonatal seizures; BFNIS, benign familial neonatal–infantile seizures; BFIS, benign familial infantile seizures; GEFS+, generalized epilepsy with febrile seizures 'plus'; SMEI, severe myoclonic epilepsy of infancy (Dravet's syndrome); CAE, childhood absence epilepsy; CAE&FS, childhood absence epilepsy and febrile seizures; JAE, juvenile absence epilepsy; JME, juvenile myoclonic epilepsy; ADNFLE, autosomal dominant nocturnal frontal lobe epilepsy; EGMA, epilepsy with grand mal on awakening; GEEA, generalized epilepsy with episodic ataxia; KCN, potassium channel; SCN, sodium channel; GABR, GABA A receptor; CLCN, chloride channel; CACN, calcium channel; CHRN, neuronal nicotinic acetylcholine receptor.

phenotype,' adding to the complex genotype–phenotype relationship. GEFS+ mutation carriers who remain asymptomatic have been identified, suggesting that other disease-modifying genes or possibly environmental factors play a role in the pathogenesis.

Genetics

Genes encoding both voltage-gated and ligand-gated ion channels have been implicated in the etiology of GEFS+. In 1998, linkage to chromosome 19q was demonstrated, and soon after, the site of the $\beta 1$ subunit of the voltage-gated Na^+ channel gene (*SCN1B*) was identified. To date, only a few mutations have been recognized in *SCN1B*, suggesting a minor role as a causative gene. Later, two French families with GEFS+ were mapped to chromosome 2q24 and mutations were identified in the aα1 subunit of the voltage-gated sodium channel (*SCN1A*). Subsequently, more than 100 mutations have been described in this gene. *SCN1A* is probably the most important gene in the pathophysiology of GEFS+.

Missense mutations are the most common defects identified in GEFS+, but *de novo* mutations in *SCN1A* have also been identified in patients with severe myoclonic epilepsy of infancy (SMEI), which also features seizures associated with fever but typically has a more severe phenotype. A single base mutation in *SCN2A* has been found in 1 among 19 unrelated Japanese families. However, the significance of *SCN2A* as a disease-causing gene remains controversial. Mutations in *SCN2A* have also been found in families with benign neonatal–infantile familial seizures and benign infantile familial seizures.

The GABA A receptor, a ligand-gated chloride channel, is a heteromeric complex with five subunits (most native brain receptors contain two α, two β, and one δ subunit). The gene (*GABRG2*) encoding the $\gamma 2$ subunit of the GABA A receptor was identified as a causal gene for GEFS+. The mutations for this pedigree differ from most GEFS+ pedigrees, in the sense that idiopathic generalized epilepsy (IGE) phenotypes, including classical childhood absence epilepsy, can be expressed together in the same pedigree. One *GABRG2* mutation was found recently in a patient with the SMEI phenotype. The family had a bilinear inheritance and it was hypothesized that a second mutation could have been contributed to the phenotype. Another gene encoding the δ subunit of the GABA A receptor (*GABRD*) has been lately identified in the etiology of GEFS+.

Treatment

Given the wide variability in seizure phenotype, treatment can be tailored to best suit the clinical situation.

Patients with isolated febrile seizures may not require treatment, while those with febrile seizures plus other seizure types may benefit from a broad spectrum of antiepileptic drugs.

Severe Myoclonic Epilepsy of Infancy: Dravet's Syndrome

Severe myoclonic epilepsy of infancy (SMEI) is a well-defined syndrome first described by Dravet in 1978. The 1989 International League against Epilepsy classifies this syndrome under undetermined epilepsies and syndromes, depending on whether seizures are focal or generalized.

Clinical Features

Symptoms usually appear before 1 year of age, and the average age of onset was approximately 5 months in Dravet's series. The first seizure is typically precipitated by fever and can be generalized or focal with variable side predominance. Individual seizures are often prolonged and can evolve into status epilepticus. Seizures may become recurrent. These generalized or partial febrile seizures are followed by different types of afebrile seizures, including myoclonic, partial seizures, and absence.

The myoclonic seizures usually occur later in the course of the syndrome, but they may appear earlier. Some children have numerous, even relentless, myoclonic seizures, while others have them only on awakening or during the short interval preceding another seizure. The myoclonias can be generalized or segmental. The generalized myoclonias can be massive, causing the child to fall. In some cases they are focal, involving one limb or the head prior to becoming generalized. Segmental myoclonus affecting distal part of the upper extremities and face can be observed, especially in the periods with more frequent seizures. These myoclonic seizures are accompanied by generalized spike-wave or polyspike-wave discharges seen on electroencephalography (EEG).

The partial seizures are complex partial with adversive or atonic features and can present with autonomic changes, including cyanosis, and they can become secondarily generalized. The absence may present atypical features, sometimes with a myoclonic or atonic component and less rhythmic spike-wave discharges in the EEG. Patients can develop frequent episodes of status epilepticus, either convulsive, precipitated by fever, or 'obtundation status' with erratic myoclonias and increase in muscular tone.

Development is usually normal prior to seizure onset, but later psychomotor slowing and neurological signs, including ataxia and pyramidal signs, are observed. Occasionally, patients whose seizures are treated effectively retain good cognition. The EEG may be normal at the beginning but progressively changes to show generalized and focal or multifocal abnormalities. Photosensitivity is present in more than 40% of cases. Recently, similar phenotypes without myoclonus have been described and are considered to be a clinical variant of SMEI. It has been suggested that SMEI could represent the more severe end of the spectrum of GEFS+.

Genetics

Because fever-induced seizures are known to occur in both GEFS+ and SMEI patients, a mutation analysis of *SCN1A* was performed in seven patients with SMEI. *De novo* dominant mutations were found and the phenotype of *SCN1A* mutations was extended to include SMEI. A majority of the *SCN1A* mutations are truncating alleles and are presumed to result in a loss of Na^+ channel function.

Treatment

Seizures are often refractory to treatment with antiepileptic drugs. Valproate and benzodiazepines are the most useful drugs. It has been observed that carbamazepine and lamotrigine may aggravate the syndrome. Stiripentol (a drug not available in the US) and topiramate have been shown to be effective in the convulsive seizures. Ethosuximide can be helpful for absences and myoclonic seizures.

Benign Familial Neonatal Seizures

Benign familial neonatal seizures (BFNS) represent a type of rare autosomal-dominant inherited epilepsy syndrome with a penetrance as high as 85%. The seizures occur in otherwise well newborns, typically beginning on the second or third day of life (2–8 days in the majority of neonates) and typically remit after a few weeks. Up to 31% of patients may have seizures during the neonatal period after the first week of life. Affected premature babies will have their seizure onset at an older chronological age. Seizures may be focal clonic or may have a tonic or tonic–clonic component and are often accompanied by apnea. Usually they are brief, but the rate of recurrence can be high and they have a tendency to cluster. These seizures often spontaneously remit, but about 11% of patients may develop other types of seizures later in life.

Genetics

BFNS exhibits both clinical and genetic heterogeneity. The disease was first mapped to chromosome 20q, and later a second focus was identified in chromosome 8q. The genes (*KCNQ2* and *KCNQ3*, respectively) were identified as encoding voltage-dependent

potassium channels. Both KNCQ2 and KNCQ3 channels co-assemble to form heteromeric channels (KCNQ2/KCNQ3), expressing larger currents. It has been postulated that the association of these channels is the equivalent of the M current (named for its regulation by muscarinic receptors), a slowly activating and deactivating potassium current that functions as a brake for repetitive action potentials. A slight reduction by approximately 25% in KNCQ2/KNCQ3 currents, caused by mutations, can lead to an increase in neuronal hyperexcitability. *KCNQ2* and *KCNQ3* mutations can produce the same phenotype. Most of the mutations have been identified in *KCNQ2* and recently a mutation in *KCNQ2* combined BFNS patients and affected members who subsequently developed myokymia in the same pedigree, suggesting that other gene–environmental factors could modify the phenotype.

It has been postulated that the seizures occur in newborns because there is a general increase in excitation during the neonatal period. GABA is excitatory early in brain development, and this is probably due to the low expression of a potassium chloride cotransporter (KCC2), so the intracellular concentration of chloride is higher than in the extracellular space, and when chloride channels open, chloride ions exit the cell, causing depolarization. On the other hand, the expression of KCNQ2/KCNQ3 currents probably plays a more important role early in life than they do in the mature brain.

Treatment

Since seizures usually remit spontaneously, the best treatment approach is not clear. Phenobarbital, phenytoin, and valproate have been used. Treatment is usually for a brief period of time. Retigabine, an experimental drug currently in trials, activates KCNQ2/KCNQ3 channels by shifting their voltage dependence to more negative stages.

Benign Familial Infantile Seizures

Benign familial infantile seizures (BFIS) is the name given a newly described syndrome characterized by focal seizures with or without secondary generalization, appearing usually between 4 and 8 months of life. It has been observed that the seizures have a tendency to occur in clusters and they are brief. Slow deviation of head and eyes to one side, hypertonia, limb jerks, and cyanosis have been described in the clinical characteristics. This clinical entity has an autosomal-dominant pattern of inheritance and a benign outcome, since seizures resolve within the first year.

BFIS is a genetically heterogeneous condition, with loci mapped to chromosomes 16 and 19, but recently a mutation in *SCN2A* was identified in a family with BFIS and good outcome, thus expanding further the group of the epilepsies caused by channelopathies.

Benign Familial Neonatal–Infantile Seizures

In recent years a mutation in *SCN2A* was described in two families with a mean seizure onset of 1–9 months and mean offset of 3–8 months of age. This condition was named benign familial neonatal infantile seizures (BFNIS), demonstrating the overlapping clinical features between the genetic epileptic syndromes.

Autosomal-Dominant Nocturnal Frontal Lobe Epilepsy

Clinical Features

Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE) is a clinical entity characterized by clusters of nocturnal seizures with a predisposition to occur during non-rapid eye movement (NREM) sleep, especially during stage 2. The attacks consist of sudden arousals with hypermotor manifestations with bipedal or bimanual movements, kicking or cycling, and agitated motor behavior. The seizures can manifest with abnormal dystonic postures or complex motor activities, with expression of fear or shouting, and can be accompanied by autonomic manifestations, in particular tachycardia. There is marked familial variation in semiology and severity.

The majority of patients retain consciousness during the events. The seizures usually start in the first or second decade of life and have a tendency to decrease in frequency during adulthood, but rarely disappear. Diurnal attacks can be present in some patients, especially in those with refractory epilepsy. The seizures can be misdiagnosed as parasomnias, but the epileptic events have a tendency to cluster. Interictal EEGs can be normal, and ictal recordings are difficult to interpret due to movement artifacts, but frontal spikes or rhythmic theta–delta activity in the anterior regions have been reported. It is impossible to distinguish ADNFLE from sporadic NFLE by clinical semiology alone.

Genetics

ADNFLE was the first familial focal epilepsy for which a genetic background was identified. The transmission pattern is autosomal dominant with

reduced penetrance (84%), but depending on the family, the penetrance can vary from 29% to 87%, to 100%. Three loci (chromosomes 20q13, 15q24, and 1q21) but only two genes have been identified. These genes encode for the $\alpha 4$ and $\beta 2$ subunit of the neuronal nicotinic acetylcholine receptor (*CHRNA4* in chromosome 20q13 and *CHRNB2* in chromosome 1q21). Altogether the *CHRNA4* and *CHRNB2* mutations account for the minority of cases, and for the vast majority the causal gene remains unknown.

It is unclear how the *CHRNA4* and *CHRNB2* mutations increase neuronal hyperexcitability specifically affecting the frontal lobes. Mutations can cause either loss or gain of function, and it has been postulated that reduction in the calcium dependence of the receptors could facilitate glutamate release at excitatory synapses, since calcium modulation could act as a negative feedback mechanism, preventing the overstimulation of glutamate release by the presynaptic $\alpha 4$ and $\beta 2$ neuronal acetylcholine receptors (nAChRs) at central excitatory synapses.

Treatment

Carbamazepine has been the drug of choice. One-third of patients become intractable. Recently, good results with nicotine patches and acetazolamide have been reported.

Other Types of Common Idiopathic Generalized Epilepsies Associated with Mutations in Ion Channel-Encoding Genes

The idiopathic generalized epilepsies include a distinctive spectrum of generalized epilepsies that range from rare syndromes to more common phenotypes, such as childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), juvenile myoclonic epilepsy (JME), and epilepsy with grand mal on awakening (EGMA). A hallmark of generalized epileptic disorders is the generation of synchronous spike-wave discharges (SWDs) in the range of 3–6 Hz recorded bilaterally over both brain hemispheres during the seizure event. Several chromosomes have been implicated in IGEs, including 3q26, 2q36.1, 14q23, 6p21.2, 8p11.2, and 18q21.1. This indicates that IGEs are a group of genetically heterogeneous disorders that are associated with mutations in several genes. Several clinical studies suggest that all IGEs share common genetic etiologies, as all major IGE syndromes have been found to occur within the same families. Recently, mutations in genes encoding different types of ion channels have been found in families affected with the most common forms of IGEs, including CAE, JAE, and JME.

Childhood Absence Epilepsy (Pyknolepsy)

CAE (pyknolepsy) accounts for 5–15% of childhood epilepsies. CAE typically manifests at age 6–7 years of age, with recurrent absence attacks that are characterized by an abrupt alteration of consciousness presenting with brief alteration in responsiveness and awareness. The seizures are accompanied on EEG by stereotyped 3 Hz bihemispheric spike-wave complexes that are most prominent in the frontal regions.

Fourteen of 118 patients with CAE were reported to have 12 putative mutations in the T-type calcium channel gene *CACNA1H*. It was concluded that missense mutations in this gene may predispose to CAE. The role of *CACNA1H* variants in the cause of human epilepsy still remains unclear, as these findings could not be replicated in another study. Furthermore, analysis of some of these putative mutations revealed changes in channel properties which were consistent with epileptogenesis. Interestingly, ethosuximide, the drug of choice for CAE, modulates the thalamocortical network that is synchronized by the voltage-dependent T-type calcium channel (Cav3.2).

GABRG2 mutations have been implicated in families with CAE and febrile seizures. These families probably represent a different subtype of GEFS+ phenotypes. Recently, mutations of *CLCN2* in the 3q26 region were found in families with IGEs, including CAE, JAE, JME, and EGMA. *CLCN2* mutation was estimated to be responsible for 40% of all familial IGEs, although this was challenged in a separate study that found it only in 3 out of 46 families with IGEs. CLCN2 channels play an important role at the GABAergic inhibitory synapses. CLCN2 channels are believed to play a role in maintaining a low intracellular Cl^- concentration. GABAergic stimulation leads to Cl^- flux intracellularly, resulting in hyperpolarization inhibition. Therefore, a dysfunctional CLCN2 channel results in buildup of intracellular Cl^-, leading to reduction in the inhibitory GABA response.

Juvenile Absence Epilepsy

JAE is mainly differentiated from CAE based on age of onset, which is usually between 9 and 13 years of age. Otherwise, JAE and CAE share many clinical similarities. As stated previously, mutations in the *CLCN2* gene have been also associated with JAE. GTC seizures tend to occur more often in JAE, especially in the morning. Like CAE, bursts of generalized spike-wave discharges are also seen in JAE, but usually at a higher frequency of 3–4 Hz. Although clinically a unique syndrome, it is not clear if JAE is a genetically distinct condition different from CAE. Two recent studies suggest that JAE and CAE share a common genetic relationship that is different from

that of JME. Despite these similarities, prognosis of JAE is not as benign as it is for CAE. While seizure control is usually achieved in JAE, most patients require treatment indefinitely.

Juvenile Myoclonic Epilepsy

JME is a common epilepsy syndrome, representing 20–27% of all patients with IGEs and accounting for 5–10% of all epilepsy cases. JME usually presents between 12 and 18 years of age. Early morning myoclonic seizures are a prominent part of this syndrome. These are symmetric shocklike jerks involving mainly the upper extremities, resulting frequently in sudden dropping of objects but almost never causing the patient to fall. These myoclonic jerks can be precipitated by alcohol, fatigue, or menstruation. Unlike CAE and JAE, absence seizures in JME occur only in about 30% of patients, while GTC seizures can occur in over 90% of cases. The EEG usually shows a normal background with intermittent generalized bursts of symmetric 3.5–6 Hz polyspikes and wave discharges that are far less regular than the spike waves seen in CAE. The prognosis for seizure control is excellent. Similar to JAE, JME responds remarkably to antiepileptic treatment, though this treatment may be required lifelong. Neurologic outcome and cognitive outcome are also excellent.

Extensive genetic work has been done to understand the inheritance of JME. It has been linked to several chromosomes, indicating that JME is a genetically heterogeneous disorder. *GABRA1* mutation (A322D) on chromosome 5q34–q35 was implicated in causing autosomal-dominant JME (AD-JME) in a large French-Canadian kindred. This mutation can impair the fast synaptic inhibition of the brain at the GABA A receptor. Involvement of the calcium (Ca^{2+}) channel was suggested when a nonsense mutation of the gene (*CACNB4*), mapped to 2q22–q23, encoding the Ca^{2+} channel β4 subunit was found in a German family with IGE and in a woman with JME. Mutation in the chloride channel-2 gene (*CLCN2*) on chromosome 3q26 was also found in a family with JME.

Generalized Epilepsy with Episodic Ataxia

Generalized epilepsy and episodic ataxia, two distinct paroxysmal disorders, have been recently linked together and related to calcium channel gene mutations. A heterozygous nonsense mutation in *CACNA1A* was reported in a patient with generalized tonic–clonic seizures, absences, and episodic ataxia.

Conclusion

The recognition that some of the 'generalized and partial idiopathic epilepsies' are caused by alterations in ion channel function (channelopathies) not only provides us with a better understanding of the molecular mechanisms implicated in seizure generation, but also improves our present ability as clinicians to make more precise diagnosis. This knowledge increases the possibilities for potential development of newer antiepileptic drugs with more specific mechanisms of action, as is the case of retigabine, designed to operate on the KCNQ2/KCNQ3 channels.

In addition, we have learned of the complex genotype–phenotype relationship between the different genetic epilepsy syndromes. Mutations in different genes may cause a similar phenotype, as is the case for BFNS, in which mutations in *KCNQ2* and *KCNQ3* are associated with seizures in the neonatal period. Conversely, mutations in the same gene can produce different phenotypes, as in *SCN2A* mutations that have been linked to GEFS+, BFNIS, and BFIS. This implies that different modifier genes or environmental factors play a role in the final phenotypic expression (see **Figure 1**).

The genetics of these epilepsy syndromes becomes even more complex with the discovery that epileptic channelopathies can be caused by *de novo* mutations, and a family history may be lacking, as is the case of the *SCN1A de novo* mutation causing the SMEI phenotype. Even if considerable progress has been achieved in this field, the genes for the vast majority of idiopathic epilepsies remain unknown, but we are at the beginning of a new era in the discovery of the genetics behind the different seizure types.

Occurrence of Neurodegeneration in Epilepsy

Approximately 0.8% of the world population (50 million) has epilepsy, according to the World Health Organization. Epilepsies can be divided into three major categories based on etiology: idiopathic, symptomatic, and presumed symptomatic (previously called 'cryptogenic'). In idiopathic epilepsies, genetic factors causing, for example, channelopathies, are presumed to have a major causative role in the development of seizures. In symptomatic epilepsies, there is an identifiable lesion in the brain that triggers seizures. The lesion can be, for example, a genetically programmed molecular defect leading to cortical dysplasia, or an acquired lesion like traumatic brain injury (TBI). Presumed symptomatic epilepsies are those most likely to be symptomatic, but no lesion can be identified by currently available methods. Neurodegeneration in epilepsy is a multifaceted issue. For example, in some epilepsies progressive neurodegeneration can be caused by genetically encoded enzymatic defect that leads to brain atrophy and mental retardation, and epilepsy is just one component of the clinical phenotype. Here we focus exclusively on acquired symptomatic epilepsies that typically develop in previously normal brain. In these patients epileptic process has three phases: a brain-damaging insult (BDI) (e.g., status epilepticus (SE), TBI, or stroke) leading to epileptogenesis (latency period, during which there are no seizures), followed by recurrent seizures or epilepsy. Most of the available information comes from models where epileptogenesis is triggered by electrically or chemically induced SE. It is noteworthy that neurodegeneration is just one component of reorganization of neuronal circuits that eventually lead to occurrence of spontaneous seizures after epileptogenic BDI. Other changes include axonal and dendritic plasticity, neurogenesis and gliogenesis, vascular alterations, axonal damage, and remodeling of extracellular matrix and cellular membranes (Figure 1). The mechanisms of neurodegeneration are under most intense investigations because of the promise of neuroprotective therapies to improve the long-term outcome after various epileptogenic BDIs.

Where in Epileptic Brain Do Neurons Die?

Analysis of surgically resected hippocampal tissue from patients who have been operated due to drug-refractory temporal lobe epilepsy (TLE) show that about 90% of patients have neuronal loss in the hippocampus (Figure 1). This patient group represents, however, only a small subpopulation of epilepsy patients. Currently, we do not have histological data about newly diagnosed patients with acquired symptomatic epilepsies. Magnetic resonance imaging (MRI) studies have shown that hippocampal or amygdaloid volume reduction can be seen in less than 10% of newly diagnosed patients. Other brain areas showing damage in histologic or MR images include the medial temporal cortex (entorhinal cortex, perirhinal cortex, parahippocampal cortex), thalamus, and cerebellum. All these studies point out that structural alterations in epileptic brain are not limited to the hippocampus.

Timing of Neurodegeneration in Epilepsy

In acquired symptomatic epilepsies the neurodegeneration can relate to acute damage caused by epileptogenic BDI (like TBI, stroke, infection, SE) or its progression over time. The contribution of recurrent seizures on neurodegeneration in epilepsy is still under dispute. Animal studies have shown that an electrical stimulation of the ventral hippocampus lasting for about 70 s can trigger apoptosis in the hippocampal CA1 subfield. Further, studies in kindling models suggest that recurrent evoked brief seizures can trigger progressive neurodegeneration (kindling refers to a phenomenon in which an initially subthreshold stimulus, when given repeatedly, eventually evokes partial and secondarily generalized seizures). This observations has not, however, been reproduced in all kindling studies. Also, studies in spontaneously seizing rodents have not been able to demonstrate seizure-associated neurodegeneration but rather indicate that most of the damage is caused by initial BDI. Also, there is no direct evidence that epileptic seizures cause neurodegeneration in human epilepsy. However, indirect evidence available from imaging studies in humans suggests that recurrent seizures can associate with progressive reduction in brain (and hippocampal) volume in a subpopulation

Figure 1 Brightfield photomicrographs from the hippocampus of a patient who underwent epilepsy surgery due to drug-refractory TLE. (a) A Nissl-stained section demonstrating severe neuronal loss in the hilus (H) of the dentate gyrus, as well as in the CA3 and CA1 subfields of the hippocampus proper. The CA2 subfield is better preserved. (b) An adjacent section stained with an antibody raised against dynorphin to demonstrate the sprouting of granule cell (g) axons or mossy fibers to the inner molecular layer (m) of the dentate gyrus (open arrows). ir, immunoreactivity; Sub, subiculum.

of patients. Whether volume reduction is exclusively due to neurodegeneration remains to be studied.

Mechanisms of Neurodegeneration in Epilepsy

Neuronal death in epileptogenic BDI can be caused by direct mechanical forces to the brain (like TBI), as well as by vascular, cellular, or molecular alterations that result in acute and delayed neuronal death or injury. Neurodegeneration can continue for months after BDI both in humans and experimental models. Importantly, the mechanisms can differ depending on the time delay from BDI with necrosis predominating at early time points. There are number of other factors that can influence neurodegeneration. For example, the severity of neurodegeneration following SE in mice heavily depends on the genetic background, with some strains more susceptible than others. It also depends on age, that is, young animals are less susceptible to pathologic insults, including SE as compared to adult rodents. There is also evidence that gender, type, and severity of injury, metabolic state of the brain, and other conditions (e.g., other diseases, medication) associated with BDI can affect the severity and/or mechanisms of neurodegeneration.

Morphologic Features of Neurodegeneration: Necrosis and Apoptosis

Morphologically, neuronal death can be divided into two major types: necrosis and apoptosis. The two categories provide some clues about the underlying mechanisms of neuronal death even though usefulness of morphological criteria as a starting point for understanding biochemical cascades has been challenged recently. Electron microscopic morphology of necrosis consists of swollen cellular appearance with swollen mitochondria, vacuolated cytoplasm, dilation of endoplasmic reticulum (ER), pycnotic nuclei, and plasma membrane rupture. Necrosis can be initiated, for example, by mechanical damage that leads to neuronal membrane failure, Ca^{2+} influx, and disruption of ionic homeostasis which triggers the release of glutamate. In addition, spillover of lysosomal cathepsins contributes to necrotic death. Inflammatory responses caused by the extracellular release of cytoplasmic components, and/or breakdown of the blood–brain barrier is another factor that exposes adjacent neurons to deadly signals and secondary damage (e.g., activation of caspase 1). Necrotic appearance is most common for cells dying within minutes to few days after epileptogenic BDI.

Morphologic features of apoptosis include nuclear and cytoplasmic condensation, internucleosomal DNA cleavage, and packing of the cell into apoptotic bodies that are engulfed by phagocytes, preventing release of intracellular components that is typically energy and transcription dependent. Apoptosis is rarely detected in degenerating neurons in SE models of epilepsy if morphological criteria are used. Nevertheless, such neurons display other apoptotic features, for example, DNA fragmentation has been found in the brain subjected to prolonged seizures. Also, activation of number of programmed cell death pathways via caspase-dependent or-independent mechanisms has been described (Table 1 and Figure 2).

Caspase-Dependent Cell Death in Epilepsy

A number of molecular pathways can be involved in execution of apoptosis. Here we focus exclusively on pathways that are of relevance for epilepsy-related neurodegeneration.

Apoptosis can be triggered by activation of death receptors localized in the cell surface (extrinsic pathway) or by dysfunction of mitochondria or ER (intrinsic pathway). Studies indicate involvement of both intrinsic and extrinsic pathways in SE-induced neurodegeneration (Table 1).

Extrinsic, death receptor-mediated pathway is activated by binding a ligand tumor necrosis factor alpha (TNF-α or FasL) to its receptor (TNFR-1 and Fas, respectively). This leads to formation of a scaffold complex (DISC), composed of several proteins such as TRADD, FADD, Rip, TRAF2, and results in activation of caspase 2, 8, or 10. TNFR-1 and Fas death receptors, as well as components of death receptors signaling, such as TRADD and FADD, are constitutively expressed in the brain. In addition, Fas and FADD are overexpressed following kainate-induced SE. Involvement of death receptor signaling pathway in SE-induced neurodegeneration is supported by evidence of formation in the scaffold complex. Such molecular complexes, isolated from the hippocampal tissue after SE, contain TNFR1, TRADD, FADD, and caspase 8. Also, TRAF2 and RIP can be recruited to this scaffold complex. Activity of above complexes can be blocked by FLIP or by SODD protein. Elimination of SODD protein from hippocampal neurons that was shown following kainate-induced SE would lead to activation of death receptor signaling. Finally, processing of caspase 8 and 2 – targets for death receptor signaling pathway – has been observed following SE.

Activation of mitochondrial intrinsic pathways involves release of cytochrome *c* from the mitochondria. In the cytoplasm, cytochrome *c* creates so-called apoptosome by binding to APAF-1 and subsequent recruitment and activation of caspase 9. Activity of this complex can be blocked by inhibitors of apoptosis protein family members (IAPs). Inhibitory action of IAPs can be blocked by smac/DIABLO, released from mitochondria. The release of cytochrome *c* from the mitochondria following prolonged seizures is a widely observed phenomenon. Also, formation of apoptosome and activation of caspase 9 have been detected in the hippocampus following intrahippocampal kainate-induced SE. Seizures can influence progression of intrinsic pathway acting on IAPs as well. For example, XIAP is initially upregulated and then degraded in hippocampal neurons dying in a consequence of kainic acid-induced SE.

In addition to mitochondria, ER too can participate in seizure-induced neurodegeneration, for example, by releasing Ca^{2+} to the cytoplasm.

Both, caspases 8 and 2 activated in death receptor cascades, as well as caspase 9 activated in mitochondrial intrinsic pathway are able to cleave, and therefore activate executioner caspases 3, 6, and 7. Expression and activation of caspase 3 in epilepsy-related neurodegeneration have been extensively studied in experimental models and in human tissue. Increase in mRNA expression, and protein expression or activity has been detected in hippocampus, temporal lobe, and thalamus. Activation of caspase 3 leads to degradation of its cellular targets like spectrin or inhibitor of caspase-activated DNase (ICAD), that was detected following kainic acid-induced SE. Degradation of ICAD is of special interest, since it results in disinhibition of its molecular partner, Caspase-activated DNase (CAD), translocation of CAD to the nucleus, and subsequent DNA fragmentation. Translocation of CAD to the nucleus has been shown in tissue resected from patients with TLE. It should be mentioned however, that some studies did not reveal activation of caspase 3 after seizures, and its role in seizure-induced neurodegeneration is still a matter of controversy.

Changes in protein expression of the other executioner caspase, caspase 7, have been found in the rat hippocampi following intra-amygdala kainate injection. However, it was not accompanied by caspase 7 activation, and therefore its role in seizure-induced neurodegeneration is not clear. Increase in protein expression and activity of caspase 6 has been observed in hippocampi of animals subjected to prolonged seizures as well.

Caspase-Independent Cell Death in Epilepsy

The Bcl-2 family comprises large number of proteins that are of great importance in regulation of apoptosis progression. Some of the members belonging to this family promote apoptosis (Bax, Bid, Bim), others have a opposite function (Bcl-2, Bcl-xl, Bcl-w). Activity of these proteins often depends on cellular localization and interactions with other proteins. Involvement of Bcl-2 family proteins in epilepsy-related neurodegeneration has been studied extensively. Increase in expression of proapoptotic Bax and Bcl-xs proteins was detected following prolonged seizures in animals, as well as in human TLE. Seizures cause dissociation of Bad from 14-3-3 protein and binding and neutralization of antiapoptic Bcl-l. Proteolysis of Bid occurs following seizures induced by intra-amygdalar injection of kainic acid. It results in translocation of processed fragment to mitochondria and promotion of cell death. In the same animal model increased expression of Bim was also observed. Interestingly, Bim protein expression decreases in human TLE. Also, expression and activity of antiapoptotic proteins can be altered by prolonged seizures. Increased expression of Bcl-2 and Bcl-w has been found in experimental models. Expression of Bcl-2 and Bcl-xl is elevated in human epileptic tissue.

Recently, the p53 pathway has emerged as one of importance in regulation of neuronal death. The p53 protein is a nuclear phosphoprotein acting as a transcription factor. It is a key player in cell response to

DNA damage and oxidative stress and it has been implicated in neurodegeneration. There are several mechanisms postulated for the function of p53 in neurodegeneration including activation of transcription of Bcl-2 family members or Fas. Both increased expression and activation of p53 in dying neurons have been observed as a result of pilocarpine or kainic acid-induced SE. Promotion of p53 function also occurs by SE-induced inactivation of MDM2, a protein which regulates p53 degradation. Number of other proteins regulate MDM2 or p53 activity in dying neurons, such as Akt or DAP kinase are influenced by prolonged seizures.

In addition to caspase-mediated proteolysis, proteolytic activity of calpains during neuronal death is frequently implicated. There is, however, only incidental information about involvement of this pathway in seizure-induced neurodegeneration.

Does Treatment with Antiepileptic Drugs Affect Neurodegeneration?

As there is ample evidence that neurodegeneration can be one component of progressive neuropathology in symptomatic epilepsies, a critical question is: can we affect the neurodegenerative process by treatment? In theory, number of antiepileptic drugs (AEDs) have the potential to influence cell death, for example, by inhibition of voltage-activated calcium channels (felbamate, phenytoin, topiramate), by inhibiting N-and/or P-type calcium channels (gabapentin, pregabalin, lamotrigine, oaxacarbazepine, phenytoin, and topiramate), or triggering antiapoptotic signalling pathways (valproate). There is some evidence from cell culture studies that valproic acid and lamotrigine reduce experimentally induced apoptosis.

The neuroprotective potential of AEDs following epileptogenic stimuli, such as SE, TBI, or ischemia have been studied in animal models of epilepsy. Beneficial action of selected drugs has been observed at least in some studies summarized in Table 2.

Number of studies have been directed at preventing neurodegeneration following ischemic stroke, which is one of the common epileptogenic insults. For example, carbamazepine, oxacarbazepine, or lamotrigine administered at 0.5 and 24 h after insult improved outcome in permanent middle cerebral artery occlusion (MCAO). However, in another study that used transient MCAO model, no effect of carbamazepine was observed following application at 30 min before and 90 min after insult. Clonazepam, felbamate, and lamotrigine are effective in the bilateral occlusion model in gerbil when administered shortly after vessel clamping. There are inconsistent data on the action of lamotrigine in MCAO. Both, reduction of infarct volume, as well as lack of effect have been reported. A neuroprotective effect of tiagabine was observed in global ischemia in gerbil. In rat, MCAO protective effects of tiagabine were visible even if drug was given within 2 h after reperfusion. Also, topiramate is protective if applied within 2 h after MCAO in rats. Administration of topiramate reduced hipppocampal damage in gerbils too. Vigabatrin was neuroprotective in bilateral carotid artery occlusion in gerbil, when assessed 1 week after insult, but this effect was lost by 28 days after ischemia. Finally, zonisamide is protective when administered up to 4 h after MCAO in rat, but no protective effect was seen in global forebrain ischemia in gerbil. Altogether, some AEDs alleviate ischemia-induced damage when severity of damage is assessed within few days after insult.

Most of the AEDs have been studied in SE models. These reports show that some of the compounds are neuroprotective when given during and/or after SE. For example, felbamate reduces damage when administered 10 min after beginning the perforant path stimulation. Lamotrigine was beneficial when given for 2 weeks after perforant path stimulation, but not after amygdala stimulation. No effect was noted

Table 2 Effect of AEDs on neurodegeneration caused by epileptogenic brain damaging insults. Only the studies in which the AED was administered 'during' *or* 'after' the insult induced *in vivo* are included

when lamotrigine was applied 30 min before kainic acid-induced SE. Application of levetiracetam for 21 days starting 30 min after pilocarpine-induced SE was not effective when damage was assessed 3 weeks later. Chronic application of lamotrigine in the same model had a mild neuroprotective effect on hipocampal principal cells and interneurons. Chronic treatment with pentobarbital, which started 24 h after kainic acid-induced SE and lasted for the subsequent 100 days did not influence hippocampal damage. Pentobarbital was, however, effective when administered simultaneously with kainic acid. In the Li-pilocarpine model of SE, pregabalin treatment that started 20 min after pilocarpine injection and continued for 6 days, reduced damage in the piriform and entorhinal cortices, but not in the hippocampus. Effect of retigabine was investigated following SE induced by kainic acid and terminated with diazepam. The protective effect was observed in the piriform cortex, but not in the hippocampus. Topiramate neuroprotection has been shown in the hippocampus following unilateral hippocampal stimulation when administered 140 min after SE and in Li-pilocarpine-induced SE when administered 1 and 10 h after SE. Topiramate has been also shown to improve sensorimotor outcome but the effect was not associated with a neuroprotective effect. Application of valproate for 1 day starting 2 h after perforant pathway stimulation did not influence hippocampal damage. Treatment with valproate for 21 days starting 30 min after pilocarpine-induced SE also did not reduce hippocampal damage. Vigabatrin was neuroprotective in pilocarpine model when treatment started 10 min after induction of SE and continued for 45 days. On the other hand, no protective effect of vigabatrin was detected if drug was applied 1 h or 1 week after kainic acid-induced SE. Vigabatrin treatment was not, however, neuroprotective when started 2 days after amygdala stimulation-induced SE and continued for 10 weeks. Also, a 4-week treatment starting 2 days following hippocampal stimulation-induced SE was ineffective.

The effect of AEDs on neuroprotection following TBI has not been extensively studied. The effect of talampanel was studied in fluid-percussion injury model. The damage was alleviated when the compound was given at 30 min but not at 3 h after trauma.

Overall, neuroprotection evoked by AEDs is mild and in most cases can be detected only within few days after the insult. Frequently, the data available are inconsistent, which can be attributed to animal models or methodologies used to quantify the severity of neurodegeneration. Neuroprotective effects do not relate to the mechanism of drug action. One can speculate that in many cases the favorable effects likely associate with suppression of seizure activity at acute phase. Moreover, neuroprotection does not imply favorable functional outcome. Importantly, there is no hard experimental evidence that successful neuroprotective treatment would delay or prevent epileptogenesis.

The relevance of experimental data for human condition is difficult to assess. Clinical studies that have evaluated neuroprotective effects of AEDs are rare. One clinical study investigated the effect of carbamazepine or vigabatrin monotherapy on hippocampal atrophy over a 3-year follow-up. No difference was found between the treatments. In accord with experimental evidence, AEDs do not influence epileptogenesis in humans when studied in patients with TBI.

Conclusions

Experimental studies have revealed that neurodegeneration occurs both by necrotic and apoptotic mechanisms after BDIs leading to epilepsy. Most of the damage occurs soon after BDI but some damage can continue for weeks to months, even after the appearance of spontaneous seizures. Induced seizures in rodents have been shown to trigger neurodegeneration. Whether spontaneous seizures contribute to neuronal death is still under dispute. Studies in humans have revealed that progressive atrophy of the brain can occur in a subpopulation of patients with symptomatic epilepsies over time. Human studies are, however, compromised by the resolution of current imaging techniques, and it remains to be seen which component of the atrophy is actually caused by degeneration of neuronal somata. Also, further studies are needed to address a question whether treatment with AEDs or other compounds would have effect on atrophy and whether that would associate with more favorable outcome in patients with epilepsy.

Of all human capabilities, the one central to our development of a unique sense of personal identity is episodic memory. The ability to form and retrieve memories of our life experiences provides an opportunity to identify those events as our own and embed the memories in a malleable framework of related experiences. This process in turn influences our interpretation, and therefore learning, of new experiences. Indeed, people who have lost the ability to access their past episodic memories have sometimes reported feeling a loss of self identity. Over the past 50 years, significant advances in the philosophical, theoretical, and empirical study of memory have begun to shed light on the nature of memory and the intricate cognitive and neural mechanisms involved in remembering past episodes.

What Is Episodic Memory?

Episodic memories are consciously perceived memories of personal events or episodes. One defining feature of episodic memories is that they are the personal memories. Among other types of information, they include where you were, what you were doing, whom you were with, what you saw, how you felt, and what you were thinking during a particular event. A second defining feature is that episodic memories are accompanied by a conscious awareness of the temporal context in which the events occurred. In bringing to mind events from childhood, there is an awareness that the events occurred before the present time, and perhaps an awareness of precisely when they occurred.

Episodic memories represent one type of declarative memory – memories which are accessible to consciousness and which can be readily communicated or declared to others. Nondeclarative memories, such as learned skills, are memories that are not directly available to consciousness but nevertheless influence behavior. Semantic memories are memories of factual knowledge and represent a second type of declarative memory. Declarative memory is dependent upon the integrity of medial temporal lobe (MTL) structures including hippocampus, entorhinal and perirhinal cortex, and parahippocampal gyrus, and also on the fornix and anterior and mediodorsal nuclei in the thalamus. Significant damage to these structures produces amnesia and consequently an impaired ability to form and retrieve declarative memories. By some accounts, episodic and semantic memories arise from different memory, and by extension, brain systems. These accounts are supported in part by behavioral dissociations and in part by evidence that some patients are impaired on tests of episodic but not semantic memory while other patients are impaired on tests of semantic but not episodic memory. Further support for different memory systems has come from neuroimaging studies which demonstrate dissociations among brain regions associated with episodic and semantic memory tasks. By other accounts, episodic and semantic memories differ according to the presence or absence of personal spatial and temporal context, but are otherwise similar. When the initial context has been lost or is inaccessible, or the current situation does not encourage conscious recollection, the result is retrieval of semantic knowledge. By this account, the difference is due to the different processing demands of a given situation rather than differences in the underlying memory systems. These accounts are not necessarily mutually exclusive.

A distinction is often drawn between memories of personal events accompanied by subjective awareness, and memories of personal facts related to those events. For example, you may remember purchasing your first car, bringing back to mind where you found it, how it appeared, and how the seller talked. However, some of these remembered details can also be retrieved as facts. You know that you bought your car from an individual rather than a dealer. You know that it was blue. And you know that the seller was a man. Another distinction is sometimes made between episodic memories pertaining to a single event (recollections) and those pertaining to repeated similar episodes (generic personal memories). Autobiographical memory is often used synonymously with episodic memory. However, in some instances, the two terms are used to denote memories of life experiences and laboratory events, respectively.

Reconstructing Memories Using Retrieval Cues

Prevailing frameworks of episodic memory describe remembering as a dynamic process during which an active model or simulation of an event is constructed from memory traces. A memory trace, also called an engram, is a neural change reflecting the thoughts, emotions, and sensory features of the original experience. The construction account of

remembering rejects the proposition that memory traces are replayed like a song or a movie. Instead, memory cues are used to create a mental simulation of an event by drawing upon available memories and filling in the missing pieces with educated guesses. Ulric Neisser compares this process to that of assembling a dinosaur from mere bone chips. The reconstruction process begins with a retrieval cue, and subsequent retrieval is influenced by an individual's past experiences, his or her current state of mind, and the contextual demands in which remembering occurs. For example, accessing the same memory trace on two different occasions may produce qualitatively different recollections if the first occasion is immediately following a transcontinental flight and the second is after a full night of rest. The German biologist Richard Semon coined the term ecphory to describe this synergistic interaction of the original memory trace and the current retrieval cue to form the episodic memory experience. Because of an inherent dependence on the retrieval cue, memories entering consciousness need not be veridical representations of the mnemonic content of a stored engram. By this view, only the products of the interpretive interaction of current intent and past experience are available to awareness.

The effectiveness of a retrieval cue depends in large part upon the degree of similarity between the cue and the original event. The more similar the relationship, the more likely it is that the retrieval cue will lead to ecphory. Therefore, the way in which events are interpreted at encoding influences how they can later be accessed and reconstructed. Endel Tulving refers to this relationship as the encoding specificity principle. Daniel Schacter provides a memorable example of this principle by describing an experiment carried out by the artist Sophie Calle at The Museum of Modern Art. In the experiment, museum staff were asked to recollect as much detail as they could about various paintings. The level of detail provided by the staff differed widely, from just a few words to detailed sentences. Calle found that the degree and quality of detail was related to the type of work carried out by the staff member. Staff in charge of art placement provided structural descriptions of the paintings, while those in charge of procuring the art provided more detailed accounts and interpretations of the artwork. The differing experiences of the museum staff influenced how they thought about the artwork, and this in turn influenced the types of memory they were later able to retrieve. According to the encoding specificity principle, the cues that will best evoke episodic memories of the paintings will be those that most closely match the initial processing.

Components of Remembering

Episodic remembering is typically perceived as a unitary phenomenon. A memory comes to mind, sometimes easily and sometimes after some effort, but the details of the process are often unavailable to superficial introspection. There is an abundance of research demonstrating, however, that remembering depends on a variety of memory-specific and domain-general cognitive abilities, including among others, formation of search strategies, memory-based decision making, and postretrieval assessment. The most convincing evidence for separable components in human episodic memory has come from studies that produce a dissociation, either by identifying patients in whom lesions to different parts of the brain produce different types of memory deficit, or by identifying brain areas in which neural activity modulates according to variations in one component differently than the other components.

Strategic Processing

At times, memories of past events come to mind rather easily, seeming to pop into awareness after an encounter with a retrieval cue. At other times, a feeling of knowing can lead to a more strategic search through memory for the appropriate information. Strategic search involves generating retrieval cues from memory and using those cues to guide further searches. Models of strategic processing in remembering typically describe three basic stages, including initial identification of the desired information (target), a search for information and a matching process in which retrieved information is compared with the target, and an assessment or monitoring of the degree of accuracy. Neuropsychological studies of patients with lesions in the prefrontal cortex (PFC) have provided valuable insight into the role of frontal cortex in memory. Frontal patients are readily able to encode and retrieve memories. In fact, they tend to perform at levels approaching that of control subjects on simple item recognition tests that can be accomplished using nonrecollective memory (i.e., familiarity). However, patients with prefrontal damage perform significantly more poorly than control subjects on memory tests that require strategic processing, such as source memory tests of cued recall, free recall, and recognition. Source memory tests require the ability to identify the appropriate learning context, such as the time (was this item studied in the first or second study session?), place (was this item studied in the laboratory or in the classroom?), or feature (was this item presented in a male or female voice?). In these frontal patients, memory deficits are due not

to problems forming memories (as in amnesia) but instead are related to impairments of organization of new memories, strategic access to memory contexts, and the supervisory control required to maintain information in working memory and assess retrieval effectiveness. As a result, frontal patients can experience difficulty under situations that require flexible processing, such those required by source memory tasks. This difficulty is sometimes observed in the form of confabulations – the generation of false and contradictory statements.

Results from neuroimaging studies are consistent with the neuropsychological findings. Because the need for strategic search typically increases as retrieval difficulty increases, retrieval difficulty can be manipulated in order to examine the neural substrates of strategic processing in memory. For example, difficulty can be manipulated by varying encoding strength so that weakly encoded items are more difficult to retrieve than strongly encoded items, or by varying the amount of detail required so that retrieving more detail is more difficult. These studies demonstrate that frontal lobe regions near the anterior extent of the left inferior frontal gyrus (aIFG), left anterior prefrontal cortex (aPFC), and bilateral posterior middle frontal gyrus (pMFG) consistently increase activity as retrieval difficulty increases. There is also evidence for functional specialization within this set of regions. pMFG activity tends to also modulate according to the type of information retrieved, with a preference toward processing of verbal stimuli in the left hemisphere and nonverbal stimuli in the right. Other brain regions also appear to play an important role in strategic processing. Bilateral anterior insula/frontal operculum (AI/FO), the anterior cingulate cortex (ACC), and basal ganglia (bilateral caudate nucleus, putamen) also tend to increase activity as retrieval difficulty increases. While there has been relatively little attention given to the role of AI/FO and basal ganglia in these studies, the ACC has received quite a bit of attention. Current models suggest that ACC is involved in reward-based decisions, motor control, error detection, emotional self-control, problem solving, and/or conflict monitoring. The demand for all of these functions conceivably increases as retrieval difficulty increases, and therefore often it is a particular challenge to clearly identify the source of signal modulations.

Contents of Remembering

There is a host of evidence from neuropsychological, single-unit physiology, event-related potential (ERP), and neuroimaging studies supporting the view that regions of the nervous system that initially process an event (i.e., data-processing regions) are reactivated when the event is later remembered. For example, recalling your car's seller involves the coordinated recruitment of regions of the brain that initially processed the appearance of his face, the color of the car, the sound of his voice, and your thoughts about the situation. Work on human and nonhuman primates is particularly relevant to episodic remembering and mental imagery, but extends also to semantic knowledge. The findings indicate that memory traces are distributed in the nervous system as a function of the type of material encoded. For example, patients with focal lesions can exhibit impaired memory for visual objects, yet show preserved memory for spatial relationships. Neuroimaging experiments have shown that data-processing regions that are active during initial encoding of stimuli are, to some extent, reactivated during later remembering. It is yet to be determined how such a coordinated reactivation is organized and controlled, but prominent theories propose an interaction of frontoparietal attentional control processes and a medial temporal associational mechanism that provides an index of stored memory traces.

An unresolved issue concerning how memory contents are reconstructed is related to the degree to which data-processing centers are reactivated. In the visual system, for example, the most basic aspects of visual stimuli are processed in early stages, with complexity and receptive field size increasing as information is transmitted to later stages. Thus, while fundamental stimulus features such as line segments located in discrete parts of the visual field are processed in early stages of the visual processing hierarchy, more complex features that are less dependent upon location in the visual field, such as object form, are processed in later stages. Evidence that visual memories are reconstructed from the bottom up arises from studies that show involvement of early and late regions during visual retrieval. By this view, remembering the appearance of your car involves reconstructing the visual image from basic featural components up to the whole object. Other studies, however, indicate that visual memories are reconstructed by recruiting the levels most specialized to process the desired information. That is, remembering the general appearance of your car is accomplished by recruitment of higher-level object-processing regions, while remembering the color is accomplished by recruitment of color-processing regions.

Retrieval Success (Ecphory)

Episodic memory retrieval is associated with a conscious awareness of reexperiencing an event that occurred in the past. As noted previously, it has been

convincingly demonstrated that the MTL plays a critical role in retrieval success. Recent studies using ERP and neuroimaging techniques have identified a set of neo- and subcortical areas that also play a role in retrieval success. ERP studies of recognition memory were the first to note a distinct set of frontal and parietal signals related to the successful identification of previously studied items. This old/new, or retrieval-success effect, has been further studied in studies using ERP, positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). The ubiquitous finding across studies is that recognizing old versus new items modulates activity in left PFC, as well as lateral and medial posterior parietal cortex. In PET and fMRI studies, frontal activations have been identified in bilateral dorsolateral PFC, medial PFC, and frontal polar cortex. Parietal activations have been consistently found in the anterior intraparietal sulcus and lateral parietal cortex near the supramarginal gyrus. While the findings are significant because they guide future research, the functional role of each of these regions has not been elucidated by the old/new manipulation.

In dual-process accounts of memory, recognition can arise from the fundamentally different memory processes of recollection and familiarity. Recollection is the ability to retrieve episodic memories, whereas familiarity is a strength-based signal that information is old. Familiarity is not supported by recollective evidence. Source memory tests, and the remember/know test developed by Endel Tulving, have been used to successfully dissociate these processes and further characterize the role of retrieval-success regions. Importantly, activity in the hippocampus has been consistently tied to memory decisions based on recollection, but not to those based on familiarity/knowing in the absence of recollection. In contrast, a related region of MTL near the rhinal cortex has been associated more with familiarity-based decisions. The neuroimaging results are consistent with an extensive animal literature that supports a role of hippocampus in recollection, and perirhinal cortex in nonrecollective recognition decisions. However, as there is also evidence that patients with lesions restricted to hippocampus proper are impaired on recognition memory, it is not currently known precisely how different MTL structures contribute to memory.

Somewhat surprisingly, ERP and fMRI studies suggest that parietal regions involved in old/new decisions are differentially related to whether those decisions were based on recollection or familiarity/knowing. ERP studies tend to indicate that parietal signals are related to recollection rather than familiarity. This general finding is supported by fMRI such that lateral parietal cortex near the supramarginal gyrus has been shown to respond preferentially to decisions based on recollection. The supramarginal regions have also been reported in studies evaluating temporal judgments and temporal orienting of attention, suggesting that they could be involved in providing temporal context during remembering, allowing us to mentally travel through time. Functional MRI studies also suggest that slightly more medial parietal cortex, near the anterior intraparietal sulcus (particularly in the left hemisphere), is similarly responsive to decisions based on recollection and familiarity. Interestingly, the literature on patients with posterior parietal lesions offers no supporting evidence for parietal involvement in long-term memory processes. Instead, parietal lesions tend to disrupt visuospatial and visuomotor abilities. There is evidence, however, that lesions affecting the angular gyrus in the left hemisphere impair short-term memory. In addition, studies of epileptic patients indicate that seizures originating in posterior parietal cortex can be associated with déjà vu or a disturbance in consciousness. This observation is broadly consistent with neuroimaging experiments that have found posterior parietal activity related to temporal attention. Thus, posterior parietal cortex may play a role in establishing temporal context during remembering.

Retrieval Mode

What would life be like if every stimulus evoked a memory of a past experience? As noted previously, ecphory occurs when there is an interaction between a retrieval cue and a stored memory trace. A retrieval cue can be any stimulus in the internal or external environment, including a word spoken by a companion, the sight of a flower, or a thought about an aching joint. Most stimuli we encounter, however, do not evoke episodic memories. In fact, because there would be little opportunity to adequately process and interpret relevant stimuli, it could be quite detrimental to basic survival if every stimulus cued an episodic memory.

At the same time, it is possible to allow stimuli to serve as cues to remember past events. One could freely associate by allowing each thought entering awareness to serve as a cue to remember a past experience. Or one could look at items in the room and think about how they were obtained. In both cases, the thoughts and objects do not typically evoke episodic memories. However, this simple suggestion could have suddenly turned an object on your desk into a cue that sparked a memory about where you purchased it. The all-or-none state in which

stimulus cues serve to evoke memories is known as retrieval mode.

Studies using neuroimaging, ERPs, and neuropsychological techniques suggest that the most anterior portions of the PFC are important for engaging in retrieval mode. A large number of neuroimaging studies using PET have consistently found right aPFC activity during episodic memory tests. aPFC was not found to modulate depending upon whether retrieval is successful or unsuccessful, indicating that it is not important for retrieving individual items from memory. Recent studies using fMRI and ERP add some insight into the role of aPFC by showing that right aPFC is active in a sustained manner, throughout the testing session and independently of the transient trial responses. aPFC could therefore be important for maintaining task-level rather than trial-level processes, playing a role in maintaining retrieval mode.

Associative Nature of Memory

Some theories of episodic memory consider the connections between the facts of the memory and the context in which they were encoded (i.e., time, place, emotional state), as well as the connections between items presented simultaneously. Since we are constantly presented with many items at once, it may not be the case that each memory trace is completely separate from the others; it is possible that each memory item can be related to many other items for organizational and efficiency reasons. Imagine if each chapter in this encyclopedia had to describe each piece of the brain it references and how certain processes work. This would add length and complexity to every chapter. Instead, the use of linking each chapter to related items allows each chapter to describe a specific piece while the reader can reference related pieces as necessary to form a whole. In this way, each related memory item can potentially serve as a recollective cue for the others in the organized group. While this can be true for the network of declarative facts alone, it can also connect declarative facts to the contextual items that allow for episodic memory. For instance, in the first car example given above, perhaps you remember that the salesperson was nervous because he had a very clammy handshake. This would be an example of the connection between a declarative fact (the seller was nervous) and a contextual fact (your disgust at his handshake) to form an episodic memory.

Several computational models attempt to use an associative system to represent the process of memory. One example is Lynne Reder's source activation confusion (SAC) model of memory, which suggests that people create different nodes of information at the time of encoding. One type of node contains the basic semantic knowledge of the item, while another type contains the contextual elements of the encoding episode. A memory within the SAC model can have many nodes and associations between these nodes, as well as common nodes that are associated with many memories (e.g., all the words studied during in an experiment might be connected to a context node encompassing the experiment room, computer, lighting, etc). A person experiences an episodic recollection when not only the item node is reinstated during recall, but also nodes containing information about the context. It is the activation of the association between the item and context nodes that makes the difference between remembering an event episodically versus simply a feeling of familiarity. It has also been suggested that a lack of association, or binding, of elements into memory can cause a lack of episodic experience at a later time. Other models that focus on the interconnected nature of memory include the search of associative memory (SAM) model and versions based on parallel distributed processing (PDP).

Neuroimaging studies have sought to investigate the neural mechanisms behind the creation of associations among items to be remembered. These studies involve presentation of multiple stimuli at one time and participants either study the items singly or as a group. The hypothesis is that studying each item singly does not prompt the creation of associations with the other items, while studying the items as a group does. These studies have shown that the hippocampus and parahippocampal gyrus (particularly on the right) are more active during associative encoding than single item encoding. Other neuroimaging studies have focused on the encoding and retrieval of contextual information about the remembered items. A variety of paradigms can be used to test recollection of contextual information, and often include a question at test regarding the temporal order of items, list membership, or color/font/spatial location at study. These studies have also found activation in the hippocampus and parahippocampal gyrus. Other areas of interest include bilateral dorsolateral PFC and parts of parietal cortex, which may be involved in the more specific contextual memories of spatial locations.

Episodic Memory: Assessment in Animals

Episodic and Episodic-like Memory

The concept of episodic memory was introduced to refer to the capacity to remember the unique events of our lives. The memory of a sequence of events collectively comprises an episode. As originally defined, an episodic memory is a mental representation of 'what' happened during an event, 'where' it happened, and 'when.' Writing in 1983, Tulving asserted that episodic memory "receives and stores information about temporally dated episodes or events, and temporal–spatial relations among these events." Thus, remembering a summer trip to France with a friend would be an instance of episodic memory. However, the concept has developed since its original definition, and it now refers to a 'memory system' whose operation has additional attributes such as the ability to travel mentally through time and a specific form of conscious awareness during the act of recall. In both its original and modern conceptions, episodic memory can be considered a form of declarative memory because the information within it is propositional. However, it is contrasted with another form of declarative memory – factual knowledge or semantic memory – which differs in not being bound to any specific temporal–spatial context. The brain mechanisms involved in these two forms of memory are likely to differ but overlap.

It has been claimed by Tulving, and separately by Suddendorf and Corballis that episodic memory is unique to humans. This 'uniqueness hypothesis' emerges from the supposition that only humans are capable of mental time travel and a self-knowing form of consciousness called 'autonoesis.' 'Mental time travel' refers to the phenomenological experience of traveling in the mind through time to that moment in the past when a specific event happened and, importantly, to travel prospectively and so imagine future events and needs. A person's experience is then one of being simultaneously in the present (the here and now) while also reexperiencing the past or the future (the memory, or imagined event) – a mental coexistence that transcends time. It is unclear whether any nonhuman animals are capable of doing this. The possession of language, another unique attribute of humans, enables the content of episodic memories be shared between persons in a way that is impossible in animals. However, it is not regarded as necessary for episodic memory and so it may be possible to develop novel, strictly behavioral tests of these additional features of episodic memory, without recourse to language, that could be tested in animals (e.g., future planning).

However, a 'comparative hypothesis' of episodic memory should also be considered. An episodic 'memory system' may be a collection of distinct neural subsystems in both humans and animals. The comparative perspective championed independently by Aggleton and Brown, Clayton and by Morris, holds that 'episodic-like' memory systems exist in animals that differ in expressing some but not all the attributes of human episodic memory. These subsystems, which may include associative mechanisms with which episodic memory is sometimes contrasted, may also be expressed in distinct ways in different species (birds, rodents, monkeys, and apes) as a function of their ecology, social structure, and so on. The reason for considering this alternative is that animals, no less than humans, also need to remember and later recall unique events (e.g., the location of a briefly seen predator). A memory system that could do this would be of adaptive significance but also likely to be distinct from the one mediating the stable body of knowledge about the world that is analogous to semantic memory in humans. Even monkeys, which are generally assumed to lack autonoesis (they fail the test of recognizing themselves in a mirror), still need a rapid, automatic system for encoding and later recalling unique events. Such a system would also be valuable for keeping track of where transiently available food or other resources are located in space and of social relationships in a troop of apes. Rodents and birds may also possess forms of memory that are episodic-like in character. The comparative hypothesis accepts that 'true' episodic memory may be unique to humans, but it argues against an inference of the uniqueness hypothesis that all forms of propositional memory in animals are necessarily semantic in character. Episodic-like and semantic-like systems would then exist in different species with a similar interdependence to that shown by the respective systems in humans.

Support for the comparative hypothesis comes from neuroanatomical, neurophysiological, and behavioral data. First, all mammals possess a number of brain structures that studies in humans have revealed to be implicated in declarative memory. Some of these may be specifically engaged during episodic-like encoding and recall, whereas others could contribute differentially to semantic-like memory. Second, these brain structures must possess specialized neurophysiological mechanisms that are essential for the online operations

of a rapid episodic-like memory system. Third, objective studies of animals in the laboratory have revealed a range of behavioral capacities that imply the possession of a memory system in vertebrates that can encode and later recall information about unique events, about their order in a sequence, and about the temporospatial context in which they happened. We now consider these three separate strands of the 'comparative' hypothesis in turn.

Neuroanatomy

Main Brain Structures Involved in Episodic-like Memory and Their Connectivity

Anatomical studies of the hippocampal region date back to the beginning of the twentieth century, but it was not until its second half that clinical reports of patients who suffered amnesia as a consequence of medial temporal lobe removals revealed its importance for episodic memory. From then onward, the neuroanatomy of the medial temporal lobe became the neuroanatomy of memory. Research on anatomical organization of the medial temporal lobe of the primate has revealed the connections between hippocampus and the parahippocampal region with the cerebral cortex and with subcortical areas also thought to be critical for episodic-like memory formation (Figure 1).

High-order processing areas of the cerebral cortex, including perirhinal and parahippocampal cortices, superior temporal gyrus, medial frontal, orbitofrontal, insular, retrosplenial, and inferior parietal cortices, send projections to the entorhinal cortex. Neurons from layer II of the entorhinal cortex originate the major afferent projection to the dentate gyrus. This projection forms the perforant pathway to the dentate gyrus' molecular layer, where individual axons terminate en passant. The en passant rather than a topological arrangement means that individual cells in the entorhinal cortex make contact with a large number of cells in the dentate; indeed, there is also a further threefold expansion in the number of dentate neurons relative to those in entorhinal cortex. The granular cells of the dentate gyrus send axons on to the CA3 field of the hippocampus (i.e., the mossy fibers) whose pattern of termination is strikingly different from that in the dentate, with individual

Figure 1 The neuroanatomy of episodic-like memory in nonhuman primates. The diagram summarizes the cortical and thalamic connections of the hippocampus and the entorhinal, perirhinal, and posterior parahippocampal cortices.

fibers making no more than approximately 15 axon terminals. Pyramidal cells in CA3 possess massive recurrent collaterals that can innervate other CA3 neurons along its entire anteroposterior axis, a feedback arrangement that some neural network models have suggested is ideal for the algorithms of 'pattern completion' and 'sequence learning.' Area CA3 pyramidal neurons also send collaterals, the Schaffer collaterals, to fields CA1 and CA2 of the hippocampus, where they terminate in the apical dendrites of pyramidal neurons. The neurons in area CA1 receive, in parallel, a projection from neurons of layer III of the entorhinal cortex bypassing all the processing stages of intrinsic hippocampal circuitry. The unidirectional nature of the connectivity, quite different from that in the neocortex, is striking but its functional implications are not clear. These connections reflect the potential complexity of associations that may take place within the hippocampus and they have inspired many computational models of memory formation (Figure 2).

Once the information is computed by the hippocampus, it is sent back to the cerebral cortex, where it is ultimately stored. Pyramidal cells of areas CA1/subiculum are the main origin of this projection. Their major cortical targets are neurons in the deep layers of the entorhinal cortex (V and VI), but they also send parallel projections to high-order processing areas of the cerebral cortex. Although this 'bypass' projection to the cerebral cortex is smaller in scale than that leaving the hippocampus and subicular cortex via the entorhinal cortex, it may be

Figure 2 Direct hippocampal output to the cerebral cortex. The two-dimensional unfolded map of the hippocampus illustrates the topography of the origin of the projection to the areas of the cortex colored. A color code density map is shown in the inset to illustrate the subfields that carry the strongest projection (i.e., CA1/subiculum). Fields of the hippocampus: CA1; CA1d, dorsal field of CA1; CA2; and CA3. DG, dentate gyrus; Pas, parasubiculum; Prs, presubiculum; S, subiculum. Reproduced from Insausti R and Munoz M (2001) Cortical projections of the non-entorhinal hippocampal formation in the cynomolgus monkey (*Macaca fascicularis*). *European Journal of Neuroscience* 14(3): 435–451, with permission from Blackwell Publishing.

relevant for memory. In fact, the contribution of different portions of CA1, subiculum, presubiculum, and parasubiculum to this projection depends on their target area in the cerebral cortex. This connectional segregation likely reflects different information types processed and stored by the various cortical areas. Thus, a serial and parallel cascade arrangement applies both to the input to the hippocampus and to the outputs. One view is that the hippocampus always computes some common set of 'algorithms' that reflect features of its circuitry, and that it can do this to different kinds of information relayed from different cortical areas as a function of the species involved – mouse, monkey, or man. However, the local circuitry of hippocampus, including its myriad of distinct inhibitory interneurons, is not sufficiently well understood to be confident of this speculation.

Entorhinal projections to the cortex are reciprocal, organized topographically, originate primarily in its deep layers, and terminate in superficial and deep layers of the cortex – indicating they are of the feedback type. Like the entorhinal cortex, the perirhinal and posterior parahippocampal cortices (postrhinal in the rat) also send projections to the cerebral cortex. Their contribution is, in fact, quantitatively larger than that of the entorhinal cortex. There is little doubt that the feedback interactions from the medial temporal lobe to the cortex are critical for the formation, and possibly the strengthening, of distributed networks in the cerebral cortex, where consolidation of long-term declarative memory takes place. However, clinical reports and lesion studies in monkeys and rats have suggested that the cortical interaction of the hippocampus and that of the adjacent cortices seem to contribute differently to the two facets of declarative memory – that is, episodic and semantic memory. Connections formed by the hippocampus and subicular cortex on top of those formed by the entorhinal, perirhinal, and posterior parahippocampal cortices with the remaining cerebral cortex are thought to be critical for the storage of episodic information. Cortical connections of entorhinal, perirhinal, and posterior parahippocampal cortices are thought to be necessary for the storage of factual information (semantic memory).

The Contribution of the Thalamus and Frontal Lobe to Memory

Several anatomical pathways connect the hippocampal region with those areas in the thalamus that have been related to memory function – the magnocellular division of the mediodorsal, the anterior nuclei of the thalamus, and the mammillary bodies. There are other hippocampal–thalamic connections, such as with the nucleus reuniens, laterodorsal nucleus, and medial pulvinar, whose differential role in memory is unclear. These thalamic nuclei also connect with different areas of the frontal cortex and, altogether, temporal–thalamic–frontal connections are thought to participate in efficient encoding, ongoing memory processing, and recall of declarative information from long-term memory.

Based on clinical reports, anatomical studies, and experimental data from rat and monkey lesion studies, Aggleton and Brown proposed a model that divides the labor of the interactions between the medial temporal lobe and the thalamus and cerebral cortex in terms of episodic and semantic memory. Their model includes two parallel temporal–thalamic–frontal pathways that make qualitatively different contributions to learning and memory – one pathway critical for the 'recollective' aspects of recognition (episodic memory) and the other for item familiarity.

Specifically, their anatomical pathway critical for episodic memory includes projections from the subiculum, prosubiculum, and, to a lesser extent, the entorhinal cortex through the fornix to the medial mammillary nucleus. This circuit also includes the projections from the mammillary nucleus to the anterior thalamic nuclei and from there through the cingulum bundle back to the subicular cortex in the hippocampal region. Anterior thalamic nuclei connections with the medial and orbitofrontal cortices, which are the major recipient of hippocampal efferent connections from CA1/subiculum, also form part of this network critical for episodic memory.

The set of connections important for stimulus recognition comprises entorhinal, perirhinal, and posterior parahippocampal projections to the magnocellular division of the mediodorsal nucleus of the thalamus, which at least in the monkey are descendent, with no reciprocal connections. Like the anterior nuclei, the mediodorsal nucleus of the thalamus also has projections with medial and orbitofrontal cortices. These frontal areas are also a major target of entorhinal, temporal pole, and posterior parahippocampal cortices output.

However, there are a number of anatomical connections whose function remains unclear. Neuroanatomical tract tracing studies in monkeys have shown that thalamic input to the hippocampus is mainly directed to area CA1, whereas dentate gyrus and area CA3 do not receive direct thalamic connections. This input arises in nucleus reuniens and terminates with asymmetric synapses (i.e., indicative of excitatory input) in both CA1 principal and GABAergic interneurons. Polymophic cells in the deepest layer of the subicular and entorhinal cortices have reciprocal connections with the anterior thalamic nuclei and the laterodorsal nucleus of the thalamus.

It seems that the thalamic afferents to the hippocampus are reciprocated by descending corticothalamic projections that originate in the presubiculum and entorhinal, temporopolar, perirhinal, and parahippocampal cortices as well as from more distant regions, such as cingulate, retrosplenial, and ventral insula.

Comparative Aspects

The characteristic architectonic organization of the dentate gyrus and hippocampal region makes it easily recognizable in Nissl-stained sections in many species, from very early mammals to humans. Not all hippocampal fields and adjacent cortex, however, seem to have homogeneously expanded in primates compared to smaller mammals such as rats. Areas CA1, subiculum, and the entorhinal cortex appear disproportionately enlarged in the primate brain. Their increased size in primates parallels the expansion of association areas in the cerebral cortex, to which they are connected. As a consequence, rat and monkey hippocampo-cortical connections share the same basic organizational principle (i.e., convergence of inputs to the entorhinal cortex, unidirectional circuitry, etc.), but they also present some differences. The entorhinal cortex of the rat has connections with unimodal sensory areas and with the motor cortex in the frontal lobe. Whereas, with the exception of olfactory connections, minor connections with unimodal sensory areas and no connection with motor cortex have been reported to date in the monkey's entorhinal cortex. Its connections are primarily with polysensory areas. A particular case is the olfactory projection. Although both the rat and the monkey entorhinal cortex receive direct input from the olfactory bulb, this only reaches approximately 10% of the monkey entorhinal cortex, whereas it terminates in almost the entire extent of the rat entorhinal cortex.

In contrast to the expansion of hippocampal–cortical connections in the primate brain, hippocampal and dentate gyrus commissural connections seem to have recessed, perhaps reflecting a growing laterality of function that is especially clear in humans. In rats, extensive commissural connections originate in the polymorphic layer of the dentate gyrus to the contralateral molecular layer of the dentate gyrus and from the CA3 field of the hippocampus to contralateral CA3 and CA1 fields. In monkeys, only the most rostral portion of the dentate gyrus and hippocampus in monkeys seem to project to homotypical contralateral sites. Monkeys and rats, however, share a commissural projection that originates in the presubiculum and terminates in contralateral entorhinal layer III.

Comparative anatomy research is needed at different levels (i.e., physiological, cellular, neurochemical, etc.) and in different systems (i.e., hippocampal–thalamic–frontal systems) to determine additional commonalities and differences between species and how these map onto the development of episodic-like memory systems.

Neurophysiology

The neurophysiological correlates and possible mechanisms of episodic-like memory have been studied by means of (1) single-unit recording in several of the structures identified previously in behaving animals performing memory tasks; (2) studies of synaptic physiology both *in vivo* and *in vitro*, particularly synaptic potentiation, which is thought to be crucial for the rapid encoding of new information; and (3) experimental studies and computational models of rhythmical electrical patterns and their relationship to encoding and retrieval.

One major correlate includes the selective firing of neurons in the hippocampus when an animal occupies a particular place in the environment ('place cells') or is looking at a specific view ('view cells'). Neurons in the entorhinal cortex provide a metric for place specificity and information about the direction in which an animal is moving at the time that an event occurs ('grid cells'). These and other specialized single cells have all been identified and characterized in rodents and/or monkeys – and all would be useful components of a neural episodic-like memory system because they would provide information about the context or the scene and an animal's movement through it. Changes in context can also result in distinct forms of spatial remapping of an environment. Alterations occur in the relative rate at which place cells fire in some circumstances (rate remapping), whereas a radical reorganization of firing fields occurs under others (global remapping). What is not clear is how unique events and episodes are encoded with respect to these changes in the representation of contextual information. A difficulty in making single-unit observations of events is that obtaining reliable information about the firing correlates of a single neuron generally requires repetition of the sufficient stimulus for firing it – a condition that cannot be met for a unique event. Recording techniques that enable hundreds of cells to be monitored at one time have been developed and the use of these during episodic-like memory tasks may enable specific population vectors to be identified that correspond to a particular event. Once this breakthrough is achieved, it will be possible to ask analytic questions about the

association between events and the context or scene in which they occur.

Laboratory studies have also revealed that synaptic weight changes can be induced and made to last after very brief patterns of neural activation, as studied physiologically in the phenomenon of long-term potentiation (LTP). The most prominent form of LTP is known to require the momentary activation of *N*-methyl-D-aspartate (NMDA) receptors. LTP induction triggers changes in the availability of post-synaptic glutamate receptors responsible for fast synaptic transmission, perhaps by altering the rate at which α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors are trafficked to the synaptic membrane. In this way, the strength of connections between cells in a distributed associative memory of the kind that is processed in hippocampal circuitry can be altered in a sustained manner. There have been a number of demanding tests of the hypothesis that hippocampal synaptic plasticity is critical for memory. Studies of the role of LTP (and long-term depression) in learning and memory have used a variety of tasks of which some are good models of episodic-like memory. New studies revealing that LTP is selectively induced at hippocampal synapses during rapid learning and is necessary for learning to take place have complemented research showing how artificial alterations in synaptic weights after training alter memory recall.

If this way of thinking about the encoding of episodic-like memory is correct, the resulting changes in synaptic strength would occur in circuitry, such as in area CA1 of the hippocampal formation, where there is the potential for linking information about events (processed in hippocampal circuits) to the spatial context in which an event has occurred (projected in from the layer III cells of the entorhinal cortex). The value of this is that approaching such a location again in the future will retrieve a memory representation of the prior event that happened there (e.g., the prior presence of predator). It is less obvious that remembering 'when' an event happened is quite so valuable. The local circuitry of parts of the hippocampal formation (e.g., the dentate gyrus) is also ideally suited for separating or 'orthogonalizing' neural patterns such that the synaptic memory traces of very similar events can be stored in overlapping but sufficiently separated locations in downstream regions in order to minimize interference at the point of recall. Other parts of the circuitry (e.g., area CA3) may be useful for encoding sequences of events in the correct order and neural network models of such a process have been proposed. However, it is still unclear how changes of this kind within hippocampal circuitry give rise to lasting changes in connectivity in the cortex in the process of memory consolidation. The feedback connections described previously are likely to be critical for this.

Episodic-like memory involves both encoding and recall. Different computational models have each implicated the hippocampal theta rhythm in the switchover between these two modes. Theta is a rhythmical pattern of electroencephalogram (EEG) activity in the hippocampal formation, proceeding at between 5 and 10 Hz in rodents. It is contrasted a state in which the EEG shows large-amplitude irregular activity. Some suggest that the theta mode is a learning mode, at least in the rat, with irregular activity occurring during memory retrieval. Other models suggest that the switchover between encoding and retrieval happens extremely rapidly at different phases of the theta cycle, with the significance of the cycle being to modulate the probability that NMDA receptors can be successfully activated as a function of membrane potential. Further work linking these neurophysiological parameters to behavioral paradigms using valid episodic-like learning paradigms is required.

Behavior and Cognition

The neurobiology of learning and memory has been studied using a wide range of behavioral tasks in animals. Some are classified as 'declarative,' others as more 'procedural.' It is important to appreciate, however, that of those that are accepted as models of declarative memory, making the distinction between whether a specific task is 'episodic-like' and 'semantic-like' is often unclear. Certain widely used tasks, such as tests of recognition memory (delayed non-matching to sample in monkeys), paired-associate memory (e.g., object–place tasks in monkeys), spatial memory (the water maze in rats), and food caching (in birds), do not fall neatly into one or the other category. Moreover, the notion that one form of memory (e.g., spatial memory) is mediated solely by one brain area (e.g., the hippocampus) has fallen out of favor as neuroscientists recognize the complexity of different interacting memory processes (e.g., encoding vs. consolidation). However, a subset of behavioral tasks has attempted to determine the key distinction between episodic and semantic memory. We focus on these cases in this section.

Remembering 'What' and 'Where'

A common experience when remembering a specific event is that we also remember where that event happened. Can animals also do 'mental space travel'? Experiments in monkeys suggest they are very sensitive to the scene or context of events. In one study,

macaque monkeys were trained to reach for either of two objects (A or B), such that A was correct when the animals were facing one way in the laboratory room but B was correct when they were facing in the other direction. This task was relatively easy to learn and was impaired by bilateral damage to the fornix. Separately, the monkeys were also trained on a logically identical task in which the backdrop was the color of a tray rather than the scene in front of the animal. This task was unaffected by the lesion. When the monkey has to face in different directions, the scene before the monkey changes even though many elements of it are still there (e.g., the window). Neurons have also been identified in the hippocampus of monkeys whose firing patterns are exquisitely sensitive to what the animal is looking at (view cells), suggesting that scene processing is very important in the rapid learning about events.

Scenes can also be displayed on computer screens. In an object-in-place task, for example, the animal is trained to reach out and touch the 'object' (e.g., a typographical character) that occupies a particular position in a unique background of abstract colors and shapes on the screen (Figure 3(a)). Monkeys readily learn to do this and their success relies on the integrity of a circuit that includes the hippocampus, fornix, mammillary bodies, and anterior thalamus. The impairment is no greater when two of these structures are damaged sequentially, suggesting that these brain regions make their contribution to information processing in a serial manner – as if part of a circuit. Additional studies, using traditional training techniques that require monkeys to reach for objects on trays placed in front of them, further establish the importance of the entorhinal and perirhinal cortex in processing associations between 'where' and 'what.'

Rats can also learn event–location associations rapidly and can recall the location at which an event occurred when given an appropriate cue. For example, when trained to find and dig up distinctively

Figure 3 Contextually specific memory. (a, b) Memory for what and where. Monkeys can be trained to use 'touchscreens' and choose differentially between objects (typographical characters) as a function of the background scene against which they are presented. Rats can also be trained to find flavored food in sand wells at different locations in a large training arena. A short-lasting memory of a what–where association can be established in one trial. (c) Memory for what, where, and when in California scrub jays. A supply of different foods is made available to the food-caching bird at different times. This is cached in an ice cube tray filled with sand. The bird makes an appropriate free-recall judgment of what to search for where at different times after the caching episode. Courtesy of David Gaffan, Richard Morris, and Nicola Clayton.

flavored food at different locations in a training arena, rats can – after only a single training trial with each flavor – recall which location to visit to get more food when cued with a specific flavor (Figure 3(b)). Such memories do not last very long unless they are subject to repeated training, but this gradually increasing memory persistence may reflect a transition from episodic-like to semantic-like memory. Learning depends on the hippocampus and is impaired by a selective NMDA receptor antagonist, D-AP5, when given prior to information encoding. If only given prior to memory recall, the drug has no effect. This is directly analogous to its effect on LTP discussed previously: D-AP5 blocks the induction but not the expression of LTP.

Food Caching by Birds as a Model of 'What,' 'Where,' and 'When'

The temporal element of the 'what, where, when' trilogy is not captured in these tasks and is clearly critical. Work on birds, specifically Californian scrub jays, has started to address this critical element of episodic-like memory. Adult hand-raised scrub jays were allowed to cache food items, such as mealworms or peanuts, in sand-filled ice cube trays surrounded by distinctive visual objects (Figure 3(c)). The birds much prefer fresh mealworms to peanuts, but these perish over time and become distasteful, whereas peanuts last much longer. Two caching periods, up to 5 days apart, constituted the opportunity for the animals to encode into memory what food item was being cached, where (in the ice cube tray), and when (recently or some while ago). Recovery was permitted either immediately or several days later, with both sides of the ice cube tray uncovered and available. The main finding was that in nonrewarded probe tests in which neither food was actually available (thus preventing any olfactory or visual cues to guide search location), the birds searched preferentially for wax moths when recovery occurred 4 h after caching but switched their search to the peanut locations when recovery was delayed for 124 h. This switchover was not shown by birds in a control group in which, throughout training, fresh mealworms were placed in the correct places even after long caching–recovery delays. Thus, at recovery and using free recall, the birds could recollect what food item was stored where and, at least in some sense, how long ago.

In addition to careful control procedures, the different foods caching paradigm is a helpful innovation because it encourages the animal to be attentive and engaged when encoding the memory of where a specific type of food is located. The use of very long memory intervals (days) is beyond the capability of short-term memory, and the use of free recall at cache recovery obviates the use of a familiarity strategy that has been so problematic in studies of recognition memory. Clayton and Dickinson's claim that their initial study provides "the first conclusive behavioral evidence of 'episodic-like' memory in animals other than humans" has been vindicated by later studies in which a number of detailed issues have been taken further, such as applying information retrospectively at the time of retrieval and investigating prospective aspects of food caching. The birds have even been observed to do certain things at the time of caching that reflect some kind of 'awareness' of what food items they may prefer to secure at a point in the future. This ability would be outside the domain of semantic memory.

Similar behavioral studies have been conducted using monkeys living freely in a primate colony and these have provided evidence for the memory of 'what, where, whom.' However, neither the scrub jay nor the primate work has involved invasive neurobiological studies and so the anatomical and physiological basis of performance is unknown. This is unfortunate because, as discussed previously, including a temporal element in encoding and recall is desirable for distinguishing episodic-like memory from rapid semantic learning.

Sequences of Events

It was previously mentioned that area CA3 of the hippocampus has recurrent auto-associative circuitry. Neural network models have suggested that this may be useful for learning about sequences of events that would then collectively comprise an episode. Single-unit recording studies, such as studies of 'replay' following sleep episodes, offer some support for this idea, as do observations that the firing of place cells in a maze may be 'gated' in a retrospective or prospective way by preceding or anticipated events. Lesion studies indicate that damage to the hippocampus disrupts sequence memory. For example, a task involving successive digging through cups of sand with distinctive odors indicated that normal rats could remember trial-unique sequences of odor A before odor B, B before C, C before D, and so on, whereas the rats with hippocampal lesions could not. However, the lesioned rats were just as good as controls in remembering that these odors were familiar, although presented for only a single trial, when they were tested against completely novel odors. A follow-up study indicated that rats with hippocampal lesions could eventually acquire some sequential information

about repeated sequences with extended training but never well enough to disambiguate overlapping sequences. One theoretical view of this component of episodic-like memory in rats is that it can encode information about sequence but not necessarily the absolute time when an event occurs.

Current Dichotomies in the Neuroscience of Episodic Memory: Memory versus Perception, Remembering versus Knowing, Recollection versus Familiarity

As we have seen, early dissociations between memory systems emerged from studies of patients with large medial temporal lobe (MTL) damage. These reports were critical to the identification of different memory systems, such as declarative and non-declarative memory, and they stimulated research on the impact of restricted lesions in both animal models and in patients with respect to what areas within the MTL are critical for memory. This research has shed light on what medial temporal areas may be critical for certain processes, that is, the perirhinal cortex for recognition of objects, the posterior parahippocampal region for recognition of object-place associations, and the hippocampus for spatial memory. However, new questions have emerged. At present various dichotomies such as those listed above are a current focus of attention. So far, these dichotomies are proving difficult to relate precisely to specific brain structures, but the use of different behavioral methodologies, such as the analysis of performance using signal detection theory and, specifically, receiver operating characteristics (ROCs) are helping us to understand their validity and anatomical relevance. The use of ROCs has been championed by Yonelinas, and for animal studies by Eichenbaum, but the selectivity of this approach has also been the subject of criticism by Squire. Physiological techniques, such as event related potentials (ERP), functional MRI (fMRI), combined fMRI and ERP in patients with restricted lesions are collectively helping to shed light on theoretical controversies.

Conclusion and Outstanding Issues

Episodic memory can be defined in a way that essentially guarantees that it is unique to humans. However, a different and comparative hypothesis is both realistic and one supported by a body of data. First, the striking neuroanatomy of declarative memory in mammals points to intrinsic circuitry and patterns of connections that are important for the rapid encoding and recall of information from numerous sensory modalities. Second, context processing by neurons and rapid synaptic potentiation are essential neurophysiological features that a neural episodic-like system requires. Third, a range of new behavioral tasks is being developed to elucidate the subtle distinctions, within the declarative domain, of episodic-like and semantic-like memory.

A paradoxical feature of the 'uniqueness' claim that animals lack episodic memory and possess only semantic-like memory is that, in humans, the latter is most often acquired through communication – the very channel of learning that is not open to animals. If a paradigmatic example of semantic memory is knowing that 'Paris is the capital of France' despite the fact that the person knowing this need never have visited the city, then this is precisely the kind of information that animals could never acquire because their learning absolutely requires personal experience. Their personal experience of learning will also entail the circadian rhythm of night and day and, in most cases, of the different seasons. It is then reasonable to suppose that animals could perhaps acquire the knowledge that things change over time and that different frameworks of knowledge would be appropriate to different times of day or the year (e.g., in relation to safety by day or night or the availability of water). Yet the radical claim of those espousing the 'human uniqueness' view of episodic memory is that animals can know all these things and yet be 'stuck in time.' That is, they suppose that all animals have neither a sense of the past nor a sense of the future, despite possessing both declarative and procedural learning systems that enable their future behavior to profit from past experience. The claim may be right, but it is deeply paradoxical.

Based on the kinds of data presented here – anatomical, physiological, and behavioral – the idea that some animals may possess episodic-like memory systems seems strong. However, certain qualifications should be recognized. First, if true episodic memory is defined as consisting of certain mental experiences, such as reexperiencing the past, we may always be unable to assess whether animals also have such experiences and thus the claim is untestable. Suddendorf and Corballis have supported Tulving's 'uniqueness' hypothesis in suggesting that "the ability to travel mentally in time constitutes a discontinuity between humans and other animals." However, they also recognize that finding evidence for mental time travel in animals would be a major discovery. A second qualification is that, because episodic memory in humans encodes personal experiences, a sophisticated form of awareness that includes a sense of one's own individual identity may indeed be essential

for the full expression of true episodic memory. What is unclear is how to realize a scientifically acceptable measure of such a subjective concept as a 'sense of one's own individual identity.' The gap between the 'uniqueness' and 'comparative' hypotheses of episodic and episodic-like memory cannot be closed until additional behavioral techniques are developed and explored. This arsenal of tasks will then have to be examined in relation to the complex patterns of anatomical connections of the medial temporal lobe described previously. The imagination of researchers in behavioral neuroscience is such that techniques for addressing these issues may become available.

Erectile Dysfunction

S H Tariq and J E Morley, St. Louis University and Veterans Affairs Medical Center, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

Erectile dysfunction (ED) is defined as an inability to achieve or maintain an erection sufficient for satisfactory sexual performance. ED is estimated to occur in 10–20 million men, which increases to 30 million if partial ED is included. ED can occur in men of all ages, but it is more common in the elderly and is not a part of normal aging.

Prevalence

The prevalence of ED varies. The reported prevalence of ED is 5% in 40-year-olds, which triples to 15% at the age of 70. The occurrence of ED increases with age: it occurs in 27% of men at age 70 years, 55% at age 75 years, and 75% at age 80 years. The prevalence of ED is 50% in patients with renal disease and it increases to 75% in those who are on dialysis. ED develops in approximately 50% of patients with diabetes within 10 years of diagnosis.

ED is a major health concern, strongly associated with increasing age. Men with ED have impaired quality of life compared with unaffected individuals. Since sexual activity contributes significantly to quality of life, patients expect physicians to address such an important issue.

Physiology of Penile Erection and Changes with Aging

Sexual activity consists of libido and potency. Libido is the sexual desire/drive, thoughts and fantasies, satisfaction, and pleasure. Potency is the ability to attain and maintain an erection and to ejaculate. There are three pathways for penile erection, which are summarized in Table 1. Masters and Johnson described changes in the four stages of the sexual response cycle – excitement, plateau, orgasm, and resolution – with aging and these are outlined in Table 2.

Causes of ED

The etiology of ED varies significantly depending on the clinic population, as shown in Table 3. Etiologic causes for ED include vascular, endocrine (hypogonadism, thyroid problems, diabetes, and hyperprolactinemia), neurologic, urologic, psychogenic, medication, and alcoholism. Depression as a cause of ED is more common in those younger than 60 years of age. Similarly, anxiety and marital discord are more common in the population group younger than 60 years of age.

Medical Conditions Associated with ED

The most common medical conditions associated with ED are hypertension and coronary artery disease. Fifty-seven percent of patients who underwent coronary artery surgery had ED. Other conditions associated with ED include diabetes, smoking, and alcohol use. An increase in total cholesterol has been associated with ED.

Evaluation

A detailed history is absolutely essential to differentiate difficulties with ED from a decrease in libido. Table 4 highlights some of the important areas that are essential in evaluating ED. A history from a partner will help uncover some of the problems with their sex life. The risk factors for ED during history include vascular disease, hormonal problems (thyroid and diabetes), neurological dysfunction, medication, past surgery, or trauma; psychological and social factors, including an evaluation for depression, should be assessed. A number of medications are associated with an increase or decrease in libido, and these are shown in Table 5. Since depression can contribute to ED, a screening assessment tool such as the Beck Depression Inventory or Yesavage Geriatric Scale may be used. A number of screening tools are also available to screen patients for androgen deficiency, such as the Saint Louis University Androgen Deficiency in Aging Males (ADAM), which is shown in Table 6. A positive answer to question 1 or 7 or any other three questions is considered to indicate a high likelihood of low testosterone. The ADAM questionnaire has a sensitivity of 88% and a specificity of 60%. There is a clear improvement in the ADAM questionnaire after treatment with testosterone.

Physical examination should include assessment of secondary sexual characteristics along with a detailed examination searching for vascular and neurological problems. Local penile shaft examination is also important to rule out Peyronie's disease.

Laboratory investigations such as diabetes, renal functions, lipid profile, thyroid function tests, prolactin levels, and penile brachial pressure index will help search for the etiology of ED. The most important test for determining a decrease in sex drive or libido is to check total testosterone and bioavailable testosterone

Table 1 Physiology of penile erection

- Stimulation of the genitalia, in which sensation in the sensory receptors of the penile shaft and glans penis is carried to the spinal cord by afferent nerves. The sensory perception is then passed on to the higher centers, and efferent impulses leave the spinal cord via the sacral parasympathetic center to the pelvic plexus and the cavernous nerves into the corpus cavernosum.
- Psychogenic stimulation that occurs through visual or auditory stimuli. This is more complex and less understood.
- Penile erection occurs during the rapid eye movement stage of sleep. The physiology is not known.
- During erection the parasympathetic nervous system causes vasodilatation, increased blood supply and pressure to the cavernous spaces, and venous occlusion.
- Flaccid state is achieved by the release of catecholamines, which causes contraction of the smooth muscles around the sinusoids and arterioles, expelling the blood out of the sinusoidal spaces and decreasing blood flow, resulting in a flaccid state.
- Neurotransmitters such as nitric oxide, prostaglandins E_2 and E_1, vasoactive intestinal peptide, neuropeptide Y, and acetylcholine cause smooth muscle relaxation and penile erection. Smooth muscle contraction is caused by prostaglandin $F_{2\alpha}$, substance P, histamine, and norepinephrine.

Table 2 Changes with aging

- The excitement phase shows a delay in erection, decrease in erectile strength as well as decrease in scrotal congestion, and testicular elevation with advanced age.
- The plateau phase in prolonged along with a decrease in preejaculatory. The orgasmic phase is shorter, with a decrease in the ejaculatory force. The time for ejaculation is longer compared to that of young adults.
- In the resolution phase, there is rapid detumescence and rapid testicular descent.
- The refractory period is also prolonged with age.
- The penis becomes less sensitive to stimulation with age and it takes longer to achieve erection. The erection becomes more dependent on physical stimulation of the penis and less responsive to visual, nongenital, and psychologic stimulation.

Table 3 Causes of erectile dysfunction

in older adults (non-sex hormone-bound testosterone). Cross-sectional studies have demonstrated that levels of testosterone decline with age, although the Baltimore Longitudinal Aging Study failed to find a decrease in testosterone levels in males. The decline in testosterone is 100 ng/dl per decade. A number of studies have reported a decline in bioavailable testosterone with aging. A decline in bioavailable testosterone is

Drugs that possibly increase sexual desire
Androgens (in androgen-deficit states)
Baclofen (possible anti-anxiety effect)
Benzodiazepines (anti-anxiety effect)
Haloperidol (indirect effect due to improved sense of well-being)

Table 6 St. Louis University ADAM Questionnaire

1. Do you have a decrease in libido (sex drive)?
2. Do you have a lack of energy?
3. Do you have a decrease in strength and/or endurance?
4. Have you lost height?
5. Have you noticed a decreased 'enjoyment of life'?
6. Are you sad and/or grumpy?
7. Are you erections less strong?
8. Have you noted a recent deterioration in your ability to play sports?
9. Are you falling asleep after dinner?
10. Has there been a recent deterioration in your work performance?

seen in 50% of men by 50 years of age. Luteinizing hormone levels fail to increase appropriately in response to a decrease in testosterone levels with age, suggesting failure of the hypothalamic–pituitary unit (i.e., secondary hypogonadism).

Treatment

Current treatments for ED include oral medications, intracavernosal injections, testosterone therapy, vacuum pumps, penile prostheses, and vascular surgery. First-line therapy includes oral drug therapy, the use of vacuum devices, and, less frequently, sex therapy. Referral to a specialist may be required upon request of the patient if initial therapy failed or a more comprehensive evaluation is needed. Patients with a suspected psychogenic etiology should be considered for sexual counseling or psychiatric referral. Involvement of the partner in the diagnostic and therapeutic plans from the beginning is crucial. If a particular drug is related to ED, then that drug should be stopped and a different class of drug should be used.

Oral Therapy

Phosphodiesterase-5 inhibitors

Currently, there are three drugs available in the United States and all inhibit phosphodiesterase-5 (PDE-5), which is responsible for the degradation of cyclic guanosine monophosphate (cGMP) in the corpus cavernosum. When the nitric oxide and cGMP pathway is activated during sexual stimulation, inhibition of cGMP by PDE-5 inhibitors results in increased levels of cGMP in the corpus cavernosum and increased relaxation of corpus cavernosal smooth muscle cells in response to sexual stimulation. This causes an increase in penile blood flow and erection. Thus, sexual stimulation is required and PDE-5 inhibitors help maintain it.

Sildenafil is well absorbed during fasting, and the plasma concentrations are maximal within 30–120 min. It is mainly excreted by the liver, and its half-life is approximately 4 h. The starting dose is 50 mg taken 1 h before sexual activity, not more than once per day. The quality of life consequences of ED include depression, anxiety, and loss of self-esteem. One study determined correlations between erectile function (EF), intercourse success, and emotional well-being measured with the Self-Esteem and Relationship (SEAR) questionnaire in men treated with sildenafil citrate for ED and stratified by age (<50 years, 50–65 years, and >65 years). For the overall population, there was significant improvement ($p < 0.0001$) in the Self-Esteem subscale and intercourse success rate. Secondary outcomes (i.e., EF domain of the International Index of Erectile Function and event log frequency of erection hard enough for sexual intercourse and of ejaculation/orgasm) also improved. All ten correlations were positive in men of all ages. The most common adverse

events were mild to moderate headache (12%), vasodilatation (7%), and rhinitis (4%). Sildenafil improved EF and there was an increased intercourse success rate, which correlated positively with improvement in SEAR measures of self-esteem and sexual relationship.

In hypogonadal patients with ED, androgen supplementation is first-line therapy. If there is no response to androgen alone or sildenafil alone, combined use may improve EF and enhance the therapeutic effect of PDE-5 inhibitors.

Tadalafil has a half-life of 17.5 h. At a dose of 20 mg, tadalafil enabled 73–80% of sexual intercourse attempts to be completed successfully with appropriate sexual stimulation between 30 min and 36 h after dosing. Tadalafil is well tolerated. Side effects are headache and dyspepsia, which are mostly mild or moderate and transient. There were no significant laboratory abnormalities or electrocardiogram changes. It is preferred over sildenafil by men in the treatment of ED, secondary to its longer duration of action, especially by those who do not have any risk factors for developing chest pain. In a small number of patients refractory to sildenafil therapy, a trial of vardenafil might be helpful.

Vardenafil is well tolerated. Side effects are headache, cutaneous flushing, dyspepsia, and rhinitis. Vardenafil successfully treated ED after nerve sparing radical retropubic prostatectomy.

All PDE-5 inhibitors are absolutely contraindicated with the use of nitrates and are hazardous in patients with positive stress test not on nitrites; patients on a complicated, multidrug, antihypertensive program; patients with congestive heart failure and borderline low-volume status; and patients on drugs which prolong the half-life of these medications.

Phentolamine

Phentolamine is an α-adrenergic blocker with poor efficacy in improving ED but may be used with other agents. A prospective, placebo-controlled, double-blind study (40 patients) showed that phentolamine had a success rate of 20.0%, 30.0%, and 36.7% at doses of 20, 40, 60 mg, respectively, in the treatment of ED compared to placebo. The mean age was 48 years for those who responded to phentolamine compared to 52.2 years for the nonresponders. An open-label, multicenter study compared the efficacy and safety of oral sildenafil and phentolamine in men with ED. Patients received sildenafil (25–100 mg, $n = 123$) or phentolamine (40 mg, $n = 119$) for 8 weeks, and efficacy was assessed. Approximately twice as many men receiving sildenafil had successful attempts at sexual intercourse, improved erections, and improved ability to have sexual intercourse compared with men receiving phentolamine. The adverse events included rhinitis, headache, tachycardia, and nausea, with a higher frequency reported in patients receiving phentolamine than sildenafil (41% vs. 33%), with the exception of headache, which was reported more frequently in sildenafil users. Overall, sildenafil was more effective and appeared to be better tolerated than phentolamine for the treatment of ED.

Yohimbine

Yohimbine is an α_2-adrenergic receptor antagonist; it acts at the serotonergic and adrenergic receptors in brain centers associated with libido and penile erection. Its exact mechanism of action is unknown. Yohimbine has been shown to be relatively effective in psychogenic ED, although other studies have shown no statistical significant difference from placebo. Yohimbine carries a risk of hypertension, palpitation, fine tremor, and anxiety. Yohimbine has had questionable effects in men with organic ED. Of a total of 18 nonsmoking men, 50% were successful in completing intercourse in more than 75% of attempts. Yohimbine could be effective therapy to treat organic ED in some men.

Apomorphine

Apomorphine is a sublingual formulation and is now undergoing clinical trials. It acts centrally on dopamine D_2 receptors of the hypothalamus and activates pathways that involve nitric oxide and oxytocin signals. It is generally well tolerated at doses of 2 or 3 mg, and it is not an opioid. An observational cohort study was conducted in England between October 2001 and December 2002. The study cohort comprised 11 185 patients, 99.3% of whom were men, with a median age of 61 years. The study concluded that the most frequently reported prescribing indication was ED and the most frequently reported reason for stopping apomorphine was that it was "not effective." However, in a small percentage of patients apomorphine has been effective. Headache was the most commonly reported adverse drug reaction and the most frequently reported clinical condition occurring in the first month.

Medicated Urethral System for Erection

The medicated urethral system for erection (MUSE) uses prostaglandin E_1, which is an endogenous unsaturated 20-carbon fatty acid derivative of arachidonic acid, and alprostadil is a more stable, synthetic form of prostaglandin E_1. Prostaglandin E_1 causes smooth muscle relaxation and vasodilatation by acting on adenylate cyclase to increase the intracellular cyclic

adenosine monophosphate concentration. The first application is usually at a dose of 50 μg in the physician's office because of the potential complications. The dose can be titrated (250–1000 μg), depending on the erectile response. Alprostadil is well tolerated and effectively restores the capacity for erections and sexual intercourse. A restrictive band can be placed at the base of the penis to increase efficacy, especially if the phenomena of pelvic steal syndrome is present. The advantages of transurethral therapy include local application, minimal systemic effects, and the rarity of drug interactions. Side effects include penile pain, local discomfort, hypotension, dizziness, and syncope. Trauma, if it occurs, consists of a superficial urethral abrasion, no urethral stricture, penile fibrosis, or priapism.

Intracavernous Injection Therapy

The most commonly used intracavernous drugs in the United States are alprostadil and a combination of papaverine, phentolamine, and alprostadil. Intracavernous injection of alprostadil is an effective therapy with tolerable side effects. It has a success rate of 60–70% in the treatment of vasculogenic and 100% in neurogenic ED. It is contraindicated in sickle cell anemia, schizophrenia or other psychiatric disease, or severe venous leakage. Pain is reported to occur in 13–33%, fibrotic complication in 1–57%, and priapism in 5–23% of patients. If priapism does occur, the patient should be informed to take oral benadryl and, if it is not effective, should then seek immediate access for medical treatment. Injection therapy should be avoided in patients who are on chronic warfarin therapy because it increases the risk of hematomas and bleeding.

Alprostadil is the only agent approved in the United States. It is given in doses of 5–20 μg. It is indicated if oral therapy fails or is not suitable; for diabetics, especially those on insulin; for spinal cord injury; and for radical prostatectomy.

Papaverine is a nonspecific PDE inhibitor. The usual dose is 15–60 mg. It is highly effective (up to 80%) in men with psychogenic and neurogenic ED, but it is less effective when ED is of vascular etiology (36–50%). Advantages include its low cost and stability at room temperature. Its major drawbacks are priapism, corporal fibrosis, and occasional increases in serum aminotransferase concentrations.

Testosterone Therapies

Testosterone replacement can be achieved in several ways: oral and injectable therapies, transscrotal and transdermal patches, subcutaneous gels, buccal preparations, and selective androgen receptor molecule (no effects on prostate). Some preparations are under development, such as sublingual and inhalation forms.

Effects of Testosterone Replacement

Coronary artery disease Studies have shown that low testosterone levels are associated with both coronary artery disease and the degree of atherosclerosis. Testosterone dilates the brachial artery and therefore increases blood flow, decreases ST depression during exercise stress test, and reduces or has no effect on myocardial infarction. Testosterone replacement therapies have not demonstrated an increased incidence of cardiovascular disease or events.

Lipid profiles Testosterone decreases cholesterol and low-density lipoprotein cholesterol levels and high-density lipoprotein (HDL) cholesterol. A meta-analysis of testosterone replacement showed that HDL levels were reduced in three studies and unchanged in 15 studies. Five studies showed a reduction in total cholesterol, two showed an increase, and 12 were unchanged. Low-density cholesterol was either unchanged or reduced in 14 of the 15 studies.

Libido and ED Epidemiologic studies have shown that decreased sexual activity and libido are associated with a decrease in free or bioavailable testosterone levels. These studies suggested that aging was a more important contributor than androgen levels in sexual behavior in healthy older men. Testosterone replacement improves libido and quality of erection in hypogonadal men. Sildenafil is reported to improve erections in older men. It is reported that certain men with low testosterone do not respond to sildenafil alone unless their testosterone is replaced. This seems to be because testosterone is essential for the synthesis of nitric oxide synthase.

Body composition and frailty Decrease in muscle mass and strength is associated with aging. Resistance training restores the muscle mass and strength. Excessive loss of muscle in a person results in sarcopenia and increases the risk of becoming frail. Studies on testosterone replacement have clearly shown that it increases the muscle mass, and this is reported even in older men who are not hypogonadal. The increased strength is reported in the upper extremities in hypogonadal men, but studies have failed to show increased strength in men who are not hypogonadal. 5α-Dihydrotestosterone has been shown to increase knee flexion strength. Testosterone replacement is also beneficial in improving the functional index measure during rehabilitation following hospitalization.

Leptin levels increase with age in males, which has been shown to be associated with decreases in testosterone. Testosterone replacement decreases fat mass, with subcutaneous adiposity being reduced to a greater extent than abdominal visceral fat.

Behavioral effects Epidemiologists have shown a strong correlation between low testosterone and cognitive decline with aging. Low testosterone at middle age is predictive of developing Alzheimer's disease. Testosterone replacement improves working memory, spatial memory, and trail making B; effects on verbal memory are controversial and in some studies testosterone replacement has failed to alter cognition.

The SAMP8 mouse has low testosterone levels. Testosterone replacement in this mouse model of Alzheimer's disease improves learning and memory. Testosterone treatment decreased amyloid precursor protein. Patients with Alzheimer's disease have low testosterone levels in brain tissue compared with controls. Testosterone replacement has been shown to produce small improvements in cognition in people with Alzheimer's disease.

Dysphoria has been related to low levels of testosterone. Testosterone replacement did improve depression in one study, but other studies have failed to show the same results.

Bone Testosterone is converted by the process of aromatization to estradiol, which acts on bone. Testosterone increases bone mineral density by acting on the osteoblasts and thus increases bone mineral density at the hip and lumbar spine. There are no studies examining the effect of testosterone on hip fractures.

Polycythemia Lower testosterone levels are associated with anemia in men. A rise in hematocrit is generally beneficial in anemia; elevation above the normal range may have grave consequences resulting in coronary, cerebrovascular, or peripheral vascular circulation. Injections increased hematocrit by 44%, transdermal nonscrotal patch by 15%, and scrotal patch by 5%. There is a direct relationship between testosterone dosage and the incidence of erythrocytosis. Erythrocytosis was reported in 2.8% of men on 5 mg of nonscrotal patches and 11% with 50 mg day^{-1} and 18% with 100 mg day^{-1} gel, respectively.

Benign prostatic hypertrophy Benign prostatic hypertrophy (BPH) is induced by androgens and it decreases with decreases in serum testosterone. However, a number of studies have failed to show that testosterone replacement exacerbates the voiding symptoms of BPH or causes increased urinary retention compared to placebo.

Prostate cancer Case reports have suggested that testosterone replacement therapy may convert occult cancer into a clinically apparent lesion. Prospective studies demonstrate a low frequency of prostate cancer in association with testosterone replacement therapy. The prevalence rate for prostate cancer is similar to that of the general population, as evident by prospective trials of testosterone replacement therapy showing prostate cancer in 1.1% of men followed for 6–36 months. There is some concern that the underlying prevalence of occult prostate cancer in men with low testosterone levels appears to be substantial. Despite decades of research, there is no compelling evidence that testosterone has a causative role in prostate cancer. Other side effects include gynecomastia, water retention, hypertension, and sleep apnea.

External Devices

A vacuum device is an external cylinder placed over the penis to allow air to be pumped out, resulting in engorgement of the penis with blood, creating the erection. A constriction band is fitted at the base of the penis to maintain the erect state. It is a noninvasive approach. Vacuum devices are suitable for a range of patients with chronic or occasional ED. They can be used after the removal of infected or defective penile prosthesis and they may prevent scar contraction. Disadvantages are discomfort, poor erection quality, and refusal of this mechanical therapy. Overall satisfaction has been reported to be between 70 and 94%. Caution should be exercised for patients using anticoagulation therapy and those with bleeding disorders. Vacuum device therapy might be a useful option in patients for whom other therapies are contraindicated, such as patients with heart disease.

Surgery

Penile prostheses are indicated after failure of other therapies for men of middle or old age. A psychiatrist or psychologist should participate in the preoperative evaluation of patients with psychogenic ED and determine the need for the prosthesis. Advantages are ease of use, reliability, and normal appearance and sensation. It requires destruction of the corpus cavernosum, which prevents pharmacological treatment later. Arterial revascularization may be indicated in young individuals with normal corporeal venous function who have arteriogenic ED secondary to trauma. Venous ligation for veno-occlusive dysfunction was not effective and therefore was abandoned.

Estrus and Menstrual Cycles: Neuroendocrine Control

M S Smith, Oregon Health and Science University, Beaverton, OR, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Estrous or menstrual cycles occur in mammals and refer to the phenomenon of cyclic ovarian function. This cyclic function is required to produce mature ova through a process called ovulation, which is necessary for fertilization to occur. Cyclic ovarian function also results in the production of estradiol and progesterone, the primary sex steroid hormones, with their important physiological effects on all tissues and the brain. Estrous cycles are named for the cyclic appearance of behavioral sexual activity (estrus) that occurs in all mammals except for higher primates. Menstrual cycles, which occur only in primates, are named for the regular appearance of menses due to the shedding of the endometrial lining of the uterus. The factors involved in regulating the cyclic nature of ovarian function are fairly similar in all mammals and primates, and although the length of the cycle varies among species, it is relatively invariant within species. Most of the information about regulation of the ovarian cycle has been gained through studies of the laboratory rat, sheep, and primate (monkey and human).

Cyclic ovarian function is under the control of three interacting components: hypothalamus, anterior pituitary, and ovary. The hypothalamus contains neurons that release the neuropeptide gonadotropin-releasing hormone (GnRH) into the hypophysial portal vasculature, which then acts on the anterior pituitary to stimulate the release of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The gonadotropins acting on the ovary provide the hormonal signals that regulate the ovarian cycle and stimulate production of estradiol and progesterone. In turn, the steroid hormones are part of exquisitely sensitive feedback loops that suppress or stimulate the release of GnRH from the hypothalamus and LH and FSH from the anterior pituitary. Therefore, normal ovarian cycles are regulated by feed-forward and feedback control systems. In addition to the internal hormonal signals that control ovarian cycles, external signals are important in some species. For example, the rat estrous cycle is critically linked to the daily circadian rhythm, whereas the sheep estrous cycle is dependent on photoperiod to stimulate periods of seasonal breeding.

The Ovarian Cycle

Overview

Figure 1 is a diagrammatic representation of the hormonal profiles observed during an estrous or menstrual cycle. The first day of the estrous or menstrual cycle is named for an externally observable event. The onset of behavioral estrus at the time of ovulation denotes the first day of each estrous cycle, whereas the onset of menses at the end of the luteal phase indicates day one of the menstrual cycle. Estrous and menstrual cycles consist of three phases that describe ovarian events. The follicular phase encompasses the period in which the follicle matures, secretes increased amounts of estradiol, and produces a mature ovum. Ovulation is the process by which the follicle ruptures and the mature ovum is released into the oviduct, where fertilization takes place. The process of ovulation induces the luteal phase, in which ovarian cellular elements reorganize into a corpus luteum, a structure which secretes large amounts of progesterone, a hormone required to maintain uterine support of implantation and pregnancy. In the absence of fertilization and pregnancy, the corpus luteum regresses, and progesterone levels fall; these are signal events that initiate a new follicular phase.

GnRH Neurons: The Central Neural Regulators

GnRH neurons are the key central regulators of reproductive function. Their cell bodies are localized in the preoptic area, anterior hypothalamic area, and medial basal hypothalamus. It should be noted that recent studies have identified two different genes in mammals that encode GnRH: GnRH-I and GnRH-II. It is likely that these different populations of GnRH neurons have overlapping and independent functions. However, since most data concerning the role of GnRH in the regulation of ovarian cyclicity involves GnRH-I, this section refers to GnRH for ease of understanding. The GnRH nerve terminals involved in regulating anterior pituitary function reside in the median eminence, where GnRH is released into the hypophysial portal vasculature. It is well established that the pattern of GnRH secretion into the portal vasculature is pulsatile and that changes in GnRH pulse frequency have profound effects on the amounts of LH and FSH that are released from the pituitary. One of the still outstanding mysteries of neuroendocrinology is the nature of the GnRH pulse generator. Currently, the most widely held view is that pulsatility is intrinsic to the GnRH neuron. However, since GnRH neurons are widely scattered, mechanisms

Figure 1 Diagrammatic representation of hormonal patterns and phases of the estrous or menstrual cycle. Hormones shown include hypothalamic gonadotropin-releasing hormone (GnRH), pituitary gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and ovarian steroids (estradiol and progesterone). Estrus marks day 1 of the estrous cycle, and menses marks day 1 of the menstrual cycle.

Figure 2 Photomicrograph showing gonadotropin-releasing hormone (GnRH) neurons (red) in the hypothalamus and their close association with neuropeptide Y nerve fibers (green). The image was captured using confocal microscopy, and specific neuropeptide identification was accomplished using immunocytochemistry. Neuropeptide Y fibers are shown in close contact (yellow) with GnRH neurons.

must exist to synchronize GnRH activity. Although many neurotransmitter and neuromodulatory components have been identified that act at the level of GnRH cell bodies or nerve terminals, the nature of the GnRH pulse generator remains elusive. It is generally agreed that norepinephrine, glutamate, γ-aminobutyric acid, neuropeptide Y, opioids, and GnRH itself are important modulators of GnRH neuronal activity and appear to have direct actions at GnRH cell bodies (Figure 2) or nerve terminals. Other key regulators of GnRH are estradiol and progesterone, which have both negative and positive feedback effects, although the mechanisms by which they act in this differential manner remain unclear. However, the negative and positive feedback effects of steroids on GnRH, and hence on LH and FSH, are key regulatory mechanisms that underlie the ovarian cycle (see the section titled 'Follicular phase and ovulation'). Recent studies have identified kisspeptin as a new hypothalamic neuropeptide system that regulates GnRH neuronal function. Kisspeptin neurons are located in two areas of the hypothalamus, the arcuate nucleus and the anteroventral periventricular nucleus, and are differentially regulated by ovarian steroids. It is thought that kisspeptin neurons in the arcuate nucleus are involved in the negative feedback effects of steroids to inhibit GnRH neurons, whereas kisspeptin neurons in the anteroventral periventricular nucleus are stimulated by elevated levels of estrogen and may contribute to the GnRH/LH surge at the time of ovulation.

Follicular Phase and Ovulation

LH and FSH secretion are under the control of the ovarian steroids, which primarily exert negative feedback effects at the hypothalamic level to suppress GnRH and at the pituitary level to suppress LH and FSH secretion. In most species, estradiol is the primary hormone exerting negative feedback control, although progesterone may also synergize with estradiol to enhance its effects. The ability of estradiol to exert negative feedback control on gonadotropin secretion is best illustrated by examining LH and FSH levels in the absence of estradiol, such as after ovariectomy or in postmenopausal women. LH and FSH levels increase markedly under these conditions. Under normal negative feedback conditions, LH and FSH secretion is low and pulsatile, reflecting the pulsatile release of GnRH from the GnRH-secreting neurons.

At the beginning of the follicular phase, estradiol and progesterone levels are low, reflecting the immaturity of the follicles, and the pattern of basal LH and FSH secretion is pulsatile (Figure 1). The pulse frequency varies in different species but typically averages around one pulse per hour. As the basal-levels of FSH and LH begin to stimulate follicular development during the early follicular phase, estradiol secretion from the granulosa cells increases. During the latter part of the follicular phase, as estradiol

becomes more elevated, basal levels of FSH and LH decrease somewhat because of increased negative feedback effects. The rising levels of estradiol reflect the maturation of the follicles. At some point, the estradiol levels reach a sustained threshold value such that the effect of high levels of estradiol on the hypothalamus and pituitary are dramatically different from the negative feedback effects exerted by the lower estradiol levels. Under these conditions, estradiol exerts positive feedback effects to elicit massive surges of LH and FSH (Figure 1). The surge of LH is responsible for ovulation and the release of mature ova. The positive feedback effects of estradiol are exerted at both the hypothalamus to increase GnRH release and the pituitary to enhance basal LH secretion and sensitivity to GnRH stimulation. The relative importance of the positive feedback effects of estradiol at the hypothalamus versus the pituitary in generating an LH surge most likely varies among species. Furthermore, the ability of estradiol to exert positive feedback effects is a sexually differentiated phenomenon. In most mammals, excluding higher primates, masculinization of the brain suppresses the ability of estradiol to exert positive feedback effects, precluding the ability to generate LH and FSH surges.

The length of the follicular phase varies among species and is determined by the rate at which increased amounts of estradiol are secreted and the sustained threshold value required to elicit positive feedback effects of estradiol. The combination of these factors determines when the ovulatory surge of LH will occur, signaling the end of the follicular phase. In rodents, multiple follicles develop to maturity, and the follicular phase lasts about 2 days. In sheep, one or two follicles develop during a 4-day follicular phase. In primates, the follicular phase of the menstrual cycle lasts about 12–14 days, and only one follicle typically reaches maturity.

Luteal Phase

As a direct result of the preovulatory LH surge, ova are released from mature follicles, and the follicular cells remaining in the ovary undergo a transformation from primarily estradiol-secreting cells into (primarily) progesterone-secreting luteal cells. This transition from the follicular phase to the luteal phase is characterized by rising plasma progesterone concentrations, and in some species, estradiol secretion also increases (Figure 1). Although estradiol concentrations may reach preovulatory levels during the luteal phase, LH and FSH surges do not occur because the elevated levels of progesterone block the positive feedback effects of estradiol. Progesterone's inhibitory actions are probably not exerted at the pituitary level, because pituitary responsiveness to GnRH remains normal to high during the luteal phase, but are most likely acting on the hypothalamus to greatly restrain GnRH secretion. In many species, LH pulse frequency slows considerably during the luteal phase because the elevated levels of progesterone (and possibly estradiol) cause an increase in negative feedback effects at the hypothalamus, resulting in a slowing of the GnRH pulse generator. However, the slower pulse frequency is usually associated with an increase in pulse amplitude such that mean levels of LH and FSH during the luteal phase are similar to those during the follicular phase.

During the latter part of the luteal phase, the secretory activity of the corpus luteum begins to wane. The mechanisms involved in determining the life span of the corpus luteum remain unclear but in most species they likely reside within the corpus luteum itself. However, in some species, such as ruminants, regression of the corpus luteum is dependent on the presence of the uterus, which secretes prostaglandin F2α, a potent luteolysin. The termination of luteal function is essential to initiate a new ovarian cycle. The fall in progesterone and estradiol leads to menstruation in higher primates and also causes a relaxation in negative feedback inhibition of gonadotropin secretion. Therefore, LH, and particularly FSH, levels begin to rise, initiating the growth of a new crop of follicles. The length of the luteal phase is less variable among species and averages 12–14 days. In the rat, normal luteal function lasts for only 2–3 days, but if a pseudopregnancy is induced, luteal function lasts about 12 days. In all species, fertilization of the egg and implantation of the developing embryo trigger events that prevent luteal regression. The maintenance of elevated levels of progesterone is essential to sustain pregnancy.

External Environmental Factors Influencing Ovarian Cyclicity: Energy Balance

It is evident that the hypothalamus plays the key role in regulating ovarian cyclicity by synthesizing GnRH and by acting as a site for steroid modulation. The hypothalamus is also the final common pathway whereby external factors influence reproductive activity. The influence of energy balance, coital stimulation, olfactory cues, circadian rhythms, and emotional distress, as well as the phenomenon of seasonal breeding, suggests that external environmental factors can profoundly affect the neuroendocrine reproductive axis through effects on GnRH neuronal function.

The linkage of energy balance with reproductive function is a good example of integration of the regulation of critical physiological functions at the level of the hypothalamus. Because reproduction is essential to survival of the species, and reproduction is an energy-demanding function, it is not surprising that reproduction would be tightly linked to energy balance. There are many examples that conditions of negative energy balance are linked to the suppression of cyclic ovarian function; these include fasting, anorexia nervosa, exercise, and lactation. In some cases the negative energy balance is caused by a decrease in energy intake (fasting, anorexia nervosa) and in others by an increase in energy expenditure (exercise and lactation). In all cases, the primary deficit is thought to result from the suppression of GnRH. This in turn results in very low basal levels of LH and FSH that are inadequate to stimulate ovarian follicular development. As a consequence, ovarian steroids are also very low under these conditions.

A number of signals have been identified that are likely candidates for conveying information about the status of energy balance to the hypothalamus and GnRH neurons. One category of signals is derived from peripheral tissues and conveys information about energy stores to the brain; these include leptin, insulin, glucose, fatty acids, and others. Most notable is leptin, a hormone produced by adipose tissue. Leptin levels in the blood reflect body fat stores. Therefore, under conditions of negative energy balance, leptin levels are very low. Since leptin deficiency has been shown to be associated with impaired reproductive function, leptin is thought to be an important modulator of normal reproductive function. However, leptin's effects are far-reaching, including effects on hypothalamic feeding circuitry and peripheral metabolism, so it has been difficult to determine whether leptin's role in reproductive function is direct or indirect through changes in metabolic fuels. Similar difficulties confound studies with insulin and

Figure 3 Hypothalamic feeding circuitry contacting gonadotropin-releasing hormone (GnRH) neurons. Arcuate nucleus (ARH) neural systems have direct input to GnRH neurons and also indirect input through connections with neural feeding circuitry in the lateral hypothalamic area (LHA), which in turn sends direct projections to GnRH neurons. Hypothalamic areas: ARH, arcuate nucleus; POA, preoptic area; LHA, lateral hypothalamic area. Feeding circuits: POMC, proopiomelanocortin (anorexigenic); NPY/AGRP, neuropeptide Y/agouti-related protein (orexigenic); NKB, neurokinin B (anorexigenic); MCH, melanin concentrating hormone (orexigenic); orexin (orexigenic). Receptor subtypes expressed on GnRH neurons: Mu (opioid), Y5 (NPY), NK (NKB), MCHR1 (MCH), and OX-R1 (orexin). Insulin, Ins; Leptin, Lep; R, receptor.

whether it plays a direct or indirect role in hypothalamic regulation of GnRH neuronal function.

Regardless of which peripheral metabolic factors may be directly involved in regulating reproductive function, it is clear they exert their effects on neural feeding circuitry within the brain, providing critical feedback information about the status of body energy stores. A key site of action for these metabolic factors is the arcuate nucleus of the hypothalamus; this nucleus contains an array of neuropeptide systems, many of which have overlapping functions in the regulation of food intake and energy balance and of GnRH activity. In addition, neuropeptide systems in the arcuate nucleus make direct contacts with additional feeding circuitry in other hypothalamic areas and can influence their activity. Therefore, the arcuate nucleus appears to be a critical integration site where metabolic signals can act to alter the activity of neural systems regulating food intake and the GnRH pulse generator. Recent studies have provided neuroanatomical evidence for the direct interaction of hypothalamic neural systems that govern food intake with GnRH neurons. Neuropeptide Y, orexin, melanin concentrating hormone, neurokinin B, cholecystokinin, and B-endorphin have all been shown to be involved in stimulating or inhibiting food intake. These same neuropeptide systems also have been shown to send fiber projections to GnRH neurons, and appropriate receptor subtypes are expressed on GnRH cell bodies (Figure 3). Numerous studies have demonstrated their ability to modulate GnRH/LH secretion. Therefore, it appears that a number of hypothalamic neuronal systems have a duality of function: regulation of food intake and regulation of reproductive function. In this manner, the control of reproductive function is tightly linked to energy availability.

Event-Related Potentials (ERPs)

M D Rugg, University of California at Irvine, Irvine, CA, USA

Event-Related Potentials

Event-related potentials (ERPs) are scalp-recorded fluctuations in the brain's electrical activity (the electroencephalogram or EEG) elicited by a stimulus event such as the presentation of a word. The size of these changes is usually small in comparison to the background EEG activity in which they are embedded. Therefore, to obtain ERP waveforms with satisfactory signal-to-noise ratios, EEG samples time-locked to stimulus presentation on a number of experimental trials (typically, between 20 and 30) are averaged together. The waveforms represent the average of the neural activity elicited by the stimulus events belonging to each trial.

ERPs have proved to be valuable for studying cognitive functions such as memory. Neural activity (or more accurately, the fraction of activity detectable at the scalp) associated with the processing of different classes of stimulus events can be measured with a temporal resolution that allows the neural correlates of cognitive processes to be characterized with a precision of a few tens of milliseconds. This permits quite precise upper-bound estimates to be placed on the time required by the brain to discriminate between different stimulus classes (e.g., studied vs. unstudied items in a recognition memory test). This level of temporal resolution is presently unattainable with techniques, such as functional magnetic resonance imaging (fMRI), that measure neural activity indirectly by detecting changes in blood flow or oxygenation. On the other hand, the spatial resolution of the ERP technique is in general quite poor and compares very unfavorably with the resolution attainable with fMRI. The two methods thus offer complementary perspectives on the neural correlates of human memory.

Despite their poor spatial resolution, ERPs can nonetheless be used to investigate whether different experimental conditions engage functionally dissociable cognitive processes. The rationale for this application of ERPs rests on the assumption that if two experimental conditions are associated with qualitatively different patterns of scalp electrical activity, there are grounds for assuming that the conditions engaged at least partially nonoverlapping neural, and hence cognitive, processes. By contrast, purely quantitative differences in the ERPs associated with two conditions constitute evidence for different levels of engagement of the same neurocognitive processes, at least so far as can be detected from scalp recordings. To distinguish between these scenarios in practice it is necessary to record ERP waveforms from enough electrode sites to permit the spatial configurations of the electrical fields associated with different experimental conditions to be accurately characterized. In the research described below, the analysis of the spatial distribution (the 'scalp topography') of ERP effects associated with different experimental conditions occupies a central place; when two topographies differ, this is taken as evidence that the cognitive operations engaged in the respective experimental conditions are at least partially dissociable.

Memory Encoding

Even when presented under highly uniform study conditions, stimulus events vary in how likely they are to be remembered on a later memory test. It is generally assumed that one reason for such disparities in later memory performance is variability in recruitment of processes that support the initial encoding of an event into memory. Key questions include the time course of these encoding processes, and whether the processes vary according to the class of event that is presented (e.g., words vs. pictures) or the manner in which the event is processed (e.g., whether the study task emphasizes semantic or nonsemantic processing).

ERPs have been used extensively to investigate the neural correlates of memory encoding with the 'subsequent memory procedure.' The procedure was introduced in the early 1980s, and continues in its popularity to the present time. Experimental subjects are first presented with a series of items for study while their EEGs are recorded. Sometime later they undertake a memory test, allowing each study item to be classified as 'later remembered' or 'later forgotten.' The EEG data obtained during the study phase can then be retrospectively averaged to form separate ERPs for those items that were later remembered as opposed to those that were later forgotten. This makes it possible to assess whether, and in what ways, ERPs can 'predict' whether study items will be later remembered.

An example of an ERP subsequent memory effect is illustrated in Figure 1. ERP waveforms typically begin to differ according to subsequent memory performance within 200 ms or so of the presentation of the study items, the waveforms elicited by later-remembered items demonstrating a sustained positive

Figure 1 An ERP subsequent memory effect. Grand average (i.e., collapsed across subjects) ERP waveforms elicited by visually presented words from an electrode over the frontal scalp during an incidental study task. The ERPs have been segregated according to whether they were elicited by words that were remembered or forgotten on a recognition memory test undertaken approximately 30 min after the study phase. From approximately 250 ms onward, ERPs elicited by remembered words are more positive-going than the waveforms elicited by words that were later forgotten.

shift relative to those elicited by items that are destined to be forgotten. While the findings differ in detail across studies, these ERP differences – often referred to as 'subsequent memory' or 'Dm' (differences due to memory) effects – have been observed with a variety of different study materials and tasks, and with memory tests assessing both recognition and recall. Importantly, subsequent memory effects can be obtained in ERPs when measures of study task performance such as accuracy and response time do not differentiate items that are later remembered or forgotten. It seems unlikely, therefore, that the ERP effects merely reflect factors such as the amount of attention allocated to particular study items, or fluctuations in alertness or arousal, since such factors would be expected to impact behavior as well as brain activity.

It has proven difficult to identify all of the variables that determine the exact form that ERP subsequent memory effects will take in any given study, and in particular what dictates the scalp topography of the effects. The balance of the evidence suggests however that the cognitive processes reflected in the effects are recruited primarily in service of explicit rather than implicit memory. One study, for example, contrasted subsequent memory effects for word stem cued recall (held to depend largely on explicit memory) with the effects associated with stem completion in the absence of explicit memory (when completion is assumed to reflect implicit memory). Words that were later remembered explicitly elicited a subsequent memory effect similar in character to that illustrated in Figure 1. By contrast, the subsequent memory effects elicited by items later remembered implicitly were of opposite polarity, in that the waveforms for 'forgotten' items were more positive than those for 'remembered' items. In addition to shedding light on the functional significance of ERP subsequent memory effects, these findings support the notion that the processes supporting explicit and implicit memory encoding are qualitatively distinct.

Perhaps the most important conclusion to come out of ERP studies of encoding so far derives from the time course of subsequent memory effects. Typically, the effects onset within a few hundred milliseconds of the presentation of study items (Figure 1), during the time that the items are still being processed in service of the study task. Thus, the cascade of processes that culminate in the formation of a lasting memory is initiated early in the course of the processing of a stimulus event. A major challenge for future research is to integrate ERP findings with the results from the burgeoning number of fMRI studies that have also employed the subsequent memory procedure to investigate the neural substrates of memory encoding.

ERPs and Retrieval

Recognition Memory

As in the case of encoding, ERPs have been used to study the neural correlates of memory retrieval since the early 1980s. By far the most popular experimental approach has been to contrast waveforms elicited by different classes of item in tests of recognition memory. ERPs elicited by correctly detected old test items differ markedly from the ERPs elicited by items correctly rejected as new. These differences, often referred to as ERP 'old/new effects,' have long been held to represent neural correlates of successful retrieval. The effects extend over several hundred milliseconds, encompassing a negative-going deflection peaking around 400 ms and a later positive-going wave that peaks around 700 ms. As can be seen in Figure 2, the scalp distributions of the old/new effects centered on these two peaks are markedly different; whereas the earlier effect is maximal over the frontal scalp, the later-occurring effect shows a maximum over the left parietal scalp. The two effects are sometimes referred to as 'mid-frontal' and 'left parietal' old/new effects, respectively.

Recent years have seen an intensive effort to identify the functional significance of the old/new effects illustrated in Figure 2. Many of these studies have focused on whether the effects can be dissociated in ways compatible with 'dual-process' models of recognition memory. These models propose that recognition judgments are supported by two classes of memory process. Recognition can occur when a test

Figure 2 ERP old/new effects associated with recognition memory. Left: grand average ERP waveforms elicited by visually presented words in a recognition memory test. The waveforms were recorded from electrodes over mid-frontal (top) and left parietal (bottom) scalp. Illustrated are waveforms elicited by unstudied (new) items correctly judged to be new, along with waveforms elicited by recognized studied words that had been subjected to either a deep, semantic (deep hit) or a shallow, alphabetic (shallow hit) study judgment. Arrows indicate the mid-frontal and left parietal old/new effects (see text). Right: scalp distribution maps of old/new effects between 300 and 500 ms, and 500 and 800 ms, highlighting the distinct topographies of the mid-frontal and left parietal effects. Maps are arranged such that the nose is at the top, and the relative size of each effect over the scalp is scaled from blue (small) to red (large).

item elicits retrieval of a specific past episode involving the item, a form of memory termed 'recollection.' A test item can also be recognized on the basis of its 'familiarity' – a faster-acting, acontextual form of memory held to be dissociable from recollection on phenomenal, functional, and neurological grounds. According to dual-process models, recollection and familiarity depend upon qualitatively distinct cognitive (and neural) processes. A rival family of 'single-process' models propose that the two forms of memory depend upon the same underlying mechanisms, and differ in a quantitative rather than a qualitative fashion.

Several ERP studies have attempted to adjudicate between dual- and single-process models of recognition memory and, in parallel, to shed light on the functional significance of ERP old/new effects. The studies have employed a variety of experimental procedures originally developed by experimental psychologists to fractionate recollection and familiarity using behavioral methods. These procedures have generally involved manipulation of variables hypothesized to act selectively on one or the other recognition process, and hence to assess whether ERP old/new effects can be selectively modulated. In one study, for example, a study task manipulation ('depth' of processing) was employed that was assumed to vary the likelihood of later recollection while having little effect on familiarity. As is illustrated in Figure 2, this manipulation had a marked effect on the left parietal old/new effect. The effect was prominent when elicited by recognized items studied under conditions that promote recollection, but absent for items assumed to have been recognized largely on the basis of their familiarity. By contrast, a robust mid-frontal effect was elicited by both classes of recognized item. The mid-frontal effect was absent, however, for studied items that were misclassified as new, raising the possibility the effect reflects processes tied to explicit recognition judgments. These findings suggest that mid-frontal and left parietal old/new ERP effects are, respectively, correlates of familiarity and recollection.

Subsequent findings have added weight to this suggestion. Notably, words and pictures that, by virtue of their perceptual similarity to studied items, generate high levels familiarity-driven false alarms elicit the mid-frontal, but not the left parietal, old/new effect. In addition, the amplitude of the mid-frontal effect varies in a monotonic fashion with subjects' ratings of the familiarity of the test items. By contrast, the left-parietal effect appears to be associated exclusively with test items that elicit recollection, as indexed either by subjective report or, more objectively, in the contrast between items associated with successful

versus unsuccessful retrieval of information about their study context (i.e., items associated with accurate vs. inaccurate source memory).

The differing scalp distributions of the mid-frontal and left parietal old/new effects strongly suggest that the effects reflect activity in distinct brain regions or circuits. Coupled with the evidence that the two effects can also be fully dissociated experimentally, this gives strong support to dual-process models of recognition memory. The precise cognitive operations reflected in each effect remain to be elucidated, however.

Other ERP Old/New Effects

In addition to the mid-frontal and left parietal effects described previously, other ERP modulations have also been reported in studies employing recognition-like memory tests. A few studies, for example, have described effects that precede the mid-frontal effect. The functional significance of these effects remains uncertain. Other studies have reported old/new effects that appear to be independent of subjects' explicit memory judgments, and therefore which are possible correlates of implicit memory (priming). More work is needed however to fully characterize these effects and to assess their consistency across different experimental procedures and stimulus types.

One effect that has been consistently reported in a diverse range of studies has been termed the 'right frontal old/new effect.' An example of the effect is shown in Figure 3. Typically, it onsets around 500 ms poststimulus and takes the form of a sustained positive-going shift that can persist for well over a second. The effect was first identified in studies of source memory, where subjects are required to both identify previously studied test items and indicate the context in which the item had been studied (e.g., whether it had been heard in a male or female voice). Initially the effect was interpreted as a reflection of the additional processing engaged when recollected information must be evaluated prior to response selection. In later studies, however, it became clear that the right frontal effect can be elicited in the absence of recollection, especially if item familiarity is relatively weak. Under these circumstances, the information elicited by an old item is thought to require monitoring and evaluation to establish whether its familiarity is sufficiently high to warrant an 'old' response. Currently, the most popular interpretation of the right frontal effect is that it reflects the engagement of 'postretrieval' processes that support the evaluation of the products of a retrieval attempt.

ERP Studies of Recall

The requirement to identify an event to which EEG sampling can be time-locked precludes the use of ERPs to study free recall. A significant number of studies have however investigated the ERP correlates of cued recall, when retrieval is elicited not by 'copy cues,' as in recognition memory, but by partial cues such as word stems or word fragments (e.g., MOT or M-T-R). In one variant of the cued recall procedure, cues that can be completed with studied words are intermixed with other cues that cannot be completed with a studied item. Subjects are instructed to attempt to complete each cue with a studied item but, if this is not possible, to generate the first word that comes to mind. Importantly, subjects are further required to endorse each completion as either studied or unstudied, allowing correct completions associated with explicit memory for the study episode to be separated from completions due to chance or the influence of implicit memory. Figure 4 illustrates typical results

Figure 3 The right frontal ERP old/new effect. Left: Waveforms elicited by visually presented words from a right frontal electrode. Waveforms elicited by studied words accorded correct source memory judgments (source correct) are overlaid with waveforms elicited by correctly judged new items (new). Right: Scalp distribution of the old/new effect between 800 and 1100 ms. A prominent right frontal maximum is evident, along with the remains of an earlier onsetting left parietal effect.

Figure 4 Old/new ERP effects associated with cued recall. Left: ERP waveforms from frontal (FZ), central (CZ), and parietal (PZ) midline lectrodes elicited by three-letter word stems (see text). ERPs elicited by stems completed by a studied word and endorsed as old are overlaid on waveforms elicited by stems completed by unstudied items and correctly endorsed as new. Right: Scalp distribution maps of the cued-recall old/new effect between 400 and 1200 ms and 1200–1900 ms, illustrating the diffuse and relatively unchanging nature of the topography of the effect (increasing amplitude scales with increasing brightness). Reproduced from Allan K and Rugg MD (1997) An event-related potential study of explicit memory on tests of cued recall and recognition. *Neuropsychologia* 35: 387–397, with permission from Elsevier.

from a study employing this procedure with word stems as the cues. Relative to the waveform elicited by stems corresponding to new items, ERPs elicited by stems completed with studied words and endorsed as old exhibit a sustained positive-going shift. This effect is not found if a 'correct' completion is incorrectly endorsed as unstudied. Nor is it evident for incorrect completions wrongly judged to be old. These findings suggest that the effect represents processing selectively associated with veridical explicit memory retrieval. The cued recall ERP effect is more diffusely distributed over the scalp than are recognition old/new effects, suggesting the involvement of neural generators additional to those active during recognition. Moreover, unlike in the case of recognition, there is little evidence that the scalp distribution of the recall effect changes with time.

Comparison of the old/new effects elicited in recognition and recall tasks leads to two principal conclusions. First, their differing scalp distributions suggest that the processes engaged during successful recognition and recall are at least partially dissociable, a conclusion that converges well with the findings from functional neuroimaging studies that have compared retrieval-related neural activity in the two kinds of test. Second, the finding that recall and recognition effects have similar onset latencies is difficult to reconcile with 'generate-recognize' models of cued recall. These models propose that cued recall involves an iterative, two-stage process, whereby candidate responses are first generated in response to the cue and then subjected to a recognition judgment. According to such models, the onset latency for ERP recall effects should be delayed relative to recognition effects, reflecting the additional generate stage that is needed for recall but not recognition. Rather, the ERP findings lend support to rival models that propose that recall cues usually gain direct access to stored memory representations.

Neural Generators of ERP Retrieval Effects

It has already been noted that the spatial resolution of scalp-recorded ERPs is poor. Indeed, there are currently no generally accepted formal methods for localizing the neural generators of an ERP effect. A popular informal approach is to seek parallels between ERP effects and the findings from functional neuroimaging studies in which the same or closely similar experimental manipulations were employed. The most striking such parallels have been observed for the left parietal and the right frontal old/new effects described previously. The relatively focal maxima of these effects are consistent with generators located in underlying cortex, that is, left-parietal and right frontal cortex, respectively.

Several functional neuroimaging studies have employed experimental procedures that allowed recognized test items to be segregated according to whether they were recollected or instead judged old solely on the basis of familiarity. Among the most consistently reported regions to demonstrate recollection-related enhancement of activity in these studies has been left lateral parietal cortex. These findings have led several investigators to propose that the left parietal old/new effect does indeed reflect, at least in part, recollection-related activity originating in this region.

An equally striking parallel exists for the right frontal effect. Functional neuroimaging studies that have investigated the neural correlates of memory monitoring have frequently implicated dorsolateral and anterior regions of right prefrontal cortex as playing a key role in this function. Thus, it has been proposed that the right frontal ERP old/new effect originates in large part from right prefrontal cortex.

Essentially nothing is known about the intracerebral loci of the generators of the other memory-related ERP effects described in the preceding sections. Even in the case of the left parietal and right-frontal effects, it should be emphasized that the hypotheses concerning their generators are based on indirect, correlative evidence, and that the validity of hypotheses has yet to be tested directly, for example, by investigating the consequences of focal cortical lesions or transcranial magnetic stimulation.

Concluding Comments

The contribution of ERPs to the cognitive neuroscience of memory has been considerable. The combination of experimental versatility, high temporal resolution, and ability to discriminate between different patterns of neural activity has allowed researchers to use ERPs to fractionate and assign distinct neural 'signatures' to several theoretically important memory functions. The challenge for the future is to go beyond the description of ERP effects in terms of their patterning over the scalp and correlations with particular experimental manipulations, and to develop methods that allow the effects to be rigorously linked to specific cognitive operations and their neural substrates. This will require close integration with complementary methods for noninvasive measurement of brain activity, most notably, fMRI and allied techniques.

Event-Related Potentials (ERPs) and Cognitive Processing

S A Hillyard, University of California at San Diego, La Jolla, CA, USA

Origins of Event-Related Potentials

As information is processed within the neural networks of the human brain, the electrical activity arising from millions of participating neurons is summed to form field potentials that can be recorded through the intact scalp. The brain's field potentials include the rhythmic voltage oscillations of the ongoing electroencephalogram (EEG) and the briefer evoked or event-related potentials (ERPs) that are triggered in association with sensory, motor, and cognitive events. Whereas the spontaneous EEG rhythms are sensitive monitors of general states of arousal, consciousness, and the sleep–wake cycle, the ERPs reflect more discrete patterns of neural activity that underlie specific perceptual and cognitive processes. These activity patterns are revealed in the scalp-recorded ERP with a high degree of temporal precision (on the order of milliseconds), but the method generally lacks the precision of anatomical localization that is provided by neuroimaging techniques such as positron emission tomography or functional magnetic resonance imaging.

Recent approaches in modeling the neural generators of ERPs, however, have enabled their localization to specific brain structures with improved accuracy. By mapping the scalp topography of an ERP and applying algorithms based on the physics of electrical volume conduction, the positions of the underlying neural generators can be estimated with respect to brain anatomy. In a number of cases, the anatomical regions generating surface ERPs have been verified by intracranial ERP recordings, by magnetoencephalography, or by studies of patients with circumscribed brain lesions. Combined studies of ERP recordings together with neuroimaging methods that reveal patterns of cerebral blood flow and metabolism offer the possibility of defining both the precise time course and the anatomical substrates of information processing in the human brain.

The ERP recording methodology involves the computerized analysis of the voltage–time waveforms recorded from different points on the scalp. It is generally necessary to average ERP waveforms over many stimulus presentations in order to achieve adequate signal-to-noise ratios with respect to the ongoing EEG. Newer spatiotemporal filtering procedures (e.g., wavelet filters) can also help to distinguish weak ERP signals from the background EEG.

The computer-averaged ERPs triggered by sensory signals consist of a sequence of positive (P) and negative (N) voltage deflections (components) that have characteristic time delays and wave shapes. The typical ERP elicited by a brief auditory stimulus, for example, consists of 16 or more components appearing over the interval 1.5–1000 ms after stimulus (Figure 1). The early ERP components that occur before approximately 50 ms represent evoked neural activity in the auditory pathways that is relatively insensitive to changes in the psychological state of the subject. In contrast, many of the later components are highly sensitive to the significance of a stimulus and to the cognitive demands of the task. These 'endogenous' ERPs have been studied extensively as indices of perceptual and cognitive processes. Several types of endogenous ERPs are depicted by the dotted and dashed tracings in Figure 1: the Nd wave is elicited specifically by auditory signals that are actively attended, whereas the N2, P3 (P300), and SW (slow wave) components are triggered by signals that are being actively discriminated and deliver task-relevant information.

Visual and somatosensory stimuli elicit ERPs with characteristic waveforms and scalp topographies that correspond to sensory processing in their respective modality-specific cortical areas. The visual ERP to a brief flash, for example, begins with a 'C1' component at 50–60 ms that appears to originate from the primary visual (striate) cortex, followed by a 'P1' component (at 80–120 ms) that is generated in extrastriate cortical areas of both the dorsal and ventral visual streams (Figure 2). Another type of ERP is elicited by a visual stimulus that flickers continuously at a fixed rate in the range of 6–40 Hz. This steady-state visual evoked potential (SSVEP) has a sinusoidal waveform at exactly the flicker frequency (or a harmonic thereof) and provides a continuous measure of visual–cortical activation that can be readily quantified in the frequency domain.

A major research strategy is to identify individual ERP components as markers of specific perceptual or cognitive processes. This has been achieved in a number of cases through the systematic study of the stimulus, task, and behavioral performance variables that influence the component in question. These ERP markers reveal the timing and order of successive information processing stages and can thus reveal the underlying structure of cognitive operations. In this way, the ERPs yield information about the neural bases of cognitive processes including selective attention, stimulus recognition, decision making, memory storage and retrieval,

Figure 1 Waveform of the computer-averaged auditory ERP to a brief sound. The ERP is generally too small to be detected in the ongoing EEG (top) and requires computer averaging over many stimulus presentations to achieve an adequate signal-to-noise ratio. The logarithmic time display allows visualization of the early brain stem responses (waves I–VI), intermediate evoked components, and long-latency endogenous components (Nd, N2, P300, and SW, or slow wave). ERP components are labeled according to their polarity, P (positive) or N (negative), followed either by a number or letter (P3, Pa, etc.) that specifies the ordinal position of the wave in a particular sequence or by a larger number (P300, etc.) that refers to the latency of the wave in milliseconds. Courtesy of Wolfgang Teder-Salejarvi.

and language processing. As objective signs of cognitive operations, abnormal ERP waveforms have diagnostic significance for information-processing disorders associated with developmental, psychiatric, and neurological syndromes.

Selective Attention

The brain's attentional systems allow relevant sensory inputs to be processed fully while suppressing irrelevant inputs, thereby protecting higher cognitive centers from sensory overload. Considerable research has been directed at the question of whether stimulus selections occur at an early stage of processing by suppressing inputs belonging to unattended sensory channels or at a later stage of processing after stimuli have been more fully analyzed. Evidence favoring an early selection mechanism has been obtained in a number of ERP experiments in auditory, visual, and somatosensory modalities, in which discrete stimuli are delivered at rapid rates to two or more sensory channels. For example, if subjects are required to listen to a series of clicks, tones, or speech sounds in one ear and ignore a comparable sequence of sounds in the opposite ear, all stimuli in the attended ear will elicit an enlarged, negative ERP (the Nd component) starting at approximately 70 or 80 ms. Given the short-onset latency of this component and its elicitation by all stimuli belonging to the attended channel, it has been hypothesized that this ERP is a sign of an early selection process whereby stimuli are selected or rejected on the basis of whether they possess the elementary sensory feature that defines the channel (e.g., ear of entry). This early selective mechanism also appears to involve an amplitude modulation of evoked ERP components in the auditory cortex at latencies of 20–50 and 70–100 ms, as well as the longer lasting endogenous Nd wave (also called 'processing negativity') that appears to be a neural sign of the continued sensory analysis of the attended channel stimuli.

In accordance with the early selection hypothesis, stimuli in unattended channels, which lack the Nd

Figure 2 (a) Amplitude enhancement of visual ERP components during visual spatial attention. Circular checkerboard stimuli were flashed in random order to the four quadrants of the visual field (top) while subjects focused their attention on stimuli in only one quadrant at a time. The eyes remained fixed on a central cross. ERPs were recorded from 62 scalp sites and were averaged separately for stimuli in each quadrant under each attention condition. Waveforms shown are grand average ERPs from 4 scalp locations in response to the upper left field stimuli under conditions in which they were attended (red tracings) and when unattended (blue tracings, while attention was directed to the upper right stimulus). Note the attention-related enhancements of ERP components, including the contralateral P1 (130 ms), ipsilateral P1 (150 ms), posterior N1 (190 ms), and anterior N1 (150 ms) waves. In contrast, the earlier C1 component (90 ms), which is proposed to originate from the primary visual (striate) cortex, was not affected by attention. The head map shows the scalp voltage distribution of the late phase of the P1 component (100–130 ms) that was enhanced by attention over contralateral occipital areas. (b) Dipole model of the neural generators of the late P1 attention effect. Head model shows that dipoles accounting for the P1 attention effect are located in ventral occipital cortex. Waveforms at left represent the time course of activity in each model dipole corresponding to the enhanced neural activity in contralateral and ipsilateral occipital lobes. (c) These dipole positions correspond closely to focal regions of neural activity revealed by functional magnetic resonance imaging (fMRI) obtained in the same experiment but in a separate session. Red and blue regions represent cortical zones showing increased neural activity during attend-right and attend-left conditions, respectively. These findings indicate that spatial attention modulates the flow of visual information along the ventral–occipital pathway in the time range 100–130 ms after stimulus onset. Data from Di Russo F, Martinez A, and Hillyard SA (2003) Source analysis of event-related cortical activity during visuo-spatial attention. *Cerebral Cortex* 13: 486–499.

wave, are not processed as fully as are attended-channel stimuli. Thus, in experiments in which the attended channel is defined in terms of two features such as pitch and localization, stimuli that are rejected early on the basis of one feature do not show ERP signs of being processed for the other feature. These data and comparable findings in visual attention experiments support hierarchical, interactive models of attention. It appears that elementary stimulus features such as location and pitch are selected first, whereas more complex combinations of attributes are registered and selected at subsequent stages. The timing of different ERP components indicates that some feature analyses are performed serially, whereas others occur in parallel.

In the visual modality, the earliest ERP changes occur during spatial selective attention, which is employed, for example, when a subject attends to a flashing light in one visual field while ignoring concurrent flashes in the opposite field. Flashes in

the attended field elicit enhanced P1 and N1 components between 80 and 200 ms after stimulus onset (Figure 2). These ERP components that are modulated by visual–spatial attention appear to be generated in multiple extrastriate visual cortical areas rather than in the primary visual (striate) cortex. This ERP pattern of P1–N1 enhancement reflects an early selection mechanism that facilitates the processing of stimuli that are located within the 'spotlight' of spatially focused attention. In contrast, selective attention to other visual features, such as color, spatial frequency, and shape, is manifested by longer latency (150–300 ms) ERP configurations. Since these later attention-sensitive components differ from one another in scalp distribution as well as in wave shape, they can be used to chart the time course of separate feature analyses in different visual–cortical areas. Both ERP and neuroimaging studies suggest that visual attention operates by modulating the flow of information through multiple extrastriate areas under the influence of an attentional control network in the frontal and parietal lobes.

ERP recordings have also helped to clarify mechanisms of visual search in tasks in which subjects attempt to identify a target stimulus in a visual display. Detection of such a target triggers an ERP component known as the N2pc, which is proposed to reflect the focusing of attention on the target's location and the filtering out of interfering information from nearby distractor items. When multiple target items are present in a display, the timing of N2pc amplitude changes lends support to serial models rather than parallel models of visual search. The allocation of attention in a visual display can also be studied by means of the SSVEP, which is substantially increased in amplitude when attention is directed to the location of a flickering stimulus. SSVEP recordings have shown that the spotlight of spatial attention can be divided such that two separate regions of a visual display can be attended simultaneously.

Stimulus Discrimination and Classification

Discriminative processing of visual features such as color or shape in the ventral stream of extrastriate cortical areas is reflected by a negative ERP component in the latency range 140–200 ms. This negativity corresponds to the N1 component and is enhanced when stimulus features are actively discriminated and when a known object shape is recognized. Faces, in particular, elicit an occipital-negative ERP configuration at 170–180 ms that originates primarily from the fusiform gyrus area specialized for face processing. These ERPs provide valuable information about the timing of perceptual processes that underlie object recognition.

ERP recordings have shown that pictorial stimuli can be classified into high-level categories (e.g., animals vs. nonanimals) very rapidly, within 150 ms after stimulus onset. In general, the detection of a task-relevant stimulus class is associated with an ERP configuration that includes a negativity peaking at approximately 200 ms (N2 or N200) and a larger late positivity (P3 or P300). This P300 complex is readily elicited in tasks in which subjects detect and respond to infrequent targets that occur randomly in a sequence of nontargets. The P300 that is triggered on detecting such relevant 'oddball' stimuli is time locked to the moment of decision when the subject classifies the stimulus as a target. The P300 latency thus gives a measure of how rapidly stimuli can be recognized and classified as relevant to the assigned task.

The elicitation of the P300 complex depends critically on memory processes since incoming stimuli have to be matched against memory traces to recognize the relevant events. The P300 also depends on the subject's ability to judge the likelihood of upcoming events since its amplitude is highly sensitive to stimulus probability. The P300 also provides an indication of the subject's discriminative capabilities and, for that reason, has been useful for investigating cognitive development in children. To determine whether a child can discriminate between two classes of stimuli, for example, a random sequence of those stimuli can be presented with one being less probable than the other. If the child displays a P300 (or other late endogenous component) that is selectively triggered by the infrequent events, this would constitute unequivocal evidence that the child has made the discrimination. Thus, the presence of a P300 reveals the integrity of a number of cognitive systems, making this ERP useful in the assessment of different kinds of cognitive deficits. For example, a significant prolongation of P3 latency has been observed in cases of Alzheimer's disease and other dementias, presumably reflecting the slowing of memory comparison and recognition processes.

The timing of endogenous ERP components can also be used to study the time course and sequencing of the information processing stages that intervene between stimulus and response. Whereas the N200 and P300 waves primarily reflect perceptual discrimination and classification processes, the preparation for motor response is indexed by a 'lateralized readiness potential' (LRP) that is generated in the motor cortex contralateral to the responding musculature. Studies of these ERPs have demonstrated that stimulus information is passed along from one stage to the next in a continuous 'cascade' such that motor

processes may be activated before perceptual processing is completed. The timing of these components provides a means of tracking the time course at which different stimulus features are analyzed. The LRP has also been used to study the timing of the 'point of no return' – that is, the time at which an intended motor response cannot be stopped.

A specific ERP is elicited when a subject makes an incorrect response in a sensorimotor decision task. This 'error-related negativity' (ERN) is maximal at approximately 100 ms after an erroneous response is initiated and its amplitude grows with the perceived magnitude of the error. The neural generators of the ERN have been localized to the anterior cingulate gyrus and are influenced by the lateral prefrontal cortex. The ERN is proposed to reflect the operation of an error monitoring system that is disrupted by frontal lobe lesions and certain mood disorders.

Memory Processes

Several ERPs have been identified that bear a close relationship to specific forms of memory and retrieval processes. In the auditory modality, short-term sensory memory is reflected in a 'mismatch negativity' (MMN) component that is triggered by deviant stimuli within a repetitive sequence of sounds. The MMN is elicited (at 150–250 ms) by stimuli that deviate in pitch, intensity, timing, localization, or even in more complex acoustic features, and its occurrence signals a mismatch between the incoming stimulus and the sensory memory trace of the immediately preceding stimulus. Because the MMN can be elicited by deviant sounds that are ignored by the subject, this ERP provides evidence that multiple features of auditory inputs are automatically analyzed and stored in short-term memory whether they are actively attended or not. This automatic mismatch detection may constitute an early stage of the orienting response to novel and potentially important changes in the acoustic environment.

Given that the MMN can be elicited with minimal cooperation from the subject, it has become a valuable tool for clinical assessment of auditory processing. Indeed, the elicitation of MMN provides a sensitive index of a person's ability to make auditory discriminations. By using speech sounds as stimuli, for example, MMN experiments have shown that children with language disabilities are deficient in distinguishing critical sounds in their language. Schizophrenic patients have also been found to have reduced or prolonged MMNs, which provides evidence for a deficit in their preattentive auditory processing. In Alzheimer's disease the MMN is also reduced, most prominently at longer interstimulus intervals, which suggests an abnormally rapid decay of auditory sensory memory traces.

A late positive ERP (300–600 ms) has been found to be a reliable predictor of conscious (explicit) memory storage and retrieval. For example, if a subject is attempting to memorize a list of items for subsequent recall, the items that will later be successfully recalled (or recognized) correctly will elicit a larger positivity than words that are later forgotten. This positive ERP has been interpreted as a sign of either the initial encoding of the stimulus in memory or the updating of the memory trace due to its distinctiveness. Other long-latency ERPs are elicited when previously learned material is retrieved from memory. Memory-related ERPs corresponding to these surface-recorded components have been recorded from medial temporal lobe structures including the hippocampus in neurological patients studied with implanted electrodes. These ERPs thus provide a window into the timing of memory storage and retrieval operations in the human temporal lobe.

Language Processing

ERPs are being increasingly studied as online, nonintrusive measures of linguistic processing in the brain. Different classes of ERPs have been identified as indices of lexical, syntactic, and semantic aspects of language and of the hemispheric specialization for language functions. ERPs also reflect the division of the lexicon into open class (content) words such as nouns, verbs, and adjectives and closed class (function) words including prepositions, conjugations, and auxiliaries.

Specific ERP components have been associated with the development of semantic expectancy during reading or listening to a spoken message. The ERPs to semantically anomalous words in otherwise meaningful sentences are marked by an enhanced negativity between 300 and 600 ms after stimulus (the N400). In general, the amplitude of N400 is inversely proportional to the predictability or expectancy of a word presented in a semantic context. Thus, the N400 wave seems to provide a graded index of semantic expectancies and may reflect the amount of prior semantic priming for particular words. The fact that N400 is triggered immediately by each unexpected word provides strong support for linguistic models that postulate immediate, online sentence comprehension rather than the storage of words in a buffer for delayed analysis. The N400 shows a good deal of promise as a means of evaluating the intactness of a patient's semantic networks in a variety of neurological and psychiatric syndromes.

Introduction

Evoked potentials (EPs) are neural responses time-locked to some stimulation (e.g., auditory or somatosensory) and can be used for clinical purposes. EPs are often low in amplitude compared to ongoing electrical activity such as electroencephalographic (EEG) and environmental noise responses, which are not time-locked to the stimulation. Thus, averaging of the response to many stimuli is necessary to obtain reliable EPs. EPs can be characterized by waveform latency and amplitude, with the peak and interpeak latencies being the prime determinant of clinically significant changes. The series of stereotypic waveforms following each modality of stimulation are named either as a sequence (e.g., wave I to wave V) or by the average latency seen in controls (P100 being the positive wave at a latency of about 100 ms). Based on lesion studies and invasive recordings in humans, the generators of the various waveforms are known with some accuracy. The waves may be dichotomized into near-field and far-field potentials: near-field potentials require a recording electrode relatively near the generator (e.g., an ear electrode can record a distal eighth nerve potential) and far-field potentials may be recorded with electrodes at some distance from the generator (e.g., a potential generated in cervicomedullary junction can be recorded with a scalp electrode).

EPs are objective physiological markers of clinically relevant abnormalities in sensory or motor systems. EPs may be most helpful when physiological responses assessed by clinical neurological exam are unreliable or not sensitive, such as in infants, comatose patients, or patients under general anesthesia. In addition, evoked potentials may be useful to objectify symptoms that are of uncertain significance (e.g., numbness) or to detect clinically unapparent lesions (e.g., evidence of optic nerve dysfunction in a person with possible multiple sclerosis).

The methodology to obtain EPs requires appropriate signal processing. This necessitates correct sampling rate (more than twice the highest frequency component of the signal, Nyquist criteria), band pass filter settings to help exclude irrelevant neurophysiologic signals or artifact, and adequate resolution of the analog-to-digital converter. The low-pass filter needs to be at least twice the sampling rate to prevent aliasing. For determining EP amplitude, it is helpful to include a prestimulus time period in the average. The number of stimuli in the average depends on the amplitude of the time-locked electrophysiologic response compared to ongoing electrophysiologic or any unwanted activity not time-locked to the stimulus. For analysis of EPs, an artifact rejection methodology, typically based on amplitude criteria, is necessary to prevent irrelevant high-amplitude signals, such as electrical artifact or movement, from entering into the average.

Each modality of EP has one or more reliable waveforms that are used to assess the abnormality of the test result. The waveforms may be categorized as short, middle, or long latency depending on their approximate latencies and generators, with short-latency potentials generated in primary sensory pathways earlier than about 40 ms, extending to long-latency waveforms generated from association cortices later than 100 ms. The waveform latencies (absolute and interpeak), amplitudes, and interside differences obtained from a patient are compared to the range of values for the clinically relevant parameters obtained from a group of healthy controls composed of people of both genders and various ages. In general, the upper limit of normal is 2.5–3.0 standard deviations above the control mean value. Left and right sides are tested separately and interside differences are one criterion for abnormality.

Visual Evoked Potentials

Visual evoked potentials (VEPs) are used to assess the visual conduction pathways from eye to visual cortex. Many types of visual stimulation may elicit a VEP, but some elicit more reliable responses. A pattern-reversal simulation (e.g., a black and white checkerboard pattern, with black and white checks synchronously alternating) is most used clinically. Grid and sinusoidal grating stimuli may also be used but are less commonly available in clinical settings. Simple luminance changes (e.g., flash stimulation) elicit a VEP, but the lack of consistent waveform morphology across individuals has made this technique less clinically useful, compared to pattern-reversal VEPs.

The most consistent waveform of the pattern-reversal VEP is the P100, generated in the visual cortex and recorded over the occipital lobe. The P100 is a positive peak with an average latency in controls of about 100 ms. There are also earlier and later negative waves (N75 and N145) (Figure 1). The recording channel commonly links the occipital electrodes to ear or

Figure 1 Pattern reversal visual evoked potentials in a patient with multiple sclerosis. The absolute latency of the P100 was normal in both eyes but the interocular latency difference is prolonged – compare right eye (OD, oculus dexter) to left eye (OS, oculus sinister); upper limit for normal was 8 ms – implying a delay in visual conduction pathways anterior to the optic chiasm on the left, although the patient had no visual symptoms. Each of the two trials was an average of 128 stimuli. A1 is left ear, OZ is midoccipital, and CZ is vertex electrode. Electrode locations for scalp electrodes are based on the International 10–20 System. Calibration mark is 10 μV. Adapted from Chiappa KH (ed.) (1997) *Evoked Potentials in Clinical Medicine*, 3rd edn. New York: Raven Press, with permission from Wolters Kluwer.

frontal electrodes. The frontal electrode may help maximize the amplitude since there is a negative waveform generated frontally at the same latency that accompanies P100.

For the standard checkerboard pattern stimulation for VEPs, the visual angle of each check is 10 min to 1 degree, and of the overall screen size for full-field stimulation it is 15–20°. Each eye is tested separately by covering the eye not being tested. To assist in detection of retrochiasmal function, hemifield stimulation of each eye can be performed because a unilateral retrochiasmal lesion is not sufficient to cause abnormalities to full-field monocular stimulation.

Nonpathological Factors Affecting VEPs

The VEP is dependent on the luminance and contrast of the black and white checks. The VEP is also sensitive to inattention and drowsiness. If an individual does not maintain gaze and fixation on the stimulus, the VEP will be attenuated. The P100 is altered by the visual field size of the individual checks and depends on the visual angle of the entire stimulus screen. If a person cannot detect stimuli of the visual angle of the check or grating, there will be no P100.

Pathologic Changes Affecting the VEP

The P100 is altered by certain pathologies along the course of the visual pathway. While not used to evaluate ocular pathologies clinically, the VEP will be altered by significant corneal opacities, dense cataracts, and retinal disease affecting the macula. Most commonly the VEP is used to assess the optic nerve function. Retrochiasmal pathology may be detected only by using hemifield stimulation. Patients with Parkinson's disease, as a group, have prolonged VEPs relative to controls, but the overlap limits clinical use of this observation.

Somatosensory Evoked Potentials

Somatosensory evoked potentials (SEPs) are elicited in response to peripheral nerve stimulation and record the afferent signal at several locations along the pathway from site of stimulation to cerebral cortex. Vibratory, light touch, and mixed-nerve stimulations have been used to investigate dorsal column integrity, and thermal or laser pain stimuli have been used to study the more anterior spinothalamic pathway. Mixed-nerve electrical stimulation is used for most clinical applications.

Upper and lower limb stimulations provide distinct benefits. The peaks following upper limb stimulation have a greater signal-to-noise ratio, allowing for more precise identification of peaks. The peaks following lower limb are generally more sensitive to delays in conduction from demyelination due to the greater length the signal must travel.

Upper Limb SEPs

Stimulating electrodes are placed on the median or ulnar nerve at the wrist. The stimulus pulse intensity is just above motor threshold at 5–10 mA and the pulse duration is 200 μs. At least three recording sites are used: ipsilateral Erb's point (Ep), posterior neck (2nd, 5th, or 7th cervical vertebrae), and contralateral parietal scalp. To identify waves, one averages 500–1000 stimulations delivered at a frequency of 3–5 Hz and the averages are performed at least twice to document waveform reliability.

Within 30 ms of stimulation, several consistent peaks are identifiable on the averaged waveforms. A negativity occurring at 9 ms (N9) after stimulation originates from the brachial plexus and is recorded from the Ep electrode. Subsequent negativity

at 10–11 ms is generated near cervical cord root entry; at 12–14 ms after stimulation, negativity and positivity (N13, P14) are generated from the dorsal column–nucleus cuneatus–medial lemniscus and are thus recorded over cervical vertebrae. A negative peak occurring between 16 and 18 ms (N18) is generated from thalamus and/or thalamocortical radiations. There is a negative peak at 20 ms (N20) and a positive peak at 22–25 ms, generated from the sensory cortex (Figure 2(a)). To calculate central conduction time, the brachial plexus latency (Ep) is subtracted from the sensory cortex negative peak latency (N20).

Lower Limb SEPs

For the lower limb, stimulating electrodes are placed over the tibial nerve at the ankle or over the common peroneal nerve at the head of the fibula. The afferent impulse can be recorded peripherally (at electrodes over the popliteal fossa following posterior tibial

Figure 2 Normal somatosensory evoked potentials of the right median nerve and left tibial nerve. The 1000 averaged stimulations delivered at a frequency of 5.1 Hz are shown with a standard montage; several repetitions are overlaid to illustrate reliability. The vertical bars indicate stimulus onset. (a) Right median nerve stimulation: N9 is apparent at ipsilateral evoked potential and N13 is apparent at the level of cervical vertebra 2. N18, N20, and P22 can be observed at scalp electrodes. (b) Left tibial nerve stimulation: P37 and N45 can be seen maximally over central scalp electrodes Cz and C3. N29 can be seen at the level of cervical vertebra 2. In this tracing, lumbar potentials are apparent at L1 and T12 surface electrodes. Vertical calibration bar represents 0.5 μV for top tracing (Cz–Fz), 1.5 μV for bottom tracing (LPF–LR), and 1 μV for all others. C3, central right scalp; Fz, frontal midline scalp; LEP, left Erb's point; Cs2, cervical vertebra 2; REP, right Erb's point. Cz, central scalp; C4, central left scalp; T12, surface electrode over T12; L1, surface electrode over L1; IC, iliac crest; LPF, left popliteal fossa overlying tibial nerve; LR, left popliteal fossa reference.

nerve stimulation) and from the lumbar plexus or roots (LP, or lumbar potential, from electrodes over the lower back). Potentials generated from the cervicomedullary junction in the region of the nucleus gracilis are recorded from posterior cervical electrodes, and potentials generated from the sensory cortex can be recorded from central scalp electrodes. To calculate central conduction time from lower limb SEPs, latency to LP is subtracted from sensory cortex peak latency. Generally, posterior tibial nerve stimulation is used since it generates amplitude responses larger than are generated by peroneal nerve stimulation.

Following the lumbar potential elicited by posterior tibial nerve stimulation, a series of waves are generated at higher levels within the central nervous system (CNS) (Figure 2(b)). There is an N29 generated in a similar cervicomedullary region as generates the N13 that follows upper limb stimulation, and an N34 is generated in the thalamus analogous to the N18 following upper limb stimulation. About 4 ms after the initial thalamic negativity there is a positive peak (P37) generated in sensory cortex, and this is the most important waveform for assessing clinically significant changes. Following peroneal nerve stimulation at the knee, these latencies occur 5–10 ms earlier.

Nonpathological Factors Affecting SEPs

Body size will influence peak latencies and this effect is greater during lower limb testing; this can be accounted for by normalizing latencies to the height of the individual being tested. Central conduction time is calculated by subtracting latency to Ep (for upper limb) and LP (for lower limb) from the sensory cortex latency, and helps exclude peripheral pathologies as the source of SEP abnormalities. Since core temperature is usually constant, central conduction time also helps to exclude decreased limb temperature as a cause for conduction delays. Age and gender may influence some SEP characteristics, though reported findings have not been consistent. In general, age is associated with decreased conduction velocities.

Pathological Changes in SEPs

Clinical abnormalities manifest as latency prolongation (absolute or interpeak) and peak amplitude reduction. Individuals with multiple sclerosis typically exhibit increased central interpeak latencies. Peripheral demyelinating diseases may also cause increases in these so-called central interpeak latencies because peripheral myelination deficits may exist up to 12 cm from reference point (Ep or LP) to the root entry. Other disorders associated with peripheral and/or central conduction dysfunction, such as Friedrich's ataxia, produce significant SEP changes. Individuals with cortical reflex myoclonus typically have enhanced amplitude of peak components (termed 'giant SEPs'), reflecting hyperexcitability of underlying sensorimotor cortex. Attenuation or absence of cortical waveforms following hypoxic–ischemic encephalopathy or traumatic brain injury signifies a poor prognosis.

The SEP is usually less sensitive to diseases of the peripheral nervous system, compared to electromyelographic (EMG) and nerve conduction studies. Specific questions, such as whether a nerve injury is pre- or postganglionic, may be aided by SEPs. A method developed to localize nerve root pathology is dermatomal stimulation, which uses touch or vibration stimuli of a specific skin region with known sensory innervation. Considerable variability in waveforms exists in a healthy population, limiting the usefulness of this technique for identifying clinical pathologies.

Brain Stem Auditory Evoked Potentials

Brain stem auditory evoked potentials (BAEPs) are a series of waves recorded within 10 ms of an auditory stimulus and that are generated within brain stem auditory structures. The preferred stimulus is a broadband click of 90–120 dB peak sound pressure level although pure tones, or other acoustic signals may be used. All stimuli are delivered monaurally via headphones or intraaural stimulators. Click polarity is usually rarefaction, although condensation clicks are occasionally used to improve wave V definition. Stimulation intensity is 60–70 dB above the person's hearing threshold, with masking of the contralateral ear to prevent bone conduction-elicited responses from the other ear. Given the short window for averaging, stimulus repetition rate can be fairly high (usually around $10\,s^{-1}$ but up to $40\,s^{-1}$).

The waveforms used clinically are called waves I, III, and V (Figure 3). The electrocochleogram occurs prior to wave I. Wave I is thought to be generated in the distal eighth nerve, wave III within the pons in or near the superior olive, and wave V in the inferior midbrain in or near the inferior colliculus. Major criteria for clinical abnormality are delays in waves I–V or other interwave latencies, excessive interside interwave latency differences, and the wave V:wave I amplitude ratio.

Audiologic function may be assessed with BAEPs as well as electrocochleography. Wave V is the last signal to disappear when decreasing the intensity of the acoustic stimulus, and a threshold for disappearance of wave V can be obtained. In addition, wave V latency increases with decreasing stimulus intensity. The latency–intensity plot obtained by stimulating at various intensities may help define the etiology of a hearing deficit.

Figure 3 Brain stem auditory evoked potentials from left (AS, auris sinister) and right (AD, auris dexter) ears in a patient with multiple sclerosis, demonstrating a significant wave I–wave V interpeak latency delay on the right (6.7 ms, upper limit of normal 4.7 ms), along with attenuation of wave III, consistent with a defect in auditory conduction pathways between the distal eighth nerve and midpons. This pattern of abnormality is not specific for multiple sclerosis and can be seen with tumors or other lesions in the same region. Each trace is the average of 1024 clicks on the left and 2048 clicks on the right. The single traces at the bottom are the averages of the superimposed trials. Calibration marks are 0.25 μV. Adapted from Chiappa KH (ed.) (1997) *Evoked Potentials in Clinical Medicine*, 3rd edn. New York: Raven Press, with permission from Wolters Kluwer.

Clinically Relevant Changes in BAEPs

BAEPs are affected by age. This is caused in part by presbyacusis, since high-frequency components of the click stimulus are most important for generating the BAEPs. Any peripheral otologic condition decreasing auditory thresholds, such as wax in the ear canal or middle ear pathology, may increase the latency of all of the waveforms. The interwave latencies should remain normal if there is no central pathology.

Pathological Changes in BAEPs

BAEPs are used clinically for several reasons. In multiple sclerosis, BAEPs are less often abnormal than VEPs or SEPs are, so are not commonly performed in this setting. BAEPs may be used to help prognosticate coma following closed-head injuries and stroke. BAEPs are sensitive within brain stem structures to lesions such as acoustic neuromas or brain stem gliomas, but MRI scans are more helpful clinically. BAEPs can be used to help obtain auditory thresholds in patients who cannot easily cooperate for audiometry, such as infants and comatose patients. BAEPs may be used in screening for audiologic deficits secondary to ototoxic drugs.

Event-Related Potentials (P3)

Long-latency EPs are generated in higher order sensory processing areas or in heteromodal association areas. The component, called either the P3 (third positive component) or the P300 (positive component with a mean latency of about 300 ms in controls), is the only long-latency EP that has been used clinically.

The P3 is a symmetric positive wave, recorded maximally over the midline central and parietal regions, with a latency that varies from 250 to 600 ms. The P3 can be elicited with a stimulus of any modality. The most commonly used method to obtain the P3 is the 'oddball' paradigm. This involves the presentation of unexpected or infrequent stimuli randomly interspersed among more frequent stimuli. In most clinical studies, the unexpected stimuli differ from the more common stimuli in terms of frequency (e.g., pitch) or intensity. A method that augments the P3 and is generally used in conjunction with the oddball paradigm consists of attending to task-relevant target stimuli and ignoring nontarget stimuli. A P3 will be seen following the target but not the nontarget stimuli (Figure 4).

The generator site of the P3 is not known with certainty. Neuronal activity in multiple brain regions, including inferior parietal lobule, frontal lobe, hippocampus, medial temporal lobe along with other limbic structures, and locus coeruleus, correlate to scalp-recorded P3 activity. Patients with frontal lobe lesions have a significantly attenuated novelty P3 (P3a) while patients with temporoparietal junction lesions have markedly attenuated P3s to both novel and attended stimuli (P3a and P3b).

Figure 4 Auditory evoked potentials recorded from the central midline (Cz) and parietal midline (Pz) scalp following 1000-Hz tones occurring frequently (84%), interspersed with 2000 Hz tones occurring infrequently. The N1–P2 complex is relatively the same in response to frequent and infrequent tones and is not markedly affected by attending to the infrequent tones. Solid lines are in the unattended condition and dotted lines are in the attended condition, whereby participants are keeping a mental count of the rare tones. There is a marked enhancement of the N2–P3 in the attended condition with the rare tones.

At least three channels of EEG activity are used (Fz, Cz, Pz), in part to delineate the P3a and P3b components. The electrodes can be referenced to linked-ear, linked-mastoid electrodes, nose, or noncephalic electrodes. Eye movement also needs to be monitored because eye movements may be time-locked to the stimuli, especially the target (oddball) stimuli, and the field of distribution of the eye movements may include the recording electrode sites. The stimulus rate is generally about $1\,s^{-1}$. The sweep duration should be 600–1000 ms and a prestimulus period is important in assessing the baseline for amplitude measures. The P3 is a variable response, even within an individual, and, as with other EPs, it is necessary to repeat trials to ensure reproducibility.

Nonpathologic Factors Affecting the P3

The P3 is not as sensitive to physical aspects of the stimulus, such as intensity, as are shorter latency components. In fact, a very similar P3 may be elicited by stimuli of different sensory modalities. While the short-latency EPs can be recorded when the patient is under general anesthesia, the optimal P3 is recorded when the patient is alert. The two factors, stimulus infrequency or unexpectability and attention or task relevance, operate independently. In fact, they produce different P3s, with a novelty-related P3a that occurs slightly earlier and with a more frontal distribution than is seen for the parietal maximum P3b component wave, which is best elicited by attending to a task-relevant stimulus. In general, target stimulus infrequency and attention increase the amplitude of the P3, and task difficulty increases its latency.

A series of related variables affect the P3: level of attention, vigilance, and response accuracy. Drowsiness or inattention will decrease the amplitude or obliterate the P3. An assessment of behavioral response to the stimuli is important to enable estimation of the individual's vigilance or degree of attention. The P3 component does not depend on the presence of a

motor response. In fact, the P3 latency may be longer than the reaction time. The P3 latency has a positive correlation with age, with an increase in mean latency by approximately 1–1.5 ms year^{-1} after age 20 years. There is also a gradual decline of P3 latency in children, with a minimum latency being achieved between ages 15 and 25 years.

Pathologic Factors Affecting the P3

The P3 may be altered by many diseases that affect cognitive function. In Alzheimer's disease (AD), the sensitivity of a prolonged P3 latency has ranged from 10 to 80%. The sensitivity for classifying a single patient with mild AD as having an abnormal P3 latency is likely well under 50%, despite the consistently observed group difference in controls and patients with AD. Other diseases associated with cognitive change or dementia also produce changes in the P3, including vascular disease, Huntington's disease, Parkinson's disease, multiple sclerosis, human immunodeficiency virus infection, and Down's syndrome. Schizophrenia patients have a lower amplitude P3 compared to controls. Some evidence shows that patients with alcoholism or even individuals with family history of alcoholism have altered P3s when compared with groups of controls. Additionally, many CNS depressant drugs will prolong the P3 latency. Finally, the P3 following complex stimuli has been used to explore various neurobehavioral syndromes, including prosopagnosia, inattention following prefrontal lesions, visual neglect, anosognosia, blindsight, transient global amnesia, and other memory disorders.

Motor Evoked Potentials

Motor evoked potentials (MEPs) can be used to assess the integrity of the descending corticospinal tract. An electrical current is delivered or induced in the motor cortex and electromyographic recording is obtained using surface electrodes. MEPs were originally delivered using transcranial electrical stimulation (TES); however, the current attenuation by the skull is great, such that the intensity required using scalp electrodes to activate underlying neurons also activates many pain fibers and scalp muscles. The development of transcranial magnetic stimulation (TMS), which induces an electrical current orthogonal to the magnetic field of the stimulating coil, has allowed the study of MEPs without the direct application of high-intensity current.

Cortical stimulation may initially elicit a D (direct) wave, believed to represent direct activation of corticospinal axons. This is seen primarily with TES. An I (indirect) wave occurs 2 ms later, presumably through depolarization of motor cortex interneurons which synapse onto and depolarize cell bodies of the corticospinal tract. This is likely the primary descending volley from TMS, but it is also seen with TES. Both D and I waves travel down the spinal cord to synapse onto an alpha motor neuron and effectively result in a muscle twitch.

Methodology

For TMS, a magnetic stimulator is positioned over the vertex of the scalp for upper limb and lower limb MEPs, and direction of current flow through the coil can be manipulated to preferentially stimulate the right or left hemisphere. Upper or lower limb MEPs can be tested by recording EMGs of several muscles. Resting motor threshold (RMT) intensity is defined as an intensity at which 50% of trials obtain an EMG response of at least 50 μV while the muscle is relaxed. Test pulses are subsequently delivered as single pulses of electromagnetic energy at an intensity of 10% above RMT. Unlike SEPs that are on the order of 1 μV, MEPs evoke an EMG response on the order of 0.1–2 mV. As a result, trials do not need to be averaged to observe a reliable waveform, and two to three stimulations are generally sufficient to demonstrate reliability. TES is used only to elicit MEPs while someone is under general anesthesia and is used only for intraoperative neuromonitoring (see later, 'Intraoperative neurophysiologic monitoring').

Following scalp stimulation, a muscle twitch will be observed within 20–45 ms, depending on distance to recording site. For clinical purposes, response latency is the primary variable of interest, as amplitude of response will vary greatly between individuals and between sessions. Peripheral conduction time can be measured by stimulating at the root exit (upper limb, midline over cervical vertebrae; lower limb, midline over lumbar vertebrae) and measuring the latency to EMG response (Figure 5). Central conduction time can subsequently be calculated by subtracting the latency following root exit area stimulation, from the latency following scalp stimulation.

Nonpathological Changes in MEPs

As with SEPs, height will affect MEP latencies. Greater skull thickness, often associated with larger head sizes, will increase RMT. Both RMT and MEP amplitude will vary as cortical excitability of neurons underlying the stimulation site fluctuate over time from uncontrolled factors such as arousal. Pharmacological Na^+ and Ca^{2+} channel blockers will reduce RMT. MEP facilitation will be observed if the individual sustains a mild contraction of the muscle, enhancing cortical excitability (Figure 5). The latter

Figure 5 Single motor evoked potentials (MEPs) of extensor carpi radialis of a healthy individual. Single-pulse transcranial magnetic stimulation was applied over contralateral scalp; stimulus onset occurs at time zero. The amplitude of the MEP induced by stimulation at the scalp is greatly enhanced by a mild extensor carpi radialis contraction – 10 % of maximum voluntary contraction (MVC) – compared to rest, and the latency is slightly decreased. MEP latency after stimulation at the neck represents peripheral conduction time (PCT). Central conduction time can be calculated by subtracting PCT from total conduction time (TCT). Each tick mark on vertical axis represent 0.2 mV.

can be clinically useful in obtaining an MEP from an individual nonresponsive to high-intensity stimulation.

Pathological Changes in MEPs

MEP response amplitude and RMT are too variable to be used for clinical assessment. Response latency is the only current reliable measurement, and increased latencies are commonly observed in individuals with ischemic stroke, multiple sclerosis, upper motor neuron diseases, and spinal cord lesions. MEPs, SEPs and VEPs may have similar sensitivity for detection of dysfunction in multiple sclerosis . Individuals with epileptic syndromes have reduced RMT and larger amplitude MEPs.

Other Uses of TMS

Cortical circuitry can be indirectly studied using a paired-pulse TMS protocol. By varying prepulse stimulus intensity and interstimulus interval, intracortical inhibition or facilitation can be measured in motor disorders such as Parkinson's disease. The post-EMG silent period studied with TMS is also reduced in Parkinson's disease.

TMS has been used to probe changes in cortical excitability as well as shifts or expansion in motor representation areas for a muscle group after learning a new motor skill or practicing a movement. These plastic changes are observed as decreases in RMT or a spatial change in areas excited by a given stimulation intensity. Repetitive TMS has also been explored as a treatment for depression as well as other neurological disorders.

Premotor Potentials

Premotor potentials are evident in the averaged EEG waveform prior to a planned motor movement. For premotor potentials, averaging of trials is done by 'backaveraging' from the onset of EMG activity related to the movement. The bereitschaftspotential (BP) is one type of premotor potential, and it occurs prior to a voluntary movement. The BP is a slow negative shift composed of an early BP, beginning 0.8–2 s before the onset of EMG, and a later BP or negative slope (NS′) component, apparent 400 ms before the onset of EMG (Figure 6(a)). The BP is maximal over the contralateral central scalp for upper limb movements (Figure 6(b)) and midline central scalp for lower limb movements and reflects preparation for the upcoming motor movement. Unique premotor potentials, unlike the BP, can be recorded prior to pathologic unplanned movements such as myoclonus.

Generators

Dipole source analyses from EEG and MEG recordings, as well as recordings from subdural electrodes placed during neurosurgical procedures, have led several researchers to identify bilateral supplementary motor area (SMA), lateral premotor, and primary motor cortices as putative generators of the BP, with greater localization in contralateral M1 and premotor cortex 400 ms prior to movement onset in the late BP (NS′).

Nonpathological Changes in Premotor Potentials

The amplitude and duration of the early component of the BP are mediated by movement speed, movement precision, muscle force, intention, and movement selection, among other individual and task characteristics; thus, it is necessary to employ a standardized task and instruction set when assessing BPs in research settings. For this reason, BPs are not commonly used clinically to assess pathological abnormalities.

Pathological Changes in Premotor Potentials

Premotor potentials may be examined to help determine the cause of myoclonus. When premotor potentials are recorded in individuals with cortical myoclonus, a unique premotor potential is observed within 50 ms prior to the onset of the involuntary

Figure 6 Terminology of premotor potential components and scalp topography. (a) Normal tracings recorded prior to self-paced middle finger extensions are shown over central midline (Cz, top tracing) and contralateral (C4, bottom tracing) scalp areas. The early bereitschaftspotential (BP) component occurs here at about 1200 ms prior to onset of movement. About 400 ms before movement, the slope of the potential steepens; this is the negative slope (NS′). Following movement, the motor potential (MP) is identified by a further increase in slope to the peak. (b) The scalp distribution of premotor potentials for the same task as in panel a. Amplitude is maximal over central midline (Cz) and contralateral (C4) sites. Two tracings of 100–250 averaged trials are shown for each recording site. F, frontal; Fp, frontopolar; z, midline placement; C, contralateral; Cz, central midline; T, temporal; P, parietal; O, occipital; EOG, electrooculographic; EMG, electromyelographic. Reproduced from Neshige R, Luders H, and Shibasaki H (1998) Recording of movement-related potentials from scalp and cortex in man. *Brain* 111: 719–736, with permission.

contraction. This potential appears over the contralateral scalp in the form of a biphasic wave at electrodes overlying sensorimotor cortex of the contracting muscle(s) and is obtained by averaging trials backward from the onset of EMG activity of the first contracting muscle (termed 'jerk-locked back-averaging'). Subcortical forms of myoclonus often lack this wave. Patients with psychogenic causes of myoclonus may demonstrate a 1–2 s duration BP, as is seen with planned movements.

Studies of patients with Parkinson's disease have reported small early BP. However, the later NS′ component is intact. Cerebellar lesions have been associated with reduced amplitude of the early BP as well as reduced NS′ amplitude over the hemisphere contralateral to the lesion. Focal dystonia has been associated with preserved early BP amplitude but a reduction in the NS′ component. Following ischemic stroke, there is a reduced late BP over the lesioned hemisphere contralateral to movement and an

enhanced early BP amplitude over the hemisphere ipsilateral to movement, suggesting a compensatory activation.

Intraoperative Neurophysiologic Monitoring

Intraoperative neurophysiologic monitoring (IONM) is used to give information in real time to surgeons operating in or near relevant neural structures. IONM is used for several general purposes. The information may consist of ongoing assessment of integrity of signal conduction. For example, acute posterior tibial-elicited cortical SEP changes during distraction in scoliosis surgery implies a posterior column dysfunction. Following acute changes in EPs secondary to CNS perfusion while under general anesthesia, the surgical team has about 10–20 min to reverse the underlying etiology until the pathology likely becomes irreversible. EPs may also be used for localization purposes – for example, localizing motor cortex by recording SEP field potentials from a subdural electrode or from direct cortical stimulation and recording EMG.

The EP modalities used for IONM include SEP (upper and lower limb), BAEP, and MEP. Due to the marked attenuation of TMS EPs by general anesthesia, intraoperative motor EPs are performed using TES. To elicit these MEPs, brief pulse trains (4–7 pulses at 200–500 Hz) are applied to central scalp regions overlying motor cortex. VEPs using goggles have not been reliable intraoperatively. In addition to EPs, an EMG from relevant muscles is often recorded if cranial nerves or nerve roots are at risk. Nerve conductions from pedicle screw stimulation or direct nerve stimulation may be used. An EEG may be used to help determine and guide the depth of anesthesia (e.g., until suppression–burst pattern is observed) or determine focal or global cerebral dysfunction during cerebrovascular or cardiovascular surgery.

EPs during surgery are sensitive to level of anesthesia, with MEPs being potentially obliterated by commonly used levels of inhalant anesthetics. Intravenous anesthetics such as propofol and narcotics have much less of an effect on EPs than do inhalants. BAEPs are relatively insensitive to anesthesia, with SEPs being in between MEPs and BAEPs. EPs are also sensitive to other physiologic parameters during surgery, including blood pressure and temperature. EP recording within the operating room requires much expertise in managing the numerous causes of artifacts potentially obliterating the signals (e.g., electrocautery).

While IONM has become standard for many neurosurgical, orthopedic, vascular, and otolaryngology surgeries, there are no randomized trials demonstrating their utility at improving outcomes. There have been several studies carefully using historical or nonmonitored controls, with results strongly suggesting their utility for scoliosis surgery, resection of small acoustic neuromas, and microvascular decompression for trigeminal neuralgia. IONM is commonly performed in other surgeries when there is significant risk to neural structures (e.g., multilevel spine surgery with preexisting myelopathy, posterior fossa surgery, and aneurysm surgery).

Introduction

When a human receives a sensory (e.g., visual, auditory, tactile) stimulus, neurons in the corresponding sensory cortical area generate slow postsynaptic potentials, and the resulting volume currents can reach the scalp, creating potential differences (voltages) between different scalp locations. This evoked potential (EP) can be obtained by recording the electroencephalogram (EEG) from electrodes attached to the scalp and, by using prior knowledge of the EP (the signal) it can be extracted from the electrical activity of the rest of the brain (the noise). EP amplitudes range from about 0.1 to 5 μV and are buried in noise of typically 50 to 100 μV amplitude. A major limitation of the EP technique is that distant as well as nearby regions of brain tissue can contribute to the EP at any given scalp location and, because the scalp EP is affected by the conductivities of intervening tissues, sources are difficult to localize.

In addition to the electrical field, brain activity also generates a magnetic field that can be recorded outside the skull (the magnetoencephalogram, or MEG). This neuromagnetic field seems to be generated by intracellular currents rather than by the volume currents that are largely responsible for the scalp EP. Magnetic response recording has the advantage that the neuromagnetic field is unaffected by tissues between the source and the detector, because brain tissues are transparent to low-frequency magnetic fields. In addition, no reference is involved, and the evoked response near the scalp is determined by a smaller volume of brain tissue than the EP is, being little affected by distant sources. To record a neuromagnetic field, a superconducting quantum interference detector (SQUID) is placed near the head. This device converts the magnetic field into an electrical signal. Compared with imaging techniques such as functional magnetic resonance imaging (fMRI), both techniques have the advantage of millisecond resolution.

Analysis in the Time Domain

Time-Domain Averaging of Transient Evoked Responses

Signal averaging in the time domain enhances signal-to-noise ratio by exploiting prior knowledge of the instant(s) at which stimuli are applied (on the assumption that the response always occurs a fixed time after the stimulus). Figure 1 illustrates how signal averaging can enhance signal-to-noise ratio as progressively more responses are averaged. As averaging progresses, the signal-to-noise ratio increases with $\sqrt{N}$ (where N is the number of responses averaged), providing that the following requirements are satisfied: (1) the waveform to be averaged is the sum of two independent waveforms, namely the signal and the noise; (2) the signal waveform is produced by a process that is stationary from trial to trial, and its variance is negligible; (3) the noise waveform is produced by a stationary random process; and (4) the N sample of noise are uncorrelated. If these requirements are not fulfilled the signal-to-noise improvement can be much less than $\sqrt{N}$.

Finally, only if the sensory system always returns to its resting state before the next stimulus can the averaged response be regarded as the averaged transient response of the sensory system stimulated. This requirement is commonly violated.

Quantification of the Transient Evoked Response Waveform

A typical transient response consists of a series of positive and negative deflections. For example, Figure 2 shows the transient responses to the abrupt appearance and the abrupt disappearance of a checkerboard pattern. To an 'eyeball' inspection, the two responses have clearly different waveforms. But the quantification of such a difference is controversial.

A common assumption is that the waveform can be regarded as the linear sum of several component waveforms, and that each component corresponds to a functional entity in the brain. Peak analysis is a popular way of reducing the data in transient response so that the waveform can be specified in terms of a few numbers. A peak is defined as either the most positive or the most negative voltage within some specified time interval. Although this approach has intuitive appeal, peak measurements are strongly affected by noise and have dubious significance with complex waveforms that have overlapping components. An alternative approach that is less affected by noise is to measure the areas under peaks. A third possibility is principal components analysis (PCA). Whether this last approach necessarily provides the notional

Figure 1 Signal-to-noise enhancement by time-domain signal averaging. A subject viewed a pattern of black and white checks that abruptly exchanged places (reversed) 1.88 times per second. Each reversal was a single stimulus. (a) Each trace is the average of 4 single-stimulus responses. Only noise (alpha activity in this case) is evident. (b–e) Average of successively more responses (16, 36, 64, 100). (f) Two separate averages of 500 responses superimposed to show the excellent reproducibility of the averaged response. component waveforms that underlie the transient response waveform is controversial, though it has been stated that it does provide an estimate of the dimensionality of the data space.

Figure 2 Transient EP to the abrupt onset and the abrupt offset of a pattern of fine checks viewed binocularly. Mean luminance was constant. Note that though the positive-upward convention is used in basic research, a negative-upward convention is common in clinical work. Analysis in the Frequency Domain

Fourier Analysis of the Steady-State Evoked Response

It is sometimes said that the distinction between transient and steady-state responses is merely a matter of stimulus repetition frequency. This is incorrect: in principle, steady-state responses can be evoked by a very long train of identical stimuli, whether the stimulus repetition frequency is low or high. The real distinction is that the system attains a dynamic steady state throughout the duration of the recording without ever returning to its resting state, while, as already mentioned, for an averaged waveform to be a true transient response the system must always return to its resting state before the next stimulus is applied. The dynamic steady state may not be attained immediately at the onset of stimulation, but may take several seconds. This should be checked, as should the absence of any progressive change in amplitude or phase due, for example, to sensory adaptation.

The idealized steady-state response to a very long train of identical stimuli is an electrical or magnetic waveform, the discrete frequency components of which remain constant in amplitude and phase over an infinitely long time period. Although this definition does imply that the idealized steady-state response is an infinitely long train of identical waveforms, it is more insightful to think of it in terms of discrete frequency components, because different components may have different properties. For example, the steady-state EP evoked by sinusoidal flicker with frequency F of between about 15 and 20 Hz consists predominantly of a fundamental component of frequency F Hz plus a second harmonic component of frequency $2F$ Hz; the properties of the F Hz component are similar to the

properties of parvocellular neurons in the macaque monkey lateral geniculate body, while the very different properties of the $2F$ Hz component are similar to the properties of magnocellular neurons.

Steady-state response can be more unequivocally quantified than can transient responses, because they are compared of discrete frequency components that are quite separate from each other (nonoverlapping), and each is fully described by an amplitude and a phase. In some applications, frequency domain and hybrid techniques (e.g., the sweep technique) are much faster than is time domain averaging. This is because a discrete steady-state frequency component contains considerably less information than does a typical transient response.

A method for simultaneously demonstrating the existence of a steady-state response, enhancing its signal-to-noise ratio, and quantifying the response is as follows. While a subject receives repetitive, commonly sinusoidal, stimulation, the EEG (or MEG or electroretinogram) is multiplied by a sine and by a cosine, the frequency of which is some exact multiple of the F Hz stimulus repetition frequency. Multiplication by sine/cosine pairs of frequency F, $2F$, $3F$, etc. extracts the first, second, third, etc. harmonic of the response. The products of the two multiplications are each low-pass filtered to give two running averages. Figure 3 shows how the first harmonic of the steady-state flicker EP was first demonstrated and quantified. Beyond about 15 s after the onset of stimulation in Figure 3 (this delay being largely caused by the low-pass filters used to create a running average), the running average of the sine and cosine products remained approximately constant, thus demonstrating the existence of a steady-state response. Next, the mean values of θ_1 and θ_2 were calculated and the amplitude (S) and phase (ϕ) of the first harmonic were calculated as shown.

In the case of steady-state responses, signal-to-noise ratio is enhanced by exploiting prior knowledge of the exact frequencies of the discrete response components. For example, when the stimulus is sinusoidal, the response component frequencies are multiples of the frequency of the sinusoid. Each sine/cosine multiplication acts as a narrow bandwidth

Figure 3 Steady-state EP. The two traces are the running averages of the sine and cosine multiplier outputs, the instantaneous amplitudes of which (measured horizontally from the central zero) are marked θ_1 and θ_2, respectively. Time runs vertically, and the onset of sine wave flicker stimulation is denoted by an arrow. The insert shows how the amplitude (S) and phase (ϕ) of the first harmonic frequency component of the steady-state EP were obtained using Pythagoras' theorem. From Regan D (1989) *Human Brain Electrophysiology: Evoked Potentials and Evoked Magnetic Fields in Science and Medicine*, p. 83. New York: Elsevier.

Figure 4 Two-thousandths of a hertz bandwidth. At a frequency resolution of 0.0019 Hz, approximately two-thirds of the EP signal power is contained within a single bin. Therefore the EP signal's bandwidth is no more than 0.0019 Hz. Note that even if the EP signal's bandwidth were considerably less than 0.0019 Hz, more than one bin of the analyzer would contain power when the analyzer's resolution is set at 0.0019 Hz, because the sensitivity of adjacent bins overlaps. The stimulus was a vertical sine wave grating that was counterphase-modulated at nominally $F = 8$ Hz. The $4F$ component is shown. Zoom FFT was applied to the entire length of EEG samples of 520-s duration. To allow some frequency-domain averaging (with overlap), recording duration was 640 s. From Regan D (1989) *Human Brain Electrophysiology: Evoked Potentials and Evoked Magnetic Fields in Science and Medicine*, p. 95. New York: Elsevier.

Figure 5 (a) Modulating noise waveform, direct current to 5 Hz. (b) Pure sine wave, 150 Hz. (c) 150 Hz sine wave, amplitude-modulated by noise waveform of amplitude 2.5 V RMS. (d) 150 Hz sine wave, phase-modulated by a noise waveform of amplitude 2.0 V RMS. A sine wave-modulating waveform of 1.0 V amplitude produces an amplitude modulation depth of 20% and a phase excursion of 30°. Frequency resolution was 0.0078 Hz in all cases. From Regan D (1989) *Human Brain Electrophysiology: Evoked Potentials and Evoked Magnetic Fields in Science and Medicine*, p. 95. New York: Elsevier.

filter centered on the analysis frequency. If the recording duration is T seconds, the filter bandwidth is the theoretical limit of resolution – that is, T^{-1} Hz.

This last point can perhaps be more clearly understood as follows. A recording technique that uses the digital Fourier transform (fast Fourier transform (FFT) or zoom FFT) to obtain a spectrum with T^{-1} Hz resolution is in many respects more convenient than that shown in Figure 3. (Though this technique has the disadvantage that it does not immediately confirm that the amplitude and phase of a response component are stable.) In Figure 4 a subject viewed a sine wave grating that was counterphase-modulated at nominally 8 Hz. Zoom FFT was applied to the entire length of EEG samples of 520 s duration. To allow some frequency-domain averaging, the recording duration T was 640 s. Approximately two-thirds of the signal power was contained within one bin of width 0.0019 Hz. One might suppose that progressively reducing the T^{-1} Hz resolution would improve signal-to-noise ratio only up to some limit at which the broadening of a response component's bandwidth would render ineffectual any further reduction of T^{-1}. However, this is not entirely correct. Providing that the moment-to-moment variability of the amplitude and phase of the response component is not too great, the bandwidth of the physiological signal is determined entirely by the recording duration T. Figure 5 illustrates this point. Panels (b) and (c), respectively, show the spectrum of a 150 Hz sinusoid and of the same sinusoid subjected to noise (direct current to 5 Hz, panel (a)) modulation of amplitude. Panel (d) shows the spectrum of the sinusoid subjected to phase modulation. Frequency resolution was 0.0078 Hz. Panel (b) shows that the signal bandwidth

Figure 6 The sweep technique: an example. See text for details. Reproduced from Regan D (1975) Color coding of pattern responses in man investigated by evoked potential feedback and direct plot techniques. *Vision Research* 15: 175–183, with permission.

Figure 7 Ultrahigh-frequency resolution over a wide bandwidth. The EEG was analyzed by nondestructive zoom FFT at a resolution of 0.0039 Hz. See text for details. From Regan D (1989) *Human Brain Electrophysiology*: *Evoked Potentials and Evoked Magnetic Fields in Science and Medicine*, p. 106. New York: Elsevier.

remained at 0.0078 Hz, though riding on a pedestal; the larger the noise, the higher the pedestal.

In summary, any given frequency component of the steady-state response lies within a T^{-1} bandwidth (e.g., 0.008 Hz), so that the signal-to-noise enhancement is excellent because the noise is spread along the entire EEG or MEG spectrum of, for example, 0.3 to 100 Hz.

Frequency Tagging of Multiple Stimulus Locations, Submodalities, and Modalities

The steady-state technique allows the responses evoked by stimulating different locations to be recorded simultaneously from a single electrode derivation and thus to be compared more accurately than when

recorded in succession. For example, the four quadrants of the visual field have been stimulated at four different frequencies, none differing more than 0.15 Hz. These frequency differences are negligible to the visual pathway, but can easily be separated by four parallel Fourier analyzers. Different stimulus features (e.g., orientation or spatial frequency) can also be frequency tagged. (This approach is discussed further in the section entitled 'The two-frequency method.')

The Sweep Technique

Sweep averaging is a hybrid time-domain frequency-domain technique that, because of its speed and resistance to certain kinds of noise, is useful when studying labile phenomena or when recording duration is severely limited (e.g., when recording from babies). Ordinates in Figure 6 plot the amplitude of the $2F$ Hz frequency component recorded while a subject viewed a pattern of bright and dim checks that exchanged places $2F$ times per second ($2F = 6$ in this example). Log spatial contrast of the checks was ramped linearly (abscissa). Panel (a) shows four individual sweeps; panel (b) is the average of the four traces in panel (a) and shows improved signal-to-noise ratio; each of the two traces in panel (c) is the average of 16 sweeps, while the noise trace is the average of 16 sweeps made with the stimulus occluded. A single sweep can be made within 10 s, and only one sweep may be sufficient to obtain the required information.

Evoked Response Feedback

An evoked response can exert moment-by-moment control of the stimulus that evokes it, without conscious intervention by the subject. For example, a 6 Hz steady-state response was evoked by a pattern of red checks that exchanged places six times per second. A desensitizing patch of light was superimposed on the checkerboard. A feedback loop allowed the instantaneous amplitude of the EP to control the brightness of the desensitizing light so as to hold EP amplitude constant (6 μV in this case). When the color of the desensitizing light was changed the feedback altered the brightness of the desensitizing light so as to quantify the spectral sensitivity of the response.

Analysis of Nonlinear Sensory Systems

The Two-Frequency Method

Figure 7 shows the spectrum produced by subjecting a 320 s sample of EEG to Fourier analysis while the subject viewed an unpatterned patch of light flickering at F_1 Hz superimposed on a second unpatterned patch of light flickering at F_2 Hz. In addition to the harmonic components of the responses to the F_1 Hz and the F_2 Hz flicker, Figure 7 shows multiple cross-modulation components of frequency ($nF_1 \pm mF_2$) Hz, n and m being integers. A frequency-domain approach to nonlinear systems analysis is based on the mathematical finding of MP Regan that the relative amplitudes of harmonic and cross-modulation components of the response to the sum-of-sinusoids stimulus allow candidate multistage nonlinear models to be tested against data. Note that the EP components in Figure 7 show no pedestals of the kind shown in Figure 5, indicating that moment-to-moment variations of EP amplitude and phase were small.

There is an approach that is less general than that just described: if the physiological responses to two different stimuli converge at a nonlinear stage, the properties of that stage can be investigated by applying the two stimuli simultaneously and analyzing the resulting steady-state responses. For example, in Figure 8 a subject's left and right eyes were tagged by presenting F_1 Hz flicker to the left eye (producing harmonics of F_1, including a $2F_1$ Hz response) and F_2 Hz flicker to the right eye (producing harmonics of F_2, including a $2F_2$ Hz response). The $(F_1 + F_2)$ Hz response demonstrated the presence of binocularly driven neurons.

Figure 9 demonstrates that the steady-state grating EP is generated by parallel neural mechanisms that are narrowly tuned to both spatial frequency and orientation. Figure 9(a) shows that the steady-state EP evoked by a single vertical grating has broadband spatial frequency tuning that is independent of the

Figure 8 The 'frequency tagging' technique: an example. See text for details. Reproduced from Regan MP and Regan D (1989) Objective investigation of visual function using a nondestructive zoom-FFT technique for evoked potential analysis. *Canadian Journal of Neurological Sciences* 16: 168–179, with permission.

Figure 9 Selectively tuned spatial filters. (a) Normalized 20 Hz steady-state response to a single vertical grating pattern – reversing at 20 Hz for three contrasts. (b) The 20 Hz response of the fixed grating was suppressed by superimposing a second vertical grating of variable spatial frequency (abscissa), provided that the spatial frequency of the variable grating was near that of the fixed grating. (c) The 20 Hz response of the fixed grating was suppressed (open circles) by superimposing a second grating with varied orientation (abscissa). Suppression was greatest when the second grating's orientation was near vertical and near horizontal. A nonlinear $(F_1 + F_2)$ Hz component (filled circles) showed the opposite behavior. In (b) and (c) the reversal rate of the second grating was 18 Hz. (a, b) From Regan D (1983) Spatial frequency mechanisms in human vision investigated by evoked potential recording. *Vision Research* 23: 1401–1407. (c) From Regan D and Regan MP (1987) Nonlinearity in human visual responses to two-dimensional patterns and a limitation of Fourier methods. *Vision Research* 27: 2181–2183.

grating's contrast over a 15–100% range. In Figure 9(b) a second vertical grating of variable spatial frequency was superimposed on a vertical grating of fixed spatial frequency. The bright and dim bars of the gratings exchanged places $F_1 = 20$ times per second for the fixed grating and $F_2 = 18$ times second for the variable grating. The variable grating suppressed the response evoked by the first grating, but only when its spatial frequency was close to that of the fixed grating, so that the spatial filter stimulated by the fixed grating could also 'see' the variable grating. Data for only one experiment are shown in Figure 9(b), but similar results were obtained independently of the spatial frequency of the fixed grating. The bandwidth of the nonlinear suppression was 0.4 to 1.0 octaves, in good agreement with the bandwidths of spatial filters estimated psychophysically. In Figure 9(c) the spatial frequency of the variable grating was held constant while its orientation was rotated away from vertical. Evidence for an orientation-tuned mechanism is that the nonlinear suppression of the response evoked by the fixed grating (and the amplitude of the cross-modulation $(F_1 + F_2)$ Hz response) declined as the difference of the orientations of the gratings increased and reached a minimum at approximately $\pm 30°$. The suppression and the amplitude of the $(F_1 + F_2)$ component then rose to a second maximum when the two gratings were at right angles. This last finding implies that the visual processing cannot be fully understood in terms of data obtained using stimuli such as gratings or Gabors, where luminance varies along only one dimension.

A similar rationale has been used to demonstrate and locate an audio–visual convergence area in the human brain. A MEG was recorded from many sites near the scalp while a subject listened to a tone that was amplitude-modulated at F_1 Hz, while also viewing a light that flickered at F_2 Hz. Any cross-modulation response component must necessarily have been generated at some nonlinear stage where visual and auditory signals converged. The distribution of a cross-modulation component of the response allowed the site of the audio–visual convergence area to be identified.

The final example provides an indirect means of measuring the shape of the ear's hair cell transducer

function. An $f_1 = 1048.50$ Hz audio carrier tone was amplitude-modulated at $F_1 = 20.886$ Hz and fed to a subject's left ear while a second f_1 Hz carrier tone was amplitude-modulated at $F_2 = 21.778$ Hz and fed to the right ear. Clear responses at $2F_1$ Hz and $2F_2$ Hz are evident in the section of the evoked response spectrum shown in **Figure 10(A)**, but there was no $(F_1 + F_2)$ Hz component. When the two auditory stimuli were simultaneously fed to one ear, the $2F_1$ and $2F_2$ components were suppressed nonlinearly and a cross-modulation $(F_1 + F_2)$ Hz response was evident (**Figure 10(B)**). Now a small (0.1 Hz, i.e., about 0.01%) difference was introduced between the two carrier tones. **Figure 10(C)** shows that the $(F_1 + F_2)$ response component split into two parts (labeled *a* and *b*) that were separated by 0.2 Hz and, in addition, the power of the suppressed $2F_1$ Hz and $2F_2$ Hz components increased. The separation for *a* and *b* was equal to twice the frequency difference of the two carriers even when *a* and *b* moved outside the $2F_1$ and $2F_2$ components (**Figure 10(D)**, where the two carrier frequencies differed by 1.3 Hz). This strange behavior was accounted for in detail by a mathematical analysis of the processing of the sum of two amplitude-modulated auditory stimuli by the hair cell transducer function, offering a noninvasive means of detecting variations in the shape of hair cell transducer function in humans.

Figure 10 Steady-state responses evoked by amplitude-modulated tones. Ordinates are power with the dimensions of volts^2; 1.0 on the ordinate corresponds to 1.0 μV. Analysis frequency is plotted as abscissa. The EEG was amplified over a bandwidth of 1–200 Hz and analyzed by zoom FFT at 0.0078 Hz frequency resolution. Analyzer and stimulus generators had an hour-by-hour frequency stability better than 1 in 10^5. The White Noise and Related Methods

Wiener's method of nonlinear systems analysis generates a sequence of orthogonal functionals that describe the response of the system to a Gaussian white noise input. In principle, these Wiener kernels enable the response of the system to any arbitrary input to be predicted. However, the kernels can be difficult to interpret in physiological terms. Furthermore, it is difficult to obtain higher order kernels in the presence of appreciable physiological noise, and errors can be caused if the statistical properties of the stimulus deviate from those of ideal white noise.

These last two problems are reduced in an alternative approach developed by JD Victor, BW Knight, and RM Shapley. This is to replace the stochastic white noise with a deterministic input, namely a sum of several (e.g., eight) sinusoids. The nonlinear response of the system is measured as cross-talk between the multiple input frequencies.

A second deterministic alternative to the white noise method is based on binary *m*-sequences. Sutter has applied this approach to multi-input analysis of highly nonlinear systems as, for example, the multifocal electroretinogram and visual EP.

Evolution of Sensory Receptor Specializations in the Glabrous Skin

N J Dominy, University of California, Santa Cruz, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Glabrous skin is devoid of dermal filaments such as hair or feathers. It is prevalent among amphibians and reptiles and is characteristic of the maxillary rictus, interdigital web, and combs and wattles of birds. The glabrous skin of birds is lipogenic and sometimes temporary, e.g., brood (incubation) patches, or associated with the attainment of maturity. For instance, feather loss from the head is linked to maturation in some ibises and storks. Glabrous skin is more variable among mammals. The rhinarium, lips, and genitals are glabrous, as well as parts of limb extremities in contact with the physical environment during locomotion, such as the flippers of seals and sea lions and the cutaneous pads of paws. A patch of glabrous skin also exists on the prehensile tails of atelid monkeys and certain other arboreal mammals. Such animals typically suspend their bodies by way of their tail when moving or foraging on terminal branches. More specialized examples of glabrous skin include the nasal rays of the star-nosed mole, *Condylura cristata*, and the upper bill of the platypus, *Ornithorhynchus anatinus*, which is an extension of skin that covers much of the face. At the proximal end of the lower bill is a similar extension that folds over the neck. These areas are termed upper and lower shields, respectively.

Glabrous skin is a major organ for sensing the external environment. Sensation from the glabrous skin – along with sensations from hirsute skin, muscles, tendons, joints, and bones – is termed somatic sensation. It is initiated by a variety of specialized receptors, many of which have structurally elaborate terminals that transform specific stimuli into nervous impulses. The sensory terminal may be encapsulated or linked to mesodermal or ectodermal elements. The extraneural cells are not necessarily excitable, but rather create the right circumstances for the excitation of the neuronal dendrite or modify its excitation in some way. Some receptors are remarkably uniform across vertebrate and mammalian orders, although considerable variation exists in the numbers of sensory receptors per square centimeter among the different areas of the body surface, and with advancing age the density of receptors can decrease. Not surprisingly, the adaptive function of glabrous skin and its associated receptors tends to vary according to the locomotor, foraging, and reproductive behaviors particular to a certain species.

Types of Cutaneous Receptors

The histological arrangement of a cutaneous receptor can differ greatly between hirsute and glabrous skin, as well as between animal species. This article has been written with a strong emphasis on the morphology and function of specialized receptors in the glabrous skin of mammals, which includes free nerve endings (FNEs), Merkel cells, Meissner corpuscles, Ruffini corpuscles, and Pacinian and paciniform corpuscles. Before the availability of electron microscopy, several other lamellar receptors were recognized (e.g., Golgi-Mazzoni and Dogiel corpuscles). However, they all follow the lamellar design pattern of the paciniform receptor and are considered part of this group.

When stimulation of a cutaneous receptor is maintained at a steady level, there is, as in all receptors, an initial burst – the dynamic phase – followed by gradual habituation to that steady level – the static phase. Although all receptors evince these two phases, one or the other predominates, giving a distinction between rapidly adapting (RA) endings that accurately record the rate of stimulus onset and slowly adapting (SA) endings that signal the constant amplitude of a stimulus, for example, the position sense. SA endings are further classified by the regularity of their discharge properties (type I and type II).

Free Nerve Endings

FNEs are the terminal receptor structures of sensory C-fibers or Aδ fibers. FNEs are found in all connective tissues, including the epidermis and dermis of hirsute and glabrous skin. Afferent fibers are myelinated or nonmyelinated but are always of small diameter and low conduction velocity. The terminal arborizations of myelinated afferent axons are nonmyelinated and devoid of Schwann cell investment. Electrophysiological recordings of FNEs in the dermis show that they respond to several sensory modalities. Some FNEs respond to moderate cold or heat (thermoreception), to low-threshold mechanical touch (mechanoreception), or to damaging heat, cold, or deformation (nociception). The FNEs of afferent fibers are mainly nociceptive in the nonmyelinated portion. The lips and palms of primates feature an abundance of nonmyelinated C-fibers and a paucity of finely

myelinated Aδ fibers, which together give glabrous skin a lower heat detection threshold and a higher heat pain threshold than hirsute skin. This condition is hypothesized to enhance the function of glabrous skin as an exploratory surface.

The exploratory function of glabrous skin is exemplified by the nasal rays of the star-nosed mole, *Condylura cristata*, which are richly invested with Eimer's organs and are the mole's primary sense organs. Named after the German zoologist Gustav Heinrich Theodor Eimer (1843–1898), Eimer's organs are a special form of FNE found in the rhinarium of fossorial mammals such as talpid moles. In this structure, the FNE extends through a column of thickened epidermal cells. Below the column are Merkel cell complexes and lamellated paciniform corpuscle. The presence of three types of specialized receptor raises the possibility that Eimer's organs have several important functions. The primary function appears to be the tactile detection and recognition of invertebrate prey, but the presence of up to three paciniform corpuscles at the base of each Eimer's organ suggests that it may also play a role in sensing seismic vibrations. Such vibrations are important signals of communication between moles.

The importance of FNEs for sensing prey is also evident in the infrared pit organs of snakes. In the rattlesnake, *Crotalus horridus*, the morphology of the pit organ promotes efficient thermoreception by a large number (several thousand) of intradermal myelinated axons 3–16 μm in diameter.

The Merkel Cell System

Friedrich Sigmund Merkel (1845–1919) was an outstanding German anatomist of the late nineteenth century. He described cells in the skin of amphibians, birds, and mammals and referred to them as *Tastzellen,* or 'touch cells.' The cells were given the eponym Merkel cells in 1878 by Robert Bonnet (1851–1921). Distinctive traits include dense core vesicles, cytoplasmic projections, and synaptiform contacts with enlarged nerve terminals. They measure 10–15 μm across and exist in the dermis of birds and the basal layer of the epidermis of mammals. In mammals, Merkel cells are a ubiquitous component of both hirsute and glabrous skin. The myelinated afferent fiber branches extensively in the dermis within 500 μm of the epidermis. The branches lose their myelin sheaths before they penetrate the basement membrane of the epidermis to form the flattened nerve plate (Merkel disk) lying along the lower border of the Merkel cell. The disk itself is *c.* 7 μm in diameter and 1 μm thick and contains numerous mitochondria, which occupy 50% of the terminal. Merkel disks exist only in adult mammals.

Although direct evidence is lacking, correlative electrophysiological and morphological evidence suggests that Merkel cells function as SA type I mechanoreceptors. Calcium ions enter the cell in response to maintained mechanical stimuli and trigger the release of a neurotransmitter, probably glutamate. The conserved morphology and widespread distribution of Merkel cells across such divergent animals as lizards, salamanders, and lampreys suggests an early appearance during vertebrate evolution. The adaptive significance appears to be associated with generalized somatosensory reception, particularly of prey objects. They are most sensitive to perpendicular deformation of the skin surface or to the bending of sinus hairs or vibrissae. Furthermore, the density of Merkel cells is manifested most strikingly in structures associated with foraging, such as the electroreceptive snouts of the platypus and echidna and the mystacial skin of most mammals, except humans.

An association with foraging is also evident in the beak skin of birds, where Merkel-like cells occur in dense corpuscles containing up to 50 cells. The corpuscles, termed Grandry corpuscles, are present in the glabrous skin of the bill and tongue of wading birds but absent in the domestic chicken and Japanese quail. A structural resemblance of Grandry corpuscles to Merkel cells points to analogous functions, but they are not morphologically identical, and some evidence suggests that Grandry corpuscles function as RA receptors. The functional and ecological significance of such differences awaits elucidation.

The Meissner Corpuscle

Georg Meissner (1829–1905) was a German anatomist and physiologist of the nineteenth century. He and Rudolf Wagner (1805–1864) described distinctive corpuscles in 1852, which became the subject of a monograph by Meissner in 1853. This monograph is the basis for Meissner's name being associated with the receptor. Meissner corpuscles are located in the dermal papillae of glabrous skin, where they connect to and tightly abut the basal surface of the epidermis. They are innervated by one or two myelinated fibers from the subepidermal nerve plexus. The fibers lose their myelination before entering the corpuscle, an ovoid capsule of perineural cells. Therein the nerve endings branch repeatedly, adopting a ribbonlike shape with bulbous expansions. Collagen fibers and fibrocytes bond the spiraling nerve endings to stacks of lamellar Schwann cells and attach the capsule to the epidermis. The circumscribed expansion of unmyelinated nerve endings into lamellar disks is a distinctive feature of Meissner corpuscles.

Such complex innervation has led to speculation that Meissner corpuscles have a nociceptive function, although aspects of the disciform expansion suggest a primary role in mechanoreception. Takahashi-Iwanaga and Shimoda reported that the disk margins are serrated with fine projections of lamellar Schwann cells that tightly hold the collagen trabeculae to the inner aspect of the pericorpuscular capsule. They concluded that the disks are susceptible to mechanical deformations of surrounding tissues and, furthermore, that the distortion of axonal endings during the dynamic phase of tissue deformation will generate RA receptor potentials. Castano et al. observed that "the minutest deformation of the skin [can be] immediately transmitted to the capsule and, via the cross-beam system linking it to the framework, to the transducer elements of the corpuscle" (1985: 296). The disciform expansion is thus well suited to mechanotransduction. On this basis, Meissner corpuscles are hypothesized to play a key role in the perception of elastic texture. They are classified as RA receptors that respond to transient or phasic stimuli. They are particularly sensitive to vibrations at frequencies ranging from 10 to 400 Hz with maximum sensitivity between 100 and 200 Hz.

Meissner corpuscles are reported from the glabrous skin of the lips and extremities (hands, feet, and prehensile tails) of primates and one marsupial, the Virginia opossum, *Didelphis virginiana*. Murine and sciurid corpuscles are similar in shape, but smaller and less elaborate. The high concentration of Meissner corpuscles at the tips of primate digits as well as the glabrous patch of skin present on the prehensile tail of atelid monkeys suggest that they function to sense the elastic properties of support structures, which has adaptive value in an arboreal milieu. An additional hypothesis is that the concentration of Meissner corpuscles at the digits supports the perception of food texture, particularly ripening fruits, which are often palpated by foraging primates. Hoffman et al. reported that the density of Meissner corpuscles in primate digits varied positively as a function of the overall proportion of fruit in the diet. In general, the function of Meissner corpuscles appears to be related to sensing the texture of critical objects in the environment – the paucity of Meissner corpuscles in other mammalian orders is curious.

Pacinian Corpuscle

Filippo Pacini (1812–83) was an Italian anatomist posthumously famous for isolating the cholera bacillus *Vibrio cholerae* in 1854. Pacinian corpuscles, however, were first described by Abraham Vater (1684–1751) in 1741 and were rediscovered by Pacini almost 100 years later in 1840. Pacinian corpuscles are the largest and best-known corpuscles in mammals. They are oval, spherical, or irregularly coiled and are exceptionally large, up to 2 mm in length and 100–500 μm wide. Each has a capsule formed by *c*. 30 concentrically arranged lamellae of flat cells about 0.2 μm thick. Pacinian corpuscles are located in the palmar and plantar aponeurosis or genitalia deep to the skin. They are also present in ligaments and joint capsules of mammals and ostriches and the mesentery of the cat intestine where they are visible to the unaided eye. The afferent nerve fibers are myelinated with diameters between 3 and 6 μm. Extensive studies show these endings to behave as RA mechanoreceptors responding to sudden disturbances and vibrations (40–1000 Hz), with an optimal response at the higher end of the range.

The widespread distribution of Pacinian and paciniform corpuscles throughout the body makes it difficult to assign an adaptive significance to their presence in glabrous skin. Yet attendant associations between paciniform corpuscles and specialized structures such as Eimer's organs and the push rods of monotremes suggest that paciniform corpuscles are sometimes recruited for specialized roles. The push rod is a structure unique to the glabrous snout of the echidna, *Tachyglossus aculeatus*, and the upper and lower shields of the platypus, *Ornithorhynchus anatinus*. It is composed of a column of flattened spinous cells, which are cross-linked by tight junctions. The tip of the rod emerges at the skin surface with a domelike projection. The base of the push rod resembles an Eimer's organ in that it is associated with Merkel cell complexes and lamellated paciniform corpuscles. The rod is typically 300 μm long with a diameter of 50 μm. Along part of its length the rod remains separated from adjacent regions by connective tissue papillae, which gives it a degree of independent mobility. The push rod is hypothesized to play a role in signaling contact with prey, particularly in moist or aquatic environments where electroreception is advantageous.

A functionally similar structure, termed a domed pressure receptor (DPR), has been reported on the rostrum of the American alligator, *Alligator mississippiensis*. The DPR is hypothesized to play a role in detecting the disturbance of water by prey. The types of receptors present at the base of the DPR await elucidation, but it is likely that paciniform corpuscles are present. The avian homolog of the Pacinian corpuscle is the Herbst corpuscle, which is present in the skin of the bill of wading and aquatic birds and in other species, and also in other bodily locations, including the legs and trunk. Herbst corpuscles are

particularly dense in the bill tip organ of the goose and duck, and general agreement exists that they function as RA receptors with frequency-following characteristics similar to Pacinian corpuscles.

Ruffini Corpuscle

Angelo Ruffini (1864–1929) reported cigarlike structures in 1893. Ruffini corpuscles consist of a long fusiform, encapsulated structure innervated by a myelinated large-caliber (6–12 μm) axon terminating as numerous branches intertwined among collagen bundles. Ruffini corpuscles have been reported in glabrous and hirsute skin, as well as in the tendinous insertions and joint capsules of mammals. Because of their regular discharge property in cats, they are classified as SA type II mechanoreceptors in contrast to the irregular discharge properties of SA type I fibers. Ruffini corpuscles are sensitive to skin stretch, particularly tangential forces generated in the skin during tasks like grasping.

Evolution of Cutaneous Receptors

In general, the morphological principles and mechanisms of cutaneous receptors are conserved across vertebrate orders. Each type of receptor responds to specific stimuli and contributes to the global perception of texture in the central nervous system. Specialized nerve endings of the glabrous skin tend to vary in density according to the particular locomotor or foraging behavior of an animal species. For instance, Meissner corpuscles are more complex and densely packed in the digits of primates than in other mammals, which lack the same degree of forelimb opposability. Species with very specialized receptor structures, such as the star-nosed mole and platypus, tend to also have a highly developed somatosensory cortex. The evolution of specialized receptors in the glabrous skin thus appears to result primarily from selection for the reorganization and concentration of preexisting cells. Improved somatosensory acuity favored, in turn, a greater degree of cortical investment devoted to the interpretation of those sensory inputs.

Introduction

The concept of the limbic system is derived from that of the limbic lobe, which is formed primarily by the parahippocampal and cingulate gyri, as well as two underlying groups, the hippocampal formation and amygdalar complex. The various components of the limbic lobe receive and integrate visceral, olfactory, and somatic information. The limbic lobe is involved in processing recent memory (hippocampal formation) and in the expression of emotion (amygdalar complex). The term 'limbic system' expands this concept to include other structures that are functionally and anatomically related to the limbic lobe, and thus includes the hypothalamus, septal nuclei, various thalamic nuclei, and olfactory systems. Today, the hippocampal formation and the amygdalar complex are usually regarded as the primary elements of the limbic system, and their evolution is the focus of this article.

The hippocampus forms along the dorsomedial edge of the telencephalon. In mammals it expands to form an arc in the caudal telencephalon, with the most prominent part in the temporal lobe. The hippocampus plays critical roles in processing learning and memory information. The amygdalar complex is composed of multiple groups that have different origins, and unique functional, connectional, and neurochemical expression characteristics. These groups play critical roles in feeding, reproduction, and flight/defense reactions, and also contribute to higher level cognitive functions, including emotional memory processing and sensory–sensory associations.

Homologs of the hippocampus and parts of amygdalar complex are usually defined by mammalian characteristics. Comparable areas have been identified in most vertebrates classes, although they show considerable variability. The following discussions provide a review of the evidence for these limbic groups in mammals, reptiles, birds, amphibians, and jawed fish, and how they may have evolved.

Mammals

Early in neurogenesis the mammalian pallium (roof) of the telencephalon is specified into four regions, the medial, dorsal, lateral, and ventral pallia. These are generally identified in the adult as hippocampus (dentate gyrus and Ammon's horn), the 'general cortex' (nonolfactory and nonhippocampal), the olfactory cortex (piriform and entorhinal), and the pallial amygdalar complex, respectively. These four regions are believed to be present in all jawed vertebrate embryos, although divergent evolution may make them difficult to recognize (**Figures 1** and **2(a)**).

Sensory Projections to the Telencephalon

Olfaction is detected in the main olfactory organ and the vomeronasal organ, although many aquatic mammals and humans lack a vomeronasal organ. The main olfactory organ detects light, airborne molecules and projects to the main olfactory bulb, which in turn projects as a superficial sheet over portions of the telencephalon. Its targets include the olfactory cortex (piriform and entorhinal), a small rostral part of the medial cortex, and several cortical amygdalar nuclei, including the anterior cortical, posterior lateral cortical, and the anteroventral part of the medial amygdala (**Figure 3(a)**). The vomeronasal organ detects heavy odor molecules and projects to the accessory olfactory bulb, which in turn projects to most of the medial amygdala and the posterior medial cortical amygdala.

Thalamic nuclei relay auditory, visual, and somatosensory information to the striatum and lateral amygdalar nucleus, as well as to the sensory cortical areas (**Figure 4**). The auditory cortical areas receive projections from the majority of the medial geniculate nucleus. The striatum and lateral amygdala receive projections from the medial subdivision of the medial geniculate, a group that is sometimes placed within the perigeniculate area because of its amygdalar projection.

Visual information from the retina reaches the telencephalon through at least three distinct pathways: from retina to thalamus (lateral geniculate), to primary visual cortex; from retina to superior colliculus, to thalamus (lateral posterior or pulvinar nuclei), to secondary visual cortical areas; and from retina to superior colliculus, to thalamus (supragenicular nucleus of the perigeniculate area), to the striatum and lateral amygdala.

Somatosensory information reaches the thalamus from the spinal cord, dorsal column nuclei, and trigeminal sensory nuclei, and a somatosensory midbrain area. There appear to be two main groups of thalamic nuclei that relay this information to the telencephalon: the ventrobasal and posterior thalamic nuclei project to the somatosensory cortex, whereas the posterior intralaminar thalamic nucleus of the perigeniculate group projects to the striatum and lateral amygdala.

Figure 1 Relationships between the major groups of jawed vertebrates. The hypothetical pallial organization of the telencephalon of an ancestral jawed vertebrate and the variations that have evolved in six representatives are shown using the following representations: purple, medial pallium; blue, dorsal pallium; green, lateral pallium; pink, ventral pallium. The telencephala of the jawed vertebrates are derived from regions that originate from comparable parts of the embryonic ventricle. See **Figure 2** for more detailed representations of the telencephala.

In summary, auditory, visual, and somatosensory information is relayed through separate parts of the thalamus and reaches the sensory cortex and lateral amygdala through separate, parallel pathways.

Hippocampus and Cortex

The hippocampus, composed of the dentate gyrus and Ammon's horn, forms along the medial edge of the pallium. It undergoes considerable enlargement, bending caudally around the anterior commissure. The hippocampus is characterized by several massive connections. In particular, Ammon's horn receives multisensory information from the entorhinal area, projects to the subiculum, and has extensive commissural connections.

Having undergone an explosive elaboration from its ancestral tetrapod condition, the mammalian 'general cortex' is highly derived and forms numerous specific cortical subdivisions. Characteristics common to most cortical areas are: (1) descending projections to the diencephalon and midbrain, (2) commissural connections, (3) ascending projections from the thalamus, and (4) several neurochemically similar cell types.

The olfactory cortex is derived from the lateral pallium, and is distinguished by its topology, developmental origins, and connections. It is the primary target of the main olfactory bulb and reciprocates this connection. The underlying claustrum–endopiriform complex also originates mainly from the lateral pallium.

The ventral pallium consists of an amygdalar cortex, which receives olfactory and vomeronasal information, and a deep group of nuclei, the basolateral amygdalar complex, which includes the lateral, basolateral, and basomedial amygdala. Another amygdalar group, the central amygdala, originates from the subpallium. Differentiating the nuclei within the amygdalar complex requires identifying the targets of the olfactory system and the sensory projections to the telencephalon, and so these are described first.

Amygdalar Complex and Claustrum–Endopiriform Area

Five major amygdalar groups can be recognized in mammals on the basis of their connections and topological relationships (**Figure 5(a)**): (1) nuclei with long descending projections to the hypothalamus and hindbrain, (2) nuclei that receive accessory olfactory connections, (3) nuclei that receive olfactory connections and project to the hypothalamus, (4) deep amygdalar nuclei that receive ascending sensory input from the dorsal thalamus but lack hypothalamic projections, and (5) deep amygdalar nuclei that receive sensory information from the dorsal thalamus and project to the hypothalamus. In addition, the claustrum-endopiriform lies between the olfactory cortex and basolateral amygdala, and is described here because of its close association with the amygdalar complex.

Figure 2 The telencephala of the jawed vertebrates are composed of similar regions that appear to originate from comparable parts of the embryonic ventricle (center). Observed differences among vertebrate classes are generally attributed to the flexion (eversion or inversion) of the telencephalon, or to altered rates of proliferation. (a) Mouse: Cl/Endo, claustrum–endopiriform area; GenCtx, general cortex; Hip, hippocampus; Pir, piriform cortex. (b) Gecko: DC, dorsal cortex; DVR, dorsal ventricular ridge; LC, lateral cortex; MC, medial cortex. (c) Pigeon: CP, cortex piriformis; H, hyperpallium; Hp, hippocampus; M, mesopallium; N, nidopallium. (d) Frog: DP, dorsal pallium; LP, lateral pallium; LPv, ventral part of lateral pallium; MP, medial pallium. (e) Polypterus: P1d, dorsal subdivision of pallial area 1; P1v, ventral subdivisions of pallial area 1; P2, pallial area 2; P3, pallial area 3; Vn, other nucleus of ventral pallial area. (f) Goldfish: Dd, dorsodorsal area; dDl, dorsal subdivision of dorsolateral area; Dm, dorsomedial area; Dp, dorsoposterior area; vDl, ventral subdivision of dorsolateral area.

The central amygdala is characterized by long descending projections to autonomic areas of the lateral hypothalamus and hindbrain. It plays a critical role in eliciting appropriate responses to stressful environmental conditions and in regulating behaviors associated with fear. The posterior medial cortical amygdalar nucleus and most of the medial amygdala receive input from the accessory olfactory bulb. Their main output is to the ventromedial and lateral hypothalamic areas. Functionally, the medial amygdala appears to be essential for relaying olfactory information to regions of the hypothalamus that control mating behavior. In addition to its inputs to the olfactory (piriform) cortex and the entorhinal cortex, the main olfactory bulb also projects to the cortical amygdalar nuclei that cover the surface of most of the amygdalar complex. These nuclei are the anterior cortical amygdala, posterior lateral cortical amygdala, and anteroventral division of the medial amygdala. They are all connected with the hypothalamus and basolateral complex.

Auditory, visual, and somatosensory nuclei in the caudal thalamus project to the lateral amygdala, which is a subdivision of the basolateral complex. The lateral amygdala differs from sensory cortical areas because it lacks projections to the thalamus, brain stem, and opposite hemisphere. In addition, it originates from the ventral pallium, whereas sensory cortex originates from the dorsal pallium. The lateral amygdala projects mainly to the basolateral amygdala, which

Modified from Bruce LL and Neary TJ (1995) The limbic system of tetrapods: A comparative analysis of cortical and amygdalar populations. *Brain, Behavior and Evolution* 46: 224–234, with permission from S Kargel AG, Basel, with modifications from Bruce LL (2006) Evolution of the reptilian brain. In: Kaas JH (ed.) *Evolution of Nervous Systems, Vol 2: Non-Mammalian Vertebrates*, pp. 125–156. Oxford: Academic Press.

is another subdivision of the basolateral complex. The basolateral amygdala, basomedial amygdala, and the ventrolateral subdivision of the lateral amygdala all receive sensory input from the lateral amygdala and project to various parts of the hypothalamus. Some neurons within the basomedial nucleus respond to faces, and especially to faces that elicit emotional responses. The sensory input to this group appears to be critical for comprehending the emotional context of social interactions. The hypothalamic connections may contribute to responding to sensory stimuli within appropriate behavioral contexts, such as territorial signaling or courtship rituals. In addition, the claustrum and endopiriform areas develop from the lateral pallium, and can be identified by their unique gene and neurochemical expression patterns. They are extensively connected with cortical areas and the lateral amygdala.

Figure 4 Comparison of the sensory pathways through the thalamus to the cortical and amygdalar targets in mammals. Note that auditory (top), visual (middle), and somatosensory (bottom) pathways reach the cortex and amygdala through separate, parallel thalamic pathways.

Reptiles

The medial, dorsal, and lateral cortices of reptiles are generally compared to the hippocampal, general (nonolfactory and nonhippocampal), and olfactory cortices of mammals, respectively (Figure 2(b)), and are derived from the medial, dorsal, and lateral pallia. The dorsal ventricular ridge is derived from the ventral pallium and appears to be homologous to part of the mammalian basolateral amygdalar complex.

Sensory Pathways to the Telencephalon

The main olfactory organ is present in all reptiles; however, the vomeronasal (accessory olfactory) system occurs in rhynchocephalians (tuatara), lizards, snakes, and turtles, but is absent in crocodilians and birds (Figure 3(b)). The main olfactory bulb projects to superficial parts of the telencephalon, including the lateral cortex, a rostral part of the medial cortex, nucleus of the diagonal band, and several cortical amygdalar nuclei. The axons decussate in the habenular commissure and innervate similar contralateral targets. The accessory olfactory bulb projections include the medial amygdala, nucleus sphericus, and the ventral posterior amygdala. The olfactory targets are very similar in reptiles and mammals, except that mammals lack contralateral main olfactory projections.

In reptiles, as in mammals, auditory, visual, and somatosensory information reaches the telencephalon through two distinct pathways. One thalamic group projects to a cortical target, and another projects to the striatum and dorsal ventricular ridge (Figure 6). The auditory midbrain is located in the medial torus semicircularis and is comparable to the mammalian inferior colliculus. It relays auditory information to two thalamic nuclei: dorsolateralis anterior and medialis (named reuniens, in turtles and crocodiles). Dorsolateralis anterior projects to the dorsal cortex, and medialis projects to the striatum and the medial part of the dorsal ventricular ridge.

Visual information reaches the telencephalon through three distinct pathways. One is a retino–thalamic–telencephalic path, and the other two are retino–tecto–thalamic–telencephalic paths. The retina projects directly to a thalamic nucleus, called intercalatus or the lateral part of dorsolateralis anterior in lizards, and called the lateral geniculate in turtles. This nucleus then projects to the lateral part of dorsal cortex. The retina also projects to the optic tectum, which in turn projects to two thalamic nuclei, dorsolateralis anterior and rotundus. Dorsolateralis anterior projects to the dorsal cortex, and rotundus projects to the striatum and dorsal ventricular ridge. Somatosensory information reaches the thalamus from the spinal cord, dorsal column nuclei, and a somatosensory midbrain area called torus semicircularis. Two somatosensory thalamic nuclei, dorsolateralis anterior and the medialis posterior complex, relay this information to the dorsal cortex, and to the striatum and dorsal ventricular ridge, respectively.

In summary, in both mammals and reptiles there are at two distinct thalamic regions that relay auditory, visual, and somatosensory information to the telencephalon. The part of the reptilian dorsal cortex that receives sensory thalamic input is clearly homologous to parts of the mammalian sensory cortex. Whether the sensory recipient part of the dorsal ventricular ridge is homologous to the mammalian sensory temporal cortex or the lateral amygdala remains a controversial issue.

Hippocampus and Cortex

The reptilian medial, dorsal, and lateral cortices are homologous to the mammalian hippocampus,

Figure 5 Continued

general cortex, and olfactory cortices, respectively (Figure 2(b)). The medial cortex can be further subdivided into two parts that closely resemble the mammalian dentate gyrus and Ammon's horn. Most cell types identified in the mammalian neocortex have been identified in the reptilian dorsal cortex, although the lamination pattern differs. A fourth pallial region, the dorsal ventricular ridge (DVR), was traditionally compared to sensory regions of the mammalian neocortex, because both receive massive sensory thalamic projections. However, a more recent hypothesis, that the DVR is homologous to the mammalian basolateral amygdalar complex, is more consistent with experimental evidence.

Amygdalar Nuclei and Pallial Thickening

Homologs of the five major amygdalar groups and the claustrum-endopiriform area present in mammals have been identified in reptiles, using similar topological, connectional, and developmental criteria and neurochemical expression patterns (Figure 5(b)): (1) the striatoamygdalar area, (2) nuclei that receive accessory olfactory bulb projections, (3) nuclei that receive olfactory connections and project to the hypothalamus, (4) pallial nuclei that receive ascending sensory input from the dorsal thalamus but lack hypothalamic projections, and (5) pallial nuclei that receive sensory information and project to the hypothalamus.

The striatoamygdalar area of reptiles is a subpallial group, located at the caudal pole of the striatum. It appears to be homologous to the mammalian central amygdalar nucleus.

The accessory olfactory bulb projects to the medial amygdalar nucleus, the ventral posterior amygdalar nucleus, and nucleus sphericus. The medial amygdalar nucleus and ventral posterior amygdala project to the ventromedial and lateral hypothalamic areas, although few neurons within nucleus sphericus project to the hypothalamus. Thus, these amygdalar groups appear to be homologous as a group to the mammalian posterior medial cortical amygdala and most of the medial amygdala.

The ventral anterior amygdala receives an olfactory bulb projection and projects to the ventromedial hypothalamus. It thus appears to be homologous to the mammalian anteroventral division of the medial amygdala and posterior lateral cortical amygdala.

Auditory, visual, and somatosensory nuclei in the caudal thalamus project to the anterior dorsal ventricular ridge. The sensory-recipient dorsal ventricular ridge is compared traditionally to parts of the mammalian neocortex, and more recently to the mammalian lateral amygdala. The anterior DVR and mammalian lateral amygdala differ from the neocortex in several significant ways. Both the DVR and lateral amygdala lack descending projections to the thalamus, brain stem, and opposite hemisphere, and are derived from the ventral pallium; the neocortex has these connections and is derived from the dorsal pallium. Thus, the best comparison for the anterior dorsal ventricular ridge is to the mammalian lateral amygdala.

On the basis of their connections and relative topology, the reptilian caudodorsal DVR, centromedial DVR, and lateral amygdalar nucleus appear to be homologous to the mammalian basolateral amygdala, ventrolateral part of the lateral amygdala, and basomedial amygdala, respectively. The sensory-recipient anterior DVR projects to the caudodorsal DVR, the centromedial DVR, and the lateral amygdalar nucleus. The caudodorsal DVR projects to the lateral hypothalamus and the other two groups project

to the ventromedial hypothalamus. Stimulation of these DVR regions may elicit various motor responses, including head movements and escape responses.

The pallial thickening is situated at the rostrolateral pole of the DVR and appears to be homologous to the mammalian claustrum and endopiriform areas. The pallial thickening and claustro-endopiriform area are derived from the lateral pallium and have similar connections as well as neurochemical expression patterns.

Birds

The avian pallium includes the hippocampus, hyperpallium, cortex piriformis, and nidopallium (Figure 2(c)). These originate from the medial, dorsal, lateral, and ventral pallia, respectively.

Sensory Pathways to the Telencephalon

Birds have a main olfactory system that is remarkably similar to those in reptiles and mammals, although they lack a vomeronasal system (Figure 3(c)). Projections from the olfactory bulb include the olfactory tubercle, cortex piriformis, nucleus of the diagonal band, and nucleus taenia. Axons cross in the habenular commissure, as in reptiles but not mammals.

Auditory, visual, and somatosensory information is relayed through two separate thalamo-pallial pathways to the hyperpallium and the nidopallium (Figure 7). The auditory midbrain of birds, the torus semicircularis, projects mainly to nucleus ovoidalis in the thalamus, which in turn projects to the striatum and to field L in the nidopallium. Although an auditory thalamic nucleus that projects to the hyperpallium has not been described, acoustic responses

Figure 6 Comparison of the sensory pathways through the thalamus to the cortical and amygdalar targets in reptiles. Note that auditory (top), visual (middle), and somatosensory (bottom) pathways reach the cortex and amygdala through separate, parallel thalamic pathways.

Figure 7 Comparison of the sensory pathways through the thalamus to the cortical and amygdalar targets in birds. Note that auditory (top), visual (middle), and somatosensory (bottom) pathways reach the cortex and amygdala through separate, parallel thalamic pathways. DLAmc, dorsolateralis anterior thalami, pars magnocellularis; DLL, dorsolateralis anterior thalami, pars lateralis; SPC, superficialis parvocellularis; LdOPT, lateralis dorsalis nuclei optici principalis thalami; DIVA, dorsointermedius ventralis anterior.

have been described in the medial cortex, probably corresponding to a part of the hyperpallium. Thus, there appear to be two distinct routes through which auditory information reaches the pallium.

The visual thalamic nuclei of birds may be grouped based on whether they receive only retinal projections (DLAmc, dorsolateralis anterior thalami, pars magnocellularis), projections from both the retina and optic tectum (DLL, dorsolateralis anterior thalami, pars lateralis; SPC, superficialis parvocellularis; LdOPT, lateralis dorsalis nuclei optici principalis thalami), or projections only from the optic tectum (rotundus and triangularis). Of these groups, the first two project predominantly to the hyperpallium (or visual Wulst) and the last projects to the entopallium within the nidopallium. A visual thalamic projection to the striatum has not been described in birds. Thus, there are two distinct routes through which visual information reaches the pallium.

The somatosensory region of the midbrain, nucleus intercollicularis, receives projections from the dorsal column nuclei, spinal cord, and trigeminal nuclei. Nucleus intercollicularis projects to three nuclei in the dorsal thalamus. Two of these, dorsointermedius ventralis anterior (DIVA) and dorsolateralis anterior pars lateralis (DLL), project to the hyperpallium, and the third, nucleus subrotundus, projects to the caudal nidopallium.

In conclusion, most sensory connections were conserved during the evolution from reptiles to birds, although the thalamic targets are elaborated to a greater extent in birds.

Hippocampus and Cortex

The avian hippocampus, hyperpallium, and cortex piriformis are homologous to the reptilian medial cortex, dorsal cortex, lateral cortex, respectively, and to the mammalian hippocampus, 'general cortex' and olfactory cortex, respectively (Figure 2(c)). The similarities between these domains have long been recognized. The homolog of the avian nidopallium is discussed below.

Amygdalar Nuclei and Mesopallium

Although several amygdalar regions can be recognized in birds, few studies have analyzed their projections to the hypothalamus, which are a major feature for identifying some amygdalar nuclei. Thus several regions are identified tentatively (Figure 5(c)), and a great deal more research is needed.

A homolog of the mammalian central amygdala is probably located in caudal parts of the avian striatum, although it has not been delineated at this time. Birds lack an accessory olfactory system, and thus the associated amygdalar nuclei appear to be absent. Nucleus taenia receives olfactory connections and projects to the hypothalamus. It thus appears to be comparable to the mammalian anteroventral division of the medial amygdala. Homologs of the posterior medial cortical amygdala may be present along the adjacent surface of the arcopallium, but have not been identified.

The sensory-recipient parts of the nidopallium appear to be homologous to the mammalian lateral amygdala and reptilian rostral DVR based on their similar topology, connections, and neurochemical expression patterns. Although in some laboratories it is maintained that a region with such a massive sensory input can only be homologous to sensory areas of the mammalian neocortex, many other characteristics differ. Thus this homology remains controversial.

An avian homolog of the deep amygdalar nuclei that project to the hypothalamus has not yet been identified. However, the caudolateral nidopallium and/or parts of the arcopallium seem to be likely possibilities. Topological, connectional, neurochemical expression characteristics strongly suggest that the avian mesopallium is homologous to the reptilian pallial thickening and the mammalian claustrum and endopiriform areas.

Amphibians

The amphibian pallium consists of the medial, dorsal, and lateral pallia (Figure 2(d)). Based on the topological similarities, these were traditionally compared to the mammalian hippocampus, neocortex, and olfactory cortex, respectively, but recent studies have challenged this convention, comparing the dorsal and lateral pallia to the mammalian olfactory cortex, and the medial pallium to both the hippocampus and neocortex.

Sensory Pathways to the Telencephalon

All amphibians have both a main olfactory system and most have a vomeronasal (accessory olfactory) system, although it is absent in some aquatic salamanders (Figure 3(d)). Their targets are similar to those in reptiles, mammals, and birds. The main olfactory bulb projections include the lateral and dorsal pallia, the ventral part of the lateral pallium, a rostral part of the medial amygdala, and the nucleus of the diagonal band. Axons project to the contralateral side through the habenular commissure, as in reptiles. The accessory olfactory bulb projects mainly to the medial amygdalar nucleus (formerly called the lateral amygdala). Axons project contralaterally through the anterior commissure and the habenular commissure, unlike in other tetrapods.

Figure 8 Comparison of the sensory pathways through the thalamus to the cortical and amygdalar targets in amphibians. Note that auditory (top), visual (middle), and somatosensory (bottom) pathways reach the cortex and amygdala through separate, parallel thalamic pathways.

Auditory information reaches the torus semicircularis in the midbrain, which projects strongly to the central thalamic nucleus and more weakly to the lateral and anterior thalamic nuclei. The auditory part of the anterior thalamic nucleus projects primarily to the medial pallium. Auditory information in the central and lateral thalamic nuclei is conveyed primarily to the striatum and sparsely to the ventral part of the lateral pallium.

Visual information reaches both the anterior and lateral thalamic nuclei. The anterior thalamic nucleus receives a projection from the optic tectum and directly from retina. In turn it projects to the medial pallium. The optic tectum also projects to the lateral thalamic nucleus, which projects to the striatum and the ventral part of the lateral pallium. Both the anterior and central thalamic nuclei receive input from the spinal cord and somatosensory part of the torus semicircularis. The anterior thalamic nucleus conveys this information mainly to the medial pallium, whereas the central thalamic nucleus conveys it mainly to the striatum and sparsely to the ventral part of the lateral pallium.

In summary, auditory, visual, and somatosensory information reaches the medial pallium and the ventral part of the lateral pallium through two distinct routes (Figure 8). Thus two thalamic–pallial pathways are present in amphibians, as in other tetrapods. These pathways appear to be phylogenetically ancient features, although the pallial targets are much more elaborated in reptiles, birds, and mammals.

Hippocampus and Cortex

Recent connectional and developmental analyses suggest that the ventral part of the lateral pallium is homologous to the reptilian dorsal ventricular ridge and the mammalian basolateral amygdalar complex (Figures 2(d) and 9). Furthermore, both the dorsal part of the lateral pallium and the dorsal pallium are homologous to the mammalian olfactory cortex and to the reptilian lateral cortices. Finally, the amphibian medial pallium is comparable both to the mammalian hippocampus and neocortex and to the reptilian medial and dorsal cortices. Further studies are needed to determine if the ancestral tetrapod had hippocampal and neocortical-like areas that were overlapping (as in amphibians) or segregated (as in reptiles, birds, and mammals). Some clues will undoubtedly come from studies of fishes.

Amygdalar Nuclei

Amygdalar areas comparable to those in other tetrapods have been identified in amphibia (Figure 5(d)). The caudal striatum contains neurons with descending projections to the hypothalamus and hindbrain, and thus appears to be homologous to the mammalian central amygdala. The amphibian medial amygdala, traditionally known as the pars lateralis of the amygdala, receives accessory olfactory projections and projects to the hypothalamus, and thus appears to be homologous to most of the mammalian medial amygdala. Both the dorsal and lateral pallia receive olfactory projections, but only the caudal, ventral part of the lateral pallium (LPv) projects to the hypothalamus. The caudal LPv thus appears, in part, to be comparable to the olfactory cortical amygdalar areas. The rostral LPv appears to be homologous to the mammalian lateral amygdala, which receives sensory thalamic input. In addition, both are derived from the ventral pallium. The caudal LPv receives sensory information from other telencephalic areas, in addition to a direct olfactory input, and it

Figure 9 Pallial connections in (a) frog and (b) lizard. Schematic of a section through the right telencephalon shows the location of neurons that project to the thalamus (+), hypothalamus (red dots), and contralateral pallium (c). Terminal areas of olfactory projections (green) and thalamic nuclei (yellow) are also shown. Note that the characteristics of the lizard dorsal cortex are most similar to those of the frog medial pallium. (a) Frog: DP, dorsal pallium; LP, lateral pallium; LPv, ventral part of the lateral pallium; MP, medial pallium. (b) Lizard: DC, dorsal cortex; DVR, dorsal ventricular ridge; LC, lateral cortex; MCl, large-celled part of medial cortex; MCs, small-celled part of medial cortex; PT, pallial thickening. is heavily interconnected with the hypothalamus. Thus, it appears to be homologous to the mammalian basolateral, basomedial, and ventrolateral part of the lateral amygdalar nuclei.

Homologs of the mammalian claustrum and endopiriform areas have not been identified in amphibians. Embryological studies suggest the claustrum and endopiriform originate from the lateral pallium. Thus it seems likely that, if present, these homologs are associated with the amphibian lateral pallium.

Fish

Among fishes, most of the data relevant to limbic system evolution come from one large group of ray-finned bony fishes, the teleosts. In the area dorsalis (presumed pallium) of adult teleosts four major areas are generally recognized and named on the basis of their topographical positions: dorsomedial (Dm), dorsodorsal (Dd), dorsolateral (Dl), and dorsoposterior (Dp). A fifth central zone (Dc) appears to contain subdivisions related to each of the other four zones. The teleost telencephalon develops by an outward bending, or eversion, of its dorsal portion, resulting in two thick, solid masses that flank a single ventricle (Figure 2(f)). The embryological details that relate this eversion to the organization of the adult teleost telencephalon are not well understood. A simple eversion would result in a mediolateral reversal of the four major pallial areas relative to their positions in the pallium of tetrapods. This would potentially place the pallial (basolateral) amygdala/ventral pallium in a dorsomedial position, followed by the lateral pallium, the dorsal pallium, and, finally, the medial pallium in a ventrolateral position. A major impediment to such a simple eversion model is that the main pallial target of the olfactory bulb in teleosts, Dp, appears to lie in this ventrolateral position where the medial pallium might be expected. Recently, several different lines of argument have suggested that Dp actually is located (or originates) between Dm and Dd, which would be topologically appropriate for the lateral pallium. If this is correct, the following working hypothesis can be suggested: Dm, Dp, Dd, and Dl are homologs of the pallial amygdala/ventral pallium, the lateral pallium, the dorsal pallium, and the medial pallium, respectively. However, more developmental and connectional data are needed to determine whether this hypothesis or an alternative – that the pallial areas of teleosts have evolved independently from those of the tetrapods – is correct. The area ventralis (presumed subpallium) is believed to contain homologs of the striatal and septal areas of tetrapods in dorsal and ventral positions, respectively, and homologs of subpallial amygdalar populations dorsally at more caudal levels.

Sensory Pathways to the Telencephalon

In all teleosts studied, the secondary olfactory projections terminate prominently in Dp, which is considered to be homologous to the lateral pallium of tetrapods (Figure 10(a)). Other prominent olfactory targets include nucleus taenia and the dorsal, supracommissural, and postcommissural portions of the area ventralis. Some or all of these latter centers have been interpreted as homologs of various portions of the amygdala of tetrapods. Among the other sensory modalities known to project to the teleost pallium, gustatory, auditory (and, to a lesser extent, lateral line), electrosensory (in some species), and visual (from tecto-recipient cells) inputs terminate in Dm. Visual (from tecto-recipient cells), auditory, and lateral line projections also terminate in Dl. These nonolfactory sensory inputs to the pallium arise largely not from what is clearly the dorsal thalamus but rather from an enigmatic group of diencephalic nuclei, the nuclei of the posterior tuberculum. It is uncertain whether these nuclei represent an hypertrophy of the posterior tuberculum in the teleosts or

Figure 10 Comparison of projections of main olfactory bulb (green) in a teleost (the goldfish, *Carassius*) and a cladistian (the bichir, *Polypterus*). (a) Goldfish: ac, anterior commissure; Dd, dorsodorsal area; dDl, dorsal subdivision of dorsolateral area; Dm, dorsomedial area; Dp, dorsoposterior area; nT, nucleus taenia; PO, preoptic area; Vd, dorsal nucleus of ventral area; vDl, ventral subdivision of dorsolateral area; Vp, posterior nucleus of ventral area; Vs, supracommissural nucleus of ventral area; Vv, ventral nucleus of ventral area. (b) Polypterus: P1d, dorsal subdivision of pallial area 1; P1v, ventral subdivision of pallial area 1; P2, pallial area 2; P3, pallial area 3; PO, preoptic area; Vd, dorsal nucleus of ventral area; Vn, other nucleus of ventral area; Vs, supracommissural nucleus of ventral area; Vp, posterior nucleus of ventral area; Vv, ventral nucleus of ventral area.

whether some of them are homologous to parts of the dorsal thalamus of tetrapods.

Hippocampus and Cortex

The best candidate for a hippocampal (or medial pallial) homolog in teleosts appears to be Dl (Figure 2(f)). In addition to the aforementioned sensory afferents, Dl is reciprocally connected to the ventral part of the area ventralis (a presumed septal homolog) and has efferent connections to the preoptic area and the caudal hypothalamus. Behavioral studies have shown that lesions in Dl, especially its ventral division, result in deficits in spatial cognition. A small region of the pallium, Dd, that lies medially adjacent to Dl is in a position to be interpreted as the dorsal pallium (and some would lump with it the adjacent dorsal portion of Dl, dDl), but few data are known concerning its connections.

Amygdalar Areas

Although the working hypothesis suggests that all or part of Dm may constitute a pallial amygdalar/ventral pallial homolog, an alternative view that Dm (or part of it) is a dorsal cortical (isocortical) homolog has also been espoused (Figure 5(f)). If we assume that the sensory inputs to Dm from the nuclei of the posterior tuberculum are actually dorsal thalamic, we are still left with the question: are these nuclei comparable to the dorsal thalamic nuclei of tetrapods that project to the pallial amygdala/ventral pallium or to those dorsal thalamic nuclei that project to the isocortex? The topological position of Dm and its efferent connections to the hypothalamus and posterior tuberculum appear to be more consistent with the former view. In addition, lesions and electrical stimulation of Dm produce changes in aggressive and reproductive behavior, and lesions in Dm result in deficits in emotional memory. Finally, at least portions of Dm lie between the Emx-1 expression zone dorsally (characteristic of a pallial region) and the Dlx expression zone ventrally (characteristic of a subpallial region), further suggesting its similarity to the ventral pallium in tetrapods. However, the precise pattern of gene expression in this region – including that of Tbr (characteristically seen in the ventral pallium of tetrapods) – remains to be determined.

Finally, a few comments on comparative aspects of limbic telencephalic organization in another group of ray-finned fishes, the polypteriforms, are needed. The polypteriforms are the earliest derived actinopterygian lineage and thus occupy a phylogenetic position that is a key for determining the nature of the similarities found in the limbic telencephalon of the teleosts and the tetrapods (Figures 2(e) and 5(e)). As in all ray-finned fishes, the telencephalon of the polypteriforms develops by an eversion of its dorsal portion. However, this eversion is a simple outward bending in which the pallium remains thin and most neuronal populations remain in an unmigrated position. Thus there is a simple medial to lateral reversal of the pallium relative to that in tetrapods (most readily comparable to amphibians). Four pallial areas have been recognized – from medial to lateral – P1v, P1d, P2, and P3. As in the teleosts, the area ventralis is

believed to contain homologs of the striatal and septal areas of tetrapods in dorsal and ventral positions, respectively, and homologs of subpallial amygdalar populations dorsally at more caudal levels.

A simple topological comparison might nominate cell groups dorsal to the striatum as potential ventral pallial homologs. A small group, Vn (traditionally considered subpallial), and/or P1v (the most proximal portion of the traditional pallium) are thus potential candidates. This simple comparison would leave P1d as the lateral pallium, P2 as the dorsal pallium, and P3 as the medial pallium. The available data only partially support this hypothesis. The major pallial olfactory target is P1 (both portions), with a minor projection to P2 and P3 (**Figure 10(b)**). The other known sensory projection to the pallium is a visual input to P2 and P3 from tecto-recipient cells of the posterior tuberculum. Interestingly, both P2 and P3 are reciprocally connected to the ventral portion of the subpallium – the presumed septal homolog. The determination of the pallial–subpallial boundary and the further characterization of the similarities and differences of the four P divisions of the pallium in the polypteriforms are important for understanding the limbic system in this group. Moreover, they will provide strong guidance for deciding whether the limbic-like structures in telencephalon of the teleosts represent homologs of those in tetrapods or independently derived characters.

Evolution of Vertebrate Brains

Introduction and Overview

The brains of living vertebrates are a reflection of the very diverse niches occupied by the different species that comprise each major taxon (Figure 1) – agnathans (jawless vertebrates) and three radiations of jawed vertebrates: (1) the cartilaginous fishes (chimaeras and sharks, skates, and rays), (2) the ray-finned fishes (bony fishes), and (3) the sarcopterygian (fleshy-finned fish) radiation, which includes tetrapods (amphibians, mammals, reptiles, and birds). Within each of these major taxa, brain structure varies substantially, with some brains smaller relative to body size and less elaborate in terms of cytoarchitecture and others larger and more elaborate. The former can be referred to as type I brains (Figure 2) and the latter as type II (Figure 3). This type I–type II distinction is a matter of degree, and where the line is drawn is necessarily somewhat arbitrary. However, within each radiation, there are clearly some species with highly complex and enlarged brains relative to other species. Thus, this distinction is of heuristic value in appreciating the range of variation of brain evolution that has occurred within each major radiation.

That brain enlargement and elaboration has occurred four times independently presents a very different reality of how brain evolution has operated than is perceived in the widely held folk-belief of a sort of scale of nature, or Scala Naturae, that ranks all vertebrates along a simplistic scale. Instead, the picture now appreciated is a much more sophisticated and fascinating one in terms of both evolutionary history and the mechanisms by which it has proceeded. It is also important to note that the strategy of retaining a relatively simple brain in terms of cytoarchitecture, and one that is of modest size in relation to the body, is a successful one for many species, just as brain enlargement and elaboration is for other species. The variation in complexity and relative brain size that exists across all living vertebrate groups and individual species is a direct function of the available niches and the adaptations of various species that successfully occupy them.

The three major radiations of jawed vertebrates, or gnathostomes, each comprise diverse species that occupy equally diverse niches. The jawless vertebrates number fewer species and less diversity of niche but nonetheless exhibit marked diversity of brain size and degree of elaboration. Of the jawless vertebrates, or agnathans, lampreys have a relatively simple, or type I, brain (Figure 2) in terms of its number of neurons and their degree of migration away from the ventricular surface where they are generated during embryological development. In contrast, hagfishes have an enlarged and elaborated type II brain (Figure 3), characterized by considerably more neurons that are produced in and also migrate away from the ventricular surface and that form large aggregations of nuclei and/or laminated structures. Within cartilaginous fishes, chimaeras (ratfishes), and squalomorph and squantinomorph sharks have type I brains (Figure 2), while galeomorph sharks and skates and rays have type II brains (Figure 3). Within ray-finned fishes, reedfishes (Cladistia), sturgeons and paddlefishes (Chondrostei), gars (Ginglimodi), and the bowfin (Halecomorphi) have type I brains (Figure 2), while teleosts (Teleostei) have type II brains (Figure 3). Among the latter, species that exhibit complex social and territorial behaviors, such as many of the reef fish, have exceptionally complex and enlarged brains relative to other species. Within the sarcopterygian radiation that gave rise to land vertebrates, lungfishes (Dipnoi), the crossopterygian fish *Latimeria* (Actinistia), and amphibians have type I brains (Figure 2), while reptiles, birds, and mammals have type II brains (Figure 3).

The ratio of brain size to body size also varies considerably across different vertebrate groups. As shown in Figure 4, thanks to the copious data collected and analyzed by Harry Jerison, agnathans – both lampreys and hagfishes – have relatively low brain: body ratios, as do amphibians. Ray-finned fishes exhibit a wide range, with a few species overlapping the lower range of mammals. Reptiles fall within a modest range, with both mammals and birds having the largest brain:body ratios, but a number of cartilaginous fishes overlap the bird–mammal range. These data also demonstrate the wide range of variation within multiple groups of vertebrates that is the result of independent evolutionary processes.

Most of the diversity in brain complexity occurs in the dorsal part of the brain, which is derived from the alar plate during embryological development, rather than in the derivatives of the more ventrally lying basal plate. The latter gives rise to the motor nuclei for cranial nerves and reticular formation components and, while some variation occurs among these structures, they are relatively conservative in their organization and degree of development across vertebrates. The alar plate gives rise to the dorsal part of the neural tube, including the sensory nuclei of

Figure 1 Cladogram showing the relationships of the four major groups of vertebrates – agnathans, cartilaginous fishes, ray-finned fishes, and the sarcopterygian radiation of fleshy-finned fishes.

cranial nerves, roof structures (cerebellum, midbrain tectum, much of the diencephalon, and all of the telencephalon), and cerebellar and basal-ganglia-related nuclei (inferior olivary nucleus, pontine nuclei, red nucleus, substantia nigra, etc.). Among the alar plate derivatives, the most variation occurs in the forebrain and particularly within the pallium, which is the dorsal part of the telencephalon. However, substantial variation also occurs in the roof of the midbrain, the tectum, and in the roof of the hindbrain, the cerebellum.

The simplistic Scala Naturae concept of evolution ranks organisms on an ascending scale that is presumed to reflect evolutionary history and that places humans in a position that is 'superior' to that of all other animals, as in fish-to-frog-to-rat-to-cat-to-monkey-to-human. While this concept is unfortunately widely and deeply embedded in the public consciousness, it is completely unsupported by the massive amount of data on evolution, not only for the brain but for all characters across the board. This concept not only errs in implying a direction to evolution, which it does not have except in terms of responses to externally driven selective pressures that vary over space and time, but it incorrectly implies that some existing taxa are identical to shared ancestral taxa, such as extant ray-finned fishes being identical to the ancestors of both themselves and land vertebrates.

To the contrary, both evolution and embryological development proceed from the general to the specific. In regard to evolution, the common ancestor of all vertebrates, for example, gave rise to the radiation of jawless vertebrates on the one hand and to that of the jawed vertebrates on the other; lampreys did not give rise to hagfishes. The common ancestor of tetrapods gave rise to amphibians on the one hand and to amniotes (reptiles, birds, and mammals) on the other; neither frogs nor newts gave rise to reptiles, birds, or mammals. Among amniotes, mammals actually appear in the fossil record before reptiles; reptiles did not give rise to mammals any more than mammals gave rise to reptiles. In regard to embryological development, it likewise generally proceeds from the general (common ancestral features) to the specific (specializations of the taxon) – for example, for a cat: from features common to vertebrates to those common to jawed vertebrates to those common to sarcopterygians (the fleshy-finned radiation) to

Figure 2 Simplified vertebrate cladogram showing examples of some of the taxa that have type I, cytoarchitectonically simple brains – lampreys (*Ichthyomyzon*), squalomorph sharks (the spiny dogfish shark *Squalus*), reedfishes (the bichir *Polypterus*), and amphibians (the bullfrog *Rana*). those common to tetrapods to those common to amniotes to those common to mammals to those specific to cats.

Understanding the basic process of evolution in these terms is essential to understanding brain evolution, since the structures present in the telencephalon of a modern reptile, for example, were not necessarily present in the common ancestor of mammals and reptiles. In order to reconstruct the evolution of a mammalian brain one must first deduce the condition of the ancestral brain, and only a comparative analysis of tetrapod brains can provide the clues necessary to do so. Features present in all tetrapod brains are those that can be hypothesized to have been present in the ancestral brain. Features present in only reptiles or only birds or only mammals are those features that can be hypothesized to be specializations of that particular taxon. Such hypotheses are not guaranteed to be correct, but they follow the principle of parsimony, which is accepted as the most conservative and probably most accurate method of dealing with the data. What is clearly established is that all taxa have their own specializations. Each taxon has a mix of primitive features – those that resemble what a distant ancestor had – and advanced features – those that are unique specializations. The challenge is to determine which features are shared across several taxa and therefore probably primitive in order to reconstruct a model of the common ancestor, then identify the specializations in each taxon, and then investigate how such specializations might have arisen.

Evolution of the Brain in Ancestral Vertebrates

Lancelets, or amphioxus, are small invertebrate chordates that are the closest living relatives of vertebrates. They have a specialization at the rostral end of the neural tube, called the cerebral vesicle, that qualifies as a brain in terms of its position and several regional features that correspond to those of vertebrate brains. From reconstructions of thin sections analyzed at the electron microscope level by Thurston Lacalli and his colleagues, it is now known that these features include (1) a single, midline group of pigment cells and associated neuronlike cells called the frontal organ, which appears to be the homolog of the paired, retinal eyes of vertebrates; (2) a more caudally lying structure called the lamellar body, homologous to the vertebrate pineal organ; (3) a ventrally situated

Figure 3 Simplified vertebrate cladogram showing examples of some of the taxa that have type II, cytoarchitectonically more complex and elaborated brains – hagfishes (*Eptatretus*), galeomorph sharks (the nurse shark *Ginglymostoma*), teleosts (the sunfish *Lepomis*), mammals (the mouse *Mus*), and birds (the pigeon *Columba*). The photomicrographs of Nissl-stained hemisections with mirror-image line drawings shown at the right are through the telencephalon. Most Nissl photomicrographs used in this figure were kindly provided by R Glenn Northcutt.

structure called the balance organ, homologous to at least part of the hypothalamus of mammals; and (4) associated infundibular cells, homologous to the vertebrate infundibulum (neurohypophysis). Recent findings from a cache of fossils of a small creature named *Haikouella lanceolatum*, discovered in Haikou, China and analyzed by Jon Mallatt and Jun-Yuan Chen, in addition to an array of other fossil evidence, have allowed several hypotheses on early brain evolution in the vertebrate line to be substantially clarified. *Haikouella* fossils exhibit a number of relevant features, including (1) an enlarged brain with a brain: body ratio comparable to that of lampreys, (2) brain components that consist mainly of a diencephalon and hindbrain, and (3) paired eyes. The scenario presented here may be modified in the future depending upon further fossil evidence but seems the most likely one based on the multiple lines of evidence available to date.

At the origin of vertebrates, the nervous system would have had, like amphioxus, a rostral, forebrain region that contained at least the light-receptive and hypothalamic components of the diencephalon. It lacked a telencephalon and olfactory structures. The light-receptive components comprised paired eyes, like *Haikouella*, and also a pineal organ. While still small and relatively simple in construction, the paired eyes likely had a vertebrate retinal structure. The hypothalamic component included connections with an infundibulum. As evolution proceeded, subsequent gains included a host of features associated with the neurogenic placodal tissues of head and the neural crest tissue of the body and head. Together, these tissues generate the motor neurons of the autonomic

Figure 4 Convex polygons that enclose the log values for brain weight plotted against log values for body weight for a number of vertebrate taxa. Data kindly provided by Harry Jerison. Note that the polygon for birds almost completely overlaps that for mammals. The brain:body ratios for some groups of birds, including corvids (crows) and parrots, overlap the lower range of primates. Note also that the upper border of the polygon for ray-finned fishes also overlaps the lower border of the polygon for mammals and that the polygon for cartilaginous fishes substantially overlaps the polygons for both birds and mammals. These relationships demonstrate that brain elaboration and enlargement has occurred independently multiple times. Not all type II brains also show marked enlargement of brain:body ratio, however, since while hagfishes have type II brains, their brain:body ratio falls within the polygon for jawless fishes, which overlaps only the lower range for ray-finned fishes and is considerably below the polygons for cartilaginous fishes, birds, and mammals.

nervous system, the sensory neurons of cranial nerves I, V, VII, VIII, IX, and X, and the sensory neurons of the spinal nerves. Additionally, neural crest generates a host of other tissues, including the dermal bones and sensory capsules of the skull and the meninges that surround the central nervous system. Thus, with the bloom of these tissues at some point along the early vertebrate lineage, many of the structures that form the vertebrate head were gained, along with the peripheral nervous system of the head and body. Continued elaboration of the brain and spinal cord, in terms of sensory and motor nuclei and cell columns, the reticular formation, ascending and descending pathways, the telencephalon with olfactory bulbs, the dorsal and ventral thalamic components of the diencephalon, and a definitive midbrain region would likewise have been gained during this transition.

Type I Brains

As noted previously, brains that exhibit relatively little migration of neurons away from the ventricular surface and relatively simple cytoarchitecture, as compared to more complexly elaborated brains, can be classified as type I (Figure 2) for heuristic reasons. Taxa that have such brains include lampreys, some cartilaginous fishes (chimaeras, squantinomorph sharks, and squalomorph sharks), some ray-finned fishes (nonteleosts), and, among the sarcopterygian radiation, lungfishes, the crossopterygian fish *Latimeria*, and amphibians. Only a brief overview of brain organization in these taxa with selected highlights can be presented here.

Lampreys

Lampreys have most of the cranial nerve and other central nervous system components that characterize vertebrate brains in general, although there are some minor differences in the innervation pattern of the extraocular muscles. Among alar plate derivatives, a cerebellum is present but of miniscule size, consisting only of a small region of gray matter in the dorsal part of the rostral medulla. The midbrain tectum is present, with both caudal, auditory and rostral, visual and somatosensory portions. The telencephalon is of very modest size, with cell bodies migrated away from the ventricular surface to only a limited extent (Figure 2). Pallial regions homologous to those of other vertebrates have not yet been identified with certainty. A striatopallidal complex is present in the subpallium (also an alar plate derivative).

Type I Cartilaginous Fishes

Type I cartilaginous fishes comprise chimaeras (ratfishes), squantinomorph sharks, and squalomorph sharks. The latter have been most studied, particularly the spiny dogfish shark *Squalus acanthias*. In general,

the brains of these taxa exhibit many of the cranial nerve and reticular formation components of other vertebrates, a well-developed cerebellum, a moderately developed midbrain roof, an unremarkable diencephalon, and a moderately developed telencephalon. The latter in particular is less extensively populated with neurons (Figure 2) than in type II cartilaginous fishes but contains all the basic pallial and subpallial components of other vertebrates.

Type I Ray-Finned Fishes

All ray-finned fishes, both type I and type II, undergo an almost unique process of telencephalic pallial development called eversion. The only other vertebrate that shares this developmental process, and that to a lesser extent, is the crossopterygian fish *Latimeria*. Rather than undergoing an outpouching process of hemispheric expansion during development, as occurs in other vertebrate groups, eversion causes the most medial part of the telencephalic pallium to lift upward and outward, eventually arching laterally. In evagination, the pallium enlarges like a balloon expanding, with its most medial part remaining in a medial position, the dorsal part arching dorsally, and the most lateral part remaining in its lateral position. In contrast, during eversion, the medial pallium comes to lie in the most lateral position, and the originally lateral pallium remains most medially and ventrally. The geometry of eversion is akin to that of a person doing a back bend, such that the head, arms, and upper torso curve upwards and then backwards. Thus, as shown for both the reedfish telencephalon shown in Figure 2 and that of a teleost telencephalon shown in Figure 3, the ventricular surface lies dorsalmost over the dorsal aspect of the everted pallia, and the ventricular cavity extends laterally over each side to the point where the ependyma (shown as a thin line) attaches.

The brains of type I ray-finned fishes (reedfishes, sturgeons and paddlefishes, gars, and the bowfin *Amia*) are generally similar in plan and in their component parts to brains of other vertebrates, with similar cranial nerve and reticular formation components: cerebellum, midbrain roof, and forebrain components. As with other ray-finned fishes and, generally speaking cartilaginous fishes, the dorsal thalamus contains three nuclei, the more caudal two of which receive their predominant input from the midbrain roof, and the rostral one receives its predominant inputs directly from the retina, somatosensory system, and/or other sources, without relay first through the midbrain roof. The midbrain roof-recipient nuclei can be grouped as the collothalamus and the rostral dorsal thalamic component(s) can be grouped as the lemnothalamus – a basic feature of organization that applies at least to all jawed vertebrate brains.

Both ray-finned fishes and cartilaginous fishes have additional nuclei that are involved in the relay of ascending sensory information to the telencephalon, the preglomerular nuclear complex (or individual nuclei homologous to its various components), but these are better developed in type II brains than in type I brains. In reedfishes, a nucleus medianus is present that relays visual information to the pallium, and in gars and the bowfin *Amia*, a preglomerular nuclear complex is present. The latter generally relays lateral line and/or gustatory inputs to the telencephalon.

Lungfishes, Crossopterygian, and Amphibians

Less information is available for lungfish brains than for the brains of amphibians and most other major vertebrate groups, and very little information is available for the crossopterygian *Latimeria*, since this animal survives only at great ocean depths under conditions of high pressure. Nonetheless, the anatomical organization of lungfish and crossopterygian brains appears to be generally similar to that of amphibians. As already noted, the telencephalic pallium of *Latimeria* undergoes partial eversion during embryological development, whereas evagination occurs in lungfishes and amphibians.

Amphibian brains exhibit the basic structure and components of other vertebrate brains. Of note in terms of their type I development, more production and migration of neurons occurs in the medial (hippocampal) part of their pallium than in other pallial regions (Figure 2). The medial pallium is the major site to which the rostral part of their dorsal thalamus, nucleus anterior, projects. The latter nucleus constitutes the lemnothalamus, but, unlike the situation in amniotes, it does not receive direct input from either the retina or the somatosensory system (dorsal column nuclei), instead having these inputs relayed to it through the ventral thalamus. Also, the ventral thalamic projections to nucleus anterior are thought to be inhibitory, rather than excitatory as the direct inputs would be. Whether this condition represents the ancestral tetrapod condition or a secondary specialization within the amphibian lineage remains to be determined.

The collothalamus of amphibians is also different to a marked degree in its pattern of projections from the collothalamus of amniotes. These nuclei, which receive their predominant visual, somatosensory, and auditory inputs via relay through the midbrain roof, project almost exclusively to the striatum in the subpallium, with only a few fibers reaching the lateralmost aspect of the pallium. In contrast to the

medial pallium, the rest of the pallium in amphibians exhibits almost no migration of neurons away from the ventricular surface (Figure 2). Also in contrast to this pattern of projections, as will be noted subsequently, in amniotes, collothalamic projections give off collaterals to the striatum, but their heaviest targets are within the dorsolateral and lateral (lateral and ventral) portions of the pallium.

Type II Brains

As noted previously, brains that exhibit a relatively large production of neurons combined with substantial migration of most neurons away from the ventricular surface and relatively elaborate cytoarchitecture, as compared to the more simply constructed type I brains, can be classified as type II (Figure 3) for heuristic reasons. Taxa that have such brains include hagfishes, some cartilaginous fishes (galeomorph sharks, skates, and rays), many ray-finned fishes (telosts), and, among the sarcopterygian radiation, amniotes (mammals, reptiles, and birds). Only a brief overview of brain organization in these taxa, with selected highlights, can be presented here.

Hagfishes

The brain of hagfishes is largely terra incognita, due to the difficulty of obtaining and working with these animals (which are covered with a copious quantity of secreted mucus) in a laboratory setting. Also, the substantial amount of neuronal production and migration during development results in a highly complex brain in terms of its cytoarchitecture, and many features of the latter do not clearly correspond to those of other vertebrates. A telencephalon with a highly laminated pallium is present (Figure 3), and those pallial lamina are in receipt of olfactory information. A diencephalon is present with recognizable divisions of epithalamus (habenula), dorsal and (perhaps) ventral thalami, and hypothalamus. Eyes, however, are extremely reduced, and extraocular muscles are absent, with corresponding reduction of retinal projections and oculomotor nuclei. No cerebellar tissue has been identified. Instead of being similar to ancestral jawless vertebrates, a good case can be made for hagfish neural (and other) features being the consequence of evolutionary specializations.

Type II Cartilaginous Fishes

Galeomorph sharks, skates, and rays have exceptionally well-developed telencephalons, both in terms of size relative to their body size and in terms of complexity of cytoarchitecture (Figure 3). Less is known about their various neural systems and major pathways than for some other vertebrate groups – particularly ray-finned fishes and tetrapods – due to the practical difficulties of working with many of these animals in a laboratory setting. One of the major breakthroughs in comparative studies of the past century was that achieved by Sven Ebbesson, Lennart Heimer, Dolores Schroeder, and their colleagues with their work on nurse shark (*Ginglymostoma cirratum*) behavior and sensory pathways, demonstrating that (1) olfactory projections are limited to a relatively small lateral pallial area (rather than being to most or all pallial areas as previously assumed), (2) two different visual pathways to the pallium are present, one lemnothalamic (via direct projections from the retinorecipient nucleus anterior) and one collothalamic via midbrain roof relay to the dorsal thalamus and thence to the pallium, and (3) visual form discrimination requires participation of these telencephalic visual areas rather than just that of the midbrain roof. These findings, along with those of Harvey Karten and his colleagues on bird sensory system pathways and telencephalic organization (see later, the section titled 'Forebrain evolution across amniotes'), precipitated a new era of comparative insights into the evolution of vertebrate brains.

Teleosts

The range of variation in brain structure across teleosts, an exceptionally large vertebrate taxon, is extremely broad. As with cartilaginous fishes and other ray-finned fishes, teleosts exhibit many of the basic cranial nerve, reticular formation, cerebellar, midbrain, and forebrain components of the brain typical of vertebrate brains in general. As in cartilaginous fishes, olfactory projections are restricted to a small part of the pallium, leaving large areas for other sensory system inputs. Various groups and species of teleosts also exhibit a large number of specializations, mostly of alar plate derivatives but some of the basal plate as well, a sampling of which can be presented here.

A derivative of the basal plate, the oculomotor nucleus, has a very specialized structure in the stargazer, one of a number of fishes that are capable of producing an electric discharge. Part of the oculomotor nuclear complex in this fish is called the electromotor division, and it innervates specialized electric organs that are developmentally derived from the extraocular muscle anlage. Both alar and basal plate derivatives are involved in the complex circuitry that supports the sonic motor systems of a number of fishes, such as the plainfin midshipman (*Porichthys notatus*). Other cranial nerve specializations include a massive expansion of the taste-receptive nuclei in

cyprinids (which include goldfishes) and silurids (catfishes). Rather than consisting of the relatively small gustatory nucleus as in mammals and most other vertebrates, the taste-receptive cell groups in these fishes are hypertrophied into large vagal, glossopharyngeal, and facial lobes, with over a dozen cellular layers and a highly complex pattern of connections. Likewise, the lateral line system is particularly elaborated in electroreceptive teleost fishes, with mormyrids being an extreme example. These fishes have an electroreceptive cerebellum that is massively expanded relative to all of the rest of the brain and also extreme in its degree of complexity of cytoarchitecture and connections. Mormyrids use their electrosensory communication system for individual identification to conspecifics and for highly complex behavioral feats, including group cooperation in the building of underwater nests.

In addition to these cranial nerve and hindbrain specializations, teleosts display a wide range of variation in the complexity and degree of elaboration of their telencephalons (**Figure 3**). As described above for type I ray-finned fishes, the telencephalon undergoes a process of eversion during embryological development, resulting in a reversal for the adult positions of the originally medial and lateral pallial regions. Recent studies by Cosme Salas and his colleagues have demonstrated that the originally medial (hippocampal) part of the pallium in goldfish is involved in the same types of functions as the amniote hippocampus, particularly spatial mapping. In contrast, the originally lateral (amygdalar) part of the pallium in goldfish is involved in emotional, associational learning, such as the pairing of a light stimulus with an aversive, moderate electric shock. Thus, despite the process of eversion and also despite markedly different cytoarchitecture, the basic functions of pallial regions in goldfish are remarkably similar to their homologs in land vertebrates.

Amniotes

Mammals The earliest mammals appear in the fossil record slightly before the earliest reptiles. Rather than thinking of the common ancestor of all amniotes as a stem reptile, which implies reptilian structures in the brain as well as elsewhere, it is correct to think of the common ancestor as a stem amniote. Some of the most salient features of the brains of sauropsids (reptiles and birds) and those of mammals represent divergences from the common ancestral condition rather than sequential evolution of either the extant mammalian or sauropsidian condition to the other.

Cranial nerve specializations do not only occur in fishes, such as those already noted. Among mammals, a remarkable adaptation of the trigeminal nerve also occurs in monotremes – platypus and echidna. Both, but better developed in the platypus, have electroreceptors – located on the snout of the echidna and the duckbill of the platypus. These are not innervated by the lateral line system, which is present only in anamniotes, but rather by the trigeminal nerve. The platypus in particular uses these electrosensory inputs to search for prey under debris in the muddy stream beds that it inhabits. Trigeminal-associated specializations also occur in mammals such as the star-nosed mole, innervating its highly specialized Eimer's organs that cover fleshy tentacles around the oral region, and such as the barreletts-barreloids-barrels cellular formations that are present within somatosensory nuclei and cortex of rodents and some marsupials with mustacial vibrissae.

In addition to a host of features similar to those of other vertebrates, the brains of mammals vary somewhat across their taxa (monotremes vs. marsupials vs. placental mammals) and also share several salient specializations, the most prominent of which is of course the six-layered and massively developed neocortex (**Figure 3**). Likewise, the mammalian dorsal thalamus is the most highly developed and elaborated of any major taxa, in placentals containing numerous sets of multiple nuclei each. It is likely that, as in extant monotremes and to a lesser degree in extant marsupials, the earliest mammals favored a substantial expansion of the lemnothalamus (anterior, medial, rostral intralaminar, and ventral nuclear groups and the dorsal lateral geniculate nucleus) and its pallial targets. This would be in accord with the importance for early, small-sized, crepuscular mammals of depending on limbic system functions such as spatial mapping and on their lemnothalamic visual pathway to striate cortex. Subsequently, within marsupials and to a greater degree in multiple orders of placental mammals, the collothalamic (medial geniculate body and the posterior intralaminar, posterior, and LP/pulvinar nuclear groups) pathways were markedly expanded, including the collothalamic-recipient extrastriate, auditory, and secondary, etc., somatosensory cortical areas as well as the higher order association cortical areas of the temporal and parietal lobes. Likewise, a pallial part of the amygdala in mammals, its basolateral component, is in receipt of ascending collothalamic projections.

Sauropsids Just as mammals diverged from the stem amniote stock, so did the sauropsid line that gave rise first to reptiles and, subsequently, birds, which actually are a specialized group of reptiles, just as are the other extant groups of this major taxon. In fact, recent genetic analyses have demonstrated that the thecodonts (crocodiles and birds), along with

turtles and the rhynchocephalian lizardlike animal *Sphenodon*, are clustered as a monophyletic group, while the squamates (lizards and snakes) constitute the outgroup to them (Figure 1).

Among sauropsids, as in mammals and other vertebrates, cranial nerve specializations occur. In two families of snakes, boids and crotalids, sensory pits are present on the head region that can detect infrared radiation. These pits are innervated by the trigeminal nerve, and, in crotalids, the trigeminal projections terminate within a brain stem nucleus (the lateral trigeminal nucleus) unique to them. The infrared sensory information is relayed to the optic tectum (directly in boids and via another unique nucleus, the nucleus reticularis caloris, in crotalids), where it is used in conjunction with visual input to locate and accurately strike prey. Yet another specialization of the trigeminal system – the ability of magnetodetection – occurs in birds and is shared with like specializations recently found in trout, salamanders, and loggerhead sea turtle hatchlings. Naturally available magnetic stimuli are used, often in conjunction with visual clues, for navigation and orientation to the earth's magnetic field.

The telencephalic pallium of both birds (Figure 3) and reptiles contains a dorsally lying region – the Wulst of birds and the general, or dorsal, cortex/pallial thickening of reptiles – that is well established as the homolog of at least some of the more medial, lemnothalamic-recipient regions of mammalian neocortex, that is, the primary somatosensory-motor and visual cortices. Likewise, the lemnothalamus of sauropsids contains a number of individual nuclei that are homologous as either a field or one-to-one basis with various lemnothalamic nuclei and/or nuclear groups of mammals. The pallium of sauropsids also contains a structure called the dorsal ventricular ridge (DVR, also called the nidopallium and mesopallium in birds) that receives several ascending collothalamic pathways – visual, auditory, and somatosensory – and, likewise, the sauropsid collothalamus contains nuclei that are homologous to the set of collothalamic nuclei of mammals.

Within the early sauropsid line, a sequence of dorsal thalamic and pallial elaboration occurred that was opposite to that in mammals. In early sauropsids, elaboration of the collothalamus and its pallial targets was favored over that of the lemnothalamus. In some extant reptiles, such as turtles, some lizards, snakes, and the rhynchocephalian *Sphenodon*, the DVR is structured as a corticoid (layered) border of cells that surrounds a central region that hasscattered neurons but is mostly neuropil. Ascending thalamic afferents terminate on the dendrites of neurons of the corticoid band that extend into the neuropil region. In other extant reptiles – particularly crocodiles and some lizards – and birds, the DVR is a greatly expanded structure, with much more extensive and migrated populations of neurons – an exaggeration of the type II brain category. In these taxa, the DVR is composed of a number of nuclear regions, some of which receive the various ascending collothalamic projections and others of which are expanded areas of association pallium. Within the sauropsid line, birds have secondarily expanded the lemnothalamus and its pallial target area, the Wulst, although still not to as great a degree as the collothalamic-DVR systems.

Forebrain evolution across amniotes Controversy is ongoing as to the homology of the DVR with mammalian pallial components. The pioneering work of Harvey Karten and his colleagues that began in the 1960s established the pallial nature of this part of the telencephalon in birds and traced the ascending auditory and visual pathways to it, strongly indicating homology of these areas to the auditory and extrastriate visual cortices of mammals (specifically of the DVR thalamo-recipient cell populations and their efferent target cell groups to the cell populations within layer IV and the infragranular layers of neocortex, respectively). Similar pathways were then discovered in a number of reptilian taxa.

Recent embryological studies of gene expression patterns have yielded data that suggest a different correspondence – that of the sensory-recipient DVR to the basolateral amygdala of mammals. Neither of these one-to-one comparisons yet accounts for the evolution of the other structure, however; that is, the basolateral amygdala hypothesis does not yet satisfactorily explain the evolutionary derivation of the lateral neocortex, and vice versa. An alternative hypothesis that attempts to do so posits that the single DVR structure present in sauropsids is homologous, as the single derivative of a developmental field, to both of these structures in mammals. Still others argue that the pallial regions in sauropsids and mammals are so independently derived that sensible comparisons cannot be made at all. The argument also embraces the particular homologous relationships of the individual collothalamic nuclei between sauropsids and mammals and borders on becoming circular in that regard.

Whatever the outcome of the continuing research in this area in regard to phylogenetic homology of pallial areas and dorsal thalamic nuclei, it is now clearly established that the neocortex in mammals and the various pallial areas in birds, which exhibit dramatic differences in their cytoarchitecture

(Figure 3), both support highly complex cognitive abilities and may thus also both support high levels of consciousness, including working memory-related attributes such as anticipation of future events, sense of self, and theory of mind. A bounty of recent studies in birds, creatively designed to ask experimental questions of the birds in behavioral paradigms that are relevant to their response abilities, indicate extremely high levels of cognitive abilities in at least some taxa, particularly corvids (crows) and parrots. Since such abilities in humans are correlated with a high degree of consciousness, it is parsimonious to posit a similar correlation in birds. One important caveat is that high levels of consciousness also may be present but currently undetectable by us in other animal taxa, including reptiles, amphibians, and fishes, but, at least in birds, the high cognitive abilities that we can now appreciate indicate the capacity for high-level consciousness as well. A major question then becomes what role the cytoarchitecture of neocortex (six cell layers based on a pyramidal cell motif) plays in mammalian cognitive abilities and the generation of high-level consciousness and why and how a dramatically different cytoarchitecture of the DVR (nuclear) is able to support similarly high cognition and a possibly correlated high degree of consciousness as well.

Evolution of Vertebrate Respiratory Control

R J A Wilson, University of Calgary, Calgary, AB, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neil Armstrong's first step on the moon is more than matched by our vertebrate ancestors who transitioned to land. Like the first astronauts, the first vertebrates to invade land were well prepared. Key aspects of the respiratory controller appear to have predated tetrapods and to have been present in fish some 400 Ma.

Our understanding of central respiratory control is rudimentary. There have been relatively few modern studies in fish, frogs, and reptiles; the vast majority of data come from studies in mammals. Evolutionary theories should be grounded by data derived from diverse species; in this case, unfortunately, they are not. In effect, investigators are putting together a jigsaw puzzle of which most of the pieces are currently missing. Consequently, the evolutionary framework on which this article is based is speculative, and the homology hypothesis is very much a work in progress. It is presented here in the hope of provoking more work in this exciting area.

Evolution of Rhythm Generation

Evolution of Gill Ventilation: From Tunicate to Fish

The primordial motor patterns required for pumping water over gills can be traced back to the earliest chordates: aquatic animals that lived in water and were filter feeders (Figure 1). Living examples of primitive chordates include tunicates and amphioxus. The adult forms of these animals use rhythmic muscle contractions to pull water through their mouths, into pharyngeal-like structures, and out through secondary orifices.

In amphioxus, the passage of water through the pharynx and across the gills contributes little to gas exchange, suggesting that irrigation of the pharyngeal cavity in primordial vertebrates may have originated from the need to feed, not breathe. Nonetheless, recent molecular studies suggest that these rudimentary feeding behaviors may be the predecessor of vertebrate breathing. The motor neurons responsible for pulling water into the pharynx of adult tunicates, located in the cerebral ganglion which until recently was thought to be a highly derived structure, express transcription factors homologous to *Phox2a* and *Phox2b* (Figure 2). In fish and tetrapods, expression of *Phox2a* and *Phox2b* within the central nervous system is restricted to the brain stem, occurring in brain stem cranial motor neurons, used extensively (but not exclusively) for ventilation. In larval tunicates, when the caudate body plan is most obvious, transcription factors homologous to *Phox2a* and *Phox2b* are similarly restricted to the neck region of the animal.

By the time the jawless fishes (agnatha) evolved, the walls of the gills had likely thinned and become highly vascularized, becoming the primary site for gas exchange, as exemplified in extant agnatha such as the lamprey and hag fish.

Most fish ventilate their gills with water more or less continuously, and therefore the neuronal mechanism responsible likely involves a central rhythm-generating circuit. The presence of a central rhythm generator is supported by the fact that fish brain stems continue to exhibit rhythmic cranial nerve discharges when isolated and superfused.

Where the rhythm generator resides, however, is poorly understood. Several early studies in lamprey and modern ray-finned fishes have addressed the location and organization of the respiratory rhythm generator for gill ventilation. These studies uniformly identify the brain stem as the site of rhythmogenesis, but the rostrocaudal location of the rhythm generator within the brain stem is less clear.

In lamprey and dogfish, a rostrocaudal wave of muscle contraction ensures movement of water across the gills. The rostrocaudal wave of somatic muscle activation involved in swimming is produced by a chain of coupled neuronal oscillators within the spinal cord. While some earlier studies suggest that multiple brain stem oscillators combine to produce the rostrocaudal wave of muscle contraction involved in ventilating the gills, more-recent work suggests that the rostrocaudal progression is produced by differences in conduction delay as a result of rostral and caudal motor neurons having axons of different lengths.

In dogfish, respiratory neurons are distributed along the length of the brain stem, leading some researchers to suggest that the rhythm generator is distributed within either the motor column or the reticular system that runs the length of the brain stem. In addition, local ablation experiments in dogfish have so far failed to identify a discrete location

Figure 1 Phylogeny of breathing in vertebrates. Lower vertebrates use buccal and pharynx muscles to move water in and out of their buccal cavities (blue text). In the most primitive vertebrates (e.g., tunicates), this behavior may have been more important in feeding than in breathing. In bimodal ventilators that breathe air and water (e.g., gar, lungfish, and metamorphic tadpoles), the buccal musculature is also used as a 'buccal-force pump' to drive air into primitive lungs (red text). The motor pattern used to pump water appears to be retained in frogs and reptiles, co-opted into ventilating the buccal cavity with air. In reptiles, flank muscles assist the buccal-force pump to inflate the lungs. In mammals, lung inflation occurs through aspiration, the power stroke for which is provided almost entirely by the flank muscles and diaphragm. Nonetheless, even in mammals, phasic contractions of the buccal musculature retain an important respiratory role of maintaining patency of the upper airways. Blue circle, hypothesized origin of primordial neuronal circuit generating buccal contractions used to breathe water. Pink circle, hypothesized origin of air-breathing organ and primordial neuronal circuit, which inflates it. Top right, clockwise: Modern ray-finned fishes (teleosts), primitive ray-finned fishes (Amia and gar), elasmobranches (sharks and rays), tunicates, agnatha (lamprey), lobe-finned fishes (lungfish), amphibians (bullfrog), reptiles (leatherback turtle), and mammals (rat).

that stops rhythmic activity in motor nerves. However, the former evidence is correlative, and local ablation experiments may have missed a critical site. Thus, whether the rhythm generator for gill ventilation in dogfish is distributed remains an open question.

Brain stem transection studies in lamprey suggest a discrete rostral region of the brain stem, located at the level of the trigeminal nucleus, is responsible for gill ventilation. Studies of metamorphic amphibian tadpoles and juvenile frogs also suggest that a discrete region of the brain stem may be uniquely responsible for gill ventilatory rhythmogenesis, albeit at a more caudal location.

Gill Ventilation in the Amphibian Tadpole

Work to resolve the central neuronal mechanisms involved in breathing in lower vertebrates has focused mainly on the bullfrog, *Rana catesbeiana*. Based on parsimony, the paucity of data from fish to refute claims of homology, and the low likelihood that a

Figure 2 Motor neurons expressing Phox2 innervate the buccal cavity of both tunicates and higher vertebrates. Contractions caused by activity of Phox2 motor neurons in tunicates (a) and (b) and water-breathing vertebrates move water through the 'buccal' cavity. In higher vertebrates, including rats and humans (c), the expression pattern likely includes CO_2/H^+-chemosensitive neurons and cranial motor neurons that play an important role in air breathing. GFP, green fluorescent protein. From Dufour HD, Chettouh Z, Deyts C, et al. (2006) Precraniate origin of cranial motoneurons. *Proceedings of the National Academy of Sciences of the United States of America* 103(23): 8727–8732.

vital behavior such as gill ventilation would have been lost and re-evolved during the transition from fish to frogs, an assumption central to the field is that the neuronal mechanisms responsible for gill ventilation in fishes and bullfrog tadpoles are similar.

In tadpoles, which have both gills and lungs, a 500 μm isolated transverse brain stem slice at the level of the vagus is capable of generating a gill-like motor pattern. During metamorphosis, tadpoles lose their gills and depend more heavily on their lungs for gas exchange. However, despite the loss of gills, a facsimile to the gill ventilatory motor pattern is retained for flushing air in and out of the buccal cavity (i.e., buccal ventilation). This behavior likely serves to prime the buccal cavity for lung inflation and may also be important for olfaction.

Transection studies and drug microinjection studies have been used to locate the rhythmogenic site within the isolated superfused brain stems responsible for buccal ventilation. A small, bilaterally iterated site has been identified proximal to the vagus nerve that appears to be important for generating the buccal motor pattern (Figure 3). Injections of the non-*N*-methyl-D-aspartate glutamate receptor agonist α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid into isolated superfused brain stems at this

Figure 3 Two oscillators in frogs. Sufficiency (left traces) and necessity (right traces) tests suggest two areas important for generating ventilatory motor patterns, buccal (blue) and lung (red). Under control conditions the isolated juvenile frog brain stem produces buccal and lung ventilatory motor patterns in cranial nerves (CNs). These motor patterns are easily distinguished by burst amplitude (buccal small, lung large). Injecting the non-*N*-methyl-D-aspartate receptor agonist α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) into the lung area (for location see diagram on left) to produce local excitation causes an increase in lung burst frequency whereas injecting γ-aminobutyric acid (GABA) to produce local inhibition abolishes lung bursts but has no effect on buccal bursts. On the other hand, injecting AMPA into the buccal area causes an increase in buccal bursts, but abolishes lung bursts (inlay), whereas injecting GABA into the buccal area abolishes buccal bursts but has no effect on lung bursts. These data, in combination with the results of transection studies and the tight coordination of buccal and lung bursts suggest that the motor pattern is mediated by two coupled oscillators. From Wilson RJA, Vasilakos K, Harris MB, Straus C, and Remmers JE (2002) Evidence that ventilatory rhythmogenesis in the frog involves two distinct neuronal oscillators. *Journal of Physiology* 540: 557–570.

site caused an increase in the frequency of buccal bursts (sufficiency test), whereas an injection of γ-aminobutyric acid (GABA) into the same site caused cessation of buccal bursts (necessity test). These data demonstrate that the region of the brain stem at the level of the vagus is both necessary and sufficient for buccal ventilation.

The rhythmogenic mechanism responsible for generating buccal ventilation remains largely unexplored, although experiments in a number of lower vertebrates suggest that it requires postsynaptic chloride-mediated inhibition and can be abolished with strychnine and biculluline, potent agonists of GABA and glycine receptors, respectively.

Origins of Air Breathing

Ray-finned and lobe-finned fishes diverged at least 408 Ma. The ray-finned fish gave rise to modern teleosts, and the lobe-finned fish gave rise to tetrapods.

Extant but primitive ray-finned and lobe-finned fishes have saclike structures that can be opened to the atmosphere, serve a respiratory function, and have an embryonic origin similar to that of the tetrapod lung, suggesting that fish evolved lungs long before amphibians invaded land.

There are ~375 extant species of air-breathing fishes, including modern perciform teleosts such as the Siamese fighting fish, *Betta splendens*. Only a small portion of these so-called modern species use lunglike organs for gas exchange; most have secondarily derived structures that serve this purpose. Thus, while the first ray-finned fishes were capable of breathing air using a structure homologous to the tetrapod lung, air breathing was lost during the evolution of more-modern fishes, only to be rederived, in some cases, from structures unrelated to the proto-lung.

Despite the presence of lunglike organs in extant but primitive ray-finned fishes, such as the gar and amia, it has long been assumed that air breathing in this clade evolved independently from air breathing of lobe-finned fish. The following three lines of evidence, based on assumed differences in the neuronal mechanisms controlling air breathing, have been used to support this argument:

1. Compared with lobe-finned fishes and tetrapods, air breathing in ray-finned fishes is infrequent and rarely rhythmic but responds vigorously to stimulation of peripheral chemoreceptors. Therefore, some have argued that air breathing in fish is more likely to be reflex-mediated than produced by a central respiratory rhythm generator.
2. The mechanics of air breathing in ray- and lobe-finned fishes differ even though base members of both clades use buccal musculature to push air into their lungs. Specifically, ray-finned fishes use a two-cycle mechanism (one cycle of buccal dilation and constriction to expel stale air from lungs to the atmosphere, another to acquire fresh air into the buccal cavity and pump it into the lungs) whereas lobe-finned fishes and most amphibians use a one-cycle mechanism (expulsion of stale air from the lung to the atmosphere and acquisition of fresh air into the buccal cavity occur simultaneously during a single phase of buccal dilation, and the subsequent buccal constriction pumps the freshly acquired air in the buccal cavity into the lungs).
3. Air breathing in ray-finned fishes differs from that in lobe-finned fishes and tetrapods by showing little sensitivity to arterial CO_2. Therefore, unlike air breathing in tetrapods, air breathing in ray-finned fishes is not modulated by central CO_2 chemoreceptors.

Based on a study using the isolated gar brain stem, it has been proposed that the first air-breather may have predated the division of ray- and lobe-finned fish, the clades that gave rise to modern teleosts and tetrapods, respectively. Specifically, it has been shown that the isolated gar brain stem produces bursts of activity, similar to those associated with air breathing, that respond to changes in superfusate PCO_2. These controversial data suggest gar have a central CO_2-sensitive rhythm generator for air breathing, similar to lobe-finned fishes and their tetrapod descendants (**Figure 4**). If this is indeed the case, then the air-breathing ancestor of modern tetrapods likely evolved before the divergence of ray- and lobe-finned fishes some 400 Ma.

Not all evidence supports the presence of a CO_2-sensitive brain stem rhythm generator in primitive ray-finned fishes. Amia, for example, fail to increase their rate of air breathing when arterial PCO_2 is increased by systemic injection of azetazolamide. However, brain stem isolation and superfusion experiments, which are most likely to demonstrate the presence of a central rhythm generator, have yet to be performed.

The Air-Breathing Rhythm Generator in Amphibians

The presence of a central rhythm generator for air breathing in lungfish, while not investigated in any detail, is equivocal. Until data suggest otherwise, it seems reasonable to assume that the neuronal architecture is similar to that in frogs.

In frogs, a number of studies suggest that the central rhythm generator for air breathing comprises a buccal oscillator accompanied by another brain stem oscillator that is active only during lung inflation. The buccal and lung oscillators appear to be spatially distinct. Necessity, sufficiency, and transection

Figure 4 Comparison of motor patterns produced by frog and gar brain stems. Few studies have investigated the neuronal control of breathing in primitive air-breathing ray-finned fishes, and therefore uncertainty remains about the neuronal mechanisms that mediate breathing in this clade. However, data from a study in which the brain stem was isolated and superfused suggest that the gar brain stem is capable of producing both buccal and lung motor patterns in the absence of phasic input; that is, it contains a central respiratory rhythm generator. Furthermore, the putative lung bursts are CO_2/H^+-sensitive. It is remarkable that the motor output produced by the brain stem of the gar is similar to that produced by the juvenile frog, suggesting that brain stems of primitive air-breathing ray-finned fish may also contain two respiratory oscillators. From Wilson RJA, Harris MB, Remmers JE, and Perry SF (2000) Evolution of air-breathing and central CO_2/H^+ respiratory chemosensitivity: New insights from an old fish? *Journal of Experimental Biology* 203: 3505–3512.

studies suggest that the lung oscillator is located rostral to the buccal oscillator at a level just caudal to the facial nucleus (Figure 3). In contrast to the buccal oscillator, bursting of the lung oscillator does not depend on postsynaptic chloride-mediated inhibition, is inhibited by opioids, but is strongly stimulated by increased CO_2.

While spatially distinct, the buccal and lung oscillators interact functionally. In the intact brain stem, the buccal oscillator appears to play an important role in the timing of lung ventilation and may participate directly in lung inflation by priming the buccal cavity before the contraction phase (power stroke) mediated by the lung oscillator.

Given the strong temporal coordination between buccal and lung busts, a two coupled oscillator model has been proposed. While the possibility of additional oscillators is not excluded, simulations suggest that two coupled oscillators are capable of recapitulating the salient characteristics of the motor pattern produced by the isolated brain stem.

The Air-Breathing Rhythm Generator in Mammals

Unlike frogs and fish, which inflate their lungs using positive pressure generated by the buccal musculature, mammals inflate their lungs using negative pressure (aspiration) generated by the diaphragm. Despite the dichotomous biomechanics of the power stroke, in both frogs and mammals the power stroke is preceded by a phase of buccal expansion. In mammals this priming phase protects the upper airways from collapse during the ensuing negative pressure. In frogs, the buccal expansion draws fresh air into the mouth prior to the power stroke.

Recent data suggest that a neuronal architecture consisting of two coupled oscillators, the pre-Bötzinger complex (pre-BötC) and the preinspiratory (pre-I) oscillator, may participate in mammalian respiratory rhythmogenesis (Figure 5). The contribution of these oscillators when embedded within the intact respiratory network is currently under debate. The simplest viewpoint is that the pre-BötC generates inspiratory, power stroke activity, with the pre-I oscillator generating expiratory, pre-I, priming activity. However, on the other extreme, some have argued that within the context of an intact, possibly distributed rhythmogenic network, the contribution of each oscillator is minimal at best. Nonetheless, the presence of two putative oscillators in mammals raises the possibility that they evolved from the same ancestral air-breathing circuit that gave rise to the frog oscillators.

Figure 6 compares the properties of the priming and power stroke oscillators of frogs and mammals. Apparent from this comparison, the power stroke oscillators share a large number of similarities. The priming oscillators also share some similarity, but the resemblance is weaker. Therefore, the likelihood that the power stroke oscillators are homologous is good; the case for homology between priming oscillators is more tenuous.

Evolution of Chemoreceptors

Why Chemoreceptors?

The primary role of chemoreceptors is to maintain homeostasis. These receptors detect changes in blood and/or environmental levels of O_2, CO_2, and pH and initiate cardiorespiratory adjustments to keep gas

Figure 5 Recent data suggest two oscillators underlie respiratory rhythm generation in mammals. Until recently, the respiratory rhythm generator was widely considered to be composed of a single rhythmogenic kernel called the pre-Bötzinger complex (pre-BötC) embedded in a larger pattern-generating network. Substantive evidence supports the role of the pre-BötC in rhythm generation. However, recent experiments using the μ-opioid agonist DAMGO suggest that a second oscillator is also involved. The rat neonatal isolated brain stem preparation normally produces rhythmic bursts in cranial nerves and cervical nerves including the phrenic. DAMGO produces 'dropped beats' whereby occasional bursts are lost (arrows), but the underlying rhythm (illustrated with vertical bars) is not affected. Intracellular recordings from neurons within the pre-BötC demonstrate that activity of the pre-BötC is abolished during a dropped beat (a), suggesting that pre-BötC does not pace the underlying rhythm. Instead, it appears that the rhythm originates rostrally, within the parafacial respiratory group. This region is rich in preinspiratory (pre-I) neurons that fire immediately before phrenic activity and has been implicated in respiratory rhythm generation previously. It is important to note that, unlike pre-BötC neurons, rhythmic activity of neurons within this region persists during dropped beats (b). Top trace in each panel: integrated phrenic neurogram. Lower trace in (a) and (b), respectively: intracellular recording from a pre-BötC and a pre-I neuron. From Mellen NM, Janczewski WA, Bocchiaro CM, and Feldman JL (2003) Opioid-induced quantal slowing reveals dual networks for respiratory rhythm generation. *Neuron* 37(5): 821–826.

tensions and pH within set limits despite changing metabolic demands.

Water-breathing vertebrates obtain O_2 from water. The low capacity of water for O_2 necessitates a high flow across gas-exchange surfaces. In contrast, the relatively high solubility of CO_2 in water generally results in rapid CO_2 excretion. In essence, water-breathing vertebrates ventilate in order to acquire sufficient O_2 to meet metabolic demands and, in doing so, satisfy the need to excrete metabolically produced CO_2. In contrast to aquatic vertebrates, terrestrial vertebrates breathe a medium rich in O_2 but face greater limitations in the ability to excrete metabolically produced CO_2. Consequently, at rest, air-breathing terrestrial vertebrates generally ventilate to satisfy needs for CO_2 excretion and, in doing so, satisfy metabolic requirements for O_2 uptake.

The evolution from water to air thus necessitated a transition from a respiratory system dominated by the need to satisfy O_2 demand to one that is primarily preoccupied with excreting CO_2. These changing demands were met in part by the changing importance of two populations of chemoreceptors, peripheral and central, that have different sensitivities to O_2 and CO_2.

Peripheral Respiratory Chemoreceptors in Fish

The primary sites of respiratory chemoreceptors that modulate aquatic ventilation in fish are the gills. The anterior gill arches and, to a lesser extent, regions within the orobranchial pharynx contain populations of O_2-sensitive receptors oriented toward both the blood and the environment. This receptor distribution suggests that fish modulate ventilation in response to aquatic O_2 levels, the effectiveness of O_2 uptake, or the degree of metabolic O_2 consumption as indicated by blood PO_2 at the level of the gills. These locations also contain CO_2/H^+-sensitive receptors, which in most fish appear to be oriented toward the environment and, thus, likely monitor aquatic CO_2 tension.

While branches of cranial nerves (CNs) VII (facial), IX (glossopharyngeal), and X (vagus) innervate the gills, sensory information from the chemoreceptors to the brain stem is carried predominantly in CNs IX and X.

In both air- and water-breathing fishes, the peripheral chemosensory information carried by these nerves has been considered almost absolute in stimulating ventilation; in air-breathing fishes, the input was so strong that air breathing was considered an on-demand behavior, controlled entirely by a peripheral respiratory chemoreceptor-mediated reflex arch. More recent data suggest the involvement of a central rhythm generator and modulation by other sensory modalities.

Peripheral Respiratory Chemoreceptors in Tetrapods

The carotid and aortic arches house the primary peripheral respiratory chemoreceptors in tetrapods. These structures share a common embryonic origin with the gill arches of fish and, like the peripheral respiratory chemoreceptors in fish, are innervated by CNs IX and X (Figure 7). These similarities have led to the widely held view that the carotid and aortic arch chemoreceptors of tetrapods evolved from fish gill arch chemoreceptors.

In mammals, the carotid bodies dominate peripheral chemosensitivity: the ventilatory response to hypoxia decreases only slightly (<10%) when the aortic arch chemoreceptors are denervated. The carotid bodies are most strongly activated when stimulated concurrently by low levels of oxygen and high levels

Figure 6 Functional similarities between frog and rat oscillators. There are a number of similarities between the putative pairs of oscillators in frogs and rats, as illustrated. The similarities between the frog lung oscillator and the rat pre-Bötzinger complex (pre-BötC) (squares) are strongest, and therefore these are most likely to be homologous. Arguments for homology of buccal and pre-I oscillators (circles) rely on their functional similarity: both are active immediately before inspiration, priming the upper airways for the ensuing power stroke, and appear to have a primary role in setting the underlying rhythm. Diagram illustrates the anatomical arrangement of the oscillators in frogs and rats. Note that anatomy does not support dual homology.

Figure 7 Comparative anatomy of peripheral chemoreceptors. This diagram depicts the distribution of peripheral arterial and pulmonary CO_2/H^+-sensitive chemoreceptors (yellow circles) in various vertebrate groups. IX and X designate the ninth (glossopharyngeal) and tenth (vagus) cranial nerves (CNs), respectively. It is important that chemoreceptors associated with the first gill arch in fish, innervated by CN IX, are homologous to the primary peripheral chemoreceptors in all vertebrates. Modified from Milsom WK (2002) Phylogeny of CO_2/H^+ chemoreception in vertebrates. *Respiratory Physiology & Neurobiology* 131(1–2): 29–41.

of CO_2. This condition arises during suffocation, leading some to describe the peripheral chemoreceptors as the primary asphyxia sensor. Under normal conditions (i.e., when blood gases are normoxic and normocapnic), the contribution of the peripheral chemoreceptors to the overall 'drive' to breathe is still debated, with the consensus around 40% and estimates ranging from 0% to 70%. The debate is complicated by the state-dependent integration of peripheral respiratory chemoreceptor afferent information, which is subject to complex modulation depending on, among other factors, the degree of lung inflation and brain stem PCO_2.

Central CO_2 Chemoreceptors in Air-Breathing Vertebrates

Although peripheral chemoreceptors contribute in important ways to ventilatory responses to transient

changes in O_2 or CO_2/H^+ in tetrapods, responses persist despite denervation of peripheral chemoreceptors. The dominant source of chemosensory drive under steady-state conditions is central chemoreceptors: CO_2/H^+-sensitive receptors located within the central nervous system. There is some evidence (discussed later) to suggest the presence of these receptors in primitive fishes, but their general presence in fish has yet to be substantiated.

Despite considerable research effort in mammals, the nature of central chemoreceptors has made their investigation difficult. In rodents and goats, activity of multiple populations of chemosensitive cells contributes to ventilatory responses invoked by central changes in CO_2/H^+. These populations are widely distributed throughout the brain stem in important respiratory areas such as the raphe, nucleus tractus solitarius, locus coeruleus, hypothalamus, and the subpopulations of the ventral lateral medulla, including the pre-BötC and retrotrapezoid nucleus. Chemostimulation of any one of these populations can elicit substantial ventilatory responses, suggesting considerable redundancy. Moreover, these different populations may utilize a diverse array of chemosensory transduction mechanisms.

The origin of these chemoreceptor populations relative to the evolution of tetrapods and the water-to-air transition is enigmatic. There is some evidence of chemosensitive cells in the brain stem of some water-breathing fishes, including one of the most primitive extant groups, the lamprey. However, the preponderance of evidence indicates that water-breathing fishes lack central ventilatory chemosensitivity. As previously noted, air breathing is a gas exchange strategy that has evolved independently in a number of fish species. Within one of these air-breathing lineages, the tetrapod lung has its origin in now-extinct, primitive air-breathing fish. An extant species of air-breathing fish (the gar, *Lepisosteus osseus*) closely related to this lineage that gave rise to tetrapods has provided a key element in the understanding of the origin of central ventilatory chemosensitivity. Brains isolated from these fish produce neural correlates to gill ventilation and air breathing.

Figure 8 Central chemoreceptors in frogs and mammals. This diagram depicts areas within the central nervous system that have been shown to contain CO_2/H^+-sensitive cells. Longitudinal (left) and coronal sections (right) of a typical mammal (top) and amphibian (below) are shown. Areas with documented chemosensitivity are red, and their locations are presented relative to the facial nucleus (VII; shaded). Chemosensitive areas include the following: locus coeruleus (LC); fastigial nucleus (FN); rostral ventral respiratory group (rVRG); retrotrapezoid nucleus (RTN); nucleus tractus solitarius (NTS); and the amphibian rostral chemosensitive area (RCA) and caudal chemosensitive area (CCA).

Exposing isolated brains to elevated CO_2 prompts an increase in putative air breathing, indicating central ventilatory sensitivity to CO_2. Thus, like the tetrapod lung, CO_2/H^+-sensitive ventilatory chemoreceptors may also have their origin in a primitive air-breathing fish.

The amphibian tadpole metamorphoses from a fishlike, free-swimming larval stage that exchanges gas with water across its skin and gills into a mature semiterrestrial form that exchanges gas across its skin and lungs. Brains isolated from any of these stages produce neural correlates to gill ventilation and air breathing, which represent gill and lung ventilation in the intact animal. Mechanisms of ventilatory control are remarkably conserved among vertebrates, and these preparations have provided great insight into these mechanisms. Previous characterizations suggested that central CO_2/H^+ chemosensitivity for air breathing was absent in early metamorphic stages despite the presence of a lung and that this sensitivity developed only in the late stages, associated with loss of the gills, the adoption of a semiterrestrial lifestyle, and use of the lung ventilation as a primary gas exchange strategy. Subsequent investigations, however, have established that exposing brains isolated from tadpole of any stage to elevated CO_2 results in increases in putative air breathing. Thus, central CO_2/H^+ chemosensitivity for air breathing is present throughout tadpole development, including fishlike stages with fully functional gills.

Other Chemoreceptors: Upper Airways and Lung Epithelial Bodies

Many vertebrate species have olfactory and perhaps gustatory CO_2/H^+-sensitive receptors that can influence ventilation and are believed to be involved in general defense responses to environmental conditions. These include CO_2/H^+-sensitive receptors associated with pulmonary arteries and lung tissues present in amphibians, reptiles, birds, and mammals. The significance of these receptors is unclear, and their evolutionary origin has not been investigated.

Other Reflexes

Ventilation is modulated by a number of reflexes other than those initiated by chemoreceptors. Pulmonary stretch has a profound influence on breathing, termed the Hering-Breuer reflexes. Receptors located in the lung and/or pleural tissues and stimulated by the pulmonary stretch associated with lung inflation terminate inspiration in a reflex that prevents overinflation of the lung. Similarly, pulmonary stretch lengthens the period between subsequent breaths, and pulmonary deflation hastens the next inspiration. Such reflexes are present in amphibians as well as mammals. Air-breathing fishes such as gar and lungfish show similar alterations in ventilatory volume and frequency with pulmonary inflation and deflation. The origin of these reflexes may relate to either protection of the fragile lung or buoyancy control, but their presence in primitive air-breathing fishes suggests that Hering-Breuer pulmonary stretch reflexes are as old as the lung itself.

Another important reflex has been termed the mammalian diving reflex. This comprises a host of respiratory and cardiovascular adjustments associated with the presence of water in the pharynx or on the face. This reflex is more pronounced in neonates than in adults of most species, notably mammals, and in mammals it is exaggerated by low temperature. The ventilatory component of this reflex is airway closure and inhibition of breathing, measures that prevent water from entering the lungs. Some aspects of this reflex are observed in almost every air-breathing species, including fishes, suggesting that reflexes protecting the lung from water arose in conjunction with air breathing in aquatic species.

Summary and Conclusions

From a review of key aspects of respiratory control in vertebrates, it appears that many of the components characteristic of the neuronal controller for air breathing in mammals may have predated tetrapods. These include the oscillators that generate respiratory rhythm and the chemoreceptors that regulate it.

Excitotoxicity in Neurodegenerative Disease

S L Budd Haeberlein, AstraZeneca, Södertälje, Sweden

Introduction to the Excitotoxic Theory of Neurotoxicity

Glutamate is the predominant excitatory neurotransmitter in the mammalian central nervous system (CNS) and activates several subtypes of excitatory amino acid (EAA) receptors, which fall into two functional groups – the ionotropic glutamate receptors and the metabotropic glutamate receptors (mGluRs). The ionotropic receptors are further divided into *N*-methyl-D-aspartate (NMDA), α-hydroxy-5-methylisoxazole-4-propionate (AMPA), and kainate (KA) receptors, which are named on the basis of their differential sensitivity to structural analogs. Under normal conditions, neuronal and glial uptake systems maintain the extracellular concentration of glutamate at or below low micromolar levels. However, during certain pathologic conditions, which will be discussed in the following sections, the extracellular concentrations of glutamate can be elevated or their receptors may become hyperactivated for other reasons, and can lead to neurotoxicity through a mechanism called excitotoxicity. Excitotoxicity quite literally means a toxic 'effect,' the death, even, of neurons, resulting from excessive excitatory input. Overstimulation of NMDA receptors is often a predominant factor in such situations.

It was first observed in the 1950s that the excitatory neurotransmitter glutamate could exert toxic effects on the nervous system under certain conditions. Following the systemic application of glutamate to mice, toxic effects on retinal neurons were described. Subsequent extensive studies by Olney and co-workers corroborated these toxic effects and extended this view by showing neuronal cell death following oral intake of glutamate or aspartate in brain regions devoid of the blood–brain barrier in mice and nonhuman primates. Olney hypothesized that glutamate-induced neuronal cell death was a general property of excitatory amino acids acting on central neurons, and later coined the term excitotoxicity.

With the introduction of structural analogs to the glutamate receptor agonists, local injections of the glutamate agonist kainate were shown to induce cell death with a similar pattern of damage in different brain regions, thus confirming the neurotoxic effect. Knockout mice lacking the glial glutamate transporters GLT1 and GLAST show elevated extracellular glutamate levels and the neurodegeneration characteristic of excitotoxicity. The different location of the brain damage induced by kainate alludes to the parallel discovery of the different glutamate receptor subtypes and led to further understanding of both the physiological role of glutamate as an excitatory neurotransmitter and its cytotoxic effects. Today, it is well recognized, that exogenous or endogenous agonists of excitatory amino acid receptors can induce cell death in CNS neurons through excessive ionotropic glutamate receptor activation.

Overstimulation of glutamate receptors induces the intracellular accumulation of several ions and second-messenger molecules, the most important of which may be the large influx of Ca^{2+}. Consequently the dysregulation and dysfunction in calcium signaling have been studied extensively.

Concerning the mode of cell death, glutamate-induced neuronal cell death was first judged from morphological appearance as necrotic. However, the observation of a delayed neuronal cell death in the penumbra of ischemic lesions and after EAA exposure has stimulated studies focusing on the mode of cell death. Today, there is compelling evidence that failure in extracellular glutamate homeostasis can result in different modes of cell death, with morphological and biochemical features of either apoptosis or necrosis, depending on the severity of the insult.

Clinical Relevance of Excitatory Amino Acid Neurotoxicity

The excitotoxic theory of neuronal cell death is supported by the connections between abnormalities in the glutamate system and disease states.There is evidence that excitotoxicity is involved in acute brain damage under pathophysiological conditions following status epilepticus, mechanical trauma, or ischemia. Moreover, glutamate cytotoxicity may also be partly involved in many neurodegenerative diseases, ranging from Parkinson's disease, Alzheimer's disease, Huntington's disease, and amyotrophic lateral sclerosis (ALS; also called motor neuron disease) to HIV-associated dementia. Some examples are cited in the following sections.

Hypoxia/Ischemia

Under conditions of local or global ischemia, neurons are deprived of glucose and oxygen, resulting in

energetic failure and subsequent decrease of ion gradients across the plasma membrane. During hypoxic/ischemic conditions, microdialysis measurements have shown substantial elevations in extracellular glutamate and other EAAs. Severe focal cerebral ischemia lasting from 20 min to 2 h has been shown to cause up to 20-fold increase in the extracellular concentration of glutamate, reaching concentrations of 25–80 μM. Since in central neurons glutamate exists in two pools, metabolic (cytoplasmic) and neurotransmitter (synaptic vesicle), there are two routes by which glutamate is released during ischemia. The plasma membrane depolarization which occurs subsequent to the energetic failure leads to increased synaptic release of glutamate, while the diminished Na^+ gradient is followed by attenuated Na^+-dependent glutamate uptake or even reversed glutamate transport in terms of transporter-mediated release of glutamate from both neurons and astrocytes. Moreover, osmotic cell swelling following the influx of Na^+, Cl^-, and H_2O can result in plasma membrane rupture and further release of cytoplasmic glutamate into the extracellular space. In summary, hypoxia/ischemia results in a secondary net increase in the extracellular glutamate concentration. This increase in extracellular glutamate results in excitotoxic damage. The implication of excitotoxicity in hypoxia/ischemia is corroborated by the observation that NMDA-type glutamate receptor antagonists can reduce neuronal death in animal models of cerebral ischemia. However, some negative results have been reported with glutamate receptor antagonists in models of ischemia, and the actual set of circumstances in humans appears to differ from the animal models. The metabolic and ionic changes in the ischemic region are not homogeneous; at the core, depolarization and the collapse of ion homeostasis occur rapidly and cells die by necrosis. The surrounding area, or penumbra, is a region with less severe metabolic inhibition. These cells go on to die by excitotoxic mechanisms over a delayed period. In animal models this delayed excitotoxicity is mediated by apoptosis, but whether a penumbral region exists in humans is yet to be firmly established. There are several lines of evidence, that neurons can undergo apoptosis following ischemia. Among various biochemical markers of apoptosis, DNA fragmentation and activation of caspase-3 have been observed in models for cerebral ischemia. Moreover, application of caspase-inhibitors in animal models of cerebral ischemia result in reduced infarct size and decrease cell death in cultured neurons following ischemia. In line with a downstream role, the therapeutic window for application of caspase inhibitors is longer than that of NMDA receptor antagonists such as MK-801.

Epilepsy

Histopathological studies on the brains of patients suffering from chronic epilepsy have revealed that certain brain regions show structural alterations, with severe loss of neurons and reactive gliosis. Brain pathology in epilepsy is described best for human temporal lobe epilepsy, resulting in sclerosis of the hippocampus that extends into the amygdala and the parahippocampal gyrus. Pronounced brain damage has been observed following sustained epileptiform activity with seizures lasting more than 30 min, called 'status epilepticus' (SE). Importantly, neuronal cell loss after SE is not distributed equally across all hippocampal subfields, and the extent of damage is in the order CA1 > CA4 > CA3 > CA2, thus indicating different susceptibility to SE-induced cell death.

In animal models of epilepsy using chemoconvulsant-induced or electrical stimulation-induced SE, similar patterns of brain damage are observed. Experiments aimed at the observation of ultrastructural changes have demonstrated that certain features of cell damage, such as swelling of dendrites and soma, are independent of the mechanism used to induce SE. Evidence for the implication of EAA-mediated excitotoxicity in SE-induced neuronal cell death arises from several experiments. First, the morphological appearance of cell damage following SE is similar to damage following systemic or local application of the glutamate receptor agonists L-glutamate, NMDA, or kainate. Second, the administration of ionotropic glutamate receptor antagonists can prevent cell death induced by epileptiform activity. Apoptotic cell death is primarily implicated in the pathology in epilepsy, as demonstrated by the upregulation of apoptotic gene expression and protein markers. Further, antiapoptotic treatments have been shown to reduce the extent of seizure-induced neuronal cell death.

Traumatic Brain Injury

Following head trauma, mechanical brain injury can be accompanied by secondary changes as 'metabolic' glutamate leaks uncontrollably from the neuronal cytoplasm, causing subsequent excitotoxic damage of surrounding neurons. However, compared to research on mechanisms underlying the cell damage in ischemia or epilepsy, studies on traumatic injury have been sparse and are complicated by heterogeneity in the initiating event. Studies have suggested the sudden release of EAAs from the cytoplasm into the extracellular space and subsequent energetic failure, as well as ultrastructural damage that can be diminished by NMDA antagonists, indicative of excitotoxicity. Apoptotic signaling is found in traumatic brain injury

(TBI), including activation of caspase enzymes, internucleosomal DNA fragmentation, and induction of immediate-early genes. However, in neonatal models of TBI (mortality and morbidity from head trauma is highest in children), the resulting excitotoxicity has been shown to elicit both apoptosis and necrosis. Necrosis occurs localized to the site of impact, and within 4 h of the insult, whereas secondary apoptotic damage occurs between 6 and 24 h and is found in regions surrounding the area of primary necrosis. In this model, the secondary damage was more severe than the primary damage was, suggesting a preponderance of apoptosis over necrosis, at least in the developing brain. Glutamate receptor antagonists protected against the primary damage, exacerbated the secondary damage, but have also been shown to be effective in patients with severe head injury.

Neurodegenerative Diseases

In addition to acute neurological disorders, many chronic neurodegenerative diseases may exhibit a component of glutamate-dependent neuronal damage, including apoptosis or injury to dendrites, axons, and synapses. Distinct neurodegenerative pathologies can be reproduced in animal models by, for example, kainic acid injection, and one theory is that excitotoxicity in chronic neurodegeneration is secondary to an impairment of cellular energetics. This theory hypothesizes that mitochondrial dysfunction leads to a chronic energy impairment which results in a reduction in membrane potential, and allows a physiological concentration of EAAs to become toxic. In support of this theory, the injection of inhibitors of mitochondrial energy production such as 1-methyl-1,2,3,4-tetrahydroisoquinoline (MPTP), malonate, quinolinic acid (QA), and 3-nitropropionic acid (3-NPA) produces lesions in animals similar to those in neurodegenerative disorders.

Additionally, elevated inflammatory responses in many of these diseases can also contribute to excessive glutamate release or decreased glutamate clearance.

Parkinson's disease Parkinson's disease (PD) is characterized by the selective loss of dopaminergic (DA) neurons in the nigrostriatal pathway. Administration of MPTP or 6-OH-dopamine to mice induces loss of DA neurons and a disorder that behaviorally and histologically resembles Parkinson's. Nigral DA neurons possess glutamate receptors, and they degenerate when exposed to EAAs. Studies have shown that the NMDA receptor antagonists MK-801 and 3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonate (CPP), and the glutamate release inhibitors riluzole and lamotrigine, can improve parkinsonian behavioral parameters in animals lesioned with MPTP or 6-OH-dopamine.

Several antiexcitotoxins are presently used as anti-parkinsonian drugs, including amantadine, memantine, and budipine. Originally thought to be anticholinergics, these compounds are inhibitors of NMDA receptors. The drugs are used at the concentration required for NMDA receptor antagonism, though budipine may primarily enhance endogenous dopaminergic activity. These drugs provide symptomatic treatment for Parkinson's disease (reduced tremor, akinesia, and rigidity) through attenuation of the hyperactive glutaminergic mechanisms in the subthalamic nucleus (STN).

Huntington's disease Huntington's disease (HD) is a hereditary neurodegenerative disease. The disease mutation consists of an expanded CAG repeat in the gene encoding for the huntingtin protein. Huntingtin is expressed throughout the CNS; however, the striatum is the primary site affected by HD, with secondary cortical damage. At the cellular level, striatal neurons contain bodies of cleaved and ubiquitinated huntingtin. The mechanism through which mutant huntingtin mediates striatal neuronal cell death is incompletely understood, but may, at least in part, involve transcriptional dysregulation and mitochondrial dysfunction.

Injection of the NMDA-like excitotoxin, quinolinic acid (QA), into the striatum of primates elicits chorei form movements and a neuropathology that emulates that seen in HD. Moreover, NMDA receptor-mediated neuronal apoptosis is enhanced in transgenic models of HD.

Alzheimer's disease Patients with Alzheimer's disease (AD) inherit the disease as a fully penetrant, autosomal dominant trait with a young age of onset. Early-onset AD is caused by defects in any of three different genes, all related to β-amyloid pathology. In the more common sporadic form of AD, there is no clear genetic link to increased β-amyloid, and molecular genetic analyses suggest that there are likely to be many genes that influence the susceptibility to AD (presenilin, etc.). It is well established that β-amyloid induces neurotoxicity, and may do so in part through excitotoxic mechanisms. β-Amyloid has been shown to generate oxidative stress and increased intracellular Ca^{2+}, and is reported to enhance glutamate-mediated neurotoxicity *in vitro*. Additional experiments suggest that β-amyloid can increase NMDA responses and thus excitotoxicity as well as cause NMDA receptor-mediated injury to dendritic spines.

Another potential link comes from recent evidence that glutamate transporters are downregulated in Alzheimer's disease and that β-amyloid can inhibit glutamate reuptake or even enhance its release. Activated or cleaved proteins that are a result of activated apoptotic pathways have been observed in postmortem Alzheimer's disease brains, but these could be related to apoptosis induced by excitotoxic and nonexcitotoxic mechanisms such as tau hyperphosphorylation, which is present in Alzheimer's disease. Finally, memantine, an NMDA receptor antagonist, has been approved by the European Union and the US Food and Drug Administration for the treatment of moderate to severe Alzheimer's disease, and most likely acts via its antiexcitotoxic mechanism of action.

Intoxication with Exogenous Excitatory Amino Acids

Several structural analogs of endogenous EAAs naturally exist, and these exhibit similar or even higher excitatory and neurotoxic potency compared to the endogenous EAAs. In 1987, an outbreak of domoic acid poisoning following ingestion of mussels occurred in Canada. Patients suffered from acute headache, seizures, and sensory dysfunctions, and showed motor signs. In four fatal cases, neuropathological studies revealed lesions predominantly in the hippocampus and amygdala, resembling the lesion pattern after application of the exogenous excitotoxin kainate. It was reconstructed that the mussels had accumulated domoic acid, synthesized by the phytoplankton *Nitzchia pungens*. Domoic acid is a structural analog of kainic acid, and is also synthesized by seaweed, but compared to kainate, domoic acid has a higher excitatory potency. Experimental administration of domoic acid to rodents and monkeys has resulted in brain damage with ultrastructural features resembling L-glutamate excitotoxicity.

Ingestion of the chick pea *Lathyrus sativus*, which contains another EAA structural analog, results in acute spastic motor signs following the consumption. The clinical features of this motor disorder, called 'lathyrism,' were known even by the ancient Greeks, but the presumed toxic component, the amino acid β-*N*-oxalyl-L-alanine (BOAA) was identified only some decades ago. Experimental administration of BOAA is known to induce the features of lathyrism in nonhuman primates, and application of BOAA to neuronal cell cultures results in cell death with structural features of excitotoxicity, although other work has contested these results and offered other theories of lathyrism. The high excitotoxic potency of this glutamate receptor ligand is in accordance with its high excitatory potency as an agonist at AMPA receptors.

Implication of Distinct Glutamate Receptor Classes in Excitotoxicity

L-Glutamate, the most abundant excitatory transmitter in the brain, binds to different classes of receptors comprising different types of ionotropic receptors as well as metabotropic receptors. Ionotropic glutamate receptors are ligand-gated ion channels, which are named after agonists that bind preferentially to these receptor subtypes. They include AMPA, kainate, and NMDA receptors.

AMPA receptors are widely distributed in the CNS and are expressed on many different types of neurons. They control a cation channel that is permeable to Na^+ and K^+ ions. Activation of AMPA receptors results in the fast onset of an excitatory postsynaptic current, with rapid desensitization. This current shapes the fast component of glutamatergic transmission in CNS neurons. Importantly, certain AMPA receptor subtypes can exhibit substantial Ca^{2+} permeability and thereby contribute to the Ca^{2+}-dependent form of excitotoxic cell damage. Ca^{2+}-permeable channels are formed from the selective receptor subunits GluR1 or GluR3, whereas co-assembly with GluR2 results in only poor Ca^{2+} permeability.

Another type of ionotropic glutamate receptor, the kainate receptor, is less well understood because of lack of sufficiently selective agonists and antagonists, but better compounds have recently been developed. As with AMPA receptors, kainate receptors control a cation channel that desensitizes rapidly. Since the agonist kainite activates kainate receptors but also AMPA receptors, their physiological and pathophysiological role remains elusive. Recently, results based on gene-targeted rodents lacking certain kainate receptor subtypes have extended our knowledge of localization and function of kainate receptors. From these studies one can conclude that kainate receptors are not only localized to postsynaptic sites but also appear to be localized presynaptically, suggesting a role for modulation of synaptic strength.

The third type of ionotropic glutamate receptor, the NMDA receptor, which is widely distributed in different types of CNS neurons, differs fundamentally from AMPA and kainate receptors in several ways. First, the pore is in general significantly more permeable to Ca^{2+} ions, and also to K^+ and Na^+ ions. The high Ca^{2+} permeability of the NMDA receptor-associated channel probably contributes to its often predominant role in excitotoxicity. In contrast to AMPA receptors, classical NMDA receptors exhibit a high single-channel conductance and desensitize much more slowly. Second, the opening of the ligand-gated cation channel not only depends on binding of agonist but is also voltage dependent,

since the channel is blocked by Mg^{2+} ions at resting membrane potentials, and depolarization of the plasma membrane is required to relieve the Mg^{2+}-dependent block. Third, activation of NMDA receptors requires binding of a co-agonist to the so-called glycine-binding site of the NMDA receptor. In contrast to the characteristics of these so-called classical NMDA receptors, composed of NR1 and NR2A, B, C, or D subunits, the presence of the newly recognized NR3A or B subunits can alter these properties, making channels that are less permeable to Ca^{2+} and far less sensitive to Mg^{2+} blockade.

The implication of different ionotropic glutamate receptor types in induction of brain damage has been further studied by the use of selective receptor antagonists. Experimental administration of competitive or uncompetitive NMDA antagonists or application of kainate antagonists attenuates cell death in cell cultures. Unfortunately, until recently, the clinical use of these receptor antagonists has been hampered by the inhibition of physiological NMDA receptor-mediated neurotransmission, resulting in various adverse effects. However, the uncompetitive NMDA antagonist memantine (1-amino-3,5-dimethyladamantane hydrochloride), which has been used for treatment of Parkinson's disease and Alzheimer's disease, is sufficiently tolerated because of it unique mechanism of action, as first shown in the laboratory of Stuart Lipton. Memantine is an open-channel, uncompetitive blocker, but has faster kinetics, particularly 'off-rate,' than does MK-801. This results in substantial inhibitory drug action under conditions of prolonged or pathological exposure to glutamate but much less inhibition under millisecond exposure to glutamate as occurs during normal neurotransmission.

Whereas the role of ionotropic glutamate receptors in excitotoxicity has been studied extensively, the significance of metabotropic glutamate receptors in excitotoxicity is less well understood. It appears that specific mGluR subtypes can be involved in modulation of ionotropic receptor-mediated excitotoxicity. Group I mGluRs comprise the subtypes $mGluR_1$ and $mGluR_5$, which in heterologous expression systems couple to phospholipid hydrolysis through phospholipase C. Among other effects, this results in second-messenger-mediated activation of protein kinase C, and Ca^{2+} release from inositol 1,4,5-trisphosphate (IP_3)-sensitive Ca^{2+} stores. Application of recently developed selective receptor ligands suggests that activation of group I, and particularly mGluR1, receptors can exacerbate NMDA-mediated excitotoxicity.

Group II receptors comprise the subtypes $mGluR_2$ and $mGluR_3$, which are negatively coupled to the adenylate cyclase pathway. Studies using selective agonists indicate that group II receptor activation results in protection against NMDA-mediated excitotoxicity. Likewise, group III receptors ($mGluR_4$ and $mGluR_{6-8}$) are negatively coupled to adenylate cyclase, and activation of $mGluR_4$ or $mGluR_8$ group III receptors results in attenuation of NMDA-mediated neurotoxicity.

Ionic Dependence of Excitotoxic Cell Damage

Activation of different ionotropic receptor types is linked to excitotoxic cell damage through their underlying ionic currents. Depending on the predominance of either Na^+ or Ca^{2+} influx, two different components of excitotoxicity have been suggested. Na^+ ion influx mediated by activation of NMDA-type and non-NMDA-type glutamate receptors is followed by secondary influx of Cl^- and H_2O and results in swelling of neurons. This acute form of cell damage depends on the transmembrane Na^+ and Cl^- gradients and can be prevented by extracellular substitution of Na^+ and Cl^- with impermeant ions. In contrast to the acute, primarily Na^+-dependent osmotic damage, a more delayed mode of cell death has been attributed to Ca^{2+} influx. This delayed Ca^{2+}-dependent cell death can be largely attenuated by inhibition of NMDA receptors, removal of extracellular Ca^{2+} ions, or buffering of cytoplasmic Ca^{2+} by membrane-permeable chelators. Therefore, the Ca^{2+}-dependent component was traditionally believed to be induced exclusively by NMDA receptor activation.

The finding that the late component can be mimicked by calcium ionophores in presence of Ca^{2+} ions has corroborated the Ca^{2+} dependence of the delayed cell death. However, the discovery of Ca^{2+}-permeable AMPA/kainate receptors has lead to the view that neurons expressing these Ca^{2+}-permeable non-NMDA receptors can also undergo Ca^{2+}-dependent delayed cell death. In summary, different routes of Ca^{2+} influx, such as through NMDA receptors, Ca^{2+}-permeable AMPA/kainate receptors, and voltage-dependent Ca^{2+} channels, which are all involved in physiological signaling, are implicated in excitotoxic cell death.

The suggested key role of Ca^{2+} in excitotoxicity has been subsequently confirmed by the finding that the extent of excitotoxic cell death correlates with the total amount of Ca^{2+} uptake and is independent of the route of entry. The Ca^{2+} overload observed following sustained stimulation of NMDA receptors results from the inability of cellular Ca^{2+} homeostasis, such as extrusion of Ca^{2+} across the plasma membrane by the Na^+/Ca^{2+} antiporter and Ca^{2+} ATPase or Ca^{2+} sequestration by the endoplasmic reticulum and mitochondria to remove the large influx of Ca^{2+}.

Interestingly, during sustained exposure to glutamate, the intracellular calcium concentration ($[Ca^{2+}]_c$) rises rapidly to a peak value and thereafter slowly recovers to an elevated plateau level. However, the $[Ca^{2+}]_c$ can also manifest a second, delayed increase, immediately preceding cell death. This delayed $[Ca^{2+}]_c$ increase is irreversible and reflects irreversible loss of cellular Ca^{2+} homeostasis. Although the interval between the initial Ca^{2+} spike and the delayed rise varies within a cell population exposed to NMDA receptor agonists, once this rise occurs within a neuron, it invariably precedes cell death. The temporal relation between neuronal Ca^{2+} levels and delayed cell death suggests that Ca^{2+}-dependent effector mechanisms are involved, which do not need sustained high Ca^{2+} levels but are triggered by transient changes in $[Ca^{2+}]_c$. Importantly, mild excitotoxic damage often leads to apoptotic-like neuronal cell death, while more intense insults, which decrease energy production and thus disrupt ionic homeostasis, result in osmotic lysis or necrosis.

Since many enzymes are activated by transient or sustained $[Ca^{2+}]$ elevation, various effector mechanisms may be implicated in Ca^{2+}-mediated excitotoxic cell death. Consequently, a variety of Ca^{2+}-dependent hydrolytic enzymes, including lipases and proteases, have been suggested to be involved in excitotoxic neuronal damage. Activation of the Ca^{2+}-dependent phospholipase A2 has been observed following NMDA receptor activation, and the subsequent catabolism of released arachidonic acid by lipoxygenases and cyclooxygenases (COXs) is also associated with concomitant production of reactive oxygen species (ROS). In addition, activation of phospholipase A2 and subsequent release of arachidonic acid may inhibit transporter-mediated glutamate uptake from the extracellular space.

Among several Ca^{2+}-activated proteases, the activity of the Ca^{2+}-dependent cysteine protease calpain is increased following glutamate receptor-mediated Ca^{2+} loading. Calpain activation results in proteolysis of structural proteins and degradation of the neuronal cytoskeleton. Recently, Pierluigi Nicotera's group has shown that calpain-mediated cleavage of Na^+/Ca^{2+} exchanger results in a massive, secondary Ca^{2+} overload after excitotoxic insult and therefore favors necrotic over apoptotic cell death.

Ca^{2+}-mediated activation of nitric oxide synthase is also a major pathway involved in excitotoxic cell death, since neurons constitutively express the isoenzyme neuronal nitric oxide synthase (nNOS). nNOS is activated by glutamate receptor-mediated $[Ca^{2+}]_c$ increases, and there is compelling evidence that nNOS activation is linked to excitotoxic damage because inhibition of NO formation results in protection of neurons from glutamate receptor-mediated cell death. Studies on nNOS-deficient neuronal cultures have confirmed the role of NO in glutamate receptor-mediated neurotoxicity, since in nNOS-deficient cortical cultures the toxic effects elicited by administration of NMDA are markedly attenuated. The role of NO in excitotoxicity is mediated at least partly through the reaction of NO with superoxide anions (O_2^-) to form peroxynitrite ($ONOO^-$).

Mitochondrial Dysfunction

Studies on the time course of glutamate receptor-induced $[Ca^{2+}]_c$ increase have demonstrated that if the neuronal cell does not succumb to the insult, $[Ca^{2+}]_c$ slowly recovers after the termination of agonist application. This recovery is due to Ca^{2+} homeostatic mechanisms such as extrusion across the plasma membrane by the Na^+/Ca^{2+} exchanger, as mentioned previously, and the Ca^{2+}-ATPase, or sequestration of Ca^{2+} into the endoplasmic reticulum and mitochondria. In theory, the driving force for Ca^{2+} ions to enter the mitochondrial matrix in energized mitochondria is formed by the strong electrochemical gradient for Ca^{2+} across the inner mitochondrial membrane, mainly due to the mitochondrial membrane potential, $\Delta\psi_m$. Normal energized mitochondria can take up substantial amounts of calcium. Net uptake of calcium occurs in isolated mitochondria whenever $[Ca^{2+}]_c$ rises above a set point in the high nanomolar range, indicating the dynamic equilibrium of mitochondrial uptake and extrusion mechanisms. Ca^{2+} uptake into mitochondria results in a decrease in $\Delta\psi_m$ that can be monitored in isolated energized mitochondria as well as *in situ*. This depolarization is due to the balancing of the charge transfer carried by Ca^{2+} ions by reentry of protons into the mitochondrial matrix. Under normal conditions, Ca^{2+}-induced depolarization is transient and serves to activate mitochondrial dehydrogenases and the mitochondrial ATP synthase. However, studies on *in situ* mitochondrial membrane potential using cationic fluorochromes have demonstrated convincingly that the time course of $\Delta\psi_m$ depolarization can vary considerably, and depends on the time of Ca^{2+} loading. Short pulses of NMDA result in at least partial recovery of $\Delta\psi_m$, whereas prolonged NMDA exposure or higher agonist concentrations result in sustained depolarization with negligible recovery. This sustained depolarization indicates that excessive Ca^{2+} uptake triggers mitochondrial bioenergetic failure. Sustained depolarization has been ascribed to various underlying mechanisms, and ROS seem to play a key role in several of the suggested hypotheses.

Figure 1 Schema of cell death pathways triggered by excessive *N*-methyl-D-aspartate (NMDA) receptor activity. The cascade of steps leading to apoptotic-like neuronal cell injury and death include NMDA receptor hyperactivation, leading to excessive Ca^{2+} influx, Ca^{2+} uptake into mitochondria, and subsequent mitochondrial dysfunction; toxic effects of free radicals such as nitric oxide (NO) and reactive oxygen species (ROS); and activation of apoptosis-inducing enzymes, including caspases and apoptosis-inducing factor (AIF). nNOS, nitric oxide synthase; PLA_2, phospholipase A_2; Cytc, cytochrome *c*; PAR, poly(ADP-ribose); PARP-1, PAR polymerase-1; PTP, protein tyrosine phosphatase.

In neurons, as in other tissues, mitochondria are a major source of ROS; nonetheless, mitochondria are susceptible to oxidative damage and nitrosative stress. Excessive Ca^{2+} uptake into isolated mitochondria is known to result in increased formation of reactive oxygen species, which in turn inhibit pyruvate dehydrogenase and tricarboxylic acid cycle enzymes as well as complex I of the respiratory chain. In intact neurons, ROS formation has been monitored with redox-sensitive fluorochromes, which are oxidized by ROS to form fluorescent molecules. These studies indicate that ionotropic glutamate receptor-induced Ca^{2+} loading enhances the production of O_2^-. Additionally, mitochondrial dysfunction triggered by mild excitotoxic insult can lead to both caspase-dependent and -independent apoptotic-like cell death. Several studies have shown that mild NMDA receptor-mediated insults lead to mitochondrial calcium overload, cytochrome *c* release, and caspase activation. Recently, NMDA toxicity has also been shown to be mediated in part via apoptotic-inducing factor (AIF) release from mitochondria, which is triggered by poly(ADP-ribose) (PAR) polymer generated from the activation of PAR polymerase-1 (PARP-1). Figure 1 summarizes key features of several of these excitotoxic pathways.

Role of Reactive Oxygen Species in Excitotoxicity

Evidence for the implication of ROS in excitotoxic cell damage arises from experiments showing enhanced production of O_2^- following ionotropic glutamate receptor and from studies using radical scavengers or inhibitors of the formation of certain ROS. These studies unequivocally demonstrate that removal of ROS results in attenuation of glutamate receptor-induced cell death.

Several Ca^{2+}-dependent processes that increase the endogenous production of ROS have been described, which are all assumed to be implicated in excitotoxic cell death following NMDA receptor activation. As stated previously, Ca^{2+} loading into mitochondria appears to be one important mechanism of ROS production under conditions associated with excitotoxicity. Apart from this mechanism, activation of Ca^{2+}-dependent phospholipase A2 has been observed following NMDA receptor activation, and catabolism

of released arachidonic acid by lipoxygenases and cyclooxygenases has been implicated in excitotoxicity through the concomitant production of ROS. In addition to Ca^{2+}, intracellular Zn^{2+} can be involved in excitotoxic pathways. During excitotoxic insult, peroxynitrite-induced Zn^{2+} release from intraceullular stores can trigger mitochondrial production of ROS, contributing to a p38 mitogen-acitvated protein kinase (MAPK)-dependent apoptotic pathway.

Some ROS exhibit a high reactivity with correspondingly short half-lives and can undergo many different reactions. Generally speaking, ROS can exert multiple damaging reactions to proteins, lipids, carbohydrates, and nucleic acids, thereby disrupting cellular functions. The increased production of ROS is therefore a potential threat to cellular homeostasis and neuronal survival if production is not balanced by the capacity of endogenous antioxidant mechanisms.

Apart from the inhibition of enzyme activity, the opening of a large nonselective pore in the inner mitochondrial membrane, termed 'mitochondrial permeability transition' (mPT), has been suggested as a key mechanism in neuronal excitotoxicity. The basic concept of a pore-mediated permeabilization of the inner mitochondrial membrane, rather than membrane damage, had been suggested as early as the 1970s. The early studies by Haworth and Hunter showed that various divalent cations could induce or prevent pore-mediated mitochondrial swelling. Dissipation of $\Delta\psi_m$, bioenergetic failure, and disturbance of mitochondrial Ca^{2+} homeostasis following activation of NMDA receptors all could be explained by opening of the mPT. However, conclusions regarding the involvement of mPT in neuronal excitotoxicity until recently were based on pharmacological experiments using the mPT inhibitor cyclosporine A and should be treated cautiously, since cyclosporine A also inhibits calcineurin and the multidrug-resistance channel. Our group has demonstrated that bongkrekic acid, a more specific inhibitor of mPT, could prevent NMDA-induced neuronal apoptosis, suggesting the involvement of mPT in this form of excitotoxic cell death.

Role of Nitric Oxide and Other Reactive Nitrogen Species in Excitotoxicity

Nitric oxide is a messenger molecule in the CNS that affects various cellular functions (e.g., neuronal transmitter release, synaptic plasticity, and gene expression). NO is produced by several types of cells expressing three distinct isoforms of the enzyme nitric oxide synthase (NOS; NADPH-diaphorase), which converts L-arginine into NO and citrulline: (1) neuronal NOS, (2) inducible NOS (iNOS) in microglia, and (3) endothelial NOS (eNOS) in endothelial cells of brain blood vessels. Unlike classical neurotransmitters, NO is freely diffusible and therefore cannot be stored in synaptic vesicles. Once synthesized, NO diffuses across cell membranes and thus can reach various compartments within the NO-producing cells and different types of surrounding cells. The absence of control over the activity of NO by release and reuptake mechanisms is functionally compensated by a tight regulation of its synthesis. Pharmacological experiments using NO donors, NOS inhibitors, or exogenous substrates (such as reduced hemoglobin) for competitive reactions with NO have suggested that NO is linked to neuronal cell death. Importantly, cell death under conditions assumed to induce excitotoxicity could be largely attenuated by inhibition of NO formation or blockade of NO effects. Subsequent studies on nNOS-deficient neuronal cultures confirmed the role of NO in glutamate receptor-mediated neurotoxicity, since toxic effects elicited by administration of NMDA are markedly attenuated in nNOS-deficient cortical cultures, compared with wild-type neurons. Since nNOS activity is known to increase with increasing calcium concentration, NMDA receptor-mediated calcium influx provides a mechanistic link between an excitotoxic insult and NO-mediated cell damage.

Although NO is a free radical, NO is not as reactive as are some ROS (such as hydroxyl radical), and the predominant contribution of NO to excitotoxicity has been suggested to depend on increased NO formation with concomitant production of O_2^-. Under this condition, O_2^- reacts with NO extremely fast to form peroxynitrite ($ONOO^-$). $ONOO^-$ can undergo a multitude of different chemical reactions with various substrates – for example, hydroxylation or nitration of tyrosine residues, lipid peroxidation, disulfide formation, or reaction with NO_2-like and OH-like properties; subsequently, this toxic molecule has been implicated in NO-induced cell damage. To date, several pathways of $ONOO^-$ toxicity have been suggested, but with respect to its high reactivity, it appears unlikely that these are the only mechanisms involved in NO-mediated cell death. Intense exposure to NO/O_2^- with resultant $ONOO^-$ formation has been convincingly demonstrated to result in neuronal necrosis because of energy failure, while mild insults lead to apoptosis.

Recently, S-nitrosylation (transfer of the NO group to a critical cysteine thiol, to form an SNO-protein) has been shown to modulate protein function. In some cases, neuroprotective pathways are initiated by such reaction – for example, by downregulation of excessive NMDA receptor activity or caspase activity. However, in several instances, S-nitrosylation of particular targets contributes to neurotoxicity.

Examples of such proteins that are nitrosylated to trigger neurodegenerative pathways and contribute to necrosis, apoptosis, or dendritic/synaptic damage include SNO-GAPDH, SNO-matrix metalloproteinases (MMPs), SNO-parkin, and SNO-protein disulfide isomerase (PDI).

NMDA Receptors on Glial Cells

In addition to NMDA receptors found on neurons, as already discussed, three studies have recently reported evidence for NMDA receptors on oligodendrocytes. Moreover, these receptors have been show to be pathophysiologically relevant to oligodendrocyte and myelin function in that overstimulation of the receptors could cause damage. The NMDA receptor-mediated currents of oligodendrocytes were made up not only of NR1 and various NR2 NMDA receptor subunits, but also of NR3A subunits. As we and our colleagues had previously shown, NR3 subunits can render NMDA receptors much less sensitive to blockade by Mg^{2+}, as was indeed found to the be case for the NMDA receptors on oligodendrocytes. Similarly, it was recently reported that the NMDA receptor-mediated currents found on cortical astrocytes were also highly resistant to Mg^{2+} block, raising the possibility that NR3 subunits may contribute to those functional receptors as well, and could be involved in pathological responses of glial cells.

Therapeutic Implications and Future Directions

The seminal 1984 publication of Roger Simon, Brian Meldrum, and colleagues showed that excessive NMDA receptor activity underlies ischemic damage to neurons. As alluded to in the preceding discussions, several major neurodegenerative conditions are also thought to manifest a component of NMDA receptor-mediated neurotoxicity. The newer studies showing the presence of NMDA receptors on glial cells suggest that white-matter diseases, such as periventricular leukolmalacia in infants and multiple sclerosis in adults, could have components of NMDA receptor-mediated neurotoxicity. Several reports have claimed that all NMDA receptor antagonists have failed in clinical trials. However, this is not correct, and this misinformation was then followed by the further misplaced claims that the failure of clinical trials occurred because white matter did not have NMDA receptors; hence, NMDA receptor antagonists were said not to be useful in preventing ischemic damage because white matter (axons and their surrounding myelin sheaths) and astrocytes are injured in addition to gray matter (neurons).

Actually, most NMDA receptors antagonists failed in prior clinical trials because they were poorly tolerated by humans at neuroprotective doses. Many prior studies did not use neuroprotective doses of NMDA receptor antagonists because such doses proved to be too toxic, or at least exhibited severe side effects. After all, the NMDA receptor is responsible for normal synaptic transmission contributing to long-term potentiation (LTP) and other important processes in many areas of the brain. Therefore, high-affinity, effective NMDA receptor antagonists block normal brain activity and lead to intolerable side effects, such as hallucinations, sleepiness, and even coma.

In fact, what was needed was a more gentle type of NMDA receptor antagonist, one that relatively spared normal synaptic activity while blocking excessive (pathological, probably representing extrasynaptic) activity. One such example of a clinically tolerated NMDA receptor antagonist that has passed multiple clinical trials is memantine, which, as mentioned previously, was recently approved by the Food and Drug Administration for the treatment of moderate to severe Alzheimer's disease and is also used clinically in Europe for vascular (multi-infarct or multiple stroke) dementia. While memantine may also interact with α7-nicotinic and 5-hydroxytryptamine (5-HT_3) channels, its major mode of action at clinically used concentrations is at the NMDA receptor. Our group showed that memantine is clinically tolerated because of its mode of action on the NMDA receptor – it is an uncompetitive antagonist that acts as an open-channel blocker, and, most importantly, with a relatively fast 'off-rate.' Uncompetitive action means that, at a fixed dose, the drug is relatively more effective against higher concentrations of glutamate than lower. This somewhat surprising phenomenon occurs because the action of an uncompetitive antagonist is contingent upon prior activation of the receptor by agonist, and more activation of the receptor is blocked to a greater degree. Additionally, the fast off-rate is a critical factor contributing to a low-affinity mechanism of action and thus to clinical tolerability. This tolerability in large measure occurs because memantine does not accumulate in NMDA receptor-operated channels because of the fast off-rate. Hence, memantine does not block subsequent physiological neurotransmission. This mode of drug action, employing an uncompetitive, fast off-rate (UFO), has recently led to the concept of clinically tolerated 'UFO' drugs, apropos since drug is present only when needed and then vanishes.

It has been argued that memantine has only a modest effect on rodent models of cerebral ischemia; in contrast, blocking Ca^{2+} influx occurring via acid-sensing channels (ASICs) or TMP7 channels appears

to be more effective. However, it is possible that activation of these channels is downstream of hyperstimulation of NMDA receptors, and if sufficient protection is afforded by adequately blocking NMDA receptors, the activation of these channels might not come into play. Along these lines, prior reports often used a submaximal dose of memantine, so the full neuroprotective, yet clinically tolerated, action of the drug was not achieved. In point of fact, a recent publication has shown that NMDA receptors may be very important in neuronal cell death from ischemia, because excessive NMDA receptor activity leads to phosphorylation and thus activation of ASICs. Similarly, TMP7 channels are activated only after severe hypoxic insults, which might be averted with adequate NMDA receptor antagonist treatment. Thus, all of these types of channels are important, but the most recent studies converge to the view that NMDA receptors may be even more critical in cerebral ischemia and other neurodegenerative disorders than has been appreciated in past years. Hence, as of this writing, we express a sense of renewed optimism that the recent, albeit modest, clinical success of memantine in Alzheimer's disease may in fact lead to similar treatment of other neurodegenerative diseases, cerebral ischemia, multiple sclerosis, cerebral palsy, spinal cord injury, glaucoma, and, therefore, both white-matter and gray-matter diseases with UFO-type NMDA receptor antagonists. Only further experimentation will tell if this premise holds true.

Executive Function and Higher-Order Cognition: Assessment in Animals

J D Schall, Vanderbilt University, Nashville, TN, USA

© 2009 Elsevier Ltd. All rights reserved.

General Issues for Animal Testing

Any use of animals in research is governed by laws interpreted by regulatory agencies and local institutions with which researchers must be conversant and compliant. Studies of cognition of necessity require measurements of behavior, and the behavior must be controlled in the context of the experiment. Verbal instructions are not effective, so animals must be coaxed to perform a task. The motivation to perform the task can be appetitive or aversive. Appetitive control occurs through pairing an event or behavior with a food or fluid reinforcement. Aversive control occurs through pairing an event or behavior with an undesirable stimulus such as electric shock or a brief loud noise. Aversive control can be used only if scientifically justified as, for example, in studies of anxiety.

Classical (Pavlovian) conditioning is accomplished by repeatedly pairing a conditioned stimulus (e.g., a tone) with an unconditioned stimulus (e.g., a puff of air) that reliably elicits an unconditioned response (e.g., an eye blink). The sensitivity of the animal to the conditioned stimulus can then be assessed by measuring the occurrence or magnitude of the unconditioned response as some characteristic of the conditioned stimulus (intensity, frequency, etc.) is varied systematically. Operant (instrumental) conditioning is accomplished by reinforcing an emitted behavior (e.g., looking at a spot of light) with a reward (e.g., a food item or fluid) or a punishment (e.g., a mild electric shock). Behaviors followed by positive reinforcements are more likely to be emitted in the future by an organism motivated to receive the reward. Behaviors that are followed by a negative reinforcement are less likely to be emitted in the future. Decades of research has detailed many principles and nuances of operant conditioning that the interested student can learn from a textbook on learning and memory. Also, detailed procedures for various species and situations can be found in the methods sections of peer-reviewed publications. Finally, we should also note the obvious specializations of behavior and associated cognition across the phylogenetic scale.

Taxonomy of Cognition

Stimuli can be presented and overt responses measured. However, to explain orderly and arbitrary relationships between responses and stimuli, it is now regarded as useful, if not necessary, to hypothesize certain covert processes mediating the encoding, selection, and categorization of stimuli and preparation of responses.

Before reviewing methods used to investigate higher order cognition in animals, we should begin by determining how to distinguish cognition from simple sensation and movement. We can also formulate at least a provisional minimal taxonomy of cognition. Reflexes are the most direct link between sensory and motor processes. It could be argued that any behavior that is not a reflex must include some cognitive component. It could also be argued that only behaviors that arise from or are concomitant with conscious mental content qualify as cognition. For the purposes of this article, we can be satisfied with an intermediate position that only holds that processes that intervene between or adaptively adjust sensation and movement constitute cognition. If so, then we can ask, how many cognitive processes can be distinguished reasonably? We will work with the following list:

- Perception, including categorization
- Attention
- Memory, including long-term and working memory
- Response selection and preparation
- Emotion
- Executive control

We are also interested in more complex activities that involve all of the processes listed previously:

- Decision making
- Problem solving
- Communication

Less space is devoted to processes that are described elsewhere in detail, and more space is devoted to less well-studied processes.

Methods to Study Perception

Discrimination and Categorization

Distinguishing the characteristics of stimuli for the purpose of guiding behavior has been investigated in many species. The testing requires designing alternative stimuli appropriate for the sensory apparatus of the particular animal and is based on the principle that two (or more) physically distinct stimuli can be rendered indistinguishable from one another by manipulation of

the magnitude of their physical differences. Thus, a natural component of an animal's behavior is placed under control of the stimulus and then the characteristics of the stimuli are varied to determine how sensitive the animal is to the variation of the stimulus. For example, monkeys can be trained to shift gaze or press bars to signal whether a visual stimulus has a particular color, shape, or pattern of motion. Similarly, rats can be trained to perform tactile discriminations with their whiskers, such as judging the width of an aperture, the texture of a surface, or the distance of a gap, or also to signal their discrimination of mixtures of odors. Animals are capable of making more complex sensory discriminations. For example, animals as diverse as monkeys and pigeons can learn rapidly to discriminate among color photographs of different categories of objects, such as trees, humans, fish, and water, and these discriminations are generalized to novel examples from the categories of objects.

Awareness

A fruitful line of inquiry in the past decade has investigated neural correlates of awareness in monkeys. This has been accomplished by presenting a single ambiguous stimulus that can be perceived as either of (usually) two alternatives to macaque monkeys trained to report which of the alternatives they perceive. One way to dissociate the presentation of a stimulus from the phenomenal awareness of that stimulus is to employ binocular rivalry. Binocular rivalry occurs when markedly different stimuli are presented to the two eyes (e.g., horizontal stripes to the left eye and vertical stripes to the right). The perception is not of some plaid combination but instead of the stimulus in one eye and then the other, alternating randomly until one or both stimuli are removed.

Another means of dissociating presentation from report is through visual masking. This is accomplished by presenting a stimulus that may be weak in some respect but not below threshold to detect and then rapidly thereafter presenting a stronger stimulus at the same or nearby location. The presence of the subsequent stronger stimulus results in a lack of awareness of the earlier stimulus; this is referred to as backward masking. Critical to these studies is some objective measure of how the sensory system registers the stimuli because animals are very likely to respond in a biased and stereotyped manner to ambiguous stimuli unless reinforcement contingencies prevent this.

Methods to Study Attention

To study the allocation of attention, the most common procedure is to present a cue that informs the animal that a response is required for a subsequent stimulus at the same location. In a fraction of trials, the test stimulus is presented at an uncued location. The difference in response time or discriminability of the test stimulus at the cued versus the uncued location is taken as a measure of the allocation of attention. Alternatively, multiple stimuli can be presented simultaneously with one of the stimuli distinguished by sensory properties, a prior cue, or a memory template to guide the response. The quality of response to the target in the presence versus the absence of distractor stimuli is taken as a measure of the allocation of attention. The more diverse the distractors' appearance and the more similar the distractors are to the target, the more attention demanding the task becomes. In addition, a stimulus with multiple attributes (e.g., color and shape) can be presented following a cue that instructs the animal to respond according to one of the attributes. The demand for attention can be manipulated by making the cued attribute more or less difficult to discriminate and by making the noncued attribute more or less potent. Note that in studies of the allocation of visual attention in space, it is essential to monitor gaze to prevent confounds introduced by movements of the eyes.

Attention has been investigated predominantly with nonhuman primates, but procedures have also been devised for rodents and even birds such as pigeons. Procedures to assess attention in a less specific sense have been formulated to study mouse models of attention deficit disorder. For example, mice can be trained to poke their nose into a hole to receive a reinforcement in response to a visual stimulus. By offering multiple alternative holes signaled by different lights turned on for short durations, the mice must attend to the stimuli to respond quickly enough to receive reinforcement. The attention capacity of the mice can then be assessed by manipulations of target light presentation rate, duration, salience, and temporal predictability.

Methods to Study Memory

Memory can be inferred by persistent and consistent changes in behavior following learning. An overview of classical and operant conditioning learning procedures was provided previously. Memory can be divided into short-term working memory and long-term procedural and declarative memory.

Short-Term Working Memory

Short-term memory has been studied using delayed-response tasks in which a stimulus or set of stimuli are presented briefly but a response cannot be produced

until after a retention interval typically lasting approximately 1–10 s. Animals can guide their responses by the location or identity of the stimuli. The task has been elaborated in various ways. Delayed alternation requires monkeys to select the object at the location that was not selected in the previous trial (delayed spatial alternation) or to select the object that was not selected in the previous trial (delayed object alternation). This task requires working memory retention across as well as within trials. Delayed match to sample exposes monkeys briefly to an object and then after an interval presents the target object plus a distractor object. Monkeys are reinforced for selecting through a gaze shift or a reaching movement the target object that they had observed previously. Delayed nonmatch to sample reverses the logic, requiring monkeys to select the object they had not observed previously. It is important to note that delayed-response tasks require not only working memory but also response inhibition to prevent premature movements and may also invoke response preparation if the monkey can anticipate the termination of the retention interval when it can respond.

Long-Term Memory

Memory persisting over days or months must be tested in a species-specific manner. For example, rats are commonly tested using spatial navigation through locomotion in a maze to locate a reinforcement. Also, the water maze was developed to assess spatial learning and memory in rats. It is commonly used with mice, but species and strain idiosyncrasies must be recognized in the interpretation of the results. A platform is placed at a particular location beneath the surface of a round pool of murky water. When placed in the pool, mice swim to locate the hidden platform, and learning can be measured by a reduction in the amount of time taken to locate the platform as the mice or rats encode orienting cues in the environment. Contrasting performance when the platform is hidden with that when it is visible permits resolving confounds of sensory or motor impairments.

Implicit in the description of all the complex tasks monkeys can be trained to perform is the fact that they have long-term memory. The nature and capacity of that memory has been probed largely through tests of categorization of stimuli and of relations among stimuli. More evidence for long-term memory is derived from learning sets (learning to learn), an improvement in the speed of acquisition of successive discriminations between arbitrary objects or of reversing responses when reinforcement changes. Learning set has been demonstrated in nonhuman primates as well as in dogs, rats, and some birds.

Methods to Study Response Selection and Preparation

All motor responses can be explained in terms of causes (the muscle contracted because the neuron fired), but some responses can be explained also in terms of reasons (the bar was pressed to obtain the food to satisfy the hunger). This section considers movements that can be explained in terms of reasons and not just causes.

Response Selection

Requiring an arbitrary response to a particular stimulus invokes a process referred to as stimulus response mapping. A wealth of studies of human subjects can inform the design of experiments with animals; however, it should be clear that different species are incapable of producing more or less complex mappings. The capacity of rodents to learn arbitrary responses through operant conditioning is more limited than that of macaque monkeys, for example. Studies with macaque monkeys have explored progressively more complicated degrees of mapping a response onto a stimulus so that we can say that monkeys are encoding instructions and following rules or even strategies.

At the lowest level, monkeys can produce an arbitrary response not directed toward a stimulus – for example, a shift of gaze to a location directly opposite a target (antisaccade). At the next level, macaque monkeys can be trained to produce arbitrary responses to specific cues on successive trials and to change the mapping if the reinforcement contingencies change (conditional motor learning). Monkeys can also be trained to produce an arbitrary sequence of a few movements guided by particular cues. Perhaps the greatest expression of this ability is seen in apes that learn sign language. In studies with humans, evidence for response selection is an increase in the latency to initiate the first movement with an increase in the number of movements in the sequence. Unfortunately, animal studies have not performed this simple test. Beyond producing sequences of movements in response to sequences of stimuli, monkeys can be trained to produce self-ordered sequences of responses in which successive responses are guided by previous responses.

At perhaps the highest level, macaque monkeys can be trained to respond according to alternative strategies that require flexibility in applying rules with no fixed stimulus–response mapping. For example, monkeys can switch between repeat-stay and change-shift strategies. To perform a task such as this, monkeys must remember the previous response, remember the stimulus or stimulus–response pair preceding that choice, use that memory to evaluate

whether the stimulus on the current trial was different from that on the previous trial, and apply the strategy to choose the same target when the stimulus repeated and to reject that target when the stimulus changed.

Response Preparation

The time of an overt response to a given stimulus is variable and unpredictable. Within that unpredictability, however, certain trends have been observed. For example, when given a warning ('ready') before an imperative trigger signal ('go'), subjects respond earlier and more reliably than when no warning is given. The interval between the warning and trigger signals is referred to as a foreperiod. Response time can also be influenced by repetition of stimuli or responses or by success in previous trials. To explain this variation, one can hypothesize a process that transpires after an instruction or warning signal and is influenced by events in preceding trials to influence the readiness to initiate a movement. Such a covert process may be called response preparation.

The influence of foreperiod on response time varies according to the statistical properties of the foreperiod. If the foreperiod is a fixed value of the appropriate interval, then the animal can learn to anticipate when it will elapse. If the foreperiod is too short (e.g., <100 ms), response time is unaffected because some time is needed for response preparation to engage. If the foreperiod is too long (e.g., >2000 ms), response time is unaffected because it is not possible to sustain response preparation indefinitely. Thus, foreperiods ranging from 100 to 1000 ms afford the largest reduction of response time. The reduction of response time occurs because the passage of time allows a sense of expectation, permitting preparation before the trigger signal so that sometimes the movement might occur before the trigger signal (jump the gun). In fact, such self-generated responses are clear evidence of a covert response preparation process.

Foreperiods can be randomized to reduce predictability. For example, the foreperiod on a given trial could be sampled with equal probability from the range 100 to 1000 ms. This does introduce some variability in response time, but response time tends to decrease as foreperiod increases, and anticipatory responses are often generated especially at the longest foreperiods. This occurs because although the foreperiods are selected randomly across trials, they have a maximum value (i.e., a deadline that the animal can learn through experience). The more time that elapses from the warning stimulus, the higher the probability that the trigger stimulus will occur given that it has not yet. This conditional probability is referred to as the hazard rate of the foreperiod. If the hazard rate increases, the foreperiod is referred to as aging. A nonaging distribution of foreperiods has a flat hazard function; in other words, the passage of time conveys no predictability about when the foreperiod will elapse. Nonaging foreperiod distributions have many short values and exponentially decreasing probability of progressively longer values. Response times obtained with nonaging foreperiods decrease little, if at all, as a function of foreperiod and anticipatory responses are produced rarely.

Further evidence for response preparation is the fact that partially prepared responses can be withheld if an imperative 'stop' signal occurs. This ability can be explained by hypothesizing another covert process that prevents movements. The stop signal or countermanding task has been introduced in the past decade into animal studies. The countermanding paradigm probes a subject's ability to control the initiation of movements by infrequently presenting an imperative stop signal in a response time task. The subjects' task is to cancel the planned movement if a stop signal is presented. Performance on this task can be accounted for by a race between a process that generates the movement (go process) and a process that cancels the movement (stop process). This race model provides an estimate of the stop signal reaction time, which is the time needed to cancel the planned movement. The stop signal reaction time can be used in tests of neural processes and manipulations.

Intention

The disposition to perform some act is a central feature of an intention, but intention cannot be identified entirely with response preparation. A statement of intention must also answer the question, 'Why was that done?' An answer about the causal path through neurons to muscles is not as satisfying as an explanation addressing the reasons for the action based on preferences, goals, and beliefs. In other words, to judge whether a movement was intended, one must refer to the agent's beliefs about which action must be performed in what circumstances to bring about the desired object of the intention.

These concepts about intention have been formulated in the domain of human interactions, but research describing communication and deception, for example, indicates that the attribution of intention to monkeys at least seems justified. A particular form of intention involves reasoning about the relation between observations of events in the environment and actions in that environment – in other words, about how actions result in consequences. In fact, some have concluded that guiding actions based on reasoning about the causes of events is uniquely

human. However, research has shown that rats can make correct inferences guiding responses for reinforcement on the basis of purely observational learning of causal relations between events. Comparable results have been obtained from nonhuman primates.

Methods to Study Emotion

Other articles should be consulted for details on emotion, and this article does not debate whether animals have emotions like humans. Most studies of animal emotion involve fear, anxiety, and depression. Being aversive, the procedures used in these studies deserve special scrutiny and oversight to ensure animal welfare in the pursuit of scientific information.

Fear in animals has been studied most effectively using classically conditioned fear responses. Fear conditioning is a form of learning in which fear is associated with a particular neutral stimulus (e.g., a tone) by pairing the neutral stimulus with an aversive stimulus (e.g., an electric shock, loud noise, or unpleasant odor). Ultimately, the neutral stimulus elicits the state of fear. Fear conditioning has been studied in numerous species, from snails to humans. In animals, conditioned fear can be measured as a period of attentive immobility (freezing), a potentiated startle reflex, as well as changes in heart rate, respiration rate, or muscle tension.

Learned helplessness occurs when an animal is exposed to inescapable aversive stimulation (e.g., electrical shock) and learns that it cannot control its environment. This is regarded as a useful model of human depression.

Anxiety has been investigated by putting mice in an open area and measuring how much time they explore in the exposed interior of the area; more anxious mice spend more time close to the walls.

Methods to Study Executive Control

When the environment is ambiguous or presents competing demands, or the mapping of stimulus onto response is complex or contrary to habit making performance prone to errors, then executive control is required to perform the task. Such executive control over the perception, selection, and response systems is seen as a central component of human cognition, and it can be investigated in animals, particularly nonhuman primates, in a variety of ways. The basic approach is to study how performance changes according to the history of trials. For example, if a particular movement is called for in response to a given stimulus on repeated trials, and then in a subsequent trial a different movement is called for in response to the same stimulus, then a cost will be observed in the accuracy and latency of that response. Such experimental paradigms are referred to as task switching. The cost for switching tasks can arise at least in part because of the conflict between producing the rehearsed response and producing the new response.

Response conflict can be investigated by training macaque monkeys extensively to respond to objects with multiple features such as color and shape with alternative responses cued by different features (e.g., red or circle means go and green or square means nogo). Once the mapping is mastered, testing proceeds by presenting congruent (e.g., red circle) stimuli that cue the same response and incongruent stimuli (e.g., red square) that cue the opposite responses. Evidence of conflict evoked by the incongruent features is slowed response times and increased error rates. Response conflict can be elicited in rats by training them to associate a response lever with a particular reinforcement (e.g., food pellet vs. sugar water). Conflict is induced by rewarding the correct responses with the reinforcement opposite the discriminative stimulus. In other words, by correctly pressing the bar associated with the food pellet stimulus, rats receive sugar water reinforcement and vice versa.

When performing in conditions that require executive control, errors are often produced. A cognitive process of error monitoring is believed to be a component of executive control. In human studies of choice responses, a sign of error monitoring is slowing of response time on the trial after errors.

Decision Making

This process has many aspects, most of which have been summarized. If we define a choice as an action performed in the context of alternatives to achieve a goal, we can appreciate that decision making occurs when the alternatives are vague or the payoffs are unclear. Accordingly, one approach to studying decision making requires animals to perform particularly challenging sensory discriminations; this can be done in any sensory modality. Another approach is to manipulate reinforcement amount or probability in a more or less predictable manner. A classic finding is that animals will produce alternative responses (e.g., bar presses) in direct proportion to the amount or probability of reinforcement for the alternative responses; this is referred to as matching law.

A popular area of inquiry in the past few years has applied concepts and procedures formulated in game theory and economics to the study of animal behavior. For example, monkeys are trained to perform tasks resembling games such as rock–paper–scissors or matching pennies. These mixed strategy games

allow investigators to explore whether theories developed to explain human decision making in games and economic settings apply to animal behavior. All of these approaches result in behavior that is more or less stochastic but amenable to analysis in terms of quantitative models of the processes hypothesized to produce the responses. This approach has shown that animals express in at least a rudimentary manner many of the biases that characterize human decision making. For example, monkeys show aversion to inequity by refusing a lower valued reinforcement if they observe another individual obtaining a higher valued reinforcement.

Problem Solving and Tool Use

Animal cognition is perhaps nowhere more evident than in the solution of problems, especially through the use of tools as highlighted by Kohler's pioneering studies of the use of tools by apes. Although several species learn to use tools in the wild as well as in the laboratory, it remains unclear to what extent animals understand the physical processes by which these tools are effective. In fact, some of the most interesting evidence to date that animals understand the causal properties of physical objects comes from birds, particularly the corvids (crows and ravens). For example, a New Caledonian crow spontaneously bent a piece of ineffective straight wire into an effective hook tool for retrieving food, and another species of corvid learns rapidly to avoid maneuvering food into a clearly visible and inaccessible trap. Chimpanzees do not fashion tools or avoid such traps without considerable training, but they do keep objects used as tools for future use.

Communication

None doubt that animals communicate in rich and diverse manners. For example, vervet monkeys in the wild exhibit a very advanced system of communication, but it is believed to be instinctive, not learned. What is more contentious is whether animals such as great apes can be said to learn language. Investigators have trained chimpanzees, bonobos, gorillas, and orangutans to communicate through symbols on a keyboard or sign language. Individual chimpanzees have acquired vocabularies of at least 200 words or signs and have demonstrated the capacity to respond appropriately and produce meaningfully different sentences.

Learning to produce words is not limited to primates. African gray parrots have gained notoriety through a phenomenal ability to learn words or even phrases, in some cases as complicated as songs. One individual bird has been trained to use English speech to label dozens of objects, features, and categories as well as use commands and requests.

Introduction

Executive functions include a range of processes that impact attention, working memory, goal setting, action selection and sequencing, and problem solving. Theories of higher cognitive function aim to account for how complex cognitive processes are carried out in the brain and may offer conceptual-level mechanistic explanations. Yet all too often, the mechanisms proposed to explain higher functions suffer from an implicit dependence on unspecified higher level control processes so that the actual neural mechanisms subserving the cognitive phenomena remain mysterious. This problem is called the homunculus problem. The term homunculus means 'little man' and refers to the unspecified higher level controller that is implicitly required by some theories of cognition. There has been much discussion about how to banish the homunculus – that is, to provide an explicit and mechanistic description of how control functions emerge and interact so that unspecified high-level controllers will not need to be invoked. Computational models of executive function provide critical tools in this effort. When conceptual theories are fleshed out in working computational models, accounts that claim to overcome homunculus problems are more compelling for several reasons. First, a viable computational model must work; it must actually perform a task and account for data. Second, all components of the model are explicit, which makes it easy to identify any control signal components of the model that are less well specified. Third, when a computational model does exhibit properties and behavior associated with executive function, it is easier to trace, specify, and quantify the origin and nature of the computational mechanisms that produce such cognitive properties and behavioral patterns.

Computational models of executive function include a range of formalisms from production systems to neural networks. Whereas production system models are typically more abstract, and involve symbolic processing, neural network models are more closely tied to neurobiological principles and constraints. Both types of models have focused on understanding the functions subserved by specific brain regions thought to be critical for executive control, such as the prefrontal cortex (PFC), anterior cingulate cortex (ACC), and basal ganglia (BG). Work since the late 1990s has developed a distinction between performance monitoring and control processes related to executive function, and this distinction provides a useful framework for delineating components of executive function. This article discusses computational models of distinct brain centers in executive function, and it concludes with a discussion of more abstract production system models of executive function.

Prefrontal Cortex and Control

Active Goal Maintenance

The lateral PFC is important for actively maintaining information via sustained neural firing that is robust in the face of potentially distracting information. The standard neural model of PFC has cells that reciprocally excite each other so that activity is self-sustaining: active neurons send excitation to other neurons that then send excitation back, creating a self-sustaining activity pattern that constitutes a stable attractor state. Once a particular population of PFC neurons is activated in this attractor state, it suppresses other populations via lateral inhibition. The state is maintained even when the inputs that activated the PFC are no longer present (i.e., working memory), and it is robust in the sense that activity persists despite other distracting inputs. *N*-methyl-D-aspartate (NMDA) channels may provide a cellular mechanism by which PFC cells that are more active become more easily excitable. As cells become active and depolarize, NMDA channels lose their Mg^{2+} block, thus increasing their conductivities at higher levels of depolarization. In a population of cells that reciprocally excite each other, this has the effect of enhancing self-perpetuating activity.

Neural network models of PFC are generally implemented as either rate-coded or spiking models. Rate-coded models quantify the cell activity as the instantaneous average firing rate of a local population of cells. Mathematically, a population of such rate-coded cells can exhibit bistable activity if the equilibrium output activity signal increases faster than linearly within a certain range. For example, if the input signal to a cell is doubled, the output signal from the cell would need to be greater than double at equilibrium in order for reciprocal excitatory activity to be self-sustaining. Models of PFC have been developed to account for a range of empirical data, including healthy

human and monkey performance of tasks that involve working memory, as well as executive control deficits in clinical populations such as individuals with schizophrenia and individuals with focal lesions of PFC.

Spiking models of PFC attempt to simulate the actual spikes generated by individual PFC cells. Typically, these models use a simplified integrate-and-fire scheme (which simulates action potentials as a point process) rather than a more sophisticated and computationally expensive Hodgkin–Huxley formalism (which simulates actual ionic channel kinetics and thus the full time course of the action potential). Spiking models have been developed to account for the data from single-unit recordings in awake, behaving monkeys performing a variety of tasks, including delayed match to sample, sequence learning, and various types of rule-based decision making. Other more biophysically detailed models have accounted for complex interactions among specific neurotransmitters and receptor types in mediating sustained activity, especially dopamine, NMDA, α-amino-3-hydroxy-3-methyl-4-isoxazole propionic acid (AMPA), and γ-aminobutyric acid (GABA) receptors. These models make specific predictions regarding the effects of different kinds of pharmacological manipulation on executive control.

An important computational problem involves the mechanisms that enable PFC networks to maintain information in the face of interfering input while at the same time appropriately updating stored information when relevant signals arrive. Various solutions have been proposed to solve this problem, and all of them involve an input gating mechanism. Opening the gate essentially involves making the attractor states become less stable by amplifying new inputs. The result of the open gate is that PFC is rapidly updated with the new input. In contrast, when the gate is closed, input signals do not disrupt maintained states. Some models of PFC gating depend on the neuromodulator dopamine. Cells in the ventral tegmental area (VTA) provide dopaminergic signals to the PFC. According to these models, transient increases in the level of VTA firing release more dopamine in PFC, which switches the PFC between fast updating and stable maintenance. The interactions among PFC cells and various D_1 and D_2 dopamine receptor subtypes are complex, and computational modeling has clarified how these elements work together functionally. In one model, dopamine D_1 receptor activation effectively stabilizes PFC states, whereas D_2 receptor activation leads to destabilizing effects. Others have argued that PFC stability follows an inverted U pattern, such that stability is greatest for a baseline level of dopamine but falls off rapidly for either too little or too much dopamine.

The dopamine-based gating models suffer from a limitation. The gating signal is global and nonspecific, so with these models, it is not possible to update certain areas of PFC while maintaining others. To address this issue, another class of gating mechanism has been proposed based on the strong reciprocal connections between the PFC and the BG complex. Neurons in the direct pathway of the BG drive a net disinhibition of the thalamus, which may in turn allow fast updating of selected parts of PFC. Conversely, neurons in the indirect pathway of the BG drive a net inhibition of the thalamus, which may effectively close the PFC gate and maintain stable representations against distractors in selected parts of PFC. Both the dopaminergic and BG gating mechanisms have included learning mechanisms, which allow the system to discover the appropriate signals and timing for opening the gate.

Biased Competition

Most computational models of executive control cast the PFC as serving a biasing function that regulates activity in other brain areas involved in domain-specific processing and behavior. The Stroop is the best known experimental task for illustrating the need for control biases. In the task, subjects view a color word (e.g., the words 'red' or 'blue') printed with an ink color that may be the same as (congruent) or different from (incongruent) the word (**Figure 1**). Subjects are asked to respond according to the ink color (the color-naming task) but to avoid responding based on the semantic meaning of the word (the word-reading task). For example, the word red presented in green ink (**Figure 1**) should elicit the correct response green, not red. This is a difficult task because for literate individuals, the automatic tendency to read a word is stronger than the process of indicating which color ink is used to write the word.

According to conceptual framework known as biased competition, activity in PFC representing the color naming task (the task demand units in **Figure 1**) strongly activates other areas in the brain responsible for generating specific responses based on the ink color. The PFC control signal does not directly determine the response but only enhances activity in other areas that determine the response according to the current rule. In the model of **Figure 1**, there are two task pathways, one for word reading and one for ink color naming. Each pathway can work in isolation from the other to produce task-appropriate processing and responses without executive control signals. However, control is critical when both the word-reading and color-naming pathways are simultaneously engaged. Under such conditions, there is competition during processing between the two dimensions of semantic meaning and ink color. In **Figure 1**, the thicker arrows from the word-reading units to the response

Figure 1 Executive control enables correct performance of the Stroop task.

units represent the stronger connection weights due to the effects of more learning and practice of reading words. The word-reading pathway will dominate processing competition in the absence of executive control. Thus, to be successful during execution of the color-naming task, the color pathway needs additional support to counteract the stronger weights on the word pathway. This support comes in the form of top-down biasing control, carried by a task demand unit (reflecting PFC), that represents the color-naming tasks. This task demand unit sends a signal that provides an additive source of activation to the entire input color dimension. When this control signal is present, the color pathway can successfully compete with the otherwise stronger word pathway to control responding. Conversely, without the strong biasing signal from PFC, the incorrect default response of word reading would prevail. Models of PFC that implement such control biasing signals have been found to account for human behavioral performance in a range of cognitive tasks that have Stroop-like properties of competition and interference from automatic processing tendencies.

Anterior Cingulate Cortex and Performance Monitoring

A key question in understanding goal-driven or top-down executive control is how and when it is engaged. Executive control mechanisms direct behavior, but what controls the executive? This question of what controls the controller relates to the homunculus problem discussed previously. In the case of executive control, there must be a mechanism that indicates when top-down attentional control is needed. The kinds of mechanisms that determine when control must be implemented do so by monitoring performance of the behaving cognitive system to detect the need for control.

Conflict Theory

One hypothesis that has received widespread interest is the so-called conflict monitoring account. For the purposes of executive control, conflict is defined as the coactivation of mutually incompatible response processes. This hypothesis takes as its starting point the theoretical idea that control is primarily required as a means of managing the cross-talk interference that can arise between concurrent and overlapping processing pathways in the brain. A measure of conflict provides a quantitative index of the degree of cross-talk between response pathways, and therefore the degree of executive control that must be exerted to resolve the interference. The critical addition of the conflict monitoring hypothesis is the adoption of an explicit mechanism which detects the presence and level of cross-talk interference and which conveys this information as an output signal that is used to regulate the engagement of top-down control signals. In some formulations, the conflict signal is computed

as the Hopfield energy of the response system. Essentially, this reduces to the multiplicative product of activity in two mutually incompatible response pathways. In the case of the Stroop task stimulus word red written in green ink (Figure 1), the conflict signal would be computed as the product of activity in the red and green response units. Various models have used other formalisms instead of the multiplicative model, but all compute a measure of coactivation such that two incompatible response pathways must be simultaneously coactive for a conflict signal to be generated.

Neuroanatomy

Based on an accumulating literature – primarily arising from human neuroimaging studies examining conflict-based interference effects – the area surrounding and including the ACC was identified as the neural locus of a conflict monitoring mechanism. The conflict monitoring hypothesis states explicitly that ACC implements the calculation of an online index of the conflict between competing representations, particularly at the response level. In computational models of conflict monitoring, fluctuations in ACC activity index ongoing fluctuations in conflict, and this information is then conveyed to the PFC, which in turn implements control strategies and maintains representations of the ongoing behavioral context. According to this hypothesis, more cognitive control is needed when conflict is high, but less is needed when conflict is low. The system is postulated to function as a closed loop, whereby the detection of conflict (in ACC activity) serves to engage control (in the PFC), which then acts to reduce the conflict experienced in similar future situations. Thus, the ACC has been identified as a mechanism that determines when executive control is needed and in turn activates the PFC to implement executive control. Models of the role of ACC in executive control have accounted for a variety of data from functional neuroimaging studies of cognitively demanding tasks in healthy individuals and clinical populations.

Conflict and Errors

In addition to the monitoring of response conflict, ACC also appears to be critical for situations of error commission. This brain region transiently activates both when conflict is high and when errors are actually committed. Computational modeling work reflects an ongoing controversy over the ultimate nature of performance monitoring functions in ACC. Much of the empirical data have come from studies using the event-related potential technique and focused on a specific scalp activity pattern known as the error-related negativity (ERN), which occurs at the time of error commission or at the time of explicit error feedback if the error was not predictable. There have been alternative computational models developed which postulate a specific and distinct role for the ACC in error detection rather than conflict monitoring, and these models make somewhat different claims about the function of ACC outputs in regulating behavioral performance. One class of models assumes that dopaminergic error signals drive or train the ACC to respond to errors. These models have accounted for the timing of error signals in ACC, such as whether the ERN occurs before or after receipt of feedback confirming that an error has been committed. The models have also addressed the greater magnitude of ERN signals in contexts in which errors are less frequent.

Work has also suggested that many of the phenomena originally thought to be uniquely captured by the error-detection models can also be successfully explained by the conflict monitoring account. Nevertheless, there has been a growing appreciation of the idea that the ACC may play a more general role in performance prediction and action outcome monitoring than just detecting the presence of errors or conflict. One computational model proposes that since errors are more likely when conflict is present, the ACC may generally compute the likelihood of an error based on previous learning. Despite some differences in implementation and focus, computational models of ACC primarily serve as a mechanism for evaluating the level of executive control needed in a given task situation.

Time Course of Executive Control

According to the conflict model, ACC monitors performance and then drives PFC to implement executive control. Early models suggested that control is implemented quickly, but there may be distinct timescales in which monitoring and control signals are effective. In particular, some kinds of control mechanisms may be implemented rapidly enough to detect and resolve conflict within a single trial, whereas others may use conflict detected in one trial to implement control in subsequent trials. A model of the Stroop task postulates a dual form of conflict detection: one acting in the short (i.e., subsecond) timescale and another in the long (i.e., several second/multiple trial) timescale. These different conflict measures in turn activate two separate forms of cognitive control, respectively called reactive and proactive control. Thus, a temporally extended period of high conflict will push the system toward a state of preemptive attentional control in which goal-relevant context is actively maintained across

trials to bias target-relevant aspects of attention, before stimuli are actually presented. In contrast, in situations of low conflict, this type of proactive control is not engaged. Instead, the actual detection of conflict within a trial (i.e., poststimulus presentation) rapidly engages a transient goal reactivation mechanism which can do rapid biasing of the target-relevant dimension. This computational model was able to successfully account for behavioral and brain imaging data from the Stroop task under conditions involving either a high percentage of incongruent trials or a high percentage of congruent trials. It should be noted that individuals may not be explicitly aware of changes in the frequency of conflict occurrence, and therefore the adjustments in attentional control may occur even in the absence of conscious intervention.

Multiple Kinds of Control

In the event that the need for greater control is detected, the PFC must determine what kind of control to implement. Different kinds of executive control signals have been dissected using task-switching paradigms. Task switching involves interleaved performance of two different cognitively demanding tasks. For example, the previously mentioned Stroop task might be modified so that subjects must perform the ink color-naming and the word-reading tasks on alternating trials. The most basic finding of task-switching studies is the switch cost, meaning that task performance is slower and more error-prone when a new task is performed than when an old task is repeated. The origin of the switch cost is controversial. In some models, the switch cost is due to the time needed for an executive controller to reconfigure the system to perform the new task. In other models, the switch cost is simply due to the lack of priming in the new task pathways, and therefore no executive control need be invoked to explain the switch cost.

Computational models of task switching provide insight into executive function by dissociating attentional and motor control processes. Returning to the Stroop task example, stimuli may be either congruent (e.g., the word red written in green ink) or incongruent (e.g., the word red written in red ink). Incongruent stimuli require more focused attention on the color of the ink while excluding the semantic meaning of the word from further cognitive processing. In contrast, when a task switch occurs, executive control may be required to implement the new task. Alternatively, as suggested by a more recent computational model, executive processes may not implement the task switch directly but may slow responding to enable the system to adequately process the new task prior to generating a response. Regardless of the particular form of motor control implemented, a distinction can be seen between attentional control driven by incongruency and motor control associated with the task switch.

Basal Ganglia and Action Selection

When multiple completing behavioral plans are formed and activated, an action selection mechanism allows one to be executed and suppresses or defers the remaining incompatible plans. This constitutes an executive control function. Some models posit a role of ACC in action selection, but a number of models of executive function have suggested that the BG play the main role in action selection. Of note, action selection may include control of external actions as well as internal manipulations such as deciding when and how to update the PFC state.

The BG consist of several subcortical nuclei. The striatum (caudate nucleus and putamen) receive projections from a number of frontal cortical structures. The striatum provides two main output projections. The first is known as the direct pathway, by which the striatum inhibits the internal pallidum, which in turn inhibits the motor thalamus. Computational models have suggested that the net effect of direct pathway activity is to facilitate action execution because striatal inhibition of the internal pallidum results in a net disinhibition of the thalamus, which may allow actions to be executed. In contrast, activity in the second output projection from the striatum (known as the indirect pathway) results in a net increased inhibition of the motor thalamus, which may prevent other actions from being executed. In this way, computational models suggest that the BG can actively allow some motor plans to be executed while simultaneously suppressing others. A related BG structure known as the subthalamic nucleus may further prevent multiple competing plans from being simultaneously executed. Thus, according to several computational models, these components of the BG apparently monitor ongoing activity in PFC in order to control which plans are executed.

In terms of performance monitoring, a number of BG models have focused on the substantia nigra pars compacta (SNC), which includes a dense population of dopaminergic cells that project widely to the other parts of the BG, especially the striatum. These SNC cells respond transiently to unexpected rewards and unexpected cues that predict reward, and they transiently pause their firing when an expected reward is not received. As posited by several computational models, these performance-monitoring signals train other parts of the BG to select the actions that are most likely to lead to reward.

Models of executive control by the BG have addressed a wide range of empirical data. Several

models of action selection in the BG have focused on neurophysiology. These have simulated and accounted for a variety of cell types found in the BG and connected areas of awake, behaving macaque monkeys performing cognitive tasks. Cognitive-level models generally employ a connectionist framework and have accounted for behavioral data in healthy and clinical populations, such as those with schizophrenia, Parkinson's disease, and Huntington's disease. These models have accounted for specific kinds of errors, both random and perseverative, on tasks thought to involve executive control, such as the Wisconsin Card Sort Task. These models have been applied to the domain of decision making and have been extended to include other structures such as the orbitofrontal cortex, which may serve to actively maintain (in working memory) reward prediction errors over an extended delay.

Production System Models

In contrast with neural network models, production system computational models do not explicitly simulate neural activity. Instead, they are often referred to as cognitive architectures. They rely on abstract formalisms from the field of machine intelligence, using a set of if–then conditional rules. A cognitive processor regularly evaluates the environment to determine whether a particular rule is applicable. When the conditions required for a particular rule are satisfied, then the operation specified by that rule is executed. In this way, external stimuli and internal goals lead to actions. Notably, multiple rules can be active simultaneously. Some models include specific assumptions about the time needed for a conditional rule to be activated and execute an action, and this allows production systems to make specific predictions about response time for comparison with human data, such as the psychological refractory period. Such models can also make predictions about reaction time in high-level tasks involving nested goals, such as planning tasks like the Tower of London, and the comprehension and production of complex sentences. These tasks have been traditionally difficult for neural network models to simulate. Executive control in a production system is needed to mediate among multiple rules and tasks that would otherwise interfere with each other when executed simultaneously. Such control may include lockout scheduling or interleaved scheduling. In lockout scheduling, the executive processes detect when two or more rules compete for simultaneous access to the same resource and allow only one to have access at a given time. Interleaved scheduling involves switching back and forth between the two processes. When executive control is explicitly specified, it is generally implemented as a set of rules that manipulate the internal state of the production system, such as the current goal state and working memory contents.

Executive Function and Higher-Order Cognition: Definition and Neural Substrates

Cognitive, or executive, control refers to the ability to coordinate thought and action and direct it toward obtaining goals. It is needed to overcome local considerations, plan and orchestrate complex sequences of behavior, and prioritize goals and subgoals. Simply stated, you do not need executive control to grab a beer, but you will need it to finish college.

Executive control contrasts with automatic forms of brain processing. Many of our behaviors are direct reactions to our immediate environment that do not tax executive control. If someone throws a baseball toward our face, we reflexively duck out of the way. We have not necessarily willed this behavior; it seems as if our body reacts and then our mind 'catches up' and realizes what has happened. Evolution has wired many of these reflexive, automatic processes into our nervous systems. However, others can be acquired through practice because learning mechanisms gradually and thoroughly stamp in highly familiar behaviors.

For example, consider a daily walk to work. If the route is highly familiar and if traffic is light, our mind can wander. Before we know it, we may have gone a considerable distance and negotiated street crossings and turns with little awareness of having done so. In these cases, the control of our behavior occurs in a 'bottom-up' fashion: it is determined largely by the nature of the sensory stimuli and their strong associations with certain behavioral responses. In neural terms, they are dependent on the correct sensory conditions triggering activity in well-established neural pathways.

Suppose, however, that during our walk to work something unexpected happens or we encounter difficulty. For example, we might encounter a busy street that we need to cross. Then, the executive system takes over and we need to 'take charge' of our actions. We pay attention to the people and cars around us to anticipate and accommodate their actions, or we may decide to take an alternate route. Now, straightforward stimulus–response associations are insufficient to govern our behavior. We must use knowledge of our current objective (arriving at work on time and intact) and results from previous experiences to weigh the alternatives and consequences. During this 'controlled mode,' we also engage the basic sensory, memory, and motor processes that mediate automatic behavior. Only now, the environment is not simply triggering these processes. Instead, we use our current goals to shape and control these processes in a 'top-down' fashion.

Figure 1 summarizes these ideas by illustrating a widely accepted view of the architecture of cognition. At the lower level are the automatic processes, which include sensory analysis, memories, details of motor acts, and well-learned skills. The system is in automatic mode when processing flows through the lower level, from input to output, along established pathways without any hindrance or modification. However, at any given instant the executive system can step in and modify this flow should it detect that the automatic processes are no longer sufficient to obtain our goals. In understanding the neuronal mechanisms that underlie this process, the prefrontal cortex (PFC), the brain area directly behind our forehead, seems especially critical.

The Prefrontal Cortex

PFC has dramatically expanded in size and complexity across evolution, and its development correlates with the complexity of the behavioral repertoire exhibited by an organism. It has reached its pinnacle in humans, in which it accounts for approximately 30% of the total cortical area. It consists of a collection of cortical areas that differ from one another in terms of the size, density, and distribution of their neurons. Figure 2 shows the major PFC divisions of the monkey PFC, although anatomists have subdivided these further, describing at least 18 distinct areas. The subdivisions have partly unique, but overlapping, patterns of connections with the rest of the brain, which suggests some regional differences in function. As in much of the neocortex, however, there are local connections between different PFC areas that can result in an intermixing and synthesis of the disparate information needed for cognitive control.

PFC is anatomically in a good position for a central role in executive control. Collectively, the various PFC areas have interconnections with brain areas processing external information, including all sensory systems and cortical and subcortical motor system structures, as well as internal information from limbic and midbrain structures involved in affect, memory, and reward. Indeed, neuronal activity in PFC reflects the multimodal nature of its inputs. PFC neurons

Figure 1 Two levels of cognitive processes. Specialized functions that acquire information about goals and means (top) select and coordinate among innate and well-established routines (bottom). Inputs from the environment are 'bottom-up,' whereas signals based on knowledge about goals and task demands are 'top-down.' Active processing lines are shown in blue.

Figure 2 The monkey prefrontal cortical areas with some connections. (Left) Dorsal is yellow, dorsolateral is red, ventrolateral is green, and orbital is blue. The medial PFC is not pictured. (Right) Some extrinsic and intrinsic connections. Not all connections are illustrated; this figure is meant to convey how the PFC can synthesize and integrate diverse inputs from other brain structures.

encode visual, auditory, tactile, olfactory, and gustatory cues, as well as recalled memories and behavioral responses such as voluntary limb and eye movements. In short, the functional and morphological anatomy of PFC is consistent with its role in synthesizing diverse information about the external and internal world in order to produce goal-directed behavior.

PFC Contributions to Executive Control

PFC damage does not result in simple deficits; there is relatively little overt impairment, at least with superficial examination. Patients with PFC damage have intact sensory capabilities, they can remember events and facts, and they appear remarkably normal in casual conversation. However, despite the superficial appearance of normality, PFC damage devastates a person's life. Patients have trouble staying employed, married, or even completing simple daily errands. Furthermore, they often seem to act without any apparent consideration to future consequences. Careful testing of PFC patients has revealed a number of underlying cognitive deficits that might explain their impairments.

Inhibition

PFC damage often produces 'stimulus-bound' behavior. Patients engage in whatever habitual behaviors

happen to be triggered by cues in the immediate environment. For example, when they see a glass of water, they may drink it regardless of whose glass it is. Because other learning and memory systems are intact, they can learn to respond to specific cues in specific ways. However, they then become stuck in that behavioral rut, producing the same response to the cue even when it is no longer appropriate – a phenomenon called 'perseveration.'

Planning

After PFC damage, the basic units of behavior remain intact. What is lacking is the ability to organize them toward a goal. For example, one patient, when making coffee, first stirred and then added milk. Another example is a patient who had been an excellent cook until she had a large tumor removed from her frontal lobes. Her basic skills remained but she seemed unable to organize them. She would move haphazardly from preparing one part of the meal to another so that some parts of the meal would burn, whereas others had hardly been started.

Evaluating Consequences

Goal-directed behavior depends on our capacity to evaluate the consequences of our actions so that we can choose an optimal plan. Evidence that certain types of PFC damage impair this process comes from a gambling task. The subject has to choose cards from four different decks. Some cards win the subject some money, but others cause the subject to lose money. Unbeknownst to the subject, cards from two of the decks will occasionally win large amounts of money but are also occasionally associated with very large losses. Thus, consistently choosing from these decks will lead to a net loss. In contrast, if the subject chooses from the other two decks, he or she will win smaller amounts, but the losses are also smaller, so that overall the subject will obtain a net profit. Control subjects quickly learn to limit their choices to the profitable decks, whereas patients with PFC damage, particularly of the orbital region, continually choose from the decks associated with large rewards and larger losses until they lose all their money.

This led to the hypothesis that the orbital PFC is responsible for labeling cues or situations with an affective significance or 'somatic marker.' It associates memories of past, affect-laden events with a representation of the state of the autonomic nervous system that the event evoked. Similar events in the future can then evoke a 'gut feeling' of the appropriate course of action by recall of the somatic marker. This is particularly helpful in very complex situations in which it is difficult to evaluate rationally and deliberatively all the pros and cons of a choice.

Further evidence that PFC neurons participate in this process comes from studies showing that a large proportion of them encode information about expected rewards. For example, some neurons encode the delivery of a reward, whereas others respond when a reward does not occur as expected. After training, many PFC neurons will show responses to visual cues that signal whether a reward will or will not be forthcoming and reflect the identity, size, and preference of an expected reward.

Working Memory

The importance of a short-term memory buffer for cognition is apparent to anyone who has tried to do math in their head; intermediate answers and operations must be buffered in a way that allows them to be kept 'in mind.' The pattern of deficits following PFC damage might be sequelae of an underlying deficit in working memory. Patients may have difficulty planning or appear disinhibited because without working memory, goal-relevant information is lost over all but the briefest delays and thus their behavior takes its cue from the immediate environment.

This hypothesis stems from observations that PFC damage in monkeys impairs a spatial delayed-response task that requires them to remember the location of a stimulus or behavioral response over a brief delay of several seconds. In addition, there are many studies illustrating that PFC neurons sustain their activity over several seconds to bridge short delays imposed between a cue and a response – observations that Fuster, Niki, and colleagues first made in the 1970s. Goldman-Rakic and colleagues used a more controlled version of the task using an oculomotor response to a visual target presented in the periphery of the visual field. They demonstrated that dorsolateral PFC neurons have precise tuning for memories of particular visual field locations.

In humans, a similar task, called the 'two-back' task, is sensitive to PFC damage or dysfunction. Subjects observe a sequence of sample stimuli and must respond if a current sample stimulus matches one seen two samples ago. Because this involves matching to a specific stimulus, it may rely on working memory rather than other, more passive, forms of immediate memory, such as those that automatically detect repetition.

PFC activity sustains brief memories of a wide range of behaviorally relevant cues: objects, colors, the frequency of a vibration to the hand, and forthcoming movements. Similar activity is also evident in the sensory and motor systems. This is not

surprising; sustained activity is evident in many brain structures and must play a role in many neural processes from sensory afterimages to holding a motor state. However, specificity and robustness are what separates more 'cognitive' short-term memory processes, such as working memory processes, from such lower level processes. Working memory selectively retains task-relevant information, rather than just any stimulus, and does so over potential distractions. PFC neurons have this ability. For example, when monkeys are required to sustain the memory of a sample object across a delay period filled with visual distractors that require attention and processing, sustained activity within the PFC can still maintain a memory of the sample object. By contrast, sustained activity in visual cortical areas seems more labile; it is disrupted by the presence of distractors.

Learning and Using Rules

The PFC is important when we need top-down processing – that is, when our internal states or intentions guide behavior. It is critical in situations in which the mapping between sensory inputs, thoughts, and actions is weak relative to other existing ones or when the mapping is rapidly changing. In such circumstances, we often rely on previously constructed models of regularities in our environment and our expectancies of future events – the so-called 'rules of the game.'

Conditional learning tasks are a laboratory test of rule learning. They require learning of associative relationships that are arbitrary and extend beyond the simple one-to-one mappings that underlie reflexive reactions. Whether or not a given response is the correct response to a given cue constantly changes because it depends on additional information. For example, reaching for a beer can be rewarding, but only if one considers other information. If the beer belongs to another patron, the result could be disastrous. Monkeys with PFC damage are impaired at a variety of conditional learning tasks. When monkeys learn associations between, for example, three visual cues and three directional movements of a joystick, simply moving the joystick is not enough to produce reward. Rather, the specific movement direction is dependent on the specific cue. One means 'up,' the other 'down,' etc. Following PFC damage, monkeys have difficulty acquiring this task. Furthermore, PFC neurons encode multiple aspects of conditional tasks, including the sensory cues, the motor responses, and the specific associations between the cues and responses (Figure 2).

PFC is also essential in enabling the control of behavior by abstract, high-level rules. Consider, for example, dining in a restaurant. We are not born knowing how to act in this situation. Instead, after several experiences in restaurants we begin to abstract the common features of importance. For example, we learn the important sensory information deserving our attention (e.g., the wine list), typical events, appropriate actions, and expected consequences (e.g., paying the bill). The rules underlying ordering a meal in a restaurant are essentially networks of predictive relationships between immediate cues, internal and external context, and actions and consequences long divorced from the details of the individual restaurants in which we have dined. We can then use these abstract rules to order a meal in any subsequent restaurant, even those in which we have never dined before. Several investigators have argued that the encoding of rule information is a cardinal function of the PFC.

One task that directly tests this ability is the Wisconsin Card Sorting Test (WCST). The patient is required to sort a deck of cards on which there are a number of colored shapes. The patient has to determine by trial and error the correct property by which to sort the cards. For example, if the 'color' rule were in effect, the subject would have to sort the cards according to the color of the shapes. Unbeknownst to the subject, the experimenter can switch which is the correct rule, and the subject needs to detect this and modify his or her behavior accordingly. Patients with PFC damage, particularly lateral PFC, have difficulty doing this. Using more focal, experimentally induced lesions in monkeys, experimenters have confirmed that lateral PFC is the most important PFC region for rule or strategy implementation. Furthermore, studies show that single PFC neurons are capable of encoding abstract rules. For example, monkeys saw two pictures appear successively separated by a delay. At the start of the trial, a cue instructed the monkeys to release a lever if the two pictures were either the same or different. Thus, to solve the task the monkeys had to maintain in working memory both the picture and the currently relevant abstract rule (same or different) during the delay. Many PFC neurons, more than one-third, encoded the abstract rule.

What function does the ability to abstract a rule serve? Abstraction is a type of generalization that permits a shortcut in learning, allowing us to apply what we have learned in similar situations to novel circumstances. Without the ability to abstract the general principles behind related situations, we would have to learn the correct behavior on each new occasion by trial and error. The problem with such trial-and-error learning is that errors necessarily occur. This is a less efficient way of dealing with novelty since errors frequently lead to lost opportunities for reward. Consistent with these ideas, PFC seems to be most important when subjects must deal with novel situations.

Neurobiological Models of Executive Control

Note that the pattern of deficits following PFC damage seems to reflect a selective loss of the higher level functions from the bipartite cognitive architecture pictured in Figure 1. Well-established automatic routines on the lower level are intact and available to be triggered by the appropriate sensory cues. However, without the higher level functions specialized to acquire and represent goals and means, the system would be at the mercy of the environment, ruled by whatever sensory inputs happen to flow into the system and by whatever thoughts, emotions, and actions are strongly associated with these inputs. Thus, behavior would seem impulsive and disinhibited and reactions inappropriate because they would be emitted reflexively without any consideration of the future. Furthermore, without the influence of predicted goals to continually drive task-appropriate processes, individuals would be distractible and would easily go 'off track' when there are temporal gaps between sensory inputs or between those inputs and the individual's responses. The system might be capable of learning to react to cues, but this learning would be inflexible. Without the ability to predict goals and means, the system would be stuck in a behavioral rut, always reacting to a cue with whatever behavior it was first associated.

This architecture is also apparent in neurobiological models of executive control. Network models of Dehaene and Changeux include an executive layer of 'rule-coding' units, thought to correspond to the PFC, that controls the flow of information between the input and output layers (Figure 3(a)). Arthur Shimamura proposed a dynamic filtering model of PFC function in which patterns of information sustained by the PFC select and reroute the flow of activity in posterior association cortex (Figure 3(b)). Miller and Cohen proposed that the cardinal PFC function is to acquire and actively maintain patterns of activity that represent goals and the means to achieve them (rules) in terms of a map of the cortical pathways needed to perform the task (hence 'rulemaps') (Figure 3(c)). Under this model, activation of a PFC rulemap sets up bias signals that propagate throughout much of the rest of the cortex, affecting sensory systems as well as systems responsible for response execution, memory retrieval, emotional evaluation, etc. The aggregate effect is to guide the flow of neural activity along pathways that establish the proper mappings between inputs, internal states, and outputs to best perform the task. In short, rule information is acquired by the PFC, which provides support to related information

Figure 3 Models of PFC function. (a) The models of Changeux and Dehaene include an executive level (level 2, thought to correspond to the PFC) with rule-coding units and working memory units that gate the flow of activity along lower level input–output lines. (b) Shimamura's dynamic filtering model. At time 1, a region in PFC is activated by feed-forward (i.e., bottom-up) projections from posterior cortex. This activity, along with influences such as task demands, sets up a pattern of activation in PFC (light circles, activation; dark circles, inhibition). At time 2, posterior cortex is modulated by PFC via feedback (i.e., top-down) projections that enable both selection of task-relevant and inhibition of task-irrelevant neural activity. Figure provided by Arthur Shimamura. (c) In the Miller and Cohen model, a task model is formed in the PFC when reward signals link together neurons activated by the events that led to reward. A subset of cues can then activate the entire representation. Bias signals resulting from the maintenance of this pattern guide the flow of activity along neural pathways that establish the task-relevant mappings between representations of inputs (C1, C2, C3), internal states, and outputs (R1, R2) in posterior cortex. Thick lines and solid circles denote active processing lines. Reproduced from Miller EK and Cohen JD (2001) An integrative theory of prefrontal function. *Annual Review of Neuroscience* 24: 167–202.

in posterior brain systems, effectively acting as a global controller or 'traffic cop.'

A key issue is to understand how PFC acquires these high-level representations. One possibility is that they develop through the action of reinforcement signals on multimodal PFC circuitry. During learning, when a behavior meets with success, reward signals augment the unique pattern of PFC activity evoked by that situation, action, and consequence by strengthening connections between the neurons activated by those events. These representations might begin quite modestly, but with time and repeated iterations of the process, the PFC representation can 'bootstrap' into further elaboration as combinations of events and contingencies between them and the requisite actions are learned. Midbrain dopaminergic neurons have ideal properties for the reinforcement signal. Early in learning, rewards activate dopamine neurons, but later in learning the cues that predict those rewards activate dopamine neurons rather than the rewards. Furthermore, there is an inhibition of the firing rate of the dopamine neurons when an expected reward does not occur. This 'reward prediction error' signal is ideal for instructing when and what the system should learn and consequently enables the organism to acquire the representations necessary to achieve reward.

The resulting pattern of PFC activity reflects the task's contingencies and in neural terms amounts to a 'map' of the pathways between inputs, internal states, and outputs needed to perform the task successfully. The ability to construct this map arises from the intermingling of diverse information that takes place within PFC. Although the PFC may be critically involved in acquisition of this information, other parts of the brain may be responsible for its consolidation in long-term memory. The PFC, however, would retain the requisite links to retrieve the appropriate pattern and bring it online to guide behavior.

Summary

Executive control refers to the ability to take charge of one's actions and direct them toward unseen aims. Virtually all theories of cognition posit that executive control requires making predictions about available goals and what means might achieve them. This knowledge can then be used to select and coordinate among a myriad of lower level, automatic sensory, memory, and motor functions.

The PFC, a brain structure that reaches its greatest complexity in the primate brain, seems to play a central role in executive control. It has access to all major forebrain systems, as well as the means to influence them. Individuals with PFC damage seem capable only of emitting habitual or innate reactions to the immediate environment without any consideration or anticipation of future consequences and unseen goals. Neurophysiological studies indicate that PFC neurons seem to mediate the mechanisms essential for a cognitive control system: They are multimodal, they acquire and signal the formal demands of tasks, and they can sustain their activity to keep task-relevant information online and available during behavior.

Different theories of PFC function emphasize different contributions to cognitive control: maintenance and/or manipulation of information in working memory, the assignment of affective tags on events and choices, and the acquisition and online representation of task rules. These theories are not mutually exclusive; each may reflect different facets of a system that is necessarily multivariate because of its role in guiding many different behaviors and interfacing with many other brain systems. However, in the healthy individual, the different processes work in harmony and enable the organism to behave flexibly and cope efficiently with novel situations, which are hallmark features of PFC function.

Introduction

Multiple goals, from survival to pleasure, coexist at every given moment, and internal needs as well as external events act in a push–pull manner to bias behavior. To maintain optimal goal-directed behavior, a control ('executive') system is needed that will dynamically prioritize the processing of information as well as the planning of actions and their execution. In addition to direct motor planning, major components of this executive system are working memory, attention, and conflict/error monitoring. Working memory would allow maintaining a goal across time, as well as information required to achieve the goal. Selective attention ('voluntary' or 'endogenous' attention) would facilitate the processing of one stream of input and suppress another while involuntary attention mechanisms allow for changes in the environment, as well as changes in internal drives, to interfere with ongoing behavior in a rapid and flexible manner. A monitoring module is needed to assess the efficiency of the executed behavior so that behavior can be adjusted in an optimal way. Consequently, the executive system needs to interact with multiple sensory regions of the brain, as well as with motor output regions involved in orientation, locomotion, and speech. Event-related brain potentials (ERPs), recorded on the scalp (and recently also intracranially) have established scalp-recorded signatures of executive functions. The effect of brain lesions on these measures of electrical brain activity provides a window into the networks supporting the executive system. This article describes ERP studies conducted specifically with patients suffering from well-circumscribed brain lesions involving mainly the lateral prefrontal cortex (LPFC), a major hub of the executive system.

Selective Attention

Patients with LPFC damage are frequently unable to suppress inappropriate reaction to objects and events in their environment (so-called environmental dependency syndrome) or to suppress prepotent responses. Whereas some of these effects may be at the level of response selection, ERP studies of these patients suggest that LPFC is essential for normal suppression of information processing at the level of unimodal sensory cortices.

Knight and coworkers delivered auditory stimuli (clicks or tone bursts), or brief electric shocks to the median nerve, to patients with damage to LPFC and to patients with comparably sized lesions in the temporoparietal junction or the lateral parietal cortex, as well as to age-matched controls. Both types of stimuli were distractors, not relevant to the task. Lesions in posterior association cortex, sparing primary sensory regions, had no effects on the amplitudes or latencies of the primary cortical evoked responses. Lesions invading either the primary auditory or somatosensory cortex reduced early latency (20–40 ms) evoked responses generated in these regions. In a distinct contrast, LPFC damage resulted in enhanced amplitude of both the primary auditory and somatosensory evoked responses generated 20–40 ms poststimulation. Spinal cord and brain stem potentials were unaffected by prefrontal damage, indicating that the amplitude enhancement of primary cortical responses was due to abnormalities in either prefrontal-thalamic connectivity or direct interactions between LPFC and sensory cortex. Selectively attending to a sensory stream and maintaining the goal of behavior requires not only enhancement of processing of some sensory stimuli or motor plans, but also suppression, or inhibition, of competitive stimuli or plans ('biased competition'). Apparently, a signal from LPFC to upstream sensory cortices provides such a biasing signal. Failure to produce such a signal may impair selective attention.

The failure to inhibit irrelevant sensory input indeed affects the patients' performance. Chao and Knight showed that patients with LPFC lesions are impaired in an auditory delayed-match-to-sample task when the delay period is filled with irrelevant tone pips. In the same task, the irrelevant tones elicited abnormally augmented primary auditory potentials (Na, Pa) in the patients, and the performance decrement directly correlated with the Pa enhancement. Similarly, in patients with right prefrontal damage, sounds presented to an unattended ear in a dichotic paradigm abnormally reduced the attentional enhancement (see the section titled 'Novelty and deviance detection and involuntary attention shift') of subsequent to-be-attended sounds. In agreement with these findings, patients with prefrontal lesions show reduced or even reversed negative priming effects, which suggests that processing of stimuli that should be outside the focus of attention is not properly suppressed.

The role of the LPFC in biased competition is not limited to inhibition. In fact, LPFC may also provide the excitatory signal. This excitation may be

implemented through three distinct mechanisms: (1) through a tonic excitatory influence on ipsilateral posterior areas, affecting attended and nonattended sensory inputs alike; (2) by enhancement of extrastriate cortex response to attended information; and (3) by a phasic excitatory influence on ipsilateral posterior areas' response to correctly perceived task-relevant stimuli (targets). This was shown in a series of ERP studies conducted by Knight and colleagues in patients with LPFC damage (centered on Brodmann's areas 9 and 46), in which the patients were asked to detect rare (odd ball) targets (inverted triangles) in a series of distractors (upright triangles). This paradigm is referred to below as the triangles task.

When the stimuli in the triangles task were presented at fixation, the patients showed a diminished extrastriate N1 component (at 170 ms) relative to controls. A similar reduction of N1 was observed in another experiment, which used visual word stimuli. Even more revealing were conditions in which targets and nontargets were lateralized and could appear in either visual field. In one of these conditions, the patients were instructed to attend to all stimuli regardless of location. The extrastriate P1, immediately preceding the N1 component, was reduced for all stimuli presented to the contralesional hemifield. Moreover, when the patients' attention was directed to one of the fields at a time, this reduction of P1 over ipsilesional extrastriate cortex was observed for attended and nonattended contralateral stimuli alike, and can thus be considered attention independent. Thus, LPC seems to exert a modulatory, tonic, attention-independent facilitation over processing at ipsilateral extrastriate cortex. A similar effect of reduced association cortex activity ipsilateral to LPFC damage has been reported for auditory-induced N1 potentials.

Directing attention to one hemifield in a target detection task normally elicits a sustained negativity (known as 'selection negativity' or 'negative difference'), starting at around 100 ms, for all stimuli presented at this hemifield. When attention was directed to the contralesional visual field of LPFC patients, this attention effect on extrastriate cortex was normal in the first 200 ms after stimulus onset but was significantly disrupted thereafter. This finding suggests that LPFC exerts attention-dependent selective facilitation starting around 200 ms after stimulus onset. Other cortical areas are probably responsible for attention-dependent regulation of extrastriate cortex in the first 200 ms. It is conceivable that inferior parietal cortex is responsible for the early reflexive component of attention whereas LPFC is responsible for more-controlled and sustained aspects of visual attention beginning later on. The effect of LPFC lesion on the selection negativity is not limited to visual areas. In an auditory selective attention task, prefrontal lesion patients generated reduced selection negativity as well. Notably, this diminished attention effect depended on the side of the lesion. Patients with left hemisphere lesions showed a mildly reduced attention effect regardless of which ear was attended. In contrast, patients with right prefrontal damage showed reduced effect mainly when the contralateral ear was to be attended. Posterior association cortex lesions in the temporoparietal junction had comparable effects on the selection negativity regardless of ear of stimulation.

Target detection in the visual oddball paradigm described above is normally associated with a prominent late response, starting at 200 ms and continuing for the next 500 ms, including the N2–P3b complex. Since this component is elicited only by detected targets, it is considered to be a manifestation of phasic top-down effects contingent on the identity of the stimulus. Following LPFC lesions, the N2, a component which likely reflects postselection processing of the target in the inferior temporal lobe, was not observable over the lesioned hemisphere in response to targets in either visual field. The P3b was reduced over the temporo-occipital electrodes but not at parietal sites, attesting to the fact that the P3b most likely reflects multiple distinct cortical processes related to target detection. The patients' performance in this study, producing more errors, was concordant with this electrophysiological evidence of impaired top-down effects following LPFC lesion. A spatially limited reduction of target P3 was recently reported also by Daffner et al., although in that group of LPFC patients, the main reduction of target P3 was reported to be in anterior electrodes. Thus, in addition to both attention-dependent and attention-independent tonic facilitation, the LPFC is critical in establishing a phasic, stimulus-dependent facilitation.

Novelty and Deviance Detection and Involuntary Attention Shift

Task requirements in an experimental setting, as well as the ongoing goals in natural settings, require that a subset of the sensory stream and a subset of motor plans be preferentially processed and, at least in humans, be available for conscious awareness and deliberation. However, such biased selection may be perilous as events outside the focus of attention might pose either dangers (e.g., an approaching predator) or opportunities (e.g., prey). Such events may be slight perturbations of an established sensory regularity, such as an intensity decrement in background noise, or grossly unexpected ('novel') events, such as the sound of screeching brakes. This need calls for a

surveillance mechanism that automatically detects deviant events.

Automatic response to slight changes in acoustic regularity outside the focus of attention bears the electrophysiological signature of the 'mismatch negativity' (MMN), a frontal scalp negative potential accompanied by lower temporal positivity, with a peak latency of 100–250 ms following the deviation. The MMN presumably reflects an 'error signal' generated automatically in the secondary auditory cortex by a neural mechanism comparing a perceived stimulus to a sensory 'memory trace' formed by the regular stimuli or the process of updating the existing model of the environment. The MMN is elicited when participants attend to a primary task and ignore the stream of sounds in which the pertinent deviations occur. Although it might be somewhat attenuated outside the focus of attention, it is completely suppressed only under very specific circumstances of competition for processing a specific feature between two auditory streams. Moreover, whereas attention-related components of the ERP are largely absent when deviation is predictable (e.g., when a deviation occurs regularly in the stream), the MMN is immune to this manipulation. Thus, the MMN is considered to represent a nonintentional, largely preattentive process. This signal may be a trigger for an ensuing shift of attention toward the deviant event. These shifts are reflected on the scalp as a positivity following the MMN, called P3a.

The P3a is a positive frontoparietal scalp potential peaking around 300 ms following the onset of a rare, task-irrelevant distractor in an oddball sequence. The novelty P3a is similar in response to either novel sounds or visual stimuli. The P3a is considered a marker of attention orienting, elicited by a distributed multimodal corticolimbic system. Both the MMN and the novelty P3a components were shown to be reduced in patients with PFC lesions.

In paradigms designed to study the MMN, patients and controls watched silent movies or were engaged with a visual reaction time paradigm and were instructed to ignore series of repetitive sounds. Infrequently, the regularity of the sound stream was broken by the occurrence of a deviant stimulus. The MMN in response to pitch and pattern changes was reduced in patients with PFC lesions, indicating an early deficit in automatic detection of deviance outside the focus of attention. Whereas temporoparietal lesions caused an MMN reduction mainly to contralesional stimuli, LPFC lesions elicited comparable deficits regardless of stimulus side in one study, and more to ipsilesional sounds in another. In addition, there was a tendency for right prefrontal lesions to be associated with larger MMN reductions than left prefrontal lesions were, but no such asymmetry was found for the temporoparietal lesions. These results suggest different contributions of the temporoparietal region and the prefrontal region to the MMN. Further research will be needed to determine whether the reduced MMN following prefrontal damage reflects a weakened memory trace of the previous regularity due to disinhibition of irrelevant information, reduced frontal facilitation of a comparator mechanism in the secondary auditory cortex (which is the main generator of scalp MMN), a failure to initiate an attention switch following the detection of the change, or damage to a postulated frontal generator of MMN. In addition, it is still unclear whether the effect of LPFC damage is independent of the dimension of the regularity which is disturbed (e.g., spatial location, pitch, or more-abstract dimensions of the sound).

Novelty P3a responses generated over prefrontal scalp sites to unexpected novel stimuli are reduced by prefrontal lesions, with reductions observed throughout the lesioned hemisphere. Comparable P3a decrements have been observed in the auditory, visual, and somatosensory modalities in humans with prefrontal damage. Reductions appear to be more severe after right prefrontal damage. In most studies of novelty P3a, the novel stimuli are completely task irrelevant, and the response is considered to reflect an 'involuntary' orienting response toward the salient event. Accordingly, galvanic skin response, a peripheral marker of the orienting response, is also reduced by damage to the prefrontal as well as posterior association cortex. LPFC damage caused a dramatic reduction in P3a amplitude even in a paradigm in which the novels where relevant to one of two tasks the patients were involved with. In the paradigm used by Daffner et al., patients had to self-pace a succession of visual stimuli while also looking for a designated (non-novel) target. LPFC patients not only showed a significantly attenuated P3a response to novel visual stimuli but also spent less time than controls did looking at novels, suggesting a more general decrement of 'novelty seeking.' Taken together, these findings converge with both clinical observations and animal experimentation supporting a critical role of prefrontal structures in the processing of novel stimuli, probably as part of a prefrontal-hippocampal network.

Monitoring

In demanding task situations, it is important to detect when actions may be erroneous and to adjust behavior to avoid additional mistakes. Evidence from electrophysiological and neuroimaging studies suggests that the anterior cingulate cortex (ACC) and the LPFC are active in situations demanding such monitoring activity. Evidence linking the ACC to action monitoring

derives from studies of error-related negativity (ERN), an ERP that occurs at the moment of an error in cognitive reaction time tasks. Dipole localization studies of ERN suggest that it is generated by a medial frontal structure, most likely the ACC. Functional magnetic resonance imaging (fMRI) studies examining error processing confirm the presence of ACC activation associated with errors or with situations prone to errors. A rare single unit recording in a human patient showed that dorsal ACC is associated with the use of rewards to guide action and further that ablation of the dorsal ACC increases errors in a situation requiring reward processing. Also, fMRI studies demonstrate that in addition to the ACC, activation may occur also in LPFC in conflict situations. Some of these studies suggest that activation in the ACC and LPFC is not related to errors *per se* but rather to the need to avoid errors or losses in more-demanding situations. Co-occurrence of prefrontal and cingulate activity related to error processing has been observed also in single-neuron recordings from nonhuman primates, as well as in intracerebral recordings from implanted depth electrodes in epileptic patients. These observations have not determined, however, whether the ACC and the LPFC interact or are independent.

The question of the interaction of the ACC and the LPFC was investigated by Gehring and Knight, who measured ERN in a group of patients with unilateral circumscribed lesions of the LPFC. A normal pattern of ERN activity in these individuals would indicate that the medial frontal regions operated independently of the LPFC in generating the ERN. In contrast, an absence or reduction of ERN activity in these individuals would indicate that the LPFC was either necessary for generation of the ERN in the ACC, or was itself a generator of the ERN. Other disruptions in the pattern of ERN activity would suggest that LPFC modulated the generation of the ERN, perhaps by supplying information or activation that was critical for ACC processing.

Six patients were studied, four with left and two with right LPFC damage. They were compared to ten age-matched controls and ten younger individuals. Participants made a squeezing response to a pair of letters, one of which was designated as a target letter. One letter appeared in red and the other in green. At 1 s before the letter pair, a precue (the word 'red' or 'green') indicated which letter was the target letter. The task was to respond with one hand if the target letter was 'H' and with the other hand if the letter was 'S'. On half of the trials, the irrelevant flanking letter was identical to the target letter; on the other half of the trials, the irrelevant flanking letter signaled the incorrect response (a manipulation that provoked erroneous responses).

The patients were slower than the control groups but did not perform with more errors than the control groups did. However, they showed less online corrective action in error trials. While controls showed reduced squeezing force during error trials, suggesting online inhibition of response, patients showed a reduction in this effect. In addition, the patients corrected their error less frequently than controls did. The pattern of the patients' electrophysiological response was also dramatically different from that of the control groups. Whereas in the young and age-matched controls, the response-locked negativity was significantly larger during error trials than during correct trials (i.e., it was an ERN), there was no difference between the error and correct trials in the patients with LPFC lesions. However, this did not result from absence of negativity. Rather, an ERN was seen for correct trials just as often as for incorrect trials, and this ERN was not different in amplitude from the response elicited by the controls during incorrect trials.

This pattern suggests an interaction or interdependence between the LPFC and the ACC in error or conflict monitoring. However, it is not consistent with a simple serial model in which the LPFC detects the need for executive control during high-conflict situations and signals the ACC, which performs the actual control function. Nor is it compatible with a serial model in which the ACC detects conflicts and transmits to the LPFC, which exerts its executive control functions. Since the most conspicuous observation was the lack of differentiation between correct and error trials, one possible account suggested by Gehring and Knight was that the damaged LPFC failed to represent or transmit the contextually appropriate stimulus–response mapping. As a consequence, the ACC may not have been able to confirm a correct response and thus elicited an ERN by default for every trial. Alternatively, the impaired stimulus–response representation in the LPFC might have created an additional conflict in each trial, detected by the ACC. In both cases, the ACC would produce an unreliable cue for errors, reflected in the disruption of corrective responses.

Conclusion

The behavior of patients with LPFC lesions suggests an interruption of executive and attentional control at multiple levels. Thus, in everyday life, patients may inadequately respond to environmental stimuli, be disproportionately distracted by irrelevant information, and be unable to focus on a task, on the one

hand, and unable to flexibly shift from one goal to another (perseveration), on the other hand. The data from electrophysiology reveal the role of LPFC in automatic processes such as maintaining an adequate level of responsiveness to all stimuli, detecting change, and processing novelty, as well as controlled processes such as inhibition of irrelevant information, enhanced processing of relevant information, phasic responses to targets, and conflict monitoring. Moreover, the electrophysiological data reveal that LPFC implements some of these functions through interaction with remote regions of the brain, including unimodal sensory cortices, the hippocampus, and the ACC. All these effects are evident early (100–300 ms) in the course of neural processing.

Executive Function

The terms executive function and cognitive control-refer to cognitive processes associated with the control of thought and action. Putative control functions include the ability to (1) selectively attend to relevant information while filtering out distracting information (selective attention and interference suppression), (2) work with information that is currently being held in working memory (manipulation), (3) flexibly switch between tasks (task switching), (4) inhibit inappropriate response tendencies (response inhibition), and (5) represent contextual information that determines whether a thought is relevant or whether an action is appropriate (e.g., task-set representation).

Although a number of control processes have been proposed, it is unclear which of these putative processes are distinct from one another. Thus, an important challenge in cognitive control research is to identify a set of elemental control processes and to understand the brain mechanisms underlying each of these processes. One approach that has proven useful for dissociating cognitive processes is the study of patients with various forms of neurological disease and damage. This approach, however, is not without its limitations. As such, convergent evidence from brain imaging techniques is proving increasingly useful.

Probing Executive Function with Neuroimaging Techniques

Functional magnetic resonance imaging (fMRI) has proven useful for identifying brain regions involved in cognitive control. As such, this technique allows us to test whether tasks involving putatively distinct control processes recruit separable brain networks. On the other hand, fMRI allows us to determine whether different tasks that involve a common control process recruit some of the same brain regions.

Prefrontal cortex (PFC) has long been implicated in executive function. Indeed, in 1895, the Italian physiologist Bianchi observed that experimental ablations of the frontal lobes destroyed the ability to synthesize incoming percepts together and to integrate these with outgoing motor commands. Since this early work more than a century ago, countless experiments have been conducted with a variety of techniques to better understand how PFC exerts control over other brain regions.

It is now clear that PFC should not be considered a monolithic structure; indeed, this expansive region constitutes roughly one-third of the human brain and consists of a number of different subregions. Each of these subregions is thought to provide a distinct contribution to cognition via different cellular characteristics and anatomical connectivity. As such, the use of a technique with high spatial resolution, such as fMRI, is essential for determining whether two executive tasks rely on the same or different PFC subregions.

Additionally, it is clear that if we want to understand cognitive control mechanisms, we must examine how PFC interacts with other brain regions. Some information about these interactions can be gleaned from functional connectivity analyses of fMRI data, although fMRI provides little information about the timing of these interactions. For several decades, event-related potential (ERP) data from electroencephalography (EEG) studies have contributed to our knowledge about the timing of control mechanisms. The ERP research of Robert Knight, involving patients with PFC lesions and healthy controls, demonstrated that PFC is necessary for top-down enhancement of relevant information in primary sensory regions.

Tasks Used to Study Executive Function

The most common type of executive task requires participants to override a prepotent response tendency. In the widely used Stroop task, one must override the impulse to read a word out loud and instead indicate the name of the color in which the word is printed (Figure 1a). In the go/no-go paradigm, one must press a button in response to a series of rapidly presented visual stimuli but must inhibit responding to a particular stimulus (Figure 1b). The continuous performance test known as AX-CPT is similar to go/no-go but additionally has a monitoring component because one must respond to an X followed by an A, but not to an X followed by a B. In the flanker paradigm, one must press one of two buttons in response to a central target stimulus while overriding the response specified by distracters on either side of the target (Figure 1c). In a task-switching paradigm, one must switch abruptly from one task rule to another (Figure 1d). This type of paradigm is thought to involve both suppression of the prior task rule and retrieval of the new rule. Here, several experimental paradigms are discussed in-depth.

Selective Attention

Goal-directed behavior hinges on the ability to focus on relevant information and ignore distracters, a

Figure 1 Standard versions of several tasks commonly used to study executive function: (a) the Stroop task, (b) the go/no-go task, (c) the Flanker task, and (d) an example of a task-switching paradigm. Variants of these basic paradigms have been used in a number of brain imaging studies.

function referred to as selective attention and/or interference suppression. Although the neural mechanisms are not yet fully understood, a widely accepted model proposed by Desimone and Duncan postulates that selective attention relies on top-down biasing mechanisms. The model proposes that long-range excitatory projections from PFC to posterior cortical regions enhance the activation of relevant representations, which in turn serve to suppress irrelevant representations through local inhibitory interactions. Herd et al. adapted this model in such a way that it can better account for performance and brain activation data from the Stroop task.

Building on earlier behavioral and fMRI work by Lavie and collaborators, Gazzaley and colleagues have conducted fMRI and ERP studies that provide compelling evidence for separable top-down enhancement and suppression effects in a selective attention paradigm. In their task, participants viewed a series of pictures of faces and scenes pseudorandomly intermixed. They were instructed to (1) remember the faces and ignore the scenes, (2) remember the scenes and ignore the faces, (3) remember both, or (4) passively view the stimuli.

The researchers found that a region involved in processing faces – the fusiform face area (FFA) – exhibited enhanced activation relative to the other conditions when participants selectively attended to faces. They further showed that FFA activation was lower relative to the passive view condition when participants ignored faces and attended to scenes instead. The opposite pattern of results was found for the parahippocampal place area (PPA), a region involved in processing scenes (Figure 2).

An ERP study involving the same paradigm also showed an enhancement of face processing-related neural activity (the face-selective N170 component)

Figure 2 Data from 18 adults aged 19–30 years in an fMRI study on selective attention by Gazzaley and colleagues. These data show that the PPA was more active when participants selectively attended to scenes rather than faces than when they passively viewed both scenes and faces. Additionally, the PPA was less active when participants selectively attended to faces (ignored scenes) than in the passive viewing condition. Participants view the same number of scenes across tasks, and therefore the modulation observed in PPA must be mediated by top-down mechanisms. BOLD: Blood-oxygen level dependent. Courtesy of Adam Gazzaley.

when subjects were instructed to selectively attend to faces. The ERP data further revealed that attention to faces led to faster face processing: indeed, the peak latency of the N170 component was shifted 10 ms earlier for the 'remember faces' condition than for 'ignore faces.' Taken together, these fMRI and ERP results provide strong evidence for top-down modulation of posterior cortical representations as a function of goal relevance.

A large behavioral literature suggests that older adults have difficulty ignoring irrelevant information, but it is unclear from these data whether this deficit is rooted in a specific deficit in top-down suppression of irrelevant information, top-down enhancement of relevant information, or both. As such, Gazzaley and colleagues used the paradigm discussed previously to study selective attention in older adults. Their fMRI data revealed that in older adults, the PPA was not suppressed in the 'ignore scenes' condition relative to the 'passive view' condition (Figure 3). In contrast, the PPA did exhibit enhancement for the 'remember scenes' condition relative to 'passive view.' These data indicate that older adults showed a specific deficit in top-down suppression. In addition to providing insight into cognitive changes during aging, this finding lends credence to the idea that suppression and enhancement mechanisms are neurally separable.

Response Inhibition

The ability to inhibit a contextually inappropriate response tendency is central to goal-directed behavior. Numerous brain imaging studies have been conducted in an effort to identify the brain structures that mediate response inhibition. In the go/no-go paradigm, participants must respond to the presentation of each of a rapidly presented stream of visual stimuli, thereby building up a prepotent response tendency. Participants are also instructed to withhold their response to a particular stimulus (the 'no-go' stimulus), which will be presented without warning from time to time (Figure 1b). fMRI studies involving the go/no-go paradigm have revealed a network of largely right-hemispheric brain regions associated with successful response inhibition, including right ventrolateral PFC. The go/no-go paradigm has been used not only to study inhibitory control in healthy young adults but also to probe the neural basis of inefficient inhibitory control in children and in patient populations.

Another paradigm used to study response inhibition is the stop-signal task. In the most common variant of this paradigm, participants press a button in response to visual stimuli but must on some occasions (e.g., if they hear a tone) inhibit their response at the last moment (Figure 4a). This task is thought to tax

Figure 3 The data from younger adults in **Figure 2** are replotted here as a point of comparison for PPA activation in 16 older adults, aged 60–77 years. For the older adults, like the younger adults, activation in PPA was greater during selective attention to scenes than during passive viewing. In contrast, PPA activation for older adults did not differ between the ignore scenes condition and the passive viewing condition. Thus, the older participants exhibited top-down enhancement of PPA activation but failed to demonstrate top-down suppression. Blood-oxygen level dependent. Courtesy of Adam Gazzaley.

Figure 4 (a) A simplified illustration of the stop-signal paradigm used by Aron and Poldrack. (b) The neural correlates of successful inhibition of motor programs are shown in these activation maps. In particular, three regions – all in the right hemisphere – have been associated with stopping: the subthalamic nucleus (STN), pre-supplementary motor area (pre-SMA), and ventrolateral prefrontal cortex (VLPFC). This pattern of activation suggests that stopping behavior relies on the hyperdirect pathway from PFC to the STN.

response inhibition more heavily than the go/no-go paradigm because participants must override a motor response that they have already initiated. The stop-signal paradigm has an advantage over other response inhibition paradigms for use in clinical and developmental brain imaging studies: the task difficulty varies dynamically on a trial-by-trial basis to ensure a fixed level of performance across participants. As such, differences in brain activation between groups cannot simply be attributed to differences in performance.

In an fMRI study involving the stop-signal paradigm, Aron and Poldrack proposed that stopping is

achieved through excitation of the subthalamic nucleus by PFC (Figure 4b). From prior work in animals, it is known that the subthalamic nucleus is inhibitory, and that excitation of this nucleus should result in a dampening of activity in the thalamus and cortex. This fMRI study provides evidence in humans for hyperdirect inhibition, bypassing the slower, indirect loop through the basal ganglia. It is likely that some response inhibition paradigms engage the hyperdirect pathway, whereas others engage either the indirect pathway through the basal ganglia or cortico-cortical projections that result in top-down biasing of posterior representations. Further brain imaging research is needed to determine whether various types of response inhibition are indeed neurally separable.

Task-Set Representation

The majority of research on cognitive control focuses on the issue of how PFC controls thought and behavior. An equally interesting question is how PFC 'knows' which thoughts and behaviors to facilitate or suppress. Until we have a satisfactory answer for this question, we will continue to treat PFC as a homunculus – a little man inside the brain who mysteriously knows everything and can direct our thoughts and actions accordingly.

Computational modelers have attempted to decompose or decentralize the homunculus. However, more neuroanatomically detailed computational models will be needed to account for the roles of distinct PFC subregions and other parts of the brain. Such models await a larger body of research on context representations – that is, the information that is used to decide on an appropriate course of action. Context representations could include information about current goals, motivational state, the current situation, rules for behaving in this situation, etc.

The type of context representation that can perhaps be most readily operationalized and studied is the representation of a currently relevant task rule. Research in our laboratory is focused on understanding how rules for behavior are stored in long-term memory, retrieved, maintained online during task preparation, and implemented. Along the same lines, Sakai and Passingham have conducted several elegant studies examining the role of anterior prefrontal cortex (APF; lateral Brodmann area 10) in task preparation.

In these studies, Sakai and Passingham provide evidence from functional connectivity analyses that APF interacts with different brain regions during task preparation, depending on the type of task to be performed. Their first study, in 2003, showed that when participants prepared to perform either a challenging verbal or spatial working memory task, APF activation was strongly correlated with regions involved in verbal or spatial working memory, respectively. Their second study, in 2006, focused exclusively on the verbal domain, and it showed that when participants prepared to perform either a semantic or phonological task, APF was correlated with distinct regions in ventrolateral PFC that have been associated with either semantic or phonological processing. These studies show that APF coordinates task performance by interacting with brain regions that are needed to perform an upcoming task.

Current and Future Directions

During the past decade of brain imaging research, the emphasis has been on using fMRI to localize individual brain regions engaged in various tasks. These endeavors have given us a fairly good idea of the key players in cognitive control and have allowed us to test specific hypotheses regarding their contributions. Furthermore, fMRI studies focusing on adult-individual differences have shown that task performance can be tightly correlated with level of engagement of specific brain regions. Similarly, developmental and clinical fMRI studies have identified brain regions for which differences in level of activation across groups may underlie performance differences.

The next generation of brain imaging techniques will need to combine high-resolution spatial and temporal information. Additionally, further research is needed to better characterize neuropharmacological and genetic influences on brain activation. Several methods that hold promise for the next wave of studies probing executive function are discussed here.

Combined fMRI and EEG Methodology

fMRI and EEG are complimentary techniques in that the former allows for the precise spatial localization of active brain regions, and the latter provides exquisite timing information about the onset and offset of neural activity. To push our understanding of cognitive control mechanisms to the next level, it will be necessary to acquire data with high spatial and temporal resolution.

One approach is to acquire fMRI and EEG data on the same group of participants, in separate sessions. The set of brain regions identified from the fMRI data can then be used to constrain the source localization of the ERP data. Another, more technically challenging, approach is to simultaneously acquire fMRI and EEG data from the same participants. This latter approach has been used successfully in a study on performance monitoring by Debener and colleagues. Several groups are working on multimodal imaging approaches, including combined fMRI/EEG, and the further development of these methods should provide new insights into the neural mechanisms of executive function.

Event-Related Optical Signals

Gratton and Fabiani and their colleagues have developed an optical imaging technique with high spatial and temporal resolution known as EROS, or the event-related optical signal. The standard analytic approach for optical imaging data analysis is to focus on changes in optical properties of the cortical brain tissue associated with changes in blood flow, which are only indirectly related to changes in neural activity. Given the sluggish blood flow response to neuronal activity, optical imaging – like fMRI – typically has poor temporal resolution. In contrast, with EROS, the optical changes that are being analyzed are directly related to neural activity. In addition to having high temporal resolution, the EROS signal also has a high degree of spatial resolution; it can be localized to an area of less than a cubic centimeter. The main drawback of this method is that it can only be used to measure activity within 3–5 cm of the surface of the brain.

The developers of EROS have used it to study response competition in a Stroop task. They showed that both left and right motor cortices were active in response to an incongruent Stroop stimulus, even though participants were instructed to respond to the stimulus by pressing a button with only one hand. In contrast, congruent Stroop stimuli, which did not elicit response competition, elicited activation of only the contralateral motor cortex. Since this validation study was performed approximately 5 years ago, the technique has been further fine-tuned and validated. Although only a few published studies have employed EROS thus far, the use of this technique may spread as more researchers become aware of its potential.

Executive Functions: Eye Movements and Neuropsychiatric Disorders

A B Sereno, S L Babin, A J Hood, and C B Jeter, The University of Texas Health Science Center at Houston, Houston, TX, USA

What Are Executive Functions?

Executive functions are complex, higher order processes moderated primarily by the frontal lobe, specifically the prefrontal cortex. The complexity of executive function has made a universally accepted definition elusive, but attention (focusing on relevant information and ignoring distractors), working memory (maintaining information until execution), and motor planning (goal-directed motor planning and programming) are generally considered key executive functions. Executive functions influence social, emotional, intellectual, and organizational aspects of one's life. Life can be devastated when executive functions are disrupted. Unfortunately, such disruptions occur in many human disorders.

Eye Movements and Executive Functions

Eye movements are any shift of position of the eye in its orbit. There are many different kinds of eye movements, which are defined in the next section titled 'Classes of eye movements.' Eye movements determine what information reaches our retina, visual cortex, and most important, higher cortical centers. Hence, eye movements are critically important for vision, attention, and memory; they determine what we see, attend to, and remember about our surroundings. They are thus central to executive functions. Much scientific work also suggests that the brain circuitry subserving certain executive functions, such as that for spatial attention and spatial working memory, overlaps parts of the brain circuitry subserving control of eye movements. Thus, better understanding of eye movements provides a valuable window into executive functions.

Classes of Eye Movements

There are several classes of eye movements, with, for the most part, distinct neural circuitry. Eye movements serve to stabilize images on the retina and to keep objects of interest on the fovea, the retinal area that has the greatest visual acuity and the greatest representation in visual cortices. Without compensatory eye movements during self-motion (locomotion) or head movement, images of the visual world would blur and slip across the retina with each movement. Two classes of eye movements, vestibulo-ocular and optokinetic reflexes, evolved to stabilize images on the retina during such head and body perturbations. In the case of the vestibulo-ocular reflex, when the head moves to the right, 'vestibular' sensors in the inner ear are triggered and signal nuclei in the horizontal and vertical gaze centers of the brainstem to create an equal and opposite eye velocity signal. The result is that the vestibulo-ocular reflex initiates a rapid eye movement to the left (within about 15 ms) to compensate for the head movement, keeping the retina stable with respect to the world. The second mechanism, the optokinetic reflex, complements the first by using full-field 'visual' information about self-movement to compensate for the perturbation of the visual world on the retina. That is, as a result of self-motion to the right, the entire visual image will move across the retina in a leftward direction. The speed of the image drift on the retina triggers nuclei in the brainstem to create an equal leftward eye velocity signal. The result is the optokinetic reflex, an eye movement in the same direction as the retinal slip to keep the retina stable with respect to the world.

A third class of eye movements serves to rapidly shift gaze (up to $900^{\circ}s^{-1}$) to bring a new object of interest to the fovea. These saccades are often further subdivided into two general subclasses: reflexive and voluntary. Reflexive saccades are elicited in response to a sudden movement, flash, or change in the environment. The latency (onset of movement) of a reflexive saccade to a visual target is typically about 200–250 ms, but it can be as short as 70–80 ms. Voluntary saccades are more complex, involve executive functions, are thought to critically involve frontal cortex, and have latencies as long as 400 ms. In real life, for instance, the same environment can result in different voluntarily controlled saccadic eye movements, depending on what information is sought or needs to be remembered. This was elegantly demonstrated by Yarbus in 1967 when he presented the same picture to participants several times but each time asked a different question. Depending on the question, the participants scanned the picture with a strikingly different set of voluntary saccades to acquire the pertinent information. In a similar fashion, Figure 1 illustrates an example of the scanpaths of a naïve participant viewing a Vermeer painting.

Figure 1 Scanpaths of a naïve individual viewing Vermeer's *Mistress and Maid*. This person was told that two pictures would be presented sequentially for 5 s each and that before each picture, a question would be asked. The person was told to look at the picture for the answer and reply after the viewing finished. (Left) The first question asked was, "What are they doing?" The picture was then presented, and the person's scanpath was recorded for 5 s. The individual then replied, "delivering and receiving a letter." (Right) The second question asked was, "How old are they?" The same picture was presented again and the scanpath recorded for 5 s. The person then replied "35." The scanpaths for the same picture were very different based simply on the context of what the individual was asked.

The first panel illustrates the scanpath when the picture was preceded with the question, "What are they doing?" The participant made saccades that followed the gaze of the two women in the picture and then dwelled on the hands, the table, and the objects on the table. The second panel illustrates the scanpath when the same picture was preceded with the question, "How old are they?" In this context, the participant looked almost exclusively at the women's faces.

In the research lab or clinic, a prosaccade task is frequently used to elicit reflexive saccades (see Figure 2). In this paradigm, the participant fixates a center spot, a visual target appears to the left or right of center, and the participant is instructed to look at the target. Voluntary saccades can be elicited by many different eye movement paradigms (see also Figure 2). In an antisaccade task, a peripheral target is presented (as in the prosaccade task), but the correct response is to look to the opposite side of the screen, away from the target. The antisaccade task requires a person to (1) inhibit the reflexive inclination to look at the target and (2) generate a voluntary saccade to the correct location opposite the target. Abnormal responses in the antisaccade task include increased latency and directional errors (looking to the target). A delayed saccade task also requires a voluntary saccade. This task is similar to a prosaccade task in that the person is required to make an eye movement to the target. However, the person is also instructed to wait until a go signal is given (a tone or change in fixation cue). Therefore, the person must inhibit the reflexive tendency to look at the target immediately and generate a voluntary saccade when the go signal is presented. A third commonly used voluntary saccade paradigm is a memory-guided saccade task. This task is identical to the delayed saccade task, except that the target is removed from the screen during the delay period. Now, the person must inhibit the eye movement until the go signal and also remember where the target was presented. Hence, this task also demands working memory.

Smooth pursuit eye movements (SPEMs) function to keep a small moving stimulus on the fovea and are typically much slower than saccades, with a maximum velocity of about $100\,^{\circ}\mathrm{s}^{-1}$. Smooth pursuit is a voluntary task requiring both motivation and attention. Hence, if one chooses to track a mosquito, when the mosquito takes off, one's eyes would initiate smooth pursuit 100–150 ms later, an onset of movement that is generally shorter than that for a saccade. Thus, the eyes would first begin to pursue but lag a bit behind the mosquito. After about another 100 ms, this is remedied by a 'catch-up saccade' that repositions the moving eyes directly on the mosquito. SPEMs are the result of a complex transformation from visual motion signals at the fovea to an oculomotor signal. Cortical input to the smooth eye movement generation centers in the brainstem is required to enable smooth tracking motion. At the same time, however, there must be suppression of the optokinetic reflex and, if the eye movement is accompanied by head tracking, the vestibulo-ocular reflex. SPEM paradigms are used frequently to measure executive function in clinical populations. One measure of accuracy in SPEM paradigms is pursuit gain (the ratio between eye velocity and target velocity). Gain values below 1.0 indicate that the pursuit system is not matching the velocity of the target. Errors in gain can be amended with catch-up saccades (when

Figure 2 Examples of four saccade tasks. All tasks are presented sequentially from top to bottom, and the arrows indicate the direction of the correct eye movement. Prosaccade: This is a reflexive task in which an individual begins by fixating the center point (F). Once fixation is maintained, a target light appears, and the person makes an eye movement to the light (T&G). Antisaccade: An individual begins by fixating the center point (F). The target light then appears (T&G), and the person is to make an eye movement to the equal and opposite position of the target. Delayed Saccade: The individual begins by fixating the center point (F). Next, the target light appears (T), followed by a delay period (D), during which the person must continue fixating the center point. At some variable time, the fixation light disappears, which serves as a go signal (G) for the person to begin an eye movement to the target. Memory Saccade: The individual fixates the center point (F). The target light then flashes on the screen (T), followed by a delay period (D), during which the individual must continue fixating the center point. At some variable time, the fixation light disappears, which serves as the go signal (G) for the person to begin an eye movement to the remembered location where the target had previously flashed. F, fixation screen; T, target onset; G, go signal to begin an eye movement; D, delay period, when the participant must wait for the go signal; M, eye movement.

smooth pursuit lags behind the target) and backup saccades (when tracking gets ahead of the target). Further, there can be intrusive saccades, which interrupt smooth pursuit tracking and are indicative of inhibitory failures or inappropriate activations.

Vergence is the only disconjugate eye movement; that is, the eyes move simultaneously in opposite directions. Vergence movements occur reflexively in order to focus and reduce disparity between the locations of an image on the retina of each eye.

Eye Movements in Human Disorders

Voluntary eye movements as a general class can be used to tease out specific deficits in different aspects of executive function in clinical populations. By careful comparison of performance on voluntary eye movement tasks, a 'deficit in executive function' (as generally classified, for example, by a neuropsychiatric test) can be broken down into separable aspects of executive function, including the voluntary planning, generation, and accuracy of a response, the ability to inhibit or control impulse responding, and working memory. Voluntary eye movements have been linked to different anatomical circuitry and can be used to characterize subtypes within some patient populations.

Neurological

Tourette's syndrome and Parkinson's disease are movement disorders involving the basal ganglia. Both disorders show deficits in executive function with evidence of disrupted prefrontal–basal ganglia circuits. Voluntary eye movement deficits are consistent with these documented impaired executive functions. Both groups show increased antisaccade latency and antisaccade errors. The effect of medication on voluntary eye movements in Tourette's syndrome is not clearly known. On the other hand, dopaminergic medications, routinely given to treat Parkinson's disease, do improve voluntary eye movement performance. Further, voluntary saccade performance differentiates between subtypes of Parkinson's disease patients such that akinetic-rigid Parkinson's disease patients have more difficulty on voluntary eye movement tasks than do tremor-dominant patients.

Developmental

Autism is a developmental behavioral disorder marked by abnormal language and social communication resulting from deficits in limbic and cortical structures. Numerous studies have investigated voluntary eye movement performance in children and adults with autism as a means of understanding the etiology and social implications of this disorder. For instance, voluntary eye movements (saccades and SPEMs) have been used to show that executive function abilities are delayed in autistic patients; their voluntary abilities seem to mature to a lower level and at a slower rate. Likewise, results from voluntary saccade tasks suggest that deficits in autistic individuals critically involve the prefrontal cortex.

Psychiatric

Eye movements have been studied most extensively in schizophrenia, as is discussed in the next section. Attention-deficit/hyperactivity disorder (ADHD) is characterized by symptoms (sometimes beginning before age 7) of inattention, hyperactivity, or impulsivity that cause impairment at school, home, or work. ADHD patients have been shown to be impaired on a countermanding task (similar to a delayed saccade task, but a stop signal may be presented on some trials to indicate the response should be withheld), which suggests that their impairment mainly consists of increased impulsivity. In addition, voluntary eye movement deficits have shown subtype differences within the ADHD population. Specifically, patients classified as ADHD-Inattentive have better motor planning and are less impulsive than ADHD patients with both inattentive and impulsive characteristics. Interestingly, methylphenidate improves the voluntary eye movement performance of both ADHD subtypes. Bipolar disorder is a disturbance in mood marked by cycling periods of mania and/or depression. Bipolar patients have been shown to have an inhibition problem but to date no deficit in working memory on voluntary eye movement paradigms. Bipolar patients, as well as lithium-withdrawn manic patients, have been shown to perform more poorly than normal controls on a SPEM task.

Eye Movement Deficits in Schizophrenia

What Is Schizophrenia?

Schizophrenia is the most prevalent mental illness in the world, occurring in about 1% of the population. It is also considered the most costly and debilitating mental disorder and is among the top causes of disability in developing countries. In 2002, it cost the United States approximately $\$65 \times 10^9$, and this estimate accounted only for patient hospitalizations, loss of work, and cost of disability. Schizophrenia is a psychiatric disorder that is usually characterized by hallucinations, delusions, blunted affect, alogia (i.e., poverty of speech), and avolition. Numerous cognitive functions in areas such as executive control, working memory, and attention are disturbed. These disrupted executive functions are more persistent than psychotic symptoms. More robust measures of cognitive deficits are crucial, given that there is a strong positive correlation between improved cognitive functioning and long-term prognosis. Classically, neuropsychological tests have been used to investigate cognitive dysfunctions in schizophrenia, but recently, eye movement tasks have been shown to be a more sensitive and reliable measure of these deficits. Eye movements are also more easily mapped to specific neural structures and hence may be a more specific biological marker for differentiating subtypes. For these reasons, the study of eye movements is an important research tool that will shed light on both executive functions and debilitating human disorders such as schizophrenia.

Eye Movement Deficits

Nearly a hundred years ago (1908), using a photographic technique, Diefendorf and Dodge were the first to report that SPEMs were impaired in schizophrenia. They found that pursuit was commonly interrupted by saccades. With the advent of new techniques for measuring eye movements, as well as renewed interest, much is now known about SPEM deficits in schizophrenia.

There seem to be two basic deficits in the SPEMs of people with schizophrenia: (1) reduced gain of smooth pursuit and (2) increased saccadic events. Pursuit gain is a measure of the accuracy of the smooth eye movement, and people with schizophrenia show reduced gain, that is, their eyes do not keep up with the target, and they often fall behind. As a result, schizophrenic patients often exhibit increased saccadic activity (catch-up saccades) during smooth pursuit. These saccades are automatic and compensatory in nature and serve to quickly refoveate the target on the retina. Other increased saccadic events observed in schizophrenia are saccadic intrusions. These eye movements are not compensatory and are thus inappropriate. Common examples of saccadic intrusions are square-wave jerks and anticipatory saccades. A square-wave jerk is a small pair of saccades whose initial direction takes the eyes off the target. After a 100–250 ms intersaccadic interval, during which pursuit continues, a second saccade returns the eyes to the target. Anticipatory saccades overshoot the location of the target. These saccades have

larger amplitudes than those of square-wave jerks and longer intersaccadic intervals, and they do not maintain continuous pursuit during the intersaccadic period. Both these types of intrusive saccadic eye movements are rarely found in young controls (although they are sometimes found in older people) and indicate inappropriate activation or lack of inhibition of the saccadic system during smooth pursuit.

In addition to smoothpursuit deficits, a number of saccadic eye movement dysfunctions have been identified in schizophrenia. Numerous studies have shown deficits in various voluntary saccade tasks, including delayed, remembered, or predictive saccades. In an antisaccade task, schizophrenic participants typically are slower to generate a saccade to the correct location and make more errors (i.e., eye movements to the target) compared with normal controls. In contrast, many studies have demonstrated that schizophrenic participants perform normally or in some cases faster than controls on a prosaccade task. This pattern of saccade task performance has in some studies been related to the participant's performance on SPEMs. That is, schizophrenic patients with smooth pursuit deficits make significantly more errors on the antisaccade task than schizophrenic patients without eye tracking deficits.

Biological Basis of Eye Movement Deficits

Schizophrenic patients with SPEM deficits do not show abnormal slow phases of vestibulo-ocular and optokinetic responses. This dissociation suggests that the smooth pursuit abnormalities in schizophrenia are due to cortical deficits rather than deficits in common brainstem motor output pathways. Evidence for a prefrontal cortex dysfunction model of schizophrenia has also gained support. One key piece of evidence for such a model came from the similarity between symptoms of blunted affect, avolition, and inattention seen in schizophrenic patients and symptoms exhibited by neurological patients with a loss of frontal lobe function. A further piece of evidence in support of frontal lobe dysfunction in schizophrenia came from eye movement research. It was already well established that frontal regions, especially the frontal eye fields, play a role in saccades. Further research also demonstrated that lesions in the frontal eye fields disrupt SPEMs. Hence, frontal dysfunction could account for both pursuit deficits and saccadic deficits.

It is interesting to note that between 50% and 85% of individuals with schizophrenia exhibit SPEM dysfunction, in contrast to only about 8% of normal controls. Similarly, about 60% of individuals with schizophrenia exhibit antisaccade eye movement deficits. People with schizophrenia are heterogeneous in terms of both smooth pursuit deficits and voluntary saccade deficits. This division of impaired and nonimpaired patients (for either pursuit gain or voluntary saccade performance) may prove to be more useful than the classic clinical subtypes in characterizing homogeneous subgroups of patients.

Genetics of Eye Movement Deficits

In the late 1970s and early 1980s, a series of studies investigated the genetics of smooth pursuit deficits in monozygotic and dizygotic twins who were discordant for schizophrenia. These studies found that a larger proportion of monozygotic twins than dizygotic twins exhibited abnormal smooth pursuit eye tracking. Moreover, about half of clinically well first-degree relatives of schizophrenic patients exhibit SPEM deficits, a prevalence much greater than recurrence risk for schizophrenia in first-degree relatives, which is about 6.5%. In addition, some recent reports suggest that 25–50% of nonsymptomatic first-degree relatives of schizophrenic patients exhibit antisaccade deficits. Within the last several years, linkage has been reported for both smooth pursuit deficits and anti-saccade deficits in genetic studies of schizophrenia. Endophenotypes such as eye movement dysfunctions may be a more penetrant expression of a schizophrenia susceptibility gene than schizophrenia.

Importance of Subtypes and Genetics for Outcome

Eye movement monitoring is an important research tool because it affords the opportunity to use a quick, easy, and noninvasive technique to help identify behaviors that may indicate susceptibility for schizophrenia. Since it is possible that people with schizophrenia who exhibit eye movement deficits are genetically differentiable from those who do not, eye tracking may provide more reliable and robust criteria for the classification of different groups of people with schizophrenia. Such a biologically based classification system may allow us to investigate particular antipsychotic medication effects across different subgroups of schizophrenic patients. For example, it is possible that task-impaired patients will show a greater benefit from a specific medication. Such a finding has been reported with nicotine and schizophrenia: patients impaired on an antisaccade task showed a greater benefit from nicotine than did nonimpaired patients and controls. A similar subtype-specific medication effect has also been demonstrated in Parkinson's disease. It was found that akinetic-rigid patients are poorer than tremor-dominant patients

on voluntary eye movement tasks, such as the antisaccade task, and that only tremor-dominant patients were able to significantly improve their performance on this task after dopaminergic medications were administered. A better understanding of subtype-specific medication effects would be pivotal in assigning the most effective medication to the patients who would benefit the most.

In summary, eye movements provide invaluable information about executive functions and provide an efficient, noninvasive way to study the role of abnormal brain processes in a variety of human disorders. Their study may afford the development of more effective and efficient treatments of executive dysfunction.

Introduction

It has long been known that exercise is essential to good health. Individuals who lead a sedentary lifestyle greatly increase their risk of many diseases, including osteoporosis, cardiovascular disease, and diabetes. During the past decade, it has become apparent that physical activity also is essential to a healthy brain, particularly in aging populations. In addition to its generally beneficial effects, there is reason to believe that exercise and other forms of motor enrichment can be beneficial with regard to several neurological disorders, including Parkinson's disease (PD) and Alzheimer's disease (AD), and can even be helpful in reducing the deficits induced by stroke.

PD and AD have much in common. They involve a progressive degeneration of neurons in the brain that often goes undetected for many years. Because of this long preclinical gestation and perhaps because of a reduction in the capacity of the brain to defend itself against insults, the emergence of these conditions as clinical entities increases sharply as individuals age, with the great majority of cases emerging in people aged 60 and older. In addition, whereas their pathological and clinical manifestations are quite different at the outset, there often is an increasing overlap as PD and AD progress.

This article briefly reviews the evidence for the neuroprotective effects of exercise, discusses supportive data from animal and cellular models, and then comments on possible underlying mechanisms and implications for the causes and treatments of these neurodegenerative diseases, as well as for the treatment of stroke.

PD

The Condition

Originally identified as a clinical syndrome by James Parkinson in 1817, PD is typically characterized by its motor signs – slowness of movement (bradykinesia), stooped posture, rigidity, and tremor. In reality, however, these appear to reflect an intermediate sign of the underlying neurodegenerative process that may also affect cardiovascular function, olfactory sensitivity, speech, fatigue, and gastrointestinal function and may eventually be accompanied by cognitive dysfunction, including dementia. The prevalence of PD is about 1%. Diagnosis typically occurs at about age 60, though the disease probably has a 10- to 20-year 'preclinical' phase, during which symptoms are either not detected or not associated with PD. On the other hand, 5–10% of patients with PD are diagnosed before the age of 40. Men, particularly younger individuals, are at a slightly greater risk for the condition.

In the early 1960s, the majority of the motor deficits in PD were attributed by Oleh Hornykiewicz and his colleagues to the reduction in dopamine (DA) in the caudate and putamen (collectively referred to as the striatum). Subsequently it was shown that the DA in these regions was located in the terminals of neurons that project from the substantia nigra pars compacta (SNpc), a group of about half a million pigmented neurons per side located in the ventral mesencephalon. By the time PD is diagnosed, about half of the SNpc neurons have been lost, along with about 80% of the DA in the striatum. However, as with the symptoms of PD, the neurodegeneration underlying the condition is quite broad and eventually may include the loss of many other specific groups of neurons both caudal and rostral to the SNpc, as has been suggested most convincingly by Heiko Braak, beginning in the late 1980s. It seems likely that many of the nonmotor consequences of PD result at least in part from pathology in these extradopaminergic regions.

Clinical Evidence for the Beneficial Effects of Exercise in PD

Many drugs are used in the treatment of PD; however, virtually all of them strive directly or indirectly to replace the impact of the DA that is lost as part of the disease. Thus, current treatments target motor symptoms rather than the full complex of the disease. These medications can be highly effective for many years and usually permit patients with PD to have a normal life span. However, there is little evidence that the actual neurodegenerative process is affected by such treatments. This is also the case for surgical treatments, which have included pallidotomy and the now more common approach of deep brain stimulation of the subthalamic nucleus.

In contrast to more conventional therapies, physical exercise appears to reduce the incidence of PD and to improve the motor, cognitive, and affective deficits in patients with mild to moderate PD. A lifetime of exercise seems to reduce the incidence of PD, at least

in men. In addition, a program of aerobic activity has been reported to improve movement initiation, whereas resistance and balance training have been found to improve balance.

Despite the encouragement such studies provide, virtually all of them suffer from one of two failings. Those studies examining long-term effects of exercise derive their results from surveys. For example, a negative correlation between PD and the level of physical activity throughout life has been reported. However, whether these data are collected retrospectively or over a long period through regular questionnaires, such studies always suffer from a lack of precision. Moreover, in the case of PD, they leave open the possibility that the results reflect a tendency toward inactivity of individuals who are in the preclinical stages of the disorder.

A few studies have tried to address this problem with prospective studies, separating the patients into an exercise and a control group. However, here, too, there are serious problems. Such studies are typically very brief (weeks or at best a few months), involve relatively few participants, may not provide adequate controls for the effect of the increased attention that the exercise group receives, and fail to distinguish between symptomatic changes and an actual influence on underlying disease progression. Of course, these problems hold not only for studies of PD but also for studies of AD, described in the section titled 'AD.' Thus, although such data are encouraging, they should be viewed with caution, and for the present, studies of experimental animals form the basis for assessing the neurobiological benefits of this therapy.

Animal Studies

Although animal models of neurodegenerative diseases are of necessity imperfect, several models of PD are in use. Most rely on the fact that a major component of PD pathology is the loss of DA neurons and that these neurons can be selectively destroyed in many animals through the use of DA-specific neurotoxins. The first such toxin to be introduced was 6-hydroxydopamine (6-OHDA), which enters via DA uptake sites and, when combined with the noradrenaline uptake blocker desipramine, is selectively concentrated in DA neurons, causing toxic oxidative stress. Later, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) was introduced as a tool in the study of PD. MPTP is converted to the DA neurotoxin MPP+, which, like 6-OHDA, is concentrated in DA neurons, where it inhibits complex I of the mitochondria.

When the toxin-induced loss of DA is severe, rodents and nonhuman primates lesioned in this way show several motor deficits that are reminiscent of PD. For example, rats treated with 6-OHDA become bradykinetic or even akinetic, whereas monkeys treated with MPTP provide an even closer model of the motor symptoms of PD, exhibiting tremor, stooped posture, and rigidity.

The protective effect of constraint therapy was first used with some success in patients with stroke (see the section titled 'Stroke') and has recently been applied to 6-OHDA-treated rats as well. Adult rats receiving unilateral injections of 6-OHDA had their 'normal,' ipsilateral limb constrained by a plaster-of-paris cast for 7 days. When assessed for behavioral and neurodegenerative abnormalities several weeks later, these deficits were greatly attenuated. This was true whether the forced exercise occurred immediately before or immediately after the administration of 6-OHDA. However, if the placement of the cast on the forelimb was delayed for a week after 6-OHDA, the therapy was not effective (**Figure 1**). Moreover, if animals previously protected against 6-OHDA by limb immobilization had their 'protected' limb constrained in a cast for a 1 week period 2–3 weeks later, behavioral and neurochemical evidence of DA loss reemerged. These results indicate that there is a brief window of opportunity during which forced exercise is protective. They also suggest that continued limb use is essential to maintaining the DA neurons in a viable state.

Housing in a more complex environment or caloric restriction can also protect DA neurons. For example, the loss of DA neurons incurred from MPTP as assessed by cells immunoreactive for the rate-limiting enzyme tyrosine hydroxylase (TH) was significantly reduced by providing mice with daily access to tunnels, opportunities for climbing, running wheels, and toys for 2 months (**Figure 1**). These results have since been replicated by Dr. Richard Smeyne and colleagues by giving mice continuous access to a running wheel, suggesting that a major impact of environmental complexity is to increase exercise. Likewise, reducing caloric intake by 30–40% in young mice for 3 months prior to MPTP administration improved motor performance and caused a near-complete protection of DA cells and terminals. Similar results of caloric restriction have been obtained in a hemiparkinsonian primate MPTP model and in other brain-injury models.

The protective effects of complex environments and caloric restriction may be due at least in part to the increase in motor activity that is associated with these treatments. At least one report has indicated that the protective effects of environmental enrichment in PD models could be duplicated by housing animals with a running wheel. Moreover, running has been clearly linked to neuroprotection in studies of mouse models of AD and of stroke.

Figure 1 Effect of exercise on the response of dopamine (DA) neurons to neurotoxins in models of Parkinson's disease (PD). Upper panel: At weaning, mice were placed in either an enriched or a standard environment and examined 2 months later. Shown are the number of tyrosine hydroxylase immunoreactive (TH-IR) neurons in the substantia nigra pars compacta (SNpc) of mice from the two groups 7 days after treatment with either saline (NaCl; dark bars) or 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; 20 mg kg^{-1} intraperitoneally; open bars). From Bezard E, Dovero S, Belin D, et al. (2003) Enriched environment confers resistance to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine and cocaine: Involvement of dopamine transporter and trophic factors. *Journal of Neuroscience* 23: 10999–11007. Lower panel: Adult male rats were given a unilateral injection of 6-hydroxydopamine (6-OHDA; 10 μg) along the medial forebrain bundle. In some groups of rats, a unilateral cast was used to restrict the use of the ipsilateral forelimb for 7 days, thereby forcing the animals to rely on their contralateral limb for movement during this time. The cast was placed immediately after the 6-OHDA (c 1–7), 3 days later (c 3–9), or 7 days later (c 7–13). The animals were sacrificed 65–80 days later for analysis of DA, DOPAC, or HVA levels by high-performance liquid chromatography. Animals receiving early casts and sham animals did not show significant differences in DA, DOPAC, or HVA levels; animals receiving casts on days 3–9 showed intermediate DA levels, although still not significantly different from sham. Animals with late casts (days 7–13) and animals not receiving casts showed significantly lower DA levels when compared with sham-treated animals. These data parallel performance on a variety of behavioral tasks (data not shown). From Tillerson JL, Cohen AD, Philhower J, Miller GW, Zigmond MJ, and Schallert T (2001) Forced limb-use effects on the behavioral and neurochemical effects of 6-hydroxydopamine. *Journal of Neuroscience* 21: 4427–4435.

AD

The Condition

AD is the most common form of dementia. Like PD, it is a progressive, degenerative disorder that has an extended preclinical phase and becomes prominent with age. Whereas the prevalence rate of AD is only slightly higher than that of PD (~1.5%), about half of those who reach the age of 85 will be affected. Moreover, although patients with PD have a near-normal life span if properly treated, patients with AD seldom live for more than a decade beyond diagnosis. The deficits typically begin with memory loss and proceed to affect thinking and language. The condition has been associated with neuronal loss, particularly among subcortical neurons that project to the telencephalon. By the time that AD is identified, this loss is usually sufficient to have caused a gross reduction in brain size. At a cellular level, two abnormalities can be detected and are diagnostic for the condition: neuritic plaques containing amyloid-β (Aβ) and neurofibrillary tangles composed largely of tau protein. The condition and its neuropathological hallmarks were first described in 1906 by Alois Alzheimer.

Areas of the brain that are affected by AD are widespread. However, one group of neurons that often is targeted early is the cholinergic neurons of the basal nucleus of Meynert. This, in turn, has led to the use of inhibitors of acetylcholine esterase in the treatment of the condition, an approach that has limited, symptomatic benefit at best, with no evidence for any effect on the neurodegenerative process. As in the case of PD, many drugs are under development that are designed to influence the underlying pathophysiology of the disease, but they are still in early experimental stages. However, again as with PD, there is reason to believe that exercise can help hold AD at bay or slow its progression.

Clinical Findings on Efficacy of Exercise in AD

Evidence suggests that the incidence and progression of cognitive decline in later life are reduced by exercise. For example, individuals who engaged in strenuous walking three times a week showed improved executive function and increased brain activation,

as monitored by functional magnetic resonance imaging, compared with those who undertook stretching and nonaerobic activity. However, as in the case of PD, the field still awaits long-term clinical trials with enough power to permit definitive conclusions about exercise and cognition, as well as clear statements regarding the amounts and types of exercise that are most effective. Thus, we must again turn to animal studies.

Animal Studies

The first requirement for an animal study is the establishment of a model. As noted above, the classic hallmarks of AD are accumulation of Aβ and the development of neurofibrillary tangles. Transgenic mice with mutations in the amyloid precursor protein accumulate Aβ. This accumulation is correlated with cognitive impairment and a reduction in indications of neuroplasticity, including learning. Conversely, reductions in Aβ by pharmacological intervention improve cognitive function and synaptic plasticity. These data suggest that Aβ is causally linked to the cognitive difficulties present in these mutant, transgenic mice and that reducing Aβ is important for healthy brain aging.

Housing in a complex environment can decrease Aβ accumulation (Figure 2) and improve cognitive performance in mouse models of AD. However, at least one study indicates that these effects cannot always be duplicated by voluntary running alone and thus may be associated with more cognitive aspects of such enrichment. This would not be surprising given the clinical literature linking cognitive activity to a reduction in the incidence and progression of dementia.

Stroke

A stroke commonly results from either blockage (ischemic) or bursting (hemorrhagic) of an artery supplying blood to a region of the brain, with the former accounting for about 85% of all incidents. In major industrialized countries, stroke is the third leading cause of death, after heart disease and cancer, and the major cause of adult disability. Unlike the slow neurodegenerative process associated with PD and AD, hemorrhagic or ischemic injury is usually immediately severe, leading to total or near-total cell death within affected brain tissue. However, this primary injury is typically followed by slow secondary degeneration around the damage (termed the penumbra) as well as in remote regions, and this secondary degeneration can continue to develop for months. It is this component of the brain damage that is the main target for treatment.

Pharmacological treatment of stroke is limited. In the case of ischemic stroke, tissue plasminogen activator, a clot-dissolving drug, may be useful if given within the first 2–3 h of the incident. Glutamate antagonists have been examined extensively in stroke treatment, the rationale being that excitotoxicity appears to play a major role in the associated cell death. Unfortunately, although such agents appeared very promising in studies with animal models, they have not proven effective in clinical trials, in part because of their behavioral side effects.

Exercise

Physical therapy has been used in the treatment of stroke for decades. The concept of constraint therapy

Figure 2 Effect of exercise on amyloid-β (Aβ) load in three different brain regions of transgenic mice that normally overexpress this protein (TgCRND8). Exercising animals showed a reduction in Aβ immunoreactivity in cortical regions and in hippocampus. The photomicrograph shows a representative section from both groups. Scale bar = 200 μm. From Adlard PA, Perreau VM, Pop V, and Cotman CW (2005) Voluntary exercise decreases amyloid load in a transgenic model of Alzheimer's disease. *Journal of Neuroscience* 25: 4217–4221.

in the treatment of motor deficits in stroke victims was introduced in the early 1980s, largely because of the work of Edward Taub. The concept was to increase the use of the affected limb by constraining the use of the normal limb for several hours each day for up to 2 weeks. Some restoration of function was observed, and the approach is now often used in patients with at least some capacity to move the stroke-impaired wrist or digits of the upper extremity, presumably in part because the injury to the corresponding brain region is partial. Other types of exercise have included weight-supported and unsupported treadmill and cycling. There is no evidence that the primary injury can be reduced with poststroke exercise. However, whereas the initial effects of severe ischemic injury may not be responsive to exercise, compensatory behavioral adaptations can be promoted with constraint and other forms of motor-enrichment therapies. These treatments presumably lead to attenuation of slow secondary degeneration (though see discussion below) and promote adaptive rewiring.

Exercise of the lower extremities in human stroke patients, including facilitated treadmill walking, can improve walking ability, in contrast to stretching and other control procedures. The improvement has been linked to behavior-related induction of more normal patterns of activation in cortical and subcortical motor regions. There is some evidence that poststroke training can ameliorate speech deficits, particularly when damage to speech areas in the cortex is subtotal. However, it has been shown that intense speech therapy starting immediately after a stroke can degrade function compared with a control rehabilitative strategy involving simple social contact with limited conversation.

Animal Studies

There are three major animal models of stroke: global ischemia (blockade of all major blood vessels to forebrain), focal ischemia (blockade of specific blood vessels), and hemorrhage (disruption of blood vessels). Focal ischemia, caused by occlusion of the middle cerebral artery is the most common type of stroke, can readily be modeled in animals. Two approaches are in use, brief occlusion followed by vascular reperfusion and permanent vessel occlusion. The former approach leads to more extensive and slower secondary degeneration of peri-injury and remote tissue.

Although research suggests that stroke outcome can sometimes be improved modestly by rehabilitative training, including exercise, neurodegeneration in animals can actually be worsened by either very early forced motor inactivity or overactivity. It is currently unclear what the optimal strategies might be for different degrees, locations, or types of brain injury. Slow secondary degeneration may present a more feasible target for neuroprotection than does rapid acute cell loss.

Constraint-induced movement therapy has been examined after minor focal ischemia or hemorrhage in nonhuman primates and rodents. Where examined, such forced forelimb rehabilitative experience has been found to improve function, reduce loss of cortical motor maps of the upper extremity, and expand such maps into novel regions of cortex. Housing animals in an enriched environment (**Figure 3**) or providing skill training after focal ischemic injury can enhance dendritic arborization and synaptogenesis in remaining tissue in both the peri-injury and homotopic brain regions.

The timing of the exercise is important. In some studies, exercise (usually treadmill running) has been provided before the ischemic insult in order to mimic a more active lifestyle. These studies have generally shown a 'preconditioning' effect, that is, a reduction in the size of the ischemic damage because of prior exercise. Intense rehabilitation during the first few days after injury can worsen the injury even as it improves certain functions. The exaggeration of damage, which may take many weeks to be readily detectable, does not appear to be due to a general effect on brain because forced forelimb overuse exaggerates only injury to the forelimb region of the brain but not to injury of the visual cortex. Intense forelimb use may increase the extent of delayed secondary degeneration of vulnerable peri-injury tissue via local hyperthermia, excitotoxicity, or metabolic demands. Sudden social isolation from cagemates at the time of injury can combine with the effects of limb overuse to cause damage that is even more extensive. This may be important clinically because stroke patients often have the additional stress of being confined to a relatively isolated hospital environment rather than quickly returning home to be surrounded by family and friends.

Despite exaggerating neural injury, intense exercise and motor training can improve function or delay dysfunction through learned compensatory motor behaviors in animals. Indeed, motor enrichment can overcome deficits so effectively that the adverse effects of secondary degeneration are difficult to observe with behavioral outcome measures alone. Ideally, the rehabilitation training would be applied so that the benefits accrue without tissue loss. Based on animal

models, motor enrichment might best be applied sparingly during the acute poststroke period and gradually increased in intensity during subacute periods and chronically.

Figure 3 The effects of enriched rearing on (a) maximal dendritic length, (b) the number of intersections, and (c) branching of layer-III parietal pyramidal neurons. Rat pups were placed in an enriched environment at weaning (21 days) and examined at 3 months. As shown, environmental enrichment provoked both increased dendritic arborization and the density of dendritic spines in layer-III parietal pyramidal neurons. In addition, the rats raised in the enriched environment exhibited improved performance in a radial arm maze and a Morris water maze (data not shown). From Leggio MG, Mandolesi L, Federico F, et al. (2005) Environmental enrichment promotes improved spatial abilities and enhanced dendritic growth in the rat. *Behavioural Brain Research* 163: 78–90.

How Might Exercise Work?

It is now clear from rodent research that exercise improves learning, increases resistance to depression, and enhances synaptic plasticity such as long-term potentiation. This is accompanied in the brain by a series of biochemical events associated with enhanced plasticity (Table 1). Much of these data have come from studies of the hippocampus and cortex, but other brain regions can show plastic changes, too. In short, there are several effects of exercise on brain function, each of which could contribute to its apparent ability to reduce the incidence of neurodegeneration as well as the progression of neurodegeneration if it does occur. Thus, the question is not how exercise can be neuroprotective but which of the many changes are most critical to the neuroprotective effects of exercise and how the changes interact with each other. One of the variables in these relationships is deemed to be particularly important – trophic factors.

Table 1 Selected effects of exercise on brain[a]

Type of change	*Examples*
Transmitter release	Increased serotonin, dopamine, γ-aminobutyric acid, glutamate; decreased acetylcholinesterase
Increased levels of messenger RNA and/or protein for trophic factors or their receptors	Brain-derived neurotrophic factor, basic fibroblast growth factor, fibroblast growth factor-2, glial cell-derived neurotrophic factor, insulin-like growth factor 1, nerve growth factor, vascular endothelial growth factor, tyrosine receptor kinase B
Reduced inflammatory markers	Tumor necrosis factor-α (TNF-α), TNF-α receptors, intercellular adhesion molecule-1
Increased amounts of synaptic proteins	Synapsin, synaptophysin, NR2B, and glutamate receptor 1
Stimulation of morphological changes	Gliogenesis, neurogenesis, synaptogenesis, and vascularization (angiogenesis)
Activation of survival cascades and associated transcription factors	Ras/extracellular signal-regulated kinase and phosphoinositide-3 kinase/protein kinase B; cyclic adenosine monophosphate responsive element binding protein
Increases in antioxidant defenses	Superoxide dismutase, catalase (decreased reactive oxygen species)
Modification of brain circuitry	Increased area devoted to task; changes in anatomical circuitry, changes in activity of existing neurons and circuits

[a]Some entries are based on only one or two publications. Excluded from this list are variables that as yet have been examined only in peripheral tissue (often muscle).

Exercise Regulates Trophic Factors

Exercise is a powerful regulator of gene expression and protein levels for several trophic factors. The largest amount of data on this issue comes from studies of hippocampal brain-derived neurotrophic factor (BDNF). The neurotrophin BDNF promotes neuronal survival and resistance to insults and is essential for brain plasticity mechanisms, including certain forms of long-term potentiation. Exercise increases BDNF messenger RNA expression in hippocampal neurons. The gene upregulation is rapid (after several hours of exercise; Figure 4), occurs in both male and female rats and mice, is sustained even after several months of exercise, and is paralleled by increased amounts of BDNF protein. Once induced, protein levels remain elevated for several days after exercise has stopped, then decay back to baseline. It is interesting that an exercise regime of alternating days of exercise is as effective as daily activity for increasing hippocampal BDNF protein levels. The practical significance of these findings is that even intermittent exercise is a powerful enough stimulus to activate the molecular machinery that drives synaptic plasticity.

Can increases in trophic factors explain neuroprotection? The evidence for neuroprotective effects of trophic factors is considerable. Trophic factors such as glial cell-derived neurotrophic factor and BDNF can protect against some of the spontaneous neuronal loss that occurs *in vitro* and that is associated with normal aging. These and other trophic factors can also reduce the damage normally caused by several neurotoxins and stroke. Both of these types of neuroprotective effects may, in turn, be due in part to the ability of trophic factors to stimulate survival cascades. Further evidence for a role of trophic factors in preventing neurodegeneration comes

Figure 4 Brain-derived neurotrophic factor (BDNF) messenger RNA in rat brains obtained under (a) basal, sedentary conditions and (b) after 7 days of exercise. Neocortical layers II and V, as well as hippocampal areas CA1, CA3, and CA4 and dentate gyrus (DG) are shown. This *in situ* analysis of exercise-induced increases in BDNF message may have been the first observation of an effect of exercise on a neurotrophic factor in brain. From Neeper SA, Gómez-Pinilla F, Choi J, and Cotman C (1995) Exercise and brain neurotrophins. *Nature* 373: 109.

Figure 5 Schematic indicating multiple ways by which exercise may alter brain. Shown (orange) are several of the factors that can influence the vulnerability of neurons, which might include age, gender, environmental toxins, or other insults (e.g., head injury), hemorrhage, ischemia, genetic predisposition, or stressors. These factors can combine to cause cell death through one or more mechanisms, including inhibition of mitochondrial function (leading, in part, to a reduction in adenosine triphosphate (ATP) production), an increase in oxidative stress, and disruption of the processes involved in handling misfolded proteins (e.g., via inhibition of the proteasome $\mathcal{P}$). Exercise may counteract these events, blocking neuronal death and/or reducing its rate of progression (①). This could result from an increase in the expression of trophic factors (e.g., glial cell-derived neurotrophic factor and brain-derived neurotrophic factor) leading to an increase in prosurvival cascades, such as those involving the kinases, extracellular signal-regulated kinase and protein kinase B. Other factors include morphological changes, such as synaptogenesis, neurogenesis (and associated cell replacement), and angiogenesis (and associated increases in oxygen and nutrients) (②). Among the other changes that could ameliorate cell death are neurochemical changes that could lead to an exercise-induced increase in the activity of residual neurons within a damaged system, and changes in neuronal circuitry leading to a transfer of function from damaged neurons to healthy neurons (③). ROS, reactive oxygen species.

from observations of reductions in trophic factors in brains of patients with PD and AD.

Summary and Conclusions

Stroke and neurodegenerative diseases such as PD and AD are a major health problem throughout the world. Moreover, since the principal risk factor for these conditions is age, the burden of these conditions will only increase in years to come unless neuroprotective treatments can be found. Although a great deal of research is ongoing to develop pharmacotherapies, there is not yet convincing evidence that such drugs are now in hand. Moreover, in the condition in which drug development and testing have been most intense, the results have been extremely disappointing. This work is continuing, as it should. In the meantime, however, the evidence for neuroprotective effects of exercise, at least in animal models, is considerable and mounting. Indeed, it is now fair to say that in addition to its many other beneficial effects, exercise also is a key to brain health.

Although this discussion enumerated many possible factors (Table 1) and then focused on a role for trophic factors, this focus should suggest that changes in trophic factors exist apart from the other changes enumerated. On the contrary, changes in the availability of trophic factors may be a consequence of some of the effects listed (e.g., gliogenesis) and in turn may be the stimulus for other effects (e.g., synaptogenesis and increased antioxidant defenses; Figure 5).

In the years ahead, it will be essential to learn more about the mechanism of these effects, to move carefully with research-based treatment strategies from animal models to humans, and to determine how best to optimize an exercise intervention to promote healthy aging as well as to reduce the progression of disease.

Introduction

For many years, consistent physical activity has been associated with improved mental health as well as physical health and longevity. Through recorded history, several nonscientific assertions have been made that 'an active body makes for a healthy mind.' In the past 30 years, several reports from the sports medicine field have documented acute alterations in mood and cognitive functioning immediately following a bout of vigorous physical activity. Both aerobic and weight-bearing forms of activity have been associated with decreased anxiety, improved mood, and a subjective or actual experience of sharper mental functioning. In more recent years, formal, long-term exercise studies have been conducted, reporting improved cognitive functioning, heightened coping abilities, and decreased incidence of mental disorders such as dementia and depression. Importantly, many of these studies have focused on the aging population.

Intervention studies of the effects of exercise on mental functioning in older adults have revealed prevention of memory decline, greater attentional abilities, and substantial improvements in executive functions such as the ability to plan activities, focus on task-relevant information, and perform multiple skills concurrently. Recent prospective cohort studies indicate that regular exercise is associated with reduced risk and delayed onset of age-associated cognitive impairments and dementia. A direct imaging study of older adults has revealed decreased brain tissue volume in several brain areas with age, and a striking reduction in brain tissue loss with regular activity.

Exercise has not only shown promise as an intervention to preserve cognitive functioning, but also has been demonstrated to improve emotional functioning and mood. For example, long-term exercise has been linked with improved morale in normal elderly populations. Exercise has also been introduced as an adjunct for antidepressant medication treatment or as a single intervention in controlled clinical trials for depression, and significant improvements in symptoms have been reported. Studies have shown that a long-term (16 weeks) exercise treatment program was equally as effective as medication treatment for major depression. Regular activity has also been associated with a reduced risk for developing depression in elderly populations.

It is thought that natural selection of human ancestors, after many generations of survival as hunter-gatherers, led to the evolution of humans for whom regular vigorous activity improves and prolongs survival and function. It is likely that normal human cellular function has evolved in such a way that a threshold of physical activity is required for optimal physiologic gene expression in many tissues throughout the body, including the brain. As discussed in the following sections, exercise maintains the activity of a number of important central neurotransmitter systems, and this activation state sets into motion key signal transduction pathways promoting survival and functioning of neurons at the cellular level. It appears that the activation state of neurons (as well as the entire organism) enhances processes associated with growth and plasticity.

Exercise and Central Nervous System Activation: Neurotransmitter Function

A wealth of evidence from both animal and human studies indicates that general aerobic activity leads to enhanced secretion of a number of important neurotransmitters and neuromodulators in the central nervous system (CNS). Such findings serve as neurochemical evidence for increased activation of the CNS (both global excitation of the brain and stimulation within specific brain regions). Enhanced concentrations of neurotransmitters and neurotransmitter metabolites have been measured in blood and cerebrospinal fluid (CSF) of humans. In animal models, microdialysis studies have allowed investigators to observe dynamic neurotransmitter release within specific brain areas during (and following) exercise. These specific forms of neurotransmitter activation have important implications for vulnerability to stress and depression, and impact survival and plasticity at the cellular level.

The monoamines, most notably serotonin, norephinephrine, and dopamine, are essential for multiple CNS functions, including arousal, cognition, and the regulation of mood. The activity of these systems is compromised with chronic stress and depression, and most antidepressant treatments in current practice are designed to enhance monoaminergic activity. In animal studies, exercise has been observed to enhance norephinephrine (NE) release in the brain stem, hypothalamus, and limbic brain regions. In humans, increased NE release into plasma has been observed following acute

NRSC: 00144

exercise. These changes prevent NE depletion during stress, and thus have been demonstrated to modulate physiological vulnerability to stressors. Some evidence also exists for changes in serotonin (5-hydroxytryptamine; 5-HT) release and metabolism during exercise. Clinical studies have indicated enhanced 5-HT availability and/or release in physically trained men, or after acute exercise, and another study has demonstrated enhanced release of dopamine and tryptophan (a metabolic precursor of serotonin). It has been proposed that enhanced dopamine neurotransmission occurring during exercise may contribute to enhanced central as well as peripheral function. Adequate monoaminergic (particularly serotonergic) function optimizes behavioral neuromodulation during various stressors.

The excitatory neurotransmitter, glutamate, plays a very important role in functional neuronal plasticity, signaling changes in synaptic function and morphology occurring during learning and other forms of neuronal activation. Studies have revealed that long-term exercise increases the levels or activated forms of several postsynaptic glutamatergic receptors in the cortex and hippocampus of rodents. Exercise-enhanced neurogenesis (discussed later) has been demonstrated to be dependent upon glutamatergic (*N*-methyl-D-aspartate; NMDA) receptor function. Neuropeptides such as vasopressin and galanin have also been studied in exercise research. Investigators have demonstrated changes in affinity of vasopressin, along with noradrenergic, receptors following exercise training. Both voluntary wheel-running and treadmill exercise training increase galanin gene expression in the rat locus coeruleus. Increased serum galanin secretion has also been detected after acute exercise in humans. Galanin may have an important neuromodulatory role in the NE system adaptations occurring during exercise.

In addition to an acute impact on intracellular activity and metabolism, cellular neurotransmission, as stimulated by exercise, also directs gene expression via the activation of signal transduction pathways. A key example is the activation of protein kinase A (PKA) and cyclic adenosine monophosphate (AMP) response element-binding protein (CREB) by monoamines via G-protein-coupled receptors, subsequently directing the expression of neurotrophins (discussed later) and other molecules promoting neuronal growth and survival.

Exercise and Growth Factor Expression

The neurotrophins are a family of molecules, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophins (NT-3 and NT-4/5). These compounds promote survival, growth, and differentiation of neurons during development and throughout the life span. Recent evidence has indicated that BDNF may play an important role in supporting normal cognitive and emotional function into old age and senescence, and that its expression is influenced by neuronal activity.

It has become evident that physical activity increases the expression of BDNF and other growth factors in several areas of the CNS. In animal models, both voluntary wheel-running and forced treadmill training (under conditions controlling stress) rapidly and robustly enhance BDNF mRNA and protein expression in the hippocampus. It is known that environmental enrichment, or the addition of visual, motor, tactile, and social stimulation to the rodents' cage environment, enhances BDNF expression in the hippocampus and neocortex, and that activity has been suggested to be the single most important component of this model for the observed increases in neurotrophin expression and CNS function. Increased hippocampal BDNF mRNA occurs in as little as 6 h and is sustained with long-term (several weeks) activity. Increases in BDNF protein are evident within 1–2 weeks and are sustained for at least 3 months. Increases in both BDNF mRNA and BDNF protein are highly correlated with running distance. Increased peripheral motor activity has been demonstrated to be required for these observed changes, which are thought to mediate many of the prosurvival effects of exercise. Confocal microscopic analysis revealed that short-term (7 days) activity caused a redistribution of BDNF from the cell body to the dendrites in neurons of the lumbar spinal cord, whereas longer term (28 days) exercise also led to increased perikaryonal BDNF.

The phenomenon of increased hippocampal BDNF with exercise is very much intact throughout the life span of rodents. Even with relatively small amounts of activity, aged rats demonstrate an ability to significantly enhance BDNF mRNA and protein to an extent no less than that achieved with antidepressant medications. Voluntary wheel running has also greatly enhanced neurogenesis and hippocampal (learning) function in aged mice without prior exercise experience. Recent evidence also indicates that swimming exercise of a mother rat during pregnancy enhances hippocampal BDNF mRNA expression and neurogenesis of the offspring. Exercise can therefore represent a powerful, nonpharmacological means for maintaining neurotrophin levels and neuronal health throughout development, and throughout the life span.

It is becoming increasingly evident that exercise, and the resulting enhancement in neurotrophin expression, can improve neuronal function. Exercise has been

demonstrated to increase the levels of proteins involved in vesicle formation and neurotransmitter release, such as synaptophysin and synapsin I. Enhanced synaptic function, such as that occurring during development or learning, can thus result from exercise. One cellular phenomenon that is highly dependent upon BDNF, and that in turn stimulates additional BDNF expression, is long-term potentiation (LTP). LTP is activated in the hippocampus during the process of spatial learning. An increase in hippocampal LTP has been observed in rats undergoing voluntary wheel-running activity, which appears to reflect an alteration in the induction threshold for synaptic plasticity occurring during exercise. Voluntary wheel-running activity for 3 weeks has been shown to enhance performance of rats in the Morris water maze, a widely studied spatial learning paradigm. The acquisition of another challenging spatial learning task, the radial arm maze, has been facilitated by long-term voluntary exercise. In aged (23 months) rats, long-term (7 weeks) mild, forced treadmill exercise improved performance in the Morris water maze, demonstrating both a shorter path length and significantly decreased latency to find the hidden platform.

Evidence exists that the BDNF-increasing effects of exercise in the hippocampus follow, and are dependent upon, noradrenergic activation. In addition, some cognitive benefits of exercise, such as the augmentation of contextual fear conditioning, are attenuated by blockade of β-adrenoreceptors. Stimulation of the PKA pathway following adrenergic G-protein-coupled receptor activation mediates increased BDNF expression via the transcription factor CREB. Abundant evidence exists for increased CREB phosphorylation (activation) and expression following exercise. The enhanced neurotrophin expression brought about by exercise subsequently activates tyrosine kinase (Trk) receptors and key intracellular signaling pathways mediating survival and growth. One important transcriptional target of these pathways is, once again, CREB. CREB, along with other transcription factors (including nuclear factor-kappa B, which has been shown to be increased with exercise), enhances the expression of BDNF along with several other prosurvival genes. In this way, BDNF expression can be increased via a positive feedback mechanism. This type of mechanism may explain the very rapid and robust increase in BDNF expression observed with exercise. Researchers in several laboratories have found evidence for neurotrophin expression being enhanced via a type of positive feedback loop. One of their reports cited direct evidence for changes in neurotrophin expression being driven by neurotrophin pulses in neuronal culture. This mechanism is discussed further in the following section.

In addition to the striking changes in hippocampal BDNF, evident with exercise, increases in BDNF and/or NGF and NT-3 have been demonstrated in the hippocampus, neocortex, basal forebrain, striatum, and spinal cord. The spinal cord has been a focus area for study of the effects of activity on neurotrophin expression, survival, and recovery from injury. Motor activity (treadmill walking or stepping) has been shown to enhance the expression of several neurotrophins in the spinal cord, and to enhance neuronal outgrowth and recovery in injured areas. In intact rats, locomotor exercise increases levels of BDNF and its receptor, TrkB, in the lumbar spinal cord, and also increases levels of NT-3 and its receptor, TrkC. In models of spinal cord injury, exercise also compensated for reductions in BDNF occurring in the lumbar spinal cord after hemisection to the midthoracic region, and increased BDNF was associated with reduction in sensory symptoms such as allodynia. In the latter study, increasing BDNF protein levels were highly correlated with running distance. Exercise was also shown to enhance regrowth of axons after a nerve-crush injury; and sensory (dorsal root ganglion) neurons from animals undergoing exercise also showed increased neurite outgrowth. Exercise interventions, therefore, show much promise to promote the recovery of motor function following spinal cord injury.

Another highly important growth factor for the mediation of exercise-induced changes within the brain is insulin-like growth factor (IGF). Investigators have shown that the uptake of peripheral IGF into the CNS occurs during voluntary exercise, and that this action is essential for both increased CNS expression of neurotrophins and functional recovery from stress. Recent evidence indicates that IGF from central as well as peripheral sources participates in exercise-induced increases in hippocampal BDNF expression as well as augmentation of recall in the Morris water maze, and also increases progenitor cell proliferation in the dentate gyrus. Much evidence is accumulating that IGF plays a very important role in antiaging and anticellular stress phenomena occurring with exercise, environmental enrichment, and dietary restriction.

It is becoming increasingly evident that interaction between multiple growth factors may be playing a role in exercise-associated neurochemical changes. Glial maturation factor (GMF), production of which is increased with exercise, appears to also be essential for exercise induction of BDNF expression. Vascular endothelial growth factor (VEGF) has

NRSC: 00144

been demonstrated to be particularly important for exercise-induced adult hippocampal neurogenesis.

Exercise and Cellular Survival Signaling

The survival of neurons is dependent upon the activity of a number of finely tuned cellular signaling cascades. Two primary signaling pathways known to promote neuronal growth and survival are the phosphatidylinositol 3-kinase (PI3K)/Akt and mitogen-activated protein kinase (MAPK) pathways, which influence gene expression through activation of transcription factors, such as CREB. The MAPK and PI3K pathways are regulated by neurotrophin/Trk receptor signaling, and therefore represent two of the major signaling pathways mediating BDNF-induced TrkB activation. In cultured cortical neurons subjected to apoptotic conditions, BDNF has been shown to promote survival and neuroprotection by activating the MAPK and PI3K pathways. Consistently, BDNF stimulates the phosphorylation of Akt, which plays a critical role in controlling the balance between survival and apoptosis. Akt is activated via the PI3K pathway, following stimulation by insulin and several other growth/survival factors, and promotes cell survival by inhibiting apoptosis through its ability to phosphorylate and inactivate several substrates, including BAD, the forkhead transcription factors, caspase-9, and GSK-3β. In addition to increasing cellular survival, the PI3K and MAPK pathways play principal roles in promoting neurite growth, synaptic strength, and plasticity. Via these pathways, excitatory neural stimulation via exercise may therefore be an important means to enhance neuronal growth or recovery in an activity-dependent manner.

Microarray analyses of brain tissue from rodents undergoing physical activity have provided an excellent preliminary view of the genes and intracellular molecules activated by exercise. The 'exercise profile' includes a number of molecules along the PI3K survival pathway, and several other genes promoting cellular growth and survival. Some recent studies have also directly demonstrated increased concentrations of proteins along the PI3K and MAPK pathways in the brains of rodents undergoing chronic or subchronic voluntary activity.

Exercise enhances by two- to threefold the generation and survival of new neurons derived from progenitor cells within the adult hippocampus. Several of the key humoral factors outlined in the previous section, such as IGF-1 and BDNF, are thought to mediate exercise-stimulated neurogenesis. Evidence indicates that the MAPK signaling pathway is required for IGF-1-stimulated proliferation, whereas the PI3K/Akt pathway plays a major role in maintaining survival and inhibiting apoptosis. Recent evidence also indicates that neurogranin, a specific substrate of protein kinase C, is required for exercise-induced neurogenesis and resulting cognitive enhancements. Regarding the birth of new neurons, exercise appears to have a more profound effect upon proliferation than on differentiation or survival. Anatomical examination has revealed that the proportion of cells exhibiting an immature morphology is increased within the hippocampal dentate gyrus following exercise. Subsequent differentiation of these progenitors into mature neurons, and integration into the neuronal circuitry, may be stimulated by environmental enrichment and learning. Exercise may therefore benefit hippocampal function by increasing the potential for neurogenesis. Indeed, human evidence exists that cognitive enrichment complements physical fitness training in promoting life span and mental health.

The effectiveness of antidepressant medications for improving mood and emotional function has been attributed to increased neurotrophin expression, stable signaling changes, and increased neurogenesis within the hippocampus, all of which occur after 2–3 weeks of treatment (the time frame often required for symptom relief in humans). The relatively rapid effectiveness of exercise for improving neurotrophin expression (within hours to days) may be attributed to the simultaneous activation of several survival- and plasticity-promoting signaling cascades, including the PI3K and MAPK pathways, pathway cross-talk, and positive feedback. Several clinical studies have indicated that exercise is an effective antidepressant or adjunctive agent. Electroconvulsive therapy (ECT), a treatment of choice for medication-resistant patients with major depression, has been demonstrated to activate the expression of multiple growth-promoting genes, including the 'exercise profile.'

Investigations into the intracellular mechanisms of survival-promoting interventions such as exercise have also been pursued in cell culture models. It has been revealed that primary neurons harvested from exercising animals retain an activated or stimulated state. In one study, dorsal root ganglion neurons showed an increase in neurite outgrowth when cultured from animals that had undergone 3 or 7 days of exercise. Since much evidence has pointed to the possibility that NE activation is an essential component of the cascade of events leading to exercise-induced increases in neurotrophin expression, we studied cellular signaling within a model system of NE applied to primary hippocampal neurons. NE application to hippocampal neurons in culture significantly increased BDNF levels in a time- and dose-dependent manner, and the phenomenon appeared to be dependent upon Trk receptor activation as

well as on activity of the PI3K and MAPK pathways. The NE-induced activation of the MAPK cascade via Trk activation has also been demonstrated in primary cortical neurons.

Neurodegeneration: How Exercise Can Decrease Risk and Contribute to CNS Repair Mechanisms

The aging process is associated with metabolic dysfunction and an impaired ability of the organism to cope with adversity. With normal aging, the efficiency of metabolic processes decreases along with the efficacy of systems designed to remove molecules associated with oxidative stress. Oxidative stress can lead to neurodegeneration in many areas of the brain. The hippocampus is also particularly vulnerable to the effects of psychosocial stress and the secretion of stress hormones (glucocorticoids), since it is an area with very high glucocorticoid receptor numbers. Severe, prolonged stress is thought to play an important role in the pathophysiology of several mental disorders such as major depression. Age-associated neurological disorders such as Alzheimer's disease and Parkinson's disease involve a great pronouncement of neurodegeneration beyond the normal aging process. Exercise has shown increasing promise as a preventive or reparative intervention for these various forms of neurodegeneration.

Although exercise imposes increased metabolic demands on the organism, evidence exists that it improves metabolic efficiency and decreases cellular vulnerability. As noted earlier, exercise is capable of increasing the expression of hippocampal BDNF throughout the life span of rodents. Via neurotransmitter activation and enhanced neurotrophin production, exercise can protect neurons by stimulating the production of proteins that suppress oxyradical production, stabilize cellular calcium homeostasis, and inhibit apoptotic biochemical cascades. Decreased oxidative damage and improvement in cognitive function have been demonstrated in the rat brain following exercise. Exercise also modifies the age-related decrease of hippocampal growth-associated protein, GAP-43, and synaptophysin, and the age-related decrease in antioxidant enzyme activities. It has also been shown that exercise potentiates the expression of the heat shock protein, Hsp72, and that this could contribute to neuroprotection from stress. In addition, although exercise is associated with increased glucocorticoid secretion, voluntary activity can still decrease glucocorticoid levels and hippocampal damage associated with ongoing physical/psychological stress. Prior exercise was also demonstrated to be protective against reductions in hippocampal BDNF protein caused by acute immobilization stress, even though increased corticosterone levels were sustained. Exercise has also been demonstrated to reverse several detrimental effects of a high-fat diet, including increased levels of reactive oxygen species, decreased neurotrophin (BDNF) expression, decreased expression of downstream effectors of synaptic function, and behavioral (spatial learning) deficits.

Specific evidence is accumulating that exercise can provide benefits in the face of neurodegenerative disease. Investigators have shown that exercise almost completely protects the brain against experimentally induced parkinsonism. This finding may be associated with increased glial-derived neurotrophic factor levels. Moderate exercise has been demonstrated to induce neurotrophin production in humans (evident in serum levels), and this may underlie the benefits of exercise for multiple sclerosis. Exercise has also shown much promise as a therapeutic strategy against amyotrophic lateral sclerosis. Even brief exposures to voluntary exercise improved motor function and survival in a mouse model of this disorder. Evidence also exists that increased physical activity reduces stroke damage. Preischemic treadmill activity reduced neurologic deficits and brain infarct volume in rats; increased neurotrophin levels and microvessel density were associated findings. Microvessel integrity within the brain may be a key factor for the prevention of many types of neurodegenerative disorders. Exercise stimulates brain vessel density in experimental animals in a manner that is dependent upon IGF-1.

Aging is associated with reductions in both hippocampal neurogenesis and IGF-1 levels, and administration of IGF-1 to old rats reverses age-related changes in central energy metabolism/function, increases neurogenesis, and reverses cognitive impairments. A reduction in the activity of the growth hormone/IGF-1 axis with age is well documented in humans. Analogs of IGF-1, along with the molecules of the PI3K pathway, are present in a wide variety of organisms from nematodes to humans, and evidence is strong that their function is closely tied to stress resistance and survival. Insulin-like signaling, along with the actions of neurotransmitters and neurotrophins, therefore link energy metabolism to cellular survival in an evolutionarily conserved manner.

Conclusion

In mammals, it is becoming increasingly evident that optimal cellular function within the nervous system and throughout the body is favored by heightened

NRSC: 00144

activity. The evidence outlined in this article has shown us that various forms of physical activity, such as voluntary aerobic exercise, activate highly specific intracellular systems that optimize function and survival. These systems are put into motion by molecules such as monoaminergic neurotransmitters, IGF-1, and the neurotrophin BDNF. This brings us, at the cellular level, to a full-circle connection to our earlier discussion of evolution of humans as active hunter-gatherers, and how cellular machinery likely similarly evolved in such a way that optimal function would be favored by increased activity. The aforementioned studies have suggested that, at the molecular level, monoamines, BDNF, and IGFs can stimulate the production of proteins involved in cellular stress adaptation, survival, growth/repair, and neurogenesis. All of these actions appear to be dependent upon synaptic activity, which is enhanced during exercise. These mechanisms may also compensate for changes taking place with aging and situations of severe stress. There is much yet to be learned about the specific mechanisms involved in exercise-induced cellular adaptations, but we have much evidence that exercise is an essential intervention to maintain brain health throughout life.

Exocytosis: Ca^{2+}-Sensitivity

R Schneggenburger, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Transmission at chemical synapses is mediated by exocytosis of synaptic vesicles with the neuronal plasma membrane, a process which takes place at the active zones of nerve terminals. When an action potential arrives at a presynaptic active zone, voltage-gated Ca^{2+} channels open, causing a short inflow of Ca^{2+} ions into the cytoplasm of the presynaptic neuron (Figure 1). The subsequent increase in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) triggers the membrane fusion of neurotransmitter-loaded synaptic vesicles, probably initiated by the binding of Ca^{2+} ions to synaptotagmin molecules, which are located on the surface of synaptic vesicles. By this process of exocytosis, neurotransmitter is released from a presynaptic neuron and can activate receptors on the surface of a postsynaptic cell.

The Microdomain Ca^{2+} Signal

Although it has been known since the pioneering studies of B Katz and colleagues in the 1960s that Ca^{2+} influx through voltage-gated Ca^{2+} channel triggers vesicle fusion at synapses, it has been less clear how intracellular Ca^{2+} regulates vesicle fusion and which intracellular Ca^{2+} concentration must be reached at the sites of vesicle fusion to efficiently trigger the release of neurotransmitter. This is because action potentials in neurons are brief ($\sim$1 ms) and consequently, Ca^{2+} channels admit only a brief inflow of Ca^{2+}. Computer simulations have shown that as long as a Ca^{2+} channel stays open, a 'spike' of enhanced $[Ca^{2+}]_i$ builds up around the open Ca^{2+} channel (Figure 1). The exact Ca^{2+} concentration reached at a neighboring docked and readily releasable vesicle critically depends on the distance between the Ca^{2+} channel and the vesicle, with Ca^{2+} concentration dropping off steeply with distance to the Ca^{2+} channel. The $[Ca^{2+}]_i$ reached in this single channel 'microdomain' also depends on a number of other parameters, such as the single channel conductance of the Ca^{2+} channel and the Ca^{2+} buffering strength of the cytoplasm. When the Ca^{2+} channel closes, the $[Ca^{2+}]_i$ in the microdomain collapses rapidly, within microseconds, to much lower values. To further complicate matters, the $[Ca^{2+}]_i$ signal at any given docked and readily releasable vesicle is, in many synapses, influenced by several Ca^{2+} channels located in close vicinity. We refer to the $[Ca^{2+}]_i$ signal experienced by a docked and readily releasable vesicle as the 'local' $[Ca^{2+}]_i$ signal. Although tremendous advances have been made in microscopic imaging techniques in recent years, it is still not possible to directly measure both the amplitude and the time course of this local $[Ca^{2+}]_i$ signal.

The Ca^{2+} Uncaging Experiment

In order to learn more about how intracellular Ca^{2+} regulates vesicle fusion and transmitter release, Ca^{2+} uncaging in the cytoplasm of single cells has been used to trigger vesicle fusion. During Ca^{2+} uncaging, a Ca^{2+}-loaded photosensitive Ca^{2+} chelator in the cytoplasm of a cell is photolyzed by a brief UV light pulse from a flash lamp or a UV laser coupled with an epifluorescence microscope. With this method of $[Ca^{2+}]_i$ elevation, spatial gradients that occur during the opening of voltage-gated Ca^{2+} channels are avoided. A fluorescent Ca^{2+} indicator dye can be used to measure $[Ca^{2+}]_i$. Since the $[Ca^{2+}]_i$ signal is spatially homogeneous, this technique ensures that the Ca^{2+} indicator dye and the readily releasable vesicles docked at the membrane 'see' the same $[Ca^{2+}]_i$. Thus, the jump in $[Ca^{2+}]_i$ that triggers vesicle fusion in these experiments can be directly measured by the fluorescent Ca^{2+} indicator dye, and a quantitative relationship between the rate of vesicle fusion and $[Ca^{2+}]_i$ can be derived. Such experiments are usually combined with whole cell patch clamp recording of a single secretory cell or a nerve terminal. A solution containing the Ca^{2+}-loaded photosensitive Ca^{2+} chelator, the Ca^{2+} indicator dye, and additional constituents is perfused inside the cell via the recording patch pipette.

Ca^{2+}-Dependent Rates of Exocytosis in Secretory Cells and Nerve Terminals

Ca^{2+} uncaging experiments to measure the intracellular Ca^{2+} sensitivity of vesicle fusion were first done in neuroendocrine secretory cells such as chromaffin cells, which are easily amenable to patch clamp studies. In these cells, hormones and transmitters are released via membrane fusion of large dense core vesicles. The rate of exocytosis, as measured by membrane capacitance, depended steeply on the amplitude of the $[Ca^{2+}]_i$ step produced by Ca^{2+} uncaging, and with $[Ca^{2+}]_i$ steps to approximately 10 μM, the fastest component of membrane capacitance rise had a time constant (τ) of approximately 50 ms. This means that the fastest component of the readily releasable pool is released at a rate of $1/\tau$, or 20 s^{-1} at

10 μM $[Ca^{2+}]_i$ (Table 1). Thus, in chromaffin cells and other neuroendocrine cells, secretion takes place at low micromolar Ca^{2+} concentrations, but the kinetics of vesicle fusion at this $[Ca^{2+}]_i$ are relatively slow. This might reflect the fact that for their physiological functions, neuroendocrine cells probably do not need very fast secretory responses in the low milliseconds range.

The intracellular Ca^{2+} sensitivity of vesicle fusion has also been measured in terminals of bipolar cells of the retina and in inner hair cells of the cochlea. These cells release the neurotransmitter glutamate from small synaptic vesicles. Glutamate release from these cells occurs at specialized release sites called 'ribbon' synapses, which have a protein-containing, electron-dense organelle – the ribbon – close to their active zones. At ribbon synapses, neurotransmitter can be released both rapidly and in a sustained fashion. Ca^{2+} uncaging has shown that fast release rates of approximately 1000 s^{-1} (corresponding to a secretion time constant of 1 ms) are reached at approximately 100 μM $[Ca^{2+}]_i$ or higher in bipolar cell terminals and in inner hair cells (Table 1). Thus, the results of these experiments agreed with earlier estimates from theoretical work, which had predicted that an intracellular Ca^{2+} concentration of approximately 100 μM must occur close to docked vesicles in order to ensure fast rates of vesicle fusion.

Figure 1 Scheme of a membrane-docked, readily releasable vesicle with a neighboring Ca^{2+} channel. The intracellular Ca^{2+} signal that builds up when the Ca^{2+} channel opens is shown in red. The SNARE proteins synaptobrevin (blue), SNAP-25 (green), and syntaxin (black), which define the readily releasable state of a vesicle and contribute to tethering the vesicle to the plasma membrane, are also shown. The vesicle protein synaptotagmin 1/2 with its two Ca^{2+} binding domains (C2 domains), which is probably the Ca^{2+} sensor for vesicle fusion, is shown in red. Note that in many synapses, the microdomain Ca^{2+} signal experienced by readily releasable vesicles is created by several neighboring Ca^{2+} channels.

Table 1 Ca^{2+}-dependent rates of vesicle fusion estimated by Ca^{2+} uncaging in different secretory cells

	Rate constant (at μM $[Ca^{2+}]_i$)[a]	*Ca^{2+} cooperativity*[b]	*References*[c]
Chromaffin cells	20 s^{-1}, at 10 μM	3	1, 2

The Ca^{2+} Sensitivity of Transmitter Release at the Calyx of Held

The general expectation that fast rates of neurotransmitter release need high transients of local $[Ca^{2+}]_i$ (~100 μM) has not been found to hold true at a large, fast-releasing central nervous system (CNS) synapse, the calyx of Held. This axosomatic synapse between a large nerve terminal and a principal cell of the medial nucleus of the trapezoid body contains several hundred individual active zones. At this synaptic connection, an action potential in the presynaptic nerve cell produces a fast-rising and decaying excitatory postsynaptic current (EPSC) with an amplitude of several nanoamperes, which is mediated by the release of approximately 100–200 vesicles. The calyx of Held nerve terminal is unusually large (~10–15 μm in circumference), which has allowed researchers to make patch clamp recordings directly from this nerve terminal. This has facilitated the use of Ca^{2+} uncaging at this CNS nerve terminal (Figure 2). The calyx of Held synapse is the only nerve terminal in the mammalian CNS at which the intracellular Ca^{2+} sensitivity of vesicle fusion has been studied systematically.

Figure 2 illustrates a typical Ca^{2+} uncaging experiment performed at the calyx of Held. Two whole cell patch clamp recordings were made simultaneously, one from the soma of the postsynaptic neuron and the other from the presynaptic element, the calyx of Held nerve terminal. The presynaptic patch pipette contained 1 mM of the photolyzable Ca^{2+} chelator DM-nitrophen as well as 0.1 mM of the Ca^{2+} indicator fura-2FF, which stained the presynaptic calyceal nerve terminal (Figure 2(a)). Flashes of various intensities were given every 30–40 s to elevate the intracellular Ca^{2+} concentration in the nerve terminal (Figure 2(b)). In response to these presynaptic $[Ca^{2+}]_i$ elevations, EPSCs were recorded, which reflect the neurotransmitter release activity from the nerve terminal. As can be seen in Figure 2, Ca^{2+} uncaging stimuli of increasing amplitude evoked EPSCs of increasing amplitudes. The relationship between EPSC amplitude and presynaptic $[Ca^{2+}]_i$ was apparently strongly supralinear (Figures 2(b)–2(d)).

In order to derive the rates of transmitter release from the EPSCs recorded in the postsynaptic cell,

Figure 2 Presynaptic Ca^{2+} uncaging at the calyx of Held. (a) High-resolution image (left) and binned image (right) of a calyx of Held filled via a recording whole cell patch clamp pipette with the Ca^{2+}-sensitive fluorescent indicator, fura-2FF, and with the photolyzable Ca^{2+} chelator, DM-nitrophen. Pixel binning (see right image) was used during the fluorometric measurements of the intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$; see (b)) to enable a high time resolution. (b) Steplike presynaptic $[Ca^{2+}]_i$ elevations in response to three UV light flashes with different intensities. (c, d) Excitatory postsynaptic currents (EPSCs) measured simultaneously by a second whole cell patch clamp recording of the postsynaptic cell. The traces that correspond to the presynaptic $[Ca^{2+}]_i$ elevations shown in (b) are identified by identical colors. Note that with presynaptic $[Ca^{2+}]_i$ steps of increasing amplitude, the EPSCs increase in amplitude and their rise times decrease. (e) Transmitter release rates as analyzed by deconvolution of the two EPSC traces shown in (d). Note that the two $[Ca^{2+}]_i$ steps to 4 and 6.5 μM amplitude (see (b), red and black trace) produced peak transmitter release rates with a sixfold difference, showing the highly supralinear action of Ca^{2+} in triggering synaptic vesicle fusion. (f) Averaged miniature EPSC trace from 436 single events. The kinetic parameters of this mEPSCs were used for the deconvolution of the evoked EPSC responses (see (d) and (e)). Reproduced from Schneggenburger R and Neher E (2000) Intracellular calcium dependence of transmitter release rates at a fast central synapse. *Nature* 406: 889–893.

the EPSCs were deconvolved with the average waveform of the miniature EPSC (Figure 2(f)). Miniature EPSCs (mEPSCs) likely represent the spontaneous fusion of a single presynaptic vesicle. The transmitter release rate traces obtained from the deconvolution showed peak release rates of 10 and 60 ves/ms (Figure 2(e)), which were evoked by presynaptic $[Ca^{2+}]_i$ steps to 4 and 6.5 μM, respectively (Figure 2(e), red and black traces). This analysis thus establishes the relationship between transmitter release rate and the intracellular Ca^{2+} concentration in a presynaptic nerve terminal of the CNS.

Figure 3(a) shows a plot of peak release rates, as analyzed in Figure 2(e), as a function of the $[Ca^{2+}]_i$ step in the nerve terminal, measured in Ca^{2+} uncaging experiments such as that illustrated in Figure 2. Figure 3(b) shows a similar plot of the Ca^{2+} sensitivity of transmitter release rate at the calyx of Held, which has been established independently by another group. In the plot of Figure 3(b), the transmitter release rates were divided by the estimated number of readily releasable vesicles (~1000), thus obtaining release rates per readily releasable vesicle. The measurements shown in Figures 3(a) and 3(b) clearly establish that fast vesicle release rates of approximately 1000 s^{-1} can be reached at 10–25 μM $[Ca^{2+}]_i$.

The local $[Ca^{2+}]_i$ signal experienced by an average readily releasable vesicle at the calyx of Held during the physiological stimulus (a presynaptic action potential) has been estimated to be a brief (~0.5 ms) rise of $[Ca^{2+}]_i$ to 10–25 μM based on kinetic modeling. This was done by first fitting the relationship between

Figure 3 Intracellular Ca^{2+} dependency of the rate of transmitter release at the calyx of Held. (a) Plot of the peak transmitter release rate as a function of the peak $[Ca^{2+}]_i$ step as produced by Ca^{2+} uncaging in experiments similar to those shown in Figure 2. (b) A similar relationship obtained independently from Ca^{2+} uncaging experiments at the calyx of Held (taken from Bollmann et al., 2000, *Science* 289, 953–957). Here, the release rates were normalized to the estimated number of readily releasable vesicles (~1000). Note that high rates of transmitter release of approximately 1000 s^{-1} per readily releasable vesicle are already reached at 10 μM $[Ca^{2+}]_i$. In both (a) and (b), the relationship between transmitter release and $[Ca^{2+}]_i$ was fitted with a kinetic model of Ca^{2+} binding and vesicle fusion (lines). (c) Membrane capacitance measurements at the calyx of Held after presynaptic Ca^{2+} uncaging. During the early times after a stimulus shown here, membrane capacitance measurements report cumulative vesicle fusion. Note that with $[Ca^{2+}]_i$ steps above 30 μM, the rise of the membrane capacitance signal is faster than 1 ms, as estimated from exponential fits. This confirms that fast rates of vesicle fusion (~1000 s^{-1}, equivalent to a time constant of 1 ms) are reached at moderate $[Ca^{2+}]_i$ at the calyx of Held. (a) Reproduced from Schneggenburger R and Neher E (2000) Intracellular calcium dependence of transmitter release rates at a fast central synapse. *Nature* 406: 889–893. (b) Reproduced from Bollmann J, Sakmann B, and Borst J (2000) Calcium sensitivity of glutamate release in a calyx-type terminal. *Science* 289: 953–957. (c) Reproduced from Wölfel M and Schneggenburger R (2003) Presynaptic capacitance measurements and Ca^{2+} uncaging reveal submillisecond exocytosis kinetics and characterize the Ca^{2+} sensitivity of vesicle pool depletion at a fast CNS synapse. *Journal of Neuroscience* 23: 7059–7068.

transmitter release rates and $[Ca^{2+}]_i$ with a minimal kinetic model of Ca^{2+} binding and vesicle fusion (Figures 3(a) and 3(b), lines). Because of the steep relationship between transmitter release rates and $[Ca^{2+}]_i$, with a slope of approximately 4 or 5 in double logarithmic coordinates (Figures 3(a) and 3(b)), five Ca^{2+} binding sites needed to be postulated for the kinetic models. After fixing the parameters of the model, the local $[Ca^{2+}]_i$ compatible with the measured Ca^{2+} sensitivity of vesicle fusion as measured in the Ca^{2+} uncaging experiment was then calculated. It was found that an intracellular Ca^{2+} signal of 10–25 μM amplitude with brief half-duration (~0.5 ms) experienced by an average readily releasable vesicle could explain the physiological waveform of transmitter release at the calyx of Held.

The relatively high rates of vesicle fusion at the calyx of Held reached at surprisingly moderate $[Ca^{2+}]_i$ have been confirmed by combined presynaptic Ca^{2+} uncaging and membrane capacitance measurements (Figure 3(c)). This approach is similar to the one used in neuroendocrine cells, bipolar cells, and inner hair cells and thus allows direct comparison of the rates of exocytosis measured at the calyx of Held to that estimated in the other cell types (Table 1). The time constant of the fastest component in the membrane capacitance rise was approximately 2 ms at 15 μM $[Ca^{2+}]_i$, and it was less than 1 ms at >30 μM $[Ca^{2+}]_i$. These measurements therefore indicate secretory rates of $>1000\,s^{-1}$ that are reached at approximately 30 μM $[Ca^{2+}]_i$ and thus confirm the estimates based on measurements of EPSCs at the calyx of Held (Figures 3(a) and 3(b)). Therefore, at the calyx of Held nerve terminal, fast rates of exocytosis ($\sim 1000\,s^{-1}$) are reached at significantly lower Ca^{2+} concentrations (~10–30 μM $[Ca^{2+}]_i$) than at the ribbon-type synapses of retinal bipolar cells and inner hair cells, where comparable rates are only reached at approximately 100 μM $[Ca^{2+}]_i$ (Table 1).

Molecular Determinants for Different Ca^{2+} Sensitivities of Vesicle Fusion

The molecular differences responsible for the differences in Ca^{2+} sensitivity between different secretory cells and nerve terminals are not clearly understood. In neurons, the synaptotagmin isoform 1 or 2 is thought to be the most important Ca^{2+} sensor which initiates vesicle fusion. However, these genes are not expressed in inner hair cells of the cochlea, where other proteins with C2 domain Ca^{2+} binding sites might take over the role of the Ca^{2+} sensor for vesicle fusion. These molecular differences may explain the different intracellular Ca^{2+} sensitivities of vesicle fusion in inner hair cells and in the calyx of Held (Table 1). It is also not known whether other CNS nerve terminals have a Ca^{2+} sensitivity for vesicle fusion comparable to that of the calyx of Held, or whether they have a lower Ca^{2+} sensitivity comparable to that observed in the ribbon-type synapses (Table 1). It is possible that synapses with different forms of short-term plasticity (facilitation as opposed to depression) have different Ca^{2+} sensitivities of vesicle fusion. At neuromuscular junctions of crustaceans, a difference in the intracellular Ca^{2+} sensitivity of transmitter release has been found between two types of synapses that show different short-term plasticities (facilitation as opposed to depression).

Ca^{2+} Cooperativity in Vesicle Fusion

An important property of the action of Ca^{2+} in triggering vesicle fusion is its high cooperativity. Studies that have used Ca^{2+} uncaging to measure the intracellular Ca^{2+} sensitivity of vesicle fusion have all shown a highly supralinear relationship between the rate of vesicle fusion and the intracellular Ca^{2+} concentration which drives vesicle fusion (Table 1). When release rates were plotted as a function of $[Ca^{2+}]_i$ in double-logarithmic coordinates (Figures 3(a) and 3(b)), a region of extreme steepness (~4 or 5) became apparent in the range of 2–8 μM $[Ca^{2+}]_i$. This indicates that the Ca^{2+} sensor(s) of a given readily releaseable vesicle has to bind at least four or five Ca^{2+} ions before the vesicle can fuse with the plasma membrane. In kinetic models of Ca^{2+} binding and vesicle fusion, five Ca^{2+} ions have been found necessary to adequately describe the steep Ca^{2+} dependency of transmitter release from the calyx of Held and from inner hair cells, which both release glutamate from small synaptic vesicles. However, in chromaffin cells, which release catecholamines from larger storage vesicles, the intrinsic Ca^{2+} cooperativity is somewhat smaller (Table 1).

It has been shown at the calyx of Held synapse that below 2 μM $[Ca^{2+}]_i$, the steepness in the relationship between transmitter release and $[Ca^{2+}]_i$ is gradually reduced until a slope value of approximately 1 is reached close to the resting $[Ca^{2+}]_i$ of the nerve terminal. This indicates that at low $[Ca^{2+}]_i$, vesicles can fuse at low rates even when less than five Ca^{2+} ions are bound to the Ca^{2+} sensor for vesicle fusion. The low cooperativity of Ca^{2+} in inducing vesicle fusion close to resting $[Ca^{2+}]_i$ is probably of physiological relevance, because it prevents a large rise in asynchronous transmitter release, which would occur in response to a weak rise of basal $[Ca^{2+}]_i$ if a Ca^{2+}-sensing mechanisms with high cooperativity operated close to resting $[Ca^{2+}]_i$. Thus, the low cooperativity of Ca^{2+} in inducing vesicle fusion close to resting

$[Ca^{2+}]_i$ probably protects the nerve terminal from excessive loss of transmitter during small variations of the resting $[Ca^{2+}]_i$.

What might be the advantage of the high cooperativity of Ca^{2+} in inducing vesicle fusion at synapses? The answer might lie in an optimal signal-to-background 'noise' ratio for synaptic transmission. At the calyx of Held, it has been found that during a presynaptic action potential, the peak transmitter release rate is 10^5–10^6 fold higher than the spontaneous release rate as measured by the frequency of mEPSC events. Thus, the relative increase in transmitter release rate during an action potential is much larger than the relative increase in presynaptic $[Ca^{2+}]_i$ by which it is triggered (from a basal value of ~50 nM to ~10–25 μM local $[Ca^{2+}]_i$). The strong, 10^5–10^6 fold increase in peak transmitter release rate during an action potential can only be achieved with a highly nonlinear transduction mechanism. Thus, the nonlinear, cooperative action of Ca^{2+} at the molecular machinery that triggers vesicle fusion might have evolved to allow a high dynamic range of peak transmitter release rate compared to background release at the synapse.

The high cooperativity of Ca^{2+} in inducing vesicle fusion is also an important factor during short-term plasticity of synaptic transmission and for the modulation of transmitter release by presynaptic metabotropic receptors. Small changes in the amount of presynaptic Ca^{2+} influx that might occur during short-term plasticity or after metabotropic receptor activation will be translated into relatively large changes in transmitter output because of the highly supralinear relationship between Ca^{2+} and transmitter release.

Extinction: Anatomy

K A Corcoran and G J Quirk, University of Puerto Rico School of Medicine, San Juan, Puerto Rico

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Extinction occurs when a conditioned stimulus (CS) is repeatedly presented in the absence of reinforcement; it is measured as a decline in the frequency and amplitude of conditioned responses. Current theories of extinction suggest that this decline reflects the development of an inhibitory memory that competes with the conditioning memory to drive behavior. Like other forms of memory, extinction consists of three phases: acquisition, consolidation, and retrieval (Figure 1). Acquisition of extinction is evident as decreased responding to the CS across an extinction session. Consolidation begins some time during the extinction session and continues for several hours afterward to form a more stable, long-term memory trace. Retrieval of extinction is triggered when the CS is once again presented after the extinction session. Research on the mechanisms of extinction has pinpointed many of the molecular mechanisms involved in these processes and has identified a critical neural circuit, which includes the amygdala, medial prefrontal cortex (mPFC), and hippocampus.

Amygdala

Acquisition of Pavlovian fear conditioning depends on cellular and molecular processes in the basolateral complex of the amygdala (BLA), which includes the basal and lateral amygdalar nuclei. After pairing a tone CS with a footshock unconditioned stimulus (US), for example, neurons in the lateral amygdala (LA) demonstrate increased firing in response to the CS. This increased activity reflects *N*-methyl-D-aspartate (NMDA) receptor- and protein synthesis-dependent synaptic plasticity. Lesions in or inactivation of the amygdala prevent the acquisition of conditioned fear as well as the expression of previously acquired fear memories. Thus, the amygdala is considered an essential site for the acquisition, consolidation, and retrieval of conditioned fear memories.

Given the critical role for the BLA in fear learning, it is not surprising that it is also involved in the inhibitory learning underlying extinction. Accumulating evidence suggests that the BLA mediates the acquisition of fear extinction, similar to its role in the acquisition of fear conditioning. Extinction of conditioned fear is similar to fear acquisition in that it requires the activation of glutamate receptors in the BLA. Within-session extinction is prevented by intra-BLA blockade of NMDA or metabotropic glutamate receptors. Extinction training engages several intracellular signaling cascades in the BLA, as indicated by increased levels of phosphorylated mitogen-activated protein kinase (MAPK) and phosphatidylinositol (PI)-3 kinase. Disruption of MAPK or PI-3 kinase activity in the BLA shortly after extinction training prevents the subsequent retrieval of extinction memory. These signaling pathways lead to the activation of immediate early genes such as *c-fos* and *zif*; failure to activate these genes is correlated with poor extinction learning. Within-session extinction of appetitive instrumental responses is blocked by inactivation of the BLA, suggesting that the BLA is similarly involved in the acquisition of extinction for other forms of affective learning.

Consolidation of extinction is also reliant on synaptic plasticity in the BLA. Protein synthesis inhibition in the BLA prevents extinction recall in conditioned fear and taste aversion paradigms. Shortly after extinction training, increased levels of mRNA for the neurotropic factor brain-derived neurotropic factor (BDNF) are observed in the BLA, indicating that structural changes help stabilize the extinction memory. Interestingly, some synaptic changes underlying extinction appear to directly oppose some of the plastic changes that underlie conditioning. For example, fear conditioning decreases levels of the γ-aminobutyric acid (GABA)-clustering protein gephyrin in the BLA, whereas extinction training is correlated with an upregulation of gephyrin and an increase in the surface expression of GABA receptors. Thus, extinction memories may be represented as increases in inhibitory neurotransmission within the amygdala. Similarly, extinction can reverse conditioning-induced phosphorylation of the transcription factor cyclic adenosine monophosphate (cAMP) responsive element-binding protein (CREB). Extinction training increases the activity of the phosphatase calcineurin, which dephosphorylates CREB. This reversal suggests that, to a certain extent, extinction might cause an erasure of the conditioning memory stored in the BLA.

Medial Prefrontal Cortex

The mPFC is a higher-order processing center involved in many cognitive functions, such as working memory and decision making. The mPFC consists of several interrelated subregions; the two that have been studied most thoroughly with regard to fear and extinction are the infralimbic (IL) and prelimbic

Figure 1 Extinction is a learning process that occurs in three phases. During extinction training, when conditioned stimuli (CSs) are presented without any reinforcement, the frequency and magnitude of conditioned responses decline. Consolidation of the extinction memory begins some time during extinction training and continues for several hours after the end of the extinction session. When the CS is again presented sometime later, extinction is retrieved, as evidenced by low levels of conditioned responding. A failure to retrieve extinction (high levels of responding) occurs when CS is presented outside the extinction context.

(PL) subregions. Activity in these areas is intimately linked to amygdala function, fear expression, and extinction.

Rats with lesions of the IL subregion of mPFC are able to learn extinction within a single session, suggesting that the IL is not involved in the within-session acquisition of extinction. However, they are unable to retrieve the extinction memory the following day, demonstrating high levels of fear. Consistent with this, inactivation of the IL prior to extinction training also prevents extinction retrieval. Thus, activity in the IL during or after an extinction session is important for later extinction retrieval. Consistent with a role for the IL in consolidation of the extinction memory, local infusion of protein synthesis inhibitors or NMDA antagonists in the IL disrupts extinction retrieval the following day.

Although manipulations of the mPFC disrupt the consolidation of extinction, there is evidence that the extinction memory itself is not completely lost. When rats are reextinguished during testing via additional CS presentations, extinction proceeds at a faster rate than during the original extinction session. This faster rate of reextinction is evidence of savings of the original extinction memory. Thus, the IL is not necessary for the consolidation of the extinction memory itself. Rather, extinction-related plasticity in the IL is necessary for successfully retrieving extinction at a later time. In other words, the IL stores a memory that facilitates the retrieval of the extinction memory stored elsewhere.

One mechanism by which the IL encodes this extinction retrieval memory is by increased bursting of IL neurons. Bursting measured shortly after extinction training is correlated with the degree of extinction recall the following day. Bursting in the IL is dependent on NMDA receptors, suggesting that it may contribute to the potentiation of IL activity following extinction. During retrieval of extinction, the IL shows increases in unit activity, evoked potentials, metabolic activity, and c-Fos expression. In each case, the degree of potentiation is correlated with the amount of extinction recalled. Thus, it is believed that IL neurons specifically signal extinction retrieval. A role for the IL in extinction retrieval is also evident in studies of instrumental appetitive responses. Lesions of the IL enhance the renewal of bar-press responses outside the extinction context and the spontaneous recovery of bar-press responses after extinction.

The IL projects to both the amygdala and the amygdala's targets, and it is therefore well situated to modulate fear responses. Consistent with this, IL activity has an inhibitory influence on the amygdala. Neurons in the IL project to the intercalated GABAergic neurons (ITCs) situated between the BLA and the central nucleus of the amygdala. Stimulation of the IL activates ITCs, which subsequently inhibit neurons projecting from the central nucleus to other brain regions involved in the generation of fear responses. Stimulation of the IL also reduces the expression of conditioned fear responses, supporting a role for this pathway in fear inhibition.

Contrary to the inhibitory effects of the IL, the PL augments fear expression. Lesions or inactivation of the PL diminishes the expression of conditioned fear responses. In contrast, microstimulation of the PL increases freezing in response to CSs. Like the IL, the PL is intimately connected with the amygdala, but its targets are somewhat different. The PL projects to the BLA, and activity in the PL drives BLA neurons. The BLA projects to output neurons of the central nucleus of the amygdala. The PL could therefore be involved in the renewal or spontaneous recovery of fear after extinction. Thus, because of its ability to bidirectionally modulate amygdala activity, the mPFC can regulate both fear conditioning and extinction.

Hippocampus

Unlike the retrieval of fear memory, the retrieval of extinction memory is strongly regulated by context. When a CS is presented outside the context in which extinction training occurred, extinction memory is not retrieved and fear responses are renewed. The hippocampus plays an important role in many forms of contextual learning and in using contextual cues to aid memory retrieval. As a result, it has been the focus of several studies exploring how contexts modulate extinction retrieval.

Hippocampal inactivation does not prevent the acquisition of extinction. The next day, however, extinction retrieval in these rats is deficient, and they demonstrate higher levels of freezing than controls. The increase in freezing among these rats is equivalent to levels of renewed freezing among rats that extinguished drug-free and were tested outside the extinction context. Thus, during extinction training, the dorsal hippocampus acquires a memory of the extinction context that is used for subsequent retrieval of extinction. In contrast to preextinction inactivation of the hippocampus, inactivation prior to testing prevents fear renewal. Although the dorsal or ventral hippocampus is inactivated, rats show little freezing regardless of the context. These results suggest that, following extinction, the hippocampus uses contextual cues to determine whether fear or extinction memory is retrieved.

The pattern of effects seen with hippocampal inactivation mirrors the effects seen with mPFC inactivation, suggesting that these two structures work together to mediate extinction retrieval. The hippocampus sends dense projections to the mPFC, and hippocampal stimulation gates the response of mPFC neurons to other inputs. This pathway could trigger neural plasticity essential for extinction recall. In support of this, hippocampo-prefrontal connections are potentiated by extinction training. Thus, when a CS is presented in the extinction context, contextual information processed by the hippocampus permits the inhibition of fear expression via its connections with the mPFC (Figure 2). Activity of neurons in the BLA during extinction retrieval is less when the CS is presented inside the extinction context compared to outside. Inactivation prevents this contextual modulation of LA activity. Thus, the hippocampus is capable of modulating LA responsiveness to CSs, either directly or indirectly.

The hippocampus is necessary for context processing in a variety of learning and memory paradigms. In each of these, the hippocampus is also necessary for extinction. Acquisition of extinction of context fear requires NMDA receptors in the hippocampus, as well as various protein kinase signaling pathways, and the rearrangement of actin, a cytoskeletal protein. Another form of context learning is inhibitory avoidance, in which a rat learns to avoid stepping onto an electrified floor. Extinction of this behavior similarly requires protein kinase activation and protein synthesis in the hippocampus. Thus, the role of the hippocampus in the acquisition and consolidation of extinction for contextual memories is very much like the role of the amygdala in the extinction of cued fear conditioning.

Figure 2 Retrieval of fear extinction involves the amygdala, medial prefrontal cortex, and hippocampus. The amygdala acquires, stores, and expresses fear memories. Plasticity in the amygdala is also necessary for acquisition of extinction memory. The infralimbic subregion of medial prefrontal cortex is necessary for the retrieval of extinction memory and the inhibition of amygdala output. The hippocampus processes contextual information surrounding CS presentation and uses this information to help determine whether fear or extinction memory will be retrieved. CS, conditioned stimulus; PFC, prefrontal cortex.

Periaqueductal Gray and Error Signaling

Predominant theories of how conditioning memories are acquired hold that learning is driven by a mismatch between what an organism expects in response to a CS and what the organism actually experiences. For example, early in fear conditioning, a rat does not expect a tone to be followed by footshock. The arrival of the footshock after the tone violates this expectancy, however, and the rat quickly learns the tone–shock association. Similarly, early in extinction training, the rat expects the tone to be followed by a shock that never comes. It is thought that the error between expectancy and actual outcome during both fear and extinction learning is signaled by opioids in the midbrain periaqueductal gray (PAG).

Opioid antagonists infused directly into the PAG facilitate the acquisition of fear conditioning, but disrupt the acquisition of extinction. Likewise, increasing opioids in PAG disrupts fear acquisition and enhances extinction acquisition. Thus, in fear conditioning, opioids signal the degree to which a tone is expected to be followed by a shock. Early in extinction training, opioid release in response to the CS is high, but the expected shock never comes. This discrepancy between opioid-mediated expectancy of a shock and the actual nonreinforcement provides a mechanism to initiate the inhibitory learning that occurs as a result of extinction training. After opiod receptor blockade in PAG, the error signal that drives extinction learning is missing and within-session extinction is prevented.

Anatomy of Extinction in Humans

Neuroimaging studies of extinction learning in humans indicate that the network of structures involved in extinction learning is conserved across species.

In humans, both the amygdala and mPFC are active during extinction training. Consistent with rat findings, both the hippocampus and mPFC are activated during extinction retrieval, and this activity is correlated with the amount of extinction retrieved. Moreover, this activity during extinction retrieval is modulated by contextual cues.

Extinction learning in humans falls into a broader category of emotional regulation processes. In the cognitive sense, emotional regulation can take the form of willfully suppressing emotional responses to stimuli or reappraising the meaning of the stimuli themselves to either reduce or enhance emotional reactions. Intentional reduction of behavioral responses to emotional stimuli can facilitate cognitive reappraisals of those stimuli. Neuroimaging studies show that reappraisal of negative stimuli often decreases amygdala activity and increases activity in higher cognitive centers, such as medial and lateral prefrontal regions.

The role of the mPFC and hippocampus in extinction retrieval suggests that these structures are deficient in posttraumatic stress disorder (PTSD), which is characterized by inappropriate fear responses. In fact, PTSD patients show reduced volume and reduced activity in the mPFC and hippocampus when reexposed to traumatic reminders. As a result, PTSD subjects show exaggerated fear responses, which may reflect an inability to retrieve extinction memory. Although this remains to be confirmed experimentally, it is likely that pharmacological agents designed to strengthen extinction retrieval will help control PTSD and other disorders stemming from reduced inhibition.

Introduction

The importance of the extracellular matrix (ECM) in synaptic organization has been known for decades from structural and molecular studies of the neuromuscular junction. A striking feature of this synapse is its prominent ECM basal lamina that is interposed in its synaptic cleft. It contains several ECM molecules, of which the heparan sulfate proteoglycan agrin and laminin proved to be required for different aspects of post- and presynaptic synaptic differentiation of the neuromuscular junction.

Conspicuous aggregates of the ECM molecules in the central nervous system appear as so-called perineuronal nets, which surround axon initial segments and cell bodies and proximal dendrites of some neurons in a meshlike structure that interdigitates with synaptic contacts and astrocytic processes. Perineuronal nets are heterogeneous in structure and composition, incorporating molecules secreted from both neurons and astrocytes. Apart from these prominent ECM structures, immunoreactivity for many ECM molecules appears as diffuse staining, documenting the widespread occurrence of these molecules in the extrasynaptic space, the structural and molecular organization of which remains to be elucidated. Studies indicate that ECM molecules such as thrombospondins, reelin, tenascin-R (TN-R), chondroitin sulfate proteoglycan versican, neuronal pentraxins NP1 and NP2, and integrin ligands may shape pre- and postsynaptic differentiation of excitatory and inhibitory synapses in the central nervous system.

Not only formation and maturation of synapses but also synaptic plasticity, learning, and memory in adults are dependent on the ECM. These functions of several ECM molecules are the focus of this article.

Integrins and Synaptic Plasticity

Integrins are transmembrane heterodimeric receptors to ECM molecules, including fibronectin, laminins, and thrombospondins. There are 16 different α and eight different β mammalian integrin subunits, which associate to form $\alpha\beta$ heterodimers; many of these are expressed in the developing and adult hippocampus. Initial evidence for a potential role of integrins in hippocampal synaptic plasticity was presented in 1990 by reducing the stability of hippocampal long-term potentiation (LTP), a widely used model of synaptic plasticity, using broad-spectrum peptide ligands of integrins. Further support for integrin function in LTP was gained by experiments with injection of snake toxins (disintegrins), which preferentially inhibit the binding of ECM ligands to β_1- or β_3-containing integrins, and blocking antibodies to the α_3 integrin subunit. These treatments were efficient in blocking the stabilization of LTP and facilitation of depotentiation (i.e., reversal of LTP by low-frequency stimulation). Since laminin also modulates stabilization of LTP and the α_3 subunit was found to be associated with the β_1 subunit in synaptosomal preparations, it is plausible to assume that interactions between $\alpha_3\beta_1$ integrin receptors and laminins are important for stabilization of LTP.

The critical role of integrins in synaptic plasticity is also supported by analysis of mouse mutants deficient in integrins. Heterozygous mice with genetically reduced expression of the α_3 subunit fail to maintain CA1 LTP. Mice with reduced expression of the α_3 and α_5 subunits also exhibit a defect in paired-pulse facilitation. Furthermore, conditional mutants lacking the β_1 subunit in excitatory neurons in the postnatal forebrain have impaired synaptic transmission through α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors and diminished *N*-methyl-D-aspartate (NMDA) receptor-dependent LTP. These results demonstrate that multiple integrins are involved in synaptic plasticity.

The potential mechanisms by which integrins may affect induction of synaptic plasticity appear to involve phosphorylation of glutamate receptors. Microperfusion of a peptide integrin ligand caused an approximately twofold increase in the amplitude and duration of NMDA receptor-gated synaptic currents. Biochemical analysis demonstrated that the peptide and the native ligand fibronectin trigger β_1-dependent rapid and robust increases in tyrosine phosphorylation of focal adhesion kinase, proline-rich tyrosine kinase 2, and Src family kinases. Pharmacological experiments also support the view that integrin-triggered Src activity underlies tyrosine phosphorylation of NMDA receptor subunits NR2A and NR2B (Figure 1).

To maintain postsynaptic changes induced by synaptic stimulation, the mechanisms regulating activity, number, or composition of synaptic AMPA receptors have to come into play. In this context, it is noteworthy that infusion of the peptide integrin ligand into

Figure 1 A summary of mechanisms by which ECM molecules may regulate synaptic plasticity. Reelin and integrin ligands may bind to their cell surface receptors (ApoER2 and $\alpha\beta$ integrins) to trigger intracellular cascades via interaction with Dab1 and activation of tyrosine kinases of the Src family, which result in tyrosine phosphorylation of effectors, including the NMDA receptor (NMDARs), AMPA receptors (AMPARs), and the L-type voltage-dependent Ca^{2+} channels (L-VDCC). Additionally, integrin ligands may activate Ca^{2+}/calmodulin-dependent kinase II, which regulates the number and activity of AMPA receptors. Tenascin-C affects L-VDCC via an unknown mechanism that may involve a direct interaction with channels or signaling via integrins.

rat hippocampal slices reversibly increased the slope and amplitude of excitatory postsynaptic potentials mediated by AMPA receptors. A mixture of function-blocking antibodies to integrin subunits α_3, α_5, and α_V reduced the ligand effects on synaptic responses. The effects were also blocked by inhibitors of Src tyrosine kinase, antagonists of NMDA receptors, and inhibitors of calcium calmodulin-dependent protein kinase II. Furthermore, changes in AMPA receptor-mediated responses were accompanied by phosphorylation of both the Thr286 site on calmodulin-dependent protein kinase II and the Ser831 site on the GluR1 subunit of the AMPA receptor. Thus, integrins may affect AMPA receptors via two signaling pathways, involving Src tyrosine kinases and calmodulin-dependent protein kinase II (Figure 1).

Integrins and Learning and Memory

The first evidence that integrins are involved in memory processes came from the Volado mutant of *Drosophila*, which mutated gene encodes two isoforms of α integrin: these mutants were not able to show short-term olfactory memory, an impairment that could be rescued by conditional expression of a Volado transgene in adulthood. It is noteworthy that, as observed in *Drosophila*, integrins regulate short-term memory also in mice. Although mice heterozygous for three α integrins (α_3, α_5, and α_8) and mice deficient for the β_1 integrins showed normal learning and long-term memory in the water maze and contextual fear conditioning tasks, these mice exhibited specific memory impairments soon after training. In fact, mice heterozygous for the three α integrins did not show any preference for the platform in a probe trial performed 1 h after training in the water maze test, whereas working memory in the nonmatching-to-place task was reduced in mice deficient for the β_1 integrins when they had to retain the information of the visited arm for 10 s. Thus, it seems that integrins modulate memory formation through short-term changes in synaptic transmission independent of protein synthesis.

Reelin and Induction of NMDA Receptor-Dependent LTP

Reelin is an ECM glycoprotein with a long and exciting history of research: it is named after the spontaneously occurring *reeler* mouse mutant, which shows abnormal migration of neurons during embryonic development. These deficits result in an outside–in instead of inside–out positioning of migrating neuronal cell bodies in the cerebral cortex. Strikingly, mice deficient in receptors for reelin, the very low-density lipoprotein (VLDL) receptor and ApoE receptor 2 (ApoER2), and cytoplasmic adaptor protein mDab1, which mediates signaling through VLDL and ApoER2 receptors, also display the *reeler* phenotype.

Several studies suggest that reelin together with its receptor, ApoER2, are involved in synaptic plasticity. Application of reelin to wild-type hippocampal slices produces a significant increase in LTP. The heterozygote reeler mouse shows impaired LTP and long-term depression (LTD). Application of receptor-associated protein RAP, a specific and broad-spectrum inhibitor of ligand binding to all low-density lipoprotein receptor family members, almost completely blocks LTP. A modest decrease in short-term potentiation is observed in VLDL receptor-deficient mice, although LTP in these mutants is nearly identical to that of wild-type mice. However, ApoER2-deficient mice are strongly impaired in LTP. Importantly, when reelin was applied to slices from VLDL receptor-deficient or ApoER2-deficient mice, the LTP-enhancing effect of reelin was abolished, supporting the view that reelin signaling via ApoER2 is critical for LTP.

Two studies uncovered some of the underlying mechanisms: ApoER2 is present in the postsynaptic densities of excitatory synapses, where it forms a functional complex with NMDA receptors. Reelin signaling through ApoER2 markedly enhances LTP through a mechanism that requires the presence of a stretch of amino acid residues in the intracellular domain of ApoER2 encoded by a single exon. This exon is alternatively spliced in an activity-dependent manner and is required for reelin-induced tyrosine phosphorylation of NMDA receptor subunits (Figure 1). Furthermore, a mouse mutant in which ApoER2 is mutated to disrupt its interaction with Dab1 lacks LTP, suggesting that signaling of ApoER2 via Dab1 is necessary for LTP. Since exogenously added reelin could significantly although only slightly increase the levels of LTP in this mutant, whereas reelin does not enhance LTP in ApoER2-deficient mice, it is plausible to assume that some LTP-promoting signaling can also occur independently of ApoER2–Dab1 binding. It may involve binding of other adaptor proteins such as JIP1/2 and PSD95 to exon 19 of reelin.

Reelin and Learning and Memory

Genetic analysis of mice deficient in either ApoER2 or VLDL receptor provided evidence that both reelin receptors regulate cognitive processes, assessed as contextual long-term memory in the fear conditioning task. Similarly, contextual but not cued memory in the fear conditioning task was reduced in mice heterozygous for the *reeler* mutation. The normal spatial learning and memory in the water maze task and minor deficit in olfactory discrimination learning of heterozygote reeler mice suggest that reelin regulates some but not all hippocampus-dependent cognitive functions. Since previous studies revealed that mice deficient in reelin, ApoER2 and VLDL receptor, and Dab1 have abnormal migration patterns, the same fundamental signaling pathway appears to regulate neuronal migration during brain development and also synaptic plasticity and contextual memory in the adult brain.

Tenascin-C and Induction of Synaptic Plasticity via Ca^{2+} Channels

Induction of some forms of synaptic plasticity depends on activity of the L-type voltage-dependent Ca^{2+} channels (L-VDCC), and there is evidence that this activity is under the influence of ECM glycoprotein tenascin-C (TN-C). In TN-C-deficient mice, theta-burst stimulation of CA3–CA1 synapses resulted in impaired LTP, whereas CA1 LTD was completely abolished. Recordings of LTP in the presence of nifedipine, an antagonist of L-VDCCs, did not show an effect on TN-C-deficient mice but reduced LTP in wild-type mice to the levels seen in the mutant, implying a link between L-VDCCs and TN-C in the regulation of synaptic plasticity. Furthermore, chemical induction of an L-VDCC-dependent LTP in the CA1 region by application of the K^+ channel blocker tetraethylammonium resulted in impaired LTP in TN-C-deficient mice. Because NMDA receptor-mediated responses and three forms of L-VDCC-independent LTP are normal in TN-C-deficient mice, the data point to a specific role for TN-C in L-VDCC-mediated signaling. These results are supported by data showing a strong reduction of LTP in the CA1 hippocampal area after injection of the TN-C fragment comprising fibronectin-like repeats 6–8. This fragment is known to bind to another ECM molecule, fibronectin, and thus could act via competition with endogenous TN-C, disrupting the targeting of TN-C to the fibronectin-containing ECM.

The hypothesis that TN-C affects signaling via L-VDCCs was verified by optical measurements of intracellular Ca^{2+} concentrations in CA1 pyramidal cells. The difference between Ca^{2+} signals triggered by

theta-burst stimulation under normal physiological solution and in the presence of nifedipine was used as a measure of Ca^{2+} influx via L-VDCCs. These measurements revealed a reduction in Ca^{2+} influx in TN-C-deficient mice. The underlying mechanisms may involve direct interaction between TN-C and Ca^{2+} channels or interaction of TN-C with integrins which are known to regulate activity of L-VDCCs (Figure 1).

TN-C and Learning and Memory

Possible roles of TN-C in learning and memory have been investigated in mice deficient for TN-C and by intrahippocampal injection of TN-C fragments containing the fibronectin type III repeats in mice tested in a cognitive task. Injection of a fragment containing the fibronectin type III repeats 6–8 into the hippocampus of mice inhibited memory retention in the one-trial step-down passive avoidance task. The observation that application of this fragment also reduced LTP in the CA1 region of hippocampal slices suggested that TN-C is involved in synaptic plasticity and required for memory consolidation in hippocampus-dependent cognitive tasks. Similarly, TN-C-deficient mice had an impaired performance in the step-down avoidance task. On the other hand, they performed as well as wild-type mice in a variety of tasks designed to measure hippocampus-dependent learning and memory, such as the water maze, contextual fear conditioning, step-through passive avoidance, and spontaneous alternation tasks. A detailed analysis of the behavior of TN-C-deficient mice strongly suggested that the higher novelty- and stress-induced active responses of these mutant mice account for their poorer performance in passive avoidance tasks, whereas learning is unaltered. This conclusion is in agreement with the fact that the reduced LTP observed in the CA1 region of TN-C-deficient slices has been interpreted as a consequence of lower activity of L-VDCCs, since pharmacological studies have shown that these channels are not required for acquisition or expression of conditioned fear in mice. On the other hand, L-VDCCs are involved in extinction of fear memory, which is the decline in the expression of a conditioned response following the withdrawal of reinforcement. We found that TN-C-deficient mice exhibit reduced short- and long-term extinction of fear memories, suggesting that TN-C regulates this cognitive process by modulating the activity of L-VDCCs.

TN-R, GABAergic Transmission, and Metaplasticity

Another example of how ECM molecules affect induction of LTP is provided by the glycoprotein TN-R. TN-R is enriched at the nodes of Ranvier in the central nervous system and in perineuronal nets and is essential for assembly of these nets since distribution of net-associated ECM molecules is altered in TN-R-deficient mice. Also, TN-R-deficient mutant mice show impaired CA1 LTP, elevated levels of excitatory synaptic transmission, elevated $GABA_B$ receptor-activated K^+ currents, and reduced levels of perisomatic inhibitory currents mediated by $GABA_A$ receptors. Several studies suggest that these abnormalities are related to the deficiency in the HNK-1 carbohydrate (a structure containing a 3′-sulfated glucuronic acid, which was first discovered on human natural killer cells – hence the name), which is prominently expressed by TN-R. Mice deficient in the glucuronyltransferase and HNK-1 sulfotransferase, which are the final pathway enzymes in the synthesis of the HNK-1 carbohydrate, showed a similar reduction in CA1 LTP as was found in TN-R-deficient mice. The HNK-1 antibody produced a strong and specific reduction in perisomatic inhibitory currents when applied to hippocampal slices via a relief of a constitutive block of postsynaptic $GABA_B$ receptors exerted by endogenous HNK-1 carbohydrate in perisomatic synapses. The functional link between the HNK-1 carbohydrate and TN-R as its cognate carrier molecule was demonstrated by experiments in which the antagonistic effect of the HNK-1 antibody on inhibitory currents was abolished in TN-R mutant mice.

Thus, TN-R/HNK-1 deficiency leads to reduction in GABAergic inhibition and impairment in LTP. This appears to be due to a 10 mV shift in the threshold for induction of LTP at CA3–CA1 synapses, which develops between the second and third weeks of postnatal development (i.e., during maturation of the GABAergic system). To evaluate whether changes in LTP are related to reduced $GABA_A$ and/or increased $GABA_B$ receptor-mediated currents in TN-R-deficient mice, we examined whether changes of these currents would lead to a recovery of LTP. Pretreatment of hippocampal slices with either a $GABA_B$ receptor antagonist or $GABA_A$ receptor agonists restored theta-burst-induced LTP in TN-R-deficient mice and normalized the threshold for pairing-induced LTP. These observations provide the first evidence that reduced levels of inhibition in TN-R-deficient mice may cause metaplastic changes in LTP.

Interestingly, elevation of $GABA_A$ receptor-mediated inhibition could also lead to impairment in LTP. For instance, there is an increase in inhibitory currents and impaired LTP in heparin-binding growth-associated molecule (HB-GAM) overexpressing mice, which can be rescued by an inhibitor of $GABA_A$ receptors. Thus, the ECM and its associated molecules may regulate

synaptic plasticity by bidirectionally setting the levels of GABAergic inhibition.

TN-R and Learning and Memory

In the water maze task, mice deficient for TN-R showed an altered searching strategy, swimming more in the proximity of the wall of the maze and less in the proximity of the platform compared to wild-type littermates, although it was suggested that exploratory behavior rather than cognitive abilities was altered in these mice. Because TN-R carries the carbohydrate HNK-1, it is extremely interesting that mice deficient for HNK-1 sulfotransferase showed the same subtle but significant alterations as those observed in TN-R-deficient mice in the water maze task. Moreover, HNK-1 sulfotransferase-deficient mice were not capable of finding the platform when tested after a long time interval and did not learn a new platform position when trained with a mass protocol that required fast re-learning rate. It would therefore be interesting to test long-term memory and fast re-learning rate of TN-R-deficient mice to determine whether HNK-1 and TN-R deficiencies lead to the same phenotype. In summary, the similar behavioral alteration of TN-R and HNK-1 sulfotransferase-deficient mice in a hippocampus-dependent cognitive task correlates with reduced LTP and enhanced basal excitatory synaptic transmission in the CA1 region.

Tenascins and Neural Circuitries

Beyond modulation of synaptic efficacy, ECM molecules may influence the formation, maintenance, and functional properties of neuronal and glial cell populations and neural circuitries, and thus regulate functions of cell ensembles underlying cognition. However, little experimental evidence supporting this notion is available. Studies on mice deficient in the expression of TN-R and TN-C provide some preliminary insights into how primary effects of synaptic functions or aberrant formation of cell populations may be linked to systemic dysfunction.

Monitoring of spontaneous and event-related electrical activity in awake TN-R-deficient mice has revealed enhanced hippocampal gamma oscillations, increased neocortical electroencephalogram (EEG) activity over a wide frequency range, and enhanced responses to auditory stimuli in the hippocampus and cerebral cortex compared to wild-type mice. Stereological estimates of major neuronal cell types in the cortex and hippocampus have provided no evidence for altered ratios between inhibitory and excitatory neurons. Thus, the enhanced excitability of neuronal ensembles in the TN-R-deficient mouse might be directly related to the aforementioned deficient inhibitory input to excitatory neurons. Abnormal operation of inhibitory networks may also underlie the alterations of gamma-frequency oscillations in the hippocampus. Since these oscillations provide a temporal framework for various forms of cognitive processing, a direct link between synaptic and behavioral abnormalities is plausible. Findings of reduced extracellular space and tortuosity in the neocortex and hippocampus of TN-R-deficient mice suggest another possibility for the direct influence of an ECM molecule on synaptic efficacy and extrasynaptic transmission – that is, by regulation of extracellular diffusion of neuroactive substances.

Similar to TN-R, ablation of TN-C causes enhancement of cortical event-related responses. Synaptic dysfunction that could readily explain this phenomenon, as opposed to TN-R deficiency, has not been identified. Quantitative morphological analysis has revealed abnormally high numbers of excitatory neurons and a reduced population of parvalbumin interneurons in the motor and sensory cortices of TN-C-deficient mice. Thus, abnormal physiological responses in the TN-C-deficient mouse may be related to an altered ratio of excitatory to inhibitory neurons which, as evidenced by synaptic coverage analysis, leads to reduced inhibitory input to pyramidal cell bodies. The origin of these abnormalities apparently in part lies in early neurogenesis in which TN-C, expressed in radial glia cells, is involved. However, the failure to compensate supernumerary neuronal numbers during later development and adulthood suggests that TN-C has other, yet unknown, influences on the shaping of neuronal populations and connectivity. In accord with this speculation is the observation that posttraumatic plasticity of cortical whisker representation, requiring rewiring of circuitries and changes in synaptic efficacy, is reduced in the adult TN-C-deficient mouse. Last, it is worth mentioning that numbers of astrocytes, which normally express TN-C, are strongly increased in the TN-C-deficient neocortex and hippocampus. Since there is no evidence for neurodegenerative processes, an increase in astrocytes numbers may be a compensatory response related to synaptic functions.

Plastic and Cognitive Functions of Chondroitin Sulfate Proteoglycans

Other ECM molecules to be discussed in the context of synaptic functioning are chondroitin sulfate proteoglycans of the lectican family. This family comprises four abundant components of brain ECM: aggrecan, versican, neurocan, and brevican. Lecticans together with link proteins, hyaluronic acid, and

glycoproteins such as the tenascins form huge carbohydrate–protein aggregates of perineuronal nets.

Mice deficient in neurocan show reduced LTP of CA3–CA1 synapses. Interestingly, the deficit appears only >2 h after induction of LTP but not earlier. Since late LTP phases are characterized by synaptic remodeling, it is plausible to assume a role for neurocan in such processes. Brevican is the closest relative of neurocan and one of the most abundant chondroitin sulfate proteoglycans in mature rodent central nervous system. Application of anti-brevican antibodies to naïve hippocampal slices leads to a drastic reduction of CA1 LTP 30 min after tetanization of the Schaffer collaterals. This finding is corroborated by LTP recordings in brevican-deficient mice. Although basic properties of excitatory and inhibitory synaptic transmission in these mutants are normal, LTP maintenance is dramatically impaired within the same time frame as after application of brevican antibody. The observed LTP deficit in brevican-deficient mice, however, seems not to be accompanied by changes in learning and memory, as measured in the water maze and active avoidance tasks. However, it is noteworthy that available results were obtained with a relatively small number of mice, and that in both tests mutant mice tended to show a poorer performance (less preference for the target during the probe trial of the water maze task and lower avoidance in the active avoidance task) compared to wild-type mice, suggesting normal learning but reduced memory consolidation under brevican deficiency. If we take into consideration the subtle but significant alteration of TN-R-deficient mice or that impairments of HNK-1 sulfotransferase-deficient mice were observed only when specific cognitive abilities (e.g., long-term memory or fast re-learning rate) were challenged, it is plausible to assume that more detailed behavioral analyses could reveal a role of brevican in specific cognitive functions.

Another interesting chondroitin sulfate proteoglycan is phosphacan/receptor phosphotyrosine phosphatase beta (RPTPβ). It is expressed in close vicinity to synapses, where it is well in place to bridge and stabilize perisynaptic glial processes near synapses via an interaction with the contactin–Caspr complex. The involvement of the RPTPβ family in synaptic plasticity is suggested by the analysis of RPTPβ knockout mice. These mice exhibited enhanced hippocampal LTP in an age-dependent manner, which could be overruled by pharmacological inhibition of the Rho-associated kinase (ROCK), the major downstream effector of a small GTPase Rho. Interestingly, this finding was accompanied by impairments in the Morris in the water maze task, suggesting that enhanced LTP is not necessarily beneficial for learning.

Improvement of cognitive functions was reported for biglycan, a leucine-rich chondroitin sulfate proteoglycan with neurotrophic effects. When injected into the nucleus basalis magnocellularis of the ventral pallidum or into the ventricles, biglycan ameliorated the cognitive deficits of old rats. This effect was mediated by attached chondroitin sulfate C and not by the proteoglycan *per se*, suggesting that other chondroitin sulfate proteoglycans may have the same effects as biglycan. Similarly, intrapallidal injection of heparin, another glycosaminoglycan, facilitated memory consolidation in the step-through passive avoidance task in rats. In the case of both biglycan and heparin, the beneficial effects on cognitive abilities appeared to be mediated by increasing cholinergic activity in the frontal cortex. It should be mentioned that the improved performance in a passive avoidance task could also result from enhanced anxiety in the animals: in fact, injection of chondroitin sulfate C into the dorsal periaqueductal gray enhanced anxiety and risk assessment as tested in the elevated-plus maze. At least some plasticity-related activity of chondroitin sulfate proteoglycans is mediated via the attached chondroitin sulfate side chains because treatment of hippocampal slices with the enzyme chondroitinase ABC, which removes chondroitin sulfates from chondroitin sulfate proteoglycans, leads to a reduction in LTP and LTD.

The mechanisms of how lecticans might influence synaptic transmission are unknown, but many interesting possibilities exist. Lectican-enriched ECM may insulate synaptic contact sites to prevent spillover of released neurotransmitters to neighboring synapses or extrasynaptic neurotransmitter receptors. Proteoglycans may also shape synaptic processes via trapping and concentrating neurotrophins at synapses and presenting them to their cognate receptors. Finally, chondroitin sulfate proteoglycans may bind to not yet characterized receptors, which might actively transduce signals from the ECM to postsynaptic neurons, thus directly influencing synaptic transmission properties. A candidate receptor could be neural cell adhesion molecule (NCAM), a cell adhesion molecule implicated in synaptic plasticity, which is also known to interact with neurocan and phosphacan.

Activity-Dependent Remodeling of the ECM

Although one of ECM functions is to provide mechanical stability to a tissue, this is a dynamic structure. Some ECM molecules in the brain are secreted in an activity-dependent manner. These include neuronal pentraxin NP2, reelin, aggrecan, TN-C, and TN-R. The ECM molecules released may trigger signaling

via cognate receptors (i.e., integrins) and thus affect synaptic plasticity. Furthermore, extracellular proteases mediating proteolytic cleavage of ECM molecules are also released in an activity-dependent manner. Obviously, their activity may lead to structural changes in the ECM and inhibition of ECM-mediated signaling due to digestion of some ECM molecules. However, their activity may also lead to a relief of cryptic ECM receptor binding sites and thus trigger signaling events.

More than 20 metalloproteinases (MMPs) and four of their endogenous tissue inhibitors act together to control tightly temporally restricted, focal proteolysis of ECM. Since the cascade of proteases is initiated by plasminogen activators, these activators have the potential to be the primary enzymes in the control of events such as learning and LTP, which presumably involve matrix remodeling. Indeed, mice genetically deficient in the plasminogen activator tissue plasminogen activator (tPA) showed a decrease in late phase of LTP in the CA1 field and impaired memory in the contextual fear conditioning and two-way active avoidance tasks. Conversely, transgenic mice overexpressing tPA in postnatal neurons exhibited exaggerated LTP in CA1 and displayed better learning and re-learning in the water maze task compared to wild-type mice. There is also evidence that tPA is involved in motor learning because tPA was elevated in cerebellar Purkinje cells of rats trained to rapidly traverse an irregular pegged straight runaway.

Studies have demonstrated that MMP-3 and MMP-9 increase transiently during water maze acquisition in a NMDA receptor-dependent manner. Interestingly, whereas MMP-9 transiently increased only at the beginning of learning, MMP-3 levels were enhanced throughout the training in the water maze over several days, suggesting that the two MMPs subserve distinct functions during memory consolidation. Inhibition of MMP activity with MMP-3 and MMP-9 antisense oligonucleotides and/or MMP inhibitor FN-439 reduced LTP at CA3–CA1 synapses. Similarly, in slices from MMP-9-deficient mice, hippocampal LTP, but not LTD, was impaired in magnitude and duration, whereas adding recombinant active MMP-9 to slices derived from mutants restored the magnitude and duration of LTP to wild-type levels. Activated MMP-9 localizes in part to synapses and modulates hippocampal synaptic physiology through integrin receptors because integrin function-blocking reagents prevent an MMP-9-mediated potentiation of synaptic strength. The learning-dependent MMP alterations modify the stability of the actin-binding protein cortactin, which plays an essential role in regulating the dendritic cytoskeleton and synaptic efficiency. The important role of MMP-9 in regulating synaptic plasticity is indicated by the reduced contextual long-term memory displayed by MMP-9-deficient mice in the fear conditioning task. Tone memory (which, contrary to contextual memory, is not supposed to require the hippocampus) was normal in these mice, but it was only tested after a short interval after training, so it is not possible to conclude whether the memory impairment of MMP-9-deficient mice is specific for hippocampal function, long-term memories, or both. In summary, these results indicate that changes in MMP function and remodeling of ECM are critical to synaptic plasticity and hippocampal-dependent learning.

Conclusions and Future Directions

Several ECM molecules have been identified as crucial players in hippocampal synaptic plasticity and learning and memory (Table 1). The signaling events underlying the contributions of these and probably other ECM molecules to synaptic functions remain to be elucidated, particularly at the presynaptic level. Yet we believe that it can be concluded that the ECM in the nervous system is much more than just a passive microenvironment repellant or conducive for cells and neurites. Tight functional links to synaptic plasticity and learning, together with data showing remarkable activity and learning-induced changes in expression of ECM molecules and enzymes involved in remodeling of the ECM in the adult nervous system, suggest that the ECM is a dynamic, functionally indispensable structure between glial cells and their pre- and postsynaptic neuronal partners.

Table 1 ECM molecules, synaptic plasticity, and learning and memory

Functions	*ECM molecules*
Synaptic plasticity	
Activity of NMDARs	Reelin, integrin ligand(s)
Activity of L-type Ca^{2+} channels	Tenascin-C
GABAergic inhibition	Tenascin-R, HB-GAM
Activity/recycling of AMPARs	Integrin ligand(s)
Activity of Rho/ROCK	RPTPβ
Unknown mechanisms	Brevican, neurocan
Learning and memory	
Water maze	Tenascin-R, HNK-1, integrin ligand(s), RPTPβ, brevican[a]
Contextual fear conditioning	Reelin, tenascin-C (on extinction)
One-trial passive avoidance	Biglycan, heparin
Working memory	Integrin ligand(s)

[a]Only tendencies were observed in a small number of mice.

Interactions between the Vestibulo-Ocular Reflex and Voluntary Eye Movements

The traditional approach of studying the oculomotor subsystems that generate stabilizing reflexes (i.e., the vestibulo-ocular reflex (VOR) and optokinetic system) and voluntary eye movements (i.e., saccades, smooth pursuit, and vergence) in isolation has led to an excellent understanding of the brain stem circuitry underlying each of these types of eye movements. However, during most natural voluntary orienting and tracking behaviors, two or more subsystems work together to control gaze. When we shift our axis of gaze in space by making a combined eye–head gaze shift, the VOR and saccadic subsystems must work together to ensure that the axis of gaze (where gaze = eye-in-orbit + head-in-space) is placed precisely on the target of interest. Similarly, to track a slowly moving target, we move our head as well as eyes in a manner that is dependent on the target's velocity and eccentricity. In this case, the VOR and smooth pursuit subsystems must work together to ensure that the axis of gaze is aligned with target movement. The manner in which the brain coordinates the interactions between these eye movement subsystems and head premotor circuitry to accurately redirect gaze is an area of ongoing research.

The Control of Eye–Head Gaze Shifts

Behavioral Investigations

The VOR functions to produce a compensatory eye movement of equal and opposite amplitude to the motion of the head. This reflex rapidly (within 5–7 ms) and effectively stabilizes the visual world on the retina over the wide range of head motions that are produced during our daily activities. However, primates also make voluntary head movements to redirect their visual axis to novel targets in their environment. Under natural conditions, where the head is not restrained, coordinated eye and head movements (i.e., gaze shifts) are commonly used to rapidly redirect the visual axis to a new point in space. The eye movement command produced by the VOR during gaze shifts would be counterproductive because it would code an eye movement in the direction opposite to that of the intended shift of the axis of gaze.

Bizzi and colleagues originally proposed that the VOR remains completely functional during gaze shifts, such that it effectively eliminates the head's contribution to the change in gaze. In this schema, termed the linear summation hypothesis, the actual eye movement generated at the level of the extraocular motor neurons reflects the summation of two signals: an intact VOR from vestibular pathways (i.e., a compensatory eye movement signal (Figure 1(a)) and a separate oculocentric saccadic eye movement signal from the brain stem saccadic burst generator (Figure 1(b)), which counters the VOR and redirects the axis of gaze. The conceptual simplicity of this proposal has made it an attractive model of gaze shift generation. Figure 2(a) shows a schematic of how these two commands sum to drive to the extraocular motor neurons during a rightward eye–head gaze shift. The saccadic pathway commands a rightward eye movement, whereas the VOR pathway, in response to the rightward head movement that is produced, commands a compensatory (i.e., leftward) eye movement.

Substantial evidence, however, has accumulated over the past three decades to indicate that the linear summation hypothesis is generally not valid during gaze shifts. The status of the VOR during gaze shifts has been probed by perturbing head movement during gaze shifts using electromagnetic clutches to brake the head and torque motors to apply whole-body and head-on-body rotations. There is considerable agreement across studies that the VOR is completely turned off during large gaze shifts and is significantly suppressed during smaller gaze shifts. The attenuation of the VOR is illustrated in Figure 2 by the box labeled 'behaviorally dependent modulation.' For gaze shifts less than 50°, VOR gain (defined as the change in eye velocity/change in head velocity caused by a perturbation) decreases as a function of increasing gaze shift amplitude. Taken together, these findings indicate that the head movements generated during gaze shifts contribute to changing the axis of gaze in space because the contribution of the head movement to gaze is not completely cancelled out (i.e., VOR gain $\neq 1$). As a result, several models have been proposed to explain how eye and head movements are coordinated to produce accurate gaze shifts.

The gain of the VOR is not only dependent on the amplitude of an ongoing gaze shift, but also varies temporally during the execution of a single gaze shift such that there is a gradual restoration of the VOR efficacy from its off state. The traces in the top right corner of Figure 2(b) are examples of transient head perturbations that have been used to explicitly quantify VOR gain at specific intervals during large gaze

Figure 1 The primary inputs to the extraocular motor neurons in the abducens nucleus: (a) the VOR pathway; (b) the saccadic pathway. The panels on the right side of (a) and (b) show examples of eye- and head-velocity responses during the VOR and saccadic eye movements, respectively. shifts. The graph in Figure 2(b) shows the time course of the VOR gain before, during, and after a gaze shift. VOR suppression is maximal early in the gaze shift and progressively recovers to reach normal values near gaze shift end. The level of VOR suppression, however, is not a constant value at gaze shift onset but, instead, shows considerable variation across subjects.

Neurophysiology: Premotor Control of the Eye during Gaze Shifts

Brain stem saccadic pathway During gaze shifts, the superior colliculus (SC) generates a gaze displacement command that is used by downstream premotor neurons to control the movement of the eye and head. The output neurons of the SC send direct projections to two regions in the brain stem reticular formation which control saccadic eye movements: the paramedian pontine reticular formation (PPRF) and the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) of the midbrain. In the head-restrained condition, neurons in the PPRF and riMLF encode temporally modulated command signals that provide the primary input to the extraocular motor neurons to drive horizontal and vertical saccadic eye movements, respectively.

During head-restrained saccades, the responses of premotor burst neurons are well described by a simple model ($\mathrm{FR} = b + r\dot{E}$; where FR is firing rate, $\dot{E}$ is eye velocity, and b and r are constants), which is based on eye movement dynamics. However, the same eye-based dynamic model that describes a neuron's response during head-restrained saccades cannot be used to predict its response during gaze shifts (Figure 3(a), left inset, eye-based model, heavy line). This is because these neurons encode head as well as eye velocity during gaze shifts. In general, premotor saccadic burst neurons encode head velocity with only about half as much response sensitivity as eye velocity, whereas collicular neurons encode gaze-related information (where gaze = eye + head). This progressive loss of head-movement-related response in the saccadic pathway is consistent with downstream interactions between the saccadic and VOR circuits.

Figure 2 (a) Interactions between the VOR and saccadic pathways during a rightward gaze shift; (b) VOR gain in response increases over time from gaze shift onset, ultimately reaching unity at gaze shift end. Error bars represent standard errors. Each color shows data from a different subject. To the right in (b) are example head perturbations (vertical shaded gray bar and inset) that were applied to quantify the VOR during gaze shifts. BN, premotor saccadic burst neuron; PVP, position-vestibular-pause neuron; VOR, vestibulo-ocular reflex. (b) Data from Cullen KE, Huterer M, Braidwood DA, and Sylvestre PA (2004) Time course of vestibuloocular reflex suppression during gaze shifts. *Journal of Neurophysiology* 92: 3408–3422.

As a result, the gaze-related drive that originates in the SC ultimately becomes completely oculomotor at the level of the extraocular motor neurons (see the section titled 'Extraocular motor neurons').

Vestibulo-ocular reflex pathways A simple three neuron arc (vestibular afferents to interneurons in the vestibular nuclei to extraocular motor neurons) mediates the most direct pathway of the VOR. Investigations in head-restrained monkeys have revealed that there are several classes of vestibular nuclei neurons that discharge in relation to horizontal passive whole-body rotation and/or eye movements. One class, called position-vestibular-pause (PVP) neurons, constitutes most of the intermediate leg of the direct VOR pathway. These neurons receive a strong monosynaptic connection from the ipsilateral vestibular afferents and, in turn, project directly to contralateral extraocular motor neurons (Figure 1(b)).

Type I PVP neurons derive their name from the signals they carry during head-restrained oculomotor and vestibular paradigms: (1) their firing rates increase when the eyes move to more contralaterally directed positions; (2) during slow phase vestibular nystagmus, these neurons are sensitive to ipsilateral head rotations (i.e., a type I response); and (3) their discharges completely cease (pause) for ipsilaterally directed saccades and vestibular quick phases. Although these

Figure 3 (a) Brain stem mechanism that underlies the reduction in VOR gain during gaze shifts; (b) comparison of the percentage attenuation of PVP head-velocity sensitivity during gaze shifts and the percentage attenuation of the VOR gain, as measured in two behavioral experiments (monkeys and humans). In (a), the insets show the responses of BN and PVP neurons during gaze shifts. BN, burst neuron; $\dot{E} + \dot{H}_{BN}$, eye and head velocity encoded by saccadic burst neurons; $\dot{H}_{aff}$, head velocity encoded by horizontal semicircular canal afferents; PVP, position-vestibular-pause neuron; VOR, vestibulo-ocular reflex. Data from Cullen KE and Guitton D (1997) Analysis of primate IBN spike trains using system identification techniques, II: Relationship to gaze, eye, and head movement dynamics during head-free gaze shifts. *Journal of Neurophysiology* 78: 3283–3306; Roy JE and Cullen KE (1998) A neural correlate for vestibulo-ocular reflex suppression during voluntary eye-head gaze shifts. *Nature Neuroscience* 1: 404–410; Tabak S, Smeets JBJ, and Collewijn H (1996) Modulation of the human vestibuloocular reflex during saccades: Probing by high-frequency oscillation and torque pulses of the head. *Journal of Neurophysiology* 76: 3249–3263; Tomlinson RD (1990) Combined eye-head gaze shifts in the primate, III: Contributions to the accuracy of gaze saccades. *Journal of Neurophysiology* 64: 1873–1891.

neurons are robustly modulated in response to passive head rotations, their responses to head velocity are dramatically attenuated during gaze shifts. The response of a typical PVP neuron during gaze shifts is shown in Figure 3(a) (right inset). The neuron's activity is interrupted during the gaze shift interval, which is denoted by the two vertical dashed lines. The response predicted by the same neuron's response during passive whole-body rotation is superimposed for comparison (pVOR model, heavy line). Moreover, the head-velocity signal encoded by PVP neurons is increasingly attenuated as a function of gaze-shift amplitude. This neurophysiological trend (Figure 3(b)) is consistent with the results of the behavioral studies of the VOR which we already discussed. The results from two of these prior studies have been superimposed on PVP neuron data for comparison. Thus the amplitude-dependent reduction of the responses of VOR interneurons (i.e., PVP neurons) underlies the amplitude-dependent decrease in behavioral VOR gain that occurs during gaze shifts.

The attenuation of PVP responses during gaze shifts can be accounted for by a known mechanism, namely projections from the brain stem saccade generator to the vestibular nuclei (Figure 3(a)). During saccades, vestibular quick phases and gaze shifts, brain stem burst neurons (BNs) become active, as denoted by the gate. As a result, BNs (Figure 3(a), left inset) provide an inhibitory input related to eye velocity (E) and head velocity ($\dot{H}_{\mathrm{BN}}$) to type I PVP neurons during gaze shifts via their projections to type II neurons in the vestibular nuclei. (Note that type II vestibular nuclei neurons are activated in response to contralateral head rotations.) In contrast, immediately following a gaze shift (when the gaze is stable but the head is still moving), the head-velocity sensitivity of PVP neurons completely recovers to reach that observed during the VOR (Figure 3(a), right inset). This observation is also consistent with the mechanism illustrated because the brain stem saccade generator is not active during this interval.

Extraocular motor neurons Because the responses of PVP neurons are attenuated (but not completely abolished) during gaze shifts, some head-movement related information is directly conveyed to the extraocular motor neurons (Figure 3(a), right inset). Moreover, saccadic BNs carry head- as well as eye-movement-related signals to the extraocular motor neurons (i.e., Figure 3(a), left inset). The questions thus arise: What signals are encoded by the extraocular motor neurons during gaze shifts? Do individual motor neurons encode only eye movement, or is the relationship between firing rates and eye movement influenced by the additional premotor signals that are present during gaze shifts?

A first-order eye-movement-based model ($\mathrm{FR} = b + kE + r\dot{E}$; where FR is firing rate; E and $\dot{E}$ are the eye position and velocity, respectively; and b, k, and r are constants) provides a good representation of the firing rate of extraocular motor neurons during saccadic eye movements made in the head-restrained condition. The addition of an acceleration term ($u\ddot{E}$) and an exponentially decaying term (or slide term, $c\dot{\mathrm{F}}\mathrm{R}$) further improves our ability to mathematically describe the saccade-related activity in the head-restrained condition. During combined eye–head gaze shifts, the parametric relationship between an individual motor neuron's firing rate and eye motion does not change because the head is moving; the activity of each extraocular motor neuron is related to eye motion by the same dynamic relationship during head-unrestrained gaze shifts and head-restrained saccades. This finding is logically consistent with the projections of these neurons because they drive the extraocular muscles of the eyes alone.

The finding that premotor VOR neurons (PVPs) and saccadic BNs encode head-movement-related information but that extraocular motor neurons do not can be easily reconciled with what is known about signals encoded by these premotor pathways during gaze shifts. These two premotor pathways respond to contralaterally and ipsilaterally directed head-movement-related information, respectively. As a result, the residual head-velocity information carried by premotor VOR (i.e., PVP) neurons is appropriate to offset the incoming head-velocity-related drive from saccadic premotor BNs, such that the responses of individual extraocular motor neurons are solely related to eye motion during gaze shifts.

Neurophysiology: Premotor Control of the Head during Gaze Shifts

The SC has been identified as a primary center that controls both eye and head movements during gaze shifts. The output neurons in the intermediate layers of this structure not only send descending projections to the premotor saccadic circuitry, but also project to the neck motor neurons via two major pathways.

First a tectoreticulospinal pathway, which accesses the reticular formation of the pons and medulla, controls orienting movements in the horizontal direction. In particular, the reticulospinal neurons of the nucleus reticularis gigantocellularis (NRG) and nucleus reticularis pontis caudalis (NRPc) receive monosynaptic input from the SC. Electrical stimulation of the NRG, which is located just caudal to the abducens nucleus, evokes ipsilateral deviations of the head in the horizontal plane. The amplitudes and peak velocities of the evoked head movement depend on the frequency

and duration of stimulation, consistent with the idea that these nuclei play a critical role in transforming SC signals into horizontal head-movement commands. In cats, combined lesions of both the NRG and NRPc impair the ability to make horizontal orienting head movements. In contrast, lesions restricted to either area only minimally influence orienting head movements, suggesting that the NRG and NRPc can partially compensate for one another's loss of function.

Second, a tectoreticulospinal pathway via the reticular formation of the mesodiencephalic region controls orienting head movements in the vertical direction. The SC sends projections to an area known as the Forel's field H (FFH) in cats, which corresponds to the riMLF in monkeys. This area, in turn, projects, directly to ipsilateral neck motor neurons. During orienting head movements, the responses of FFH neurons precede the onset of head movements and are temporally related to the dynamics of the head movement. Stimulation of the FFH induces upward and torsional head movements consistent with the idea that the vertical component of orienting head movements is encoded by activation of the FFH.

The tectoreticulospinal pathways to the pons/medualla and mesodiencephalic regions of the reticular formation transform the topographic representation of gaze displacement that is encoded by the SC into the temporally modulated commands signals that are required to drive the neck musculature in the horizontal and vertical directions, respectively. These pathways function in concert with other descending pathways that also converge at the level of neck motor neurons, including the vestibulo-spinal, rubrospinal, and interstitiospinal tracts. Vestibulo-spinal pathways play a particularly important role in the regulation of gait and posture. Neurons in the vestibular cerebellum project to neurons in the vestibular nuclei, which in turn project to neck motor neurons. The modulation of this pathway is attenuated but not completely suppressed during active orienting head movements. As a result, the drive to neck motor neurons is determined by the inputs from the vestibulo-spinal pathway as well as those from the tectospinal pathways. Accordingly, temporary lesions of areas of the vestibular cerebellum, such as the rostral fastigial nucleus, not only result in postural deficits but can also alter the metrics of gaze and head orienting movements.

Overall, it is important to note that our understanding of the premotor pathways that project to the neck motor neurons is largely based on experimental studies done in cats. In this species, neurons in the reticular formation just rostral to the NRG and caudal to the abducens nucleus have been shown to project both to neck and eye motor neurons. Neurons in the corresponding location of primates are known to project to the extraocular motor neurons, but to date there has been no explicit demonstration that these same neurons also project to the cervical spinal cord.

Integrated Feedback Control of Eye–Head Gaze Shifts and Implications for Upstream Control

That the VOR is attenuated during gaze shifts has important implications regarding the premotor control of gaze control. As previously explained, if the VOR is not fully operational during gaze shift, it then follows that the head as well as the eyes contribute to shifting the axis of gaze relative to space. Thus, a fundamental question is: how are the motor commands to the eye and head musculature coordinated to ensure accurate gaze shifts? Two general classes of models have emerged that can account for the control of eye–head gaze shifts. In the first model, a single controller is used to minimize gaze error rather than enforce a specific eye or head trajectory, making it conceptually analogous to optimal feedback control. Alternatively, it has been proposed that a gaze displacement command is decomposed early on to control separate eye and head comparators. In this schema, it is the individual displacements of the eye and head, rather than the overall accuracy of the movement *per se*, that are under feedback control. To date, the available evidence has proven equivocal with respect to these two model classes. The finding that movement accuracy is preserved when head trajectories are experimentally altered during gaze shifts is readily accounted for by gaze comparator models. However, models based on separate comparators can also simulate this finding with the incorporation of neck reflexes. Likewise, the responses of saccadic brain stem neurons during gaze shifts have been reconciled with both single and separate comparator models.

Firm evidence that gaze shift accuracy is ensured by a single comparator has been provided by more recent experiments. The responses of neurons in the premotor circuit that controls saccadic eye movement (saccade related burst neurons and omnipause neurons) are instantaneously updated following experimentally applied head perturbations (**Figure 4(a)**). Rapid (>3 ms) online feedback of head-movement updates the durations and dynamics of neurons in the saccadic premotor network in order to preserve global movement accuracy during gaze shifts. This result is consistent with a single controller model because it predicts that the drive to both eye as well as head premotor circuits should be updated in response to a head perturbation in order to preserve gaze accuracy. In contrast, models in which gaze-shift accuracy is

Figure 4 Gaze shifts and example burst neuron activity recorded during the same trials: (a) control; (b) perturbed; and (c) discharges of superior colliculus neurons during control (left) and perturbed trials (right), aligned on gaze shift onset. In (a) and (b), the vertical dashed line indicates gaze onset; the shaded box indicates average increase in perturbed trials duration; and the open and filled arrows indicate average perturbation onset and time at which the resulting head perturbation reached maximum velocity, respectively. Traces are aligned on gaze shift onset. In (c), the number of control and perturbed gaze shifts used to calculate average neuronal response is provided. Data from Sylvestre PA and Cullen KE (2006) Premotor correlates of integrated feedback control for eye-head gaze shifts. *Journal of Neuroscience* 26(18): 4922–4929; Choi WY and Guitton D (2006) Responses of collicular fixation neurons to gaze shift perturbations in head-unrestrained monkey reveal gaze feedback control. *Neuron* 50(3): 491–505.

ensured by separate controllers, specifying *a priori* the amplitude of eye and head, are difficult to reconcile with the present results. These models do not predict that the neurons in the brain stem saccadic pathway should be altered to reflect the changes in gaze shift dynamics that result from experimentally applied head-movement perturbations.

Prior reports have provided evidence that an integrated controller that functions to coordinate the movements of the eyes and head during gaze shifts might be centered on the SC. The output neurons of the SC have direct access to both the saccadic and neck premotor circuitry, thereby providing a physiological substrate by which eye and head movements can be driven in a coordinated fashion during gaze shifts (see sections titled 'Behavioral investigations' and 'Neurophysiology: Premotor control of the eye during gaze shifts' before this). Firm evidence that neurons in the SC control coordinated eye–head gaze saccades has been obtained from electrical stimulation and single-unit recording experiments. However, whether the SC is within an integrated feedback loop or operates open loop has remained a point of contention. In recent experiments, recordings were made from neurons in the SC during gaze shifts that were transiently interrupted by braking head movements

(Figure 4(b)). Neurons continued to fire steadily during interrupted gaze movements in a manner consistent with the proposal that the SC is within an integrated feedback loop. However, because the mechanical perturbations employed in these previous studies interrupted gaze movements (i.e., rendered gaze stable for hundreds of milliseconds), it is difficult conclude if the perturbations' effects represent dynamic corrections to the ongoing gaze shift or, rather, the programming of a second corrective movement.

Electrical stimulation of the supplementary eye fields (SEFs), like that of the SC, can evoke coordinated eye–head gaze shifts that are kinematically indistinguishable from natural gaze shifts. Similarly, stimulation of the frontal eye field (FEF) can evoke combined movements of the eye and the head that appear qualitatively similar to natural gaze shifts. These findings have been taken as evidence that cortical areas such as these in frontal cortex are not concerned with planning only the eye but also the head, components of gaze shifts. The latencies of eye and head movements evoked by stimulation in the FEF and SEF are longer than those evoked by stimulation of the SC consistent with projections from the two cortical areas to the SC. Electrical stimulation experiments show that the SEF encodes gaze direction in a reference frame that varies across a continuum from eye- to head- to space/body-centered coding schemes. How these multiple coding schemes are reflected in the processing that takes place in the SEF before the gaze command is released toward the FEF, the SC, and brain stem structures remains to be determined.

The Control of Eye–Head Pursuit

Behavioral Investigations

Humans and other primates follow a moving visual target of interest by generating smooth pursuit eye movements (Figure 5(a), left). These slow continuous eye movements function to keep a small moving target on the fovea so that it is viewed with the greatest accuracy. When the head is unrestrained, a combination of both head and eye movements are commonly used to track target motion (Figure 5(a), right). During combined eye–head pursuit movements, also called gaze pursuit, the VOR would be counterproductive for the same reason that it is counterproductive during gaze shifts. The eye-movement commands generated would reflect the summation of two opposing signals: a VOR, which cancels out the contribution of head motion to gaze, and an oculocentric pursuit signal of cerebellar origin. As a result, a fully functional VOR generates an eye-movement command in the direction opposite to that of the ongoing tracking during eye–head pursuit. Figure 5(b) shows a schematic of how these two commands sum to drive to the extraocular motor neurons during rightward eye–head pursuit. The pursuit pathway commands a rightward eye movement, while the VOR pathway, in response to the rightward head movement that is produced, commands a compensatory (i.e., leftward) eye movement.

The results of behavioral investigations have established that the VOR is partially suppressed during combined eye–head tracking. Unambiguous evidence for non-pursuit-mediated adjustment of VOR gain during eye–head tracking was found by transiently perturbing the head while subjects voluntarily tracked a head-stationary target. In this condition, the VOR would need to be completely suppressed in order to maintain foveation of a target. Indeed, in both humans and monkeys, the gain of the evoked VOR was rapidly suppressed (i.e., within 30 ms), indicating that the latency of VOR suppression is too fast to be explained by pursuit eye movements (>90 ms). The question then arises: What is the advantage of having a non-pursuit-related mechanism to negate the VOR during eye–head tracking? The general consensus is that parametric suppression of the VOR operates to extend the range of eye–head tracking movements beyond what would be possible by the pursuit system alone. Reports that subjects can suppress their VOR gain by imaging a head-stationary target and that the ability to generate smooth pursuit eye movements to cancel the VOR are not always equally affected by central nervous system (CNS) lesions are consistent with the existence of a nonvisual VOR cancellation mechanism.

Neurophysiology: Premotor Control of the Eye during Eye–Head Pursuit

Brain stem pursuit pathways The implication of the results of the behavioral investigations just described is that interactions between premotor vestibular and oculomotor pathways must be coordinated to ensure the accurate coordination of eye and head movements during pursuit in the head-unrestrained condition. Eye–head (EH) cells receive a pursuit-related command from the cerebellar flocculus and a head-velocity-related command from the vestibular afferents and project directly to the extraocular motor neurons. EH cells encode eye velocity and provide the primary drive to the extraocular motor neurons for pursuit in the head-restrained condition (Figure 5(b)). During combined eye–head pursuit, EH neuron responses are well predicted by the sum of their gaze-movement sensitivity during smooth pursuit and their head-movement

Figure 5 (a) Pursuit response to a step-ramp target trajectory made with the head restrained (left; smooth pursuit) and head unrestrained (right; gaze pursuit); (b) interactions between VOR and smooth pursuit pathways during combined eye–head tracking. dLPN, dorsal lateral pontine nucleus; EH, eye–head cells; MT/MST, middle temporal and middle superior temporal areas; PVP, position-vestibular-pause neuron; VOR, vestibulo-ocular reflex.

sensitivity during VOR in the dark. This suggests that their response reflects the integration of head-movement-related inputs from the vestibular afferents and gaze-movement-related information from the floccular lobe.

Vestibulo-ocular reflex pathways The efficacy of the VOR pathway during combined eye–head pursuit has been directly measured. The head-velocity-related responses of PVP neurons are suppressed by 30% during eye–head tracking relative to their responses during the VOR. During cancellation of the VOR (by fixation of a head-stationary target), the velocity modulation of the direct VOR pathways is likewise attenuated by 30%. Thus, the efficacy of transmission in the direct VOR pathways is similarly suppressed during cancellation of the VOR and during the active head movements made during coordinated eye–head pursuit. The responses of PVP neurons are more attenuated during gaze shifts than during eye–head pursuit (i.e., ~70 vs. 30% attenuation). This difference in the relative levels of suppression occurs because the inhibition that is mediated by the premotor circuitry that generates smooth pursuit is less powerful than that which generates saccades. Less is currently known about the connectivity of the VOR circuitry with the brain stem premotor pathway that mediates smooth pursuit than that which mediates saccades. Accordingly, fully elucidating the mechanism responsible for the attenuation in PVP neuron responses during slow gaze redirection requires further study.

Premotor inputs to the extraocular motor neurons As previously described, PVP neurons, which mediate the VOR, remain sensitive to head movements during eye–head pursuit; their head-velocity-related responses are attenuated by only ~30% relative to VOR in the

dark. This modulation has the appropriate polarity to offset the oppositely directed head-related signals carried by premotor smooth pursuit pathways (i.e., EH cells) at the level of the extraocular motor neurons during eye–head pursuit functions. Indeed, as is the case for gaze shifts, individual motor neurons encode only eye-movement-related signals during eye–head pursuit.

Neurophysiology: Premotor Control of the Head during Eye–Head Pursuit

Much less is known about the premotor control of voluntary head movements during pursuit compared to the head movements that are made during gaze shifts. This is largely because most work on voluntary head movements has been done in cat and its pursuit system is far less developed than that of monkeys. Whether neurons in the brain stem, which are distinct from the tecto-recipient neurons that control gaze shifts, drive head movements during pursuit remains to be determined. As is the case during gaze shifts, head movements during pursuit are most likely shaped by multiple spinal projecting pathways that converge at the level of the neck motor neurons.

Upstream Control

Quantification of initial pursuit dynamics has demonstrated that: (1) eye and head movement onsets are tightly coupled and (2) initial eye and head movement dynamics both similarly vary as a function of target velocity. In addition, the primate pursuit system has the ability to use and store information about the motion of a visual stimulus in order to drive the initiation and the maintenance of both the eyes and the head during gaze pursuit. Thus, the coordination of eye and head movements during pursuit is likely to be achieved, at least in part, by a common drive mechanism, whereby a shared-controller drives both the eye and neck motor systems.

Although the neural substrate of the shared controller for pursuit is not known, one possible candidate is the cerebellar flocculus and/or ventral paraflocculus (herein referred to as the floccular lobe). Patients with cerebellar disease generally show comparable deficits during combined eye–head and ocular only pursuit of pseudorandom targets. Furthermore, electrical stimulation of the floccular lobe elicits smooth eye movements in the head-restrained primate and combined smooth eye–head movements in the head-unrestrained rabbit, suggesting that the structure may be involved in eye–head gaze control. Conversely, studies in monkeys suggest that the output of the floccular lobe is not adequate to perform this role. Instead, it has been proposed that the floccular lobe primarily controls eye movement (in the orbit) as a component of the oculomotor neural integrator, whereas the dorsal vermis of the cerebellum may be more involved in the control of gaze movement.

Another possibility, although not a mutually exclusive one, is that the coordination of the eyes and the head during pursuit emerges more centrally. For example, neurons in the SEFs and FEFs respond to smooth pursuit eye movements as well as saccadic eye movements. Moreover, as previously reviewed, stimulation of both the SEFs or FEFs evoke head as well as eye movements. Although prior studies have largely focused on the kinematics of the head movements that accompany gaze shifts, stimulation can also evoke eye and head movements that are slow and continuous. Given that (1) the SEF and FEF are reciprocally connected and (2) the FEF efferents project directly to the brain stem as well as to the dorsal lateral pontine nuclei, which in turn project to the floccular lobe of the cerebellum, these structures are well situated within a neural network that could function to coordinate combined eye–head gaze pursuit.

Conclusion

In conclusion, the premotor pathways that mediate the VOR are modulated in a manner that depends strictly on the current gaze strategy of the monkey. The head-velocity sensitivities of premotor neurons in this pathway are attenuated for the active head movements that are made during gaze shifts and gaze pursuit. This attenuation of the direct VOR pathways is mediated via inputs from the premotor circuitries that are known to generate saccades and smooth pursuit eye movements. Because the VOR is attenuated during eye–head gaze shifts and pursuit, it follows that the head and the eyes contribute to shifting the axis of gaze relative to space. How the upstream structures that are involved in the planning of these coordinated eye and head movements ensure accurate gaze is an important question that requires future investigation.

Eye Movement Disorders

R J Leigh and M Gross, Case Western Reserve University, Cleveland, OH, USA

Published by Elsevier Ltd.

Introduction

Neuroscientists have traditionally been skeptical of studies of abnormal eye movements in patients with neurological disorders because of doubts about the discreteness of lesions, the quality of experimental design or measurement of eye movements, and the potentially confounding effects of adaptive mechanisms. During the past decade, these concerns have been addressed by development of sensitive neuroimaging techniques, application of sophisticated test paradigms, use of reliable methods for measuring eye movements, and standardization of procedures to control mental set. This means that studies of eye movements now provide an important opportunity to test current hypotheses, forged by basic scientists, about how the brain controls several aspects of eye movements. Most diseases affecting the brain have some effect on eye movements.

In this article, several examples are presented of how study of eye movement disorders has provided insights, as well as instances in which basic research has translated into improved techniques for diagnosis and treatment of patients with neurological diseases. A bottom-up approach is used, proceeding from the extraocular muscles to cerebral cortex. In the final section, pathological forms of nystagmus and saccadic intrusions are summarized. Several functional classes of eye movements are summarized in Table 1.

Disorders of the Ocular Motor Periphery

Movements of each eye are controlled by six extraocular muscles, which originate at the back or side of the orbit and travel to fibromuscular pulleys that are formed by the fascia of orbit. The outer orbital part of each muscle inserts partially on the pulley, and the inner global part passes through the pulley and inserts onto the eyeball. The direction of ocular movements in three dimensions depends upon the geometry of the muscle origins, pulleys, and insertions. During saccades and pursuit movements, the eyes rotate around axes that lie in Listing's plane, which approximates the frontal (coronal) plane of the head. Palsies of the abducens, trochlear, or oculomotor nerves, which supply the extraocular muscles, acutely, but not chronically, cause the eyes to rotate out of Listing's plane. Congenital misplacement of the fibromuscular pulleys may cause some forms of childhood strabismus (misalignment of the eyes).

The unique properties of extraocular muscles result in some unusual responses to systemic disease. Thus, Duchenne muscular dystrophy, an X-linked disorder leading to profound weakness of skeletal muscles and death of affected males in their early twenties, largely spares the extraocular muscles. This insight was gained from the clinical observation that patients with advanced weakness were able to make normal-velocity saccades. It has been postulated that extraocular muscle may be protected either by endogenous upregulation of an analog of the abnormal protein (dystrophin) called utrophin, or by the unique properties of the basement membranes of the extrasynaptic sarcolemma of extraocular muscle. Improved understanding of the reason why extraocular muscles are spared in Duchenne dystrophy may provide insights into possible therapies for this disorder.

In contrast, disorders of the neuromuscular junction have a propensity for affecting eye movements. Botulinum poisoning causes slow saccades with limited range of movement. Myasthenia gravis, the commonest neuromuscular disorder in humans, which is probably due to an immune attack on nicotinic acetylcholine receptors, affects eye movements in up to 80% of affected individuals. This propensity has been attributed to the reduced 'safety factor' that relates neurotransmitter release to receptors available. Other factors, such as reduced expression of decay-accelerating factor, an inhibitor of complement-mediated responses by extraocular muscles, may play a role. Ocular myasthenia is characterized by fatigue (e.g., impaired ability to sustain the eye in eccentric gaze), variability (e.g., saccades of similar size show increased variance of peak velocity), and, ultimately, restricted range of eye movement. Administration of anticholinesterase drugs, such as edrophonium, temporally increases acetylcholine and improves neuromuscular transmission, causing improvement of eye movements. Sometimes edrophonium causes saccadic overshooting (hypermetria), reflecting central adaptive responses to ocular motor weakness.

Disorders Affecting the Brain Stem Contributions to Gaze Control – the Pons

The pons and rostral medulla are important in the control of horizontal gaze. The abducens nucleus is the horizontal conjugate gaze center; it contains motor neurons that innervate the lateral rectus muscle

Table 1 Functional classes of human eye movements

Class of eye movement	*Main function*
Gaze Holding	
Vestibular	Holds images of the seen world steady on the retina during brief head rotations or translations
Visual fixation	Holds the image of a stationary object on the fovea by minimizing ocular drifts
Optokinetic	Holds images of the seen world steady on the retina during sustained head rotation
Gaze Shifting	
Smooth pursuit	Holds the image of a small moving target on the fovea; or holds the image of a small near target on the retina during linear self-motion; with optokinetic responses, aids gaze stabilization during sustained head rotation
Nystagmus quick phases	Resets the eyes during prolonged rotation and directs gaze toward the oncoming visual scene
Saccades	Brings images of objects of interest onto the fovea
Vergence	Moves the eyes in opposite directions so that images of a single object are placed or held simultaneously on the fovea of each eye

Adapted from Leigh RJ and Zee DS (2006) *The Neurology of Eye Movements*, 4th edn. New York: Oxford University Press.

and internuclear neurons that project across the midline, via the medial longitudinal fasciculus (MLF), to the contralateral medial rectus motor neurons (Figure 1). Lesions of the abducens nucleus (site 1, Figure 1) cause loss of all conjugate movements toward the side of the lesion, but vergence movements are still possible, because they depend on independent projections to the medial rectus motor neurons. Interruption of the MLF (site 2, Figure 1) causes internuclear ophthalmoplegia (INO), with restriction and slowing of the adducting eye ipsilateral to the lesion. Multiple sclerosis is the most common etiology for an INO in young persons, especially when it is present bilaterally.

Inputs to the abducens nucleus contributing to each functional class of eye movement may be independently affected by disease. Thus, the vestibuloocular reflex (VOR) for horizontal head rotations depends on vestibular afferents from the lateral semicircular canals, which relay their signal to the contralateral abducens nucleus via the medial vestibular nucleus (MVN) (Figure 1). Wernicke's encephalopathy, a disorder in alcoholics due to thiamine deficiency, involves the vestibular nuclei (site 3, Figure 1) and thus impairs the horizontal VOR. The horizontal gaze center also receives command signals for horizontal saccades, signals which project to the abducens nucleus from the adjacent paramedian pontine reticular formation (PPRF); lesions here (site 4, Figure 1) cause slow or absent horizontal saccades.

The nucleus prepositus hypoglossi (NPH), the adjacent MVN, and the cerebellum play an important role in holding the eyes in an eccentric position (e.g., far right gaze) against the elastic pull of the orbital tissues. This function depends on mathematical integration of premotor (visual, vestibular, saccadic) signals by the NPH/MVN-cerebellar network. Impaired function of this network (leaky integration) due, for example, to intoxication with alcohol causes the eyes to drift back to the center, leading to gaze-evoked nystagmus. It has also been postulated that the ocular motor neural integrator network may become unstable, causing either increasing-velocity drifts away from center position or quasi-sinusoidal eye rotations (acquired pendular nystagmus; discussed further elsewhere in this encyclopedia.

Disorders Affecting the Brain Stem Contributions to Gaze Control – the Midbrain

The midbrain plays an important role in the control of vertical conjugate gaze and vergence eye movements. The oculomotor and trochlear nuclei (Figure 2) house the motor neurons that innervate extraocular muscles that mainly rotate the eyes vertically (superior and inferior rectus muscles) or torsionally (around the line of sight; the superior and inferior oblique muscles). These motor neurons receive their saccadic input from the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), which lies in the prerubral fields of the rostral midbrain. Bilateral lesions involving the riMLF (site 1, Figure 2) cause slow or absent vertical saccades (such as in progressive supranuclear palsy; PSP). Unilateral lesions of riMLF, such as in rostral brain stem strokes, cause loss of torsional quick phases that rotate the top pole of the eye toward the side of the lesion.

The signals for vertical vestibular and pursuit eye movements ascend from the medulla and pons to the midbrain in the MLF and other pathways. Thus, bilateral MLF lesions (site 2, Figure 2), which occur in multiple sclerosis, cause impaired vertical pursuit and vestibular responses (as well as bilateral adduction failure during horizontal saccades). The interstitial

Figure 1 Anatomic scheme for the synthesis of signals for horizontal eye movements. The abducens nucleus (CN VI) contains abducens motor neurons that innervate the ipsilateral lateral rectus muscle (LR), and abducens internuclear neurons that send an ascending projection in the contralateral medial longitudinal fasciculus (MLF) to contact medial rectus (MR) motor neurons in the contralateral third nerve nucleus (CN III). From the horizontal semicircular canal, primary afferents on the vestibular nerve project mainly to the medial vestibular nucleus (MVN), where they synapse and then send an excitatory connection to the contralateral abducens nucleus and an inhibitory projection to the ipsilateral abducens nucleus. Saccadic inputs reach the abducens nucleus from ipsilateral excitatory burst neurons (EBN) and contralateral inhibitory burst neurons (IBN). Eye position information (the output of the neural integrator) reaches the abducens nucleus from neurons within the nucleus prepositus hypoglossi (NPH) and adjacent MVN. The medial rectus motor neurons in CN III also receive a command for vergence eye movements. Putative neurotransmitters for each pathway are shown: Ach, acetylcholine; asp, aspartate; glu, glutamate; gly, glycine. The anatomic sections on the right correspond to the level of the arrowheads on the schematic on the left. Other components: Abd. nucl., abducens nucleus; CN VI, abducens nerve; CN VII, facial nerve; CTT, central tegmental tract; ICP, inferior cerebellar peduncle; IVN, inferior vestibular nucleus; Inf. olivary nucl., inferior olivary nucleus; MRF, medullary reticular formation; PPRF, paramedian pontine reticular formation; SVN, superior vestibular nucleus. nucleus of Cajal plays an important role in holding steady vertical eccentric gaze (e.g., far upward gaze); lesions here (site 3, Figure 2) cause gaze-evoked nystagmus on upward or downward gaze (due to a leaky ocular motor integrator). The superior colliculus is a midbrain tectal structure that receives inputs from the cortical eye fields, and is important for triggering both horizontal and vertical saccades. Extensive studies in the macaque monkey have demonstrated the important role of the superior colliculus in target selection and triggering of eye movements (saccades and pursuit). Functional imaging studies in humans have demonstrated activation during generation of short-latency (express) saccades. Lesions restricted to the superior colliculus in humans are rare, but more diffuse disorders (such as PSP) involve this structure.

Disorders Affecting the Cerebellar Contributions to Gaze Control

Three regions of the cerebellum contribute to the control of eye movements. The flocculus and paraflocculus

Figure 2 A sagittal section of the monkey brain stem showing the locations of premotor burst neurons: excitatory burst neurons for horizontal saccades lie in the paramedian pontine reticular formation (PPRF) and, for vertical and torsional saccades, lie in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF). Burst neurons project to ocular motor neurons lying in the abducens nucleus (VI), the trochlear nucleus (IV), and the oculomotor nucleus (III). Omnipause neurons (indicated by an asterisk) lie in the midline raphe of the pons between the rootlets of the abducens nerve (CN VI) and gate the activity of burst neurons. Other components: CG, central gray; EBN, excitatory burst neuron; IBN, inhibitory burst neuron; MB, mammillary body; CN III, rootlets of the oculomotor nerve; CN IV, trochlear nerve; MRF, medullary reticular formation; ND, nucleus of Darkschewitsch; NPH, nucleus prepositus hypoglossi; NRTP, nucleus reticularis tegmenti pontis; PC, posterior commissure; TR, tractus retroflexus. The arrow refers to the Horsley–Clarke plane of section. Numbers indicate lesion sites that are discussed in the text. Adapted courtesy of Dr. Jean Büttner-Ennever.

are important for smooth pursuit (eyes alone or eye–head tracking), eccentric gaze holding, and adjustment of the VOR so that it is optimized to guarantee clear vision during head perturbations. Lesions of the flocculus and paraflocculus impair each of these functions and also cause downbeat nystagmus. This syndrome is commonly encountered in patients with the Chiari malformation (an abnormality of brain stem and cerebellar development) and with hereditary spinocerebellar ataxias including episodic ataxia type 2, which is due to abnormal P/Q calcium channels and which can be treated with the potassium channel blocker, 4-aminopyridine.

The midline nodulus and adjacent ventral uvula regulate a property of the VOR called velocity storage, which causes the raw vestibular input to sustain vestibular nystagmus after the head has stopped turning. Lesions of the nodulus and ventral uvula cause sustained vestibular responses, which are subject to adaptive repair mechanisms resulting in periodic alternating nystagmus, a form of horizontal nystagmus that reverses direction every 2 min (see later, section titled 'Pathological nystagmus and saccadic intrusions').

The dorsal vermis and the fastigial nucleus to which it projects play an important role in making saccades accurate, perhaps by feedback control of brain stem saccade-generating burst neurons. Dorsal vermis lesions cause saccadic hypometria (undershoots). Fastigial nucleus lesions cause hypermetria (overshoots). Axons from each fastigial nucleus cross in its counterpart, thus, clinical lesions cause bilateral saccadic hypermetria. Wallenberg's syndrome (infarction of the lateral medulla) causes lateropulsion of eye movements (overshooting to the side of the lesion; undershooting to the opposite side). A similar ipsipulsion occurs after experimental inactivation of the fastigial nucleus in macaques, suggesting that lateropulsion in Wallenberg's syndrome is due to interruption of climbing fiber inputs (inferior cerebellar peduncle infarction) to Purkinje cells, which then inhibit fastigial nucleus neurons.

Disorders of the Basal Ganglia That Cause Disordered Gaze Control

The basal ganglia (caudate, substantia nigra pars reticulata, and subthalamic nucleus) are important relay sites for pathways from the cortical eye fields to the superior colliculus and brain stem nuclei. In general, to elicit disorders of eye movements with basal ganglia diseases requires special test paradigms, such as predictive saccades, saccades to remembered targets, and antisaccades (looking in the direction opposite to a visual stimulus). In Parkinson's disease, which affects dopaminergic neurons in the substantia nigra, patients are able to make relatively accurate saccades between two stationary targets, provided they are cued to do so, but saccades become progressively hypometric when they are self-generated, so that gaze shifts become a 'staircase' of saccades to the target. Procedures to treat Parkinson's disease, such as deep brain stimulation of the subthalamic nucleus, are reported to improve the ability to make saccades to remembered targets. Pallidotomy (a stereotactically guided lesion of the globus pallidus) may increase small saccadic intrusions (square-wave jerks), possibly because of interruption of inhibitory projections from the substantia nigra pars reticulata to the superior colliculus.

In Huntington's disease, a diffuse neurodegenerative disorder which prominently affects the caudate nucleus, patients show difficulties initiating saccades but, paradoxically, also have difficulties in suppressing saccades during fixation. These findings can be related to the parallel pathways that control the various types of saccadic responses (Figure 3). Thus, on the one hand, diseases affecting either the frontal lobes or the caudate nucleus, which inhibits the nondopaminergic substantia nigra pars reticulata (SNpr), may lead to difficulties in initiating voluntary saccades. On the other hand, the SNpr also inhibits the superior colliculus in order to suppress reflexive saccades to visual stimuli and, therefore, affected patients exhibit excessive distractibility during attempted fixation. Recent animal studies have emphasized how the basal ganglia pathway is concerned with behavior that is rewarded, but this role has yet to be explored in patients with basal ganglionic disease.

Disorders of the Cerebral Cortex That Affect Gaze Control

The cerebral cortex contains several areas that are important for eye movements (Figure 4). Primary visual cortex (V1) is the gateway for vision; without it, humans cannot make visually guided eye movements. Cortical areas concerned with motion vision lie in cortex at the junction of areas 19, 37, and 39, close to the intersection of the ascending limb of the inferior temporal sulcus and the lateral occipital sulcus. These areas correspond to the middle temporal visual area (MT, or V5) and the medial superior visual temporal area (MST) in the macaque. Patients with lesions affecting the human homolog MT show a defect of eye movements (saccades and pursuit) to targets moving in the contralateral visual hemifield; saccades to stationary targets may be normal. Patients with lesions involving the homolog of MST show a defect of smooth pursuit for targets moving ipsilateral to the side of the lesion. Acute parietal lobe lesions, especially affecting the right hemisphere, produce a classic syndrome of contralateral hemineglect that contributes to an ipsilateral gaze preference. The accuracy of saccades to contralateral targets may also be impaired, but a more impressive dysmetria occurs when patients are required to respond to a double-step stimulus, in which the target jumps twice before a response can be initiated. If the target jumps first into the contralateral hemifield and then into the ipsilateral field, patients cannot make accurate saccades to the final target position, even though it lies in the 'intact' hemifield. This finding has been taken as evidence that the parietal lobe plays a pivotal role in computing target position from both visual stimuli and an internal (efference) copy of eye movements (in this case, the change in eye position due to the first saccade).

The frontal eye field (FEF) is important for voluntary saccades and suppression of saccades during steady fixation. Acute lesions that involve the FEF may produce an ipsilateral gaze deviation. With more chronic FEF lesions, saccades made in response to the overlap paradigm, during which the fixation light remains on when the target light is presented, show increased reaction time, both ipsilaterally and contralaterally. The supplementary eye fields (SEFs), and adjacent presupplementary motor cortex, guide saccades during complex tasks, such as sequences of movements and responses when the instructional set changes. Patients with SEF lesions cannot make a sequence of saccades to an array of visible targets in the order that they were turned on. Another effect of SEF lesions is difficulty in changing the direction of saccades as part of a reversal of a previously established pattern of response. The dorsolateral prefrontal cortex (DLPC) is important for memory-guided saccades, and lesions in this region impair both this function and antisaccades. There is also some evidence that lesions involving the anterior cingulate cortex impair memory-guided saccades and antisaccades.

Pathological Nystagmus and Saccadic Intrusions

Abnormal eye movements that disrupt steady fixation are of two main types: pathological nystagmus and saccadic intrusions. The essential difference between

Figure 3 Block diagram of the major structures that project to the brain stem saccade generator (premotor burst neurons in pontine reticular formation and rostral interstitial nucleus of the medial longitudinal fasciculus). Also shown are projections from cortical eye fields to superior colliculus. DLPC, dorsolateral prefrontal cortex; FEF, frontal eye fields; IML, intramedullary lamina of thalamus; NRTP, nucleus reticularis tegmenti pontis; PEF, parietal eye fields; PPC, posterior parietal cortex; SEF, supplementary eye fields; SNpr, substantia nigra pars reticulata; STN, subthalamic nucleus. Not shown are the pulvinar, which has connections with the superior colliculus and both the frontal and parietal lobes, projections from the caudate nucleus to the subthalamic nucleus via globus pallidus, and the pathway that conveys efference copy from brain stem and cerebellum, via thalamus, to cerebral cortex. Reproduced from Leigh RJ and Zee DS (2006) *The Neurology of Eye Movements*, 4th edn. New York: Oxford University Press, with permission.

nystagmus and saccadic intrusions lies in the initial eye movement that takes the line of sight away from the visual target. Thus, for nystagmus, the initial movement is a slow drift (or 'slow-phase' – see Figure 5), as opposed to an initial inappropriate quick movement that interrupts steady fixation in saccadic intrusions (Figure 6). After the initial slow movement of nystagmus, corrective or abnormal eye movements may follow. Thus, a definition of nystagmus is repetitive to-and-fro movements of the eyes that are initiated by slow phases. Nystagmus may consist mainly of sinusoidal slow-phase oscillations (pendular nystagmus – Figure 5(d)) or, more commonly, of an alternation of slow drift and corrective quick phase (jerk nystagmus – Figures 5(a)–5(c)). Although nystagmus is often described by the direction of its quick phases (e.g., downbeat nystagmus), it is the slow phase that indicates the underlying disorder. Not all nystagmus is pathological. Thus, when we turn our heads, the slow phases of physiological nystagmus – vestibular and optokinetic – act to preserve clear vision by preventing excessive slip of images on the retina; quick phases reset the eyes into their working range. In contrast, saccadic intrusions are fast movements that take the eye away from the target (Figure 6), and comprise a spectrum ranging from single saccades to sustained saccadic oscillations.

Under normal circumstances, three mechanisms collaborate to prevent the line of sight drifting away from the object of regard. Disorders of each of these

Figure 4 Probable location of cortical areas important for eye movements in human brain. The medial superior temporal visual area (MST) and middle temporal visual area (MT) may form a contiguous cortical area. Reproduced from Leigh RJ and Zee DS (2006) *The Neurology of Eye Movements*, 4th edn. New York: Oxford University Press, with permission.

mechanisms disrupt steady gaze and lead to nystagmus. The first mechanism is the VOR, by which eye movements compensate for head perturbations at short latency and thereby maintain clear vision during natural activities, especially locomotion. The second mechanism (previously referred to as the neural integrator for eye movements) concerns the brain's ability to hold the eye at an eccentric position in the orbit against the elastic pull of the eyeball's suspensory ligaments and muscles. The third mechanism is visual fixation, which has three components. The first component is visual suppression of unwanted saccades during focused tasks, such as threading a needle. The second component is the ability to detect retinal image drift and rapidly program both slow and saccadic corrective eye movements. The third component is a more long-term effect of visual inputs that monitor the visual consequences of eye movements and continuously tunes them to optimize gaze stability.

Nystagmus Due to Peripheral or Central Imbalance

An important characteristic of the vestibular system is its resting discharge rate ('vestibular tone'). In response to motion stimuli, such as rotation, inputs from one end organ (the vestibular labyrinth) will increase above this background rate while the contralateral one will decrease. Thus, vestibular tone bestows increased sensitivity to motion stimuli due to this push–pull mechanism. However, the consequence of vestibular tone is that, if disease affects one labyrinth, the discharge rate may fall, and the brain will misinterpret the difference between the two end organs as self-rotation (known clinically as vertigo) and generate eye movements to compensate for the illusory motion (vestibular nystagmus). Such nystagmus (Figure 5(a)) is often mixed horizontal–torsional in direction (reflecting the sum of inputs from the three semicircular canals that sense motion in each ear) and can be suppressed by visual fixation, since central mechanisms for gaze stabilization are intact.

Imbalance may also arise within the central vestibular system. For example, the flocculus of the cerebellum governs dynamic properties of the VOR and, for vertical head rotations, achieves this through an asymmetric inhibition. Consequently, lesions of the flocculus tend to cause upward drifts of the eyes with downward quick phases (downbeat nystagmus). As noted previously, the nodulus and ventral uvula govern 'velocity storage' – perseveration of the rotational vestibular signal – so that the nystagmus response is prolonged beyond the duration of the head rotation. Lesions of the nodulus and ventral uvula further prolong velocity storage, then adaptive mechanisms attempt to correct the prolonged responses, so that the nystagmus periodically reverses, resulting in periodic alternating nystagmus, which changes direction approximately every 2 min. Periodic alternating nystagmus can be successfully abolished by the γ-aminobutyric acid ($GABA_B$)ergic drug baclofen.

Nystagmus Due to Disturbance of the Neural Integrator for Eye Movements

As already noted, if the gaze-holding mechanism is deficient, the eyes cannot be held steadily in an eccentric orbital position, but drift back to the midline with

Figure 5 Four common slow-phase waveforms of nystagmus. (a) Constant velocity drift of the eyes. This occurs in nystagmus caused by peripheral or central vestibular disease and also with lesions of the cerebral hemisphere. The added quick phases give a 'sawtooth' appearance. (b) Drift of the eyes back from an eccentric orbital position toward the midline (gaze-evoked nystagmus). The drift shows a negative exponential time course, with decreasing velocity. This waveform reflects an unsustained eye position signal caused by an impaired neural integrator. (c) Drift of the eyes away from the central position, with a positive exponential time course (increasing velocity). This waveform suggests an unstable neural integrator and is encountered in the horizontal plane in congenital nystagmus and in the vertical plane in cerebellar disease. (d) Pendular nystagmus, which is encountered as a type of congenital nystagmus and with acquired disease. Reproduced from Leigh RJ and Zee DS (2006) *The Neurology of Eye Movements*, 4th edn. New York: Oxford University Press, with permission.

Figure 6 Schematic of saccadic intrusions and oscillations. (a) Dysmetria: inaccurate saccades. (b) Macrosaccadic oscillations: hypermetric saccades about the position of the target. (c) Square-wave jerks: small, uncalled-for saccades away from and back to the position of the target. (d) Macrosquare-wave jerks or macrosaccadic pulses: large, uncalled-for saccades away from and back to the position of the target. (e) Ocular flutter: to-and-fro, back-to-back saccades without an intersaccadic interval. Reproduced from Leigh RJ and Zee DS (2006) *The Neurology of Eye Movements*, 4th edn. New York: Oxford University Press, with permission.

a decreasing-velocity waveform (Figure 5(b)); this is gaze-evoked nystagmus. Because the gaze-holding mechanism depends, in part, upon the vestibular nuclei, nystagmus due to brain stem lesions often manifests the properties of both vestibular imbalance and disturbed gaze holding. A wide range of disorders affecting the brain stem and cerebellum can cause gaze-evoked nystagmus, along with a range of sedative medicines and alcohol. Instability in the gaze-holding mechanism may lead to a slow-phase drift that increases in velocity (Figure 5(c)); this is described in patients with cerebellar disorders. It is also possible that the ocular motor neural integrator network may become unstable, causing either increasing-velocity drifts away from center position or quasi-sinusoidal eye rotations (acquired pendular nystagmus – Figure 5(d)). Determination of the neurotransmitters involved in the ocular motor neural integrator (GABA and glutamate) using the technique of pharmacological inactivation in monkeys has led to development of treatments for acquired pendular nystagmus in patients (e.g., the noncompetitive glutamate antagonist, memantine).

Nystagmus Occurring with Disorders of the Visual Pathways

Individuals who are born blind have continuous nystagmus which is constantly changing in direction (shifting null). Such nystagmus reflects an uncalibrated ocular motor system. Nystagmus also occurs with a range of less severe congenital visual disorders, such as in albinism, in which anomalies of the visual pathways are documented. Congenital nystagmus, or infantile nystagmus syndrome, may also occur in individuals who have normal visual systems, and thus may reflect a different, poorly understood mechanism. In adulthood, loss of vision due, for example, to optic nerve demyelination in multiple sclerosis may be associated with acquired pendular nystagmus.

Although it seemed possible that delays in the visual system could lead to these quasi-sinusoidal oscillations, experimental manipulation of visual delay using electronic feedback did not change the frequency of oscillations. A more plausible hypothesis, noted in the prior section, is that acquired pendular nystagmus arises from instability of the neural integrator mechanism. Other forms of nystagmus exist for which there is no good explanation; these are discussed further in the text on eye movement disorders, *The Neurology of Eye Movements*, by Leigh and Zee.

Saccadic Intrusions and Oscillations

The range of saccadic intrusions and oscillations are summarized schematically in Figure 6. Square-wave jerks are small, uncalled-for saccades that take the eye away from the fixation point and return it within 200–400 ms. Normal subjects show square-wave jerks and, in some individuals they are frequent. However, square-wave jerks are most prominent with certain disease states, especially PSP and Friedreich's ataxia. Macrosaccadic oscillations are larger saccades that oscillate the eye about the point of fixation. They usually occur in patients with midline cerebellar lesions involving the fastigial nucleus, which also cause saccadic hypermetria. Ocular flutter consists of horizontal high-frequency, back-to-back saccades without an intersaccadic interval. When such oscillations have horizontal, vertical, and torsional components they are referred to as opsoclonus. Current evidence suggests that flutter and opsoclonus, as well as brief, low-amplitude, high-frequency oscillations in normal subjects, may be generated by a brain stem network of burst neurons, although disturbed cerebellar feedback of saccades might also contribute. With improved knowledge of the pharmacology of gaze-holding and saccadic systems, new drug treatments for these disorders are becoming available.

Conclusions

This overview of abnormal eye movements briefly describes only a few examples from a broad range of disorders that are now fairly well understood. These and other examples may provide insights into current models of normal eye movements. If the goal is to develop neuromimetic models for eye movements, then abnormal eye movements are well suited to identify biologically plausible hypotheses. Indeed, certain disorders, such as slow saccades, have played a pivotal role in development of current models. Another important potential outcome of such a translational approach is development of new therapies – for example, the identification of drug treatmen ts for acquired pendular nystagmus based on the pharmacology of the neural integrator for eye movements.

Eye Tracking and Mental Illness

D L Levy, McLean Hospital, Belmont, MA, USA
J A Sweeney, University of Illinois, Chicago, IL, USA

The study of eye tracking in psychiatric populations began in 1908, when Diefendorf and Dodge first observed an association between abnormal visual pursuit tracking and the illness that we now refer to as schizophrenia. Included among their study populations were hospitalized individuals with diagnoses of dementia praecox (this term was later changed to schizophrenia), manic-depressive psychosis (now termed bipolar disorder), and organic brain disorders such as epilepsy and neurosyphilis. Subjects were asked to follow a pendulum as it moved back and forth while an ingeniously designed camera system recorded their eye movements. The key finding was that impaired smooth pursuit eye movements were characteristic of patients with a diagnosis of dementia praecox but were unusual in patients with mood and organic disorders. Because of the high degree of specificity in distinguishing dementia praecox from the other conditions, the authors labeled the phenomenon 'praecox pursuit'.

This intriguing finding went largely unnoticed for the next 65 years. By 1938, only two additional studies of oculomotor function in psychiatric populations had been published. Another 35 years would pass before Philip S Holzman and his colleagues rediscovered the association between eye-tracking dysfunction (ETD) and schizophrenia. In the context of studying vestibular function, they serendipitously found that ETD was present in 52–86% of schizophrenic patients. Chronically hospitalized patients showed a higher rate of ETD than patients who had been hospitalized for less than 6 months. This frequency of ETD was much higher than that found in patients with nonschizophrenic psychotic conditions (22%), nonpsychotic disorders (21%), or normal controls (8%). Scores of studies have since replicated the finding that ETD, or impaired smooth pursuit eye movements, is highly correlated with the diagnosis of schizophrenia. ETD is found during acute episodes as well as in remitted states, consistent with it being a trait rather than a secondary effect of an acute psychotic state. Moreover, ETD occurs in first-episode never-medicated patients, indicating that it is present at the onset of the illness and is thus not a function of chronicity, a degenerative process, or exposure to antipsychotic medication. Of particular importance ETD occurs at a much higher rate than schizophrenia in first-degree biological relatives of schizophrenics.

Quantitative Characterization of Eye-Tracking Dysfunction

During the first 15 years of modern studies of ETD in schizophrenia, performance was evaluated using one of two methods: a qualitative rating of normal or abnormal pursuit based on visual inspection of the degree to which the eye movement record matched the target waveform (see Figure 1) or global quantitative scores, such as the ln S/N or root mean square error. These measures yielded global indices of performance, but could not help to identify the nature of the abnormality, which, in turn, is relevant for localizing which brain systems are involved. More recent work has adopted the quantitative measures that are now routinely used to assess oculomotor function in clinical and basic science settings.

The smooth pursuit and saccadic eye movement systems work interactively during an eye-tracking task. Typical targets move predictably at a constant velocity (usually 10–30°s^{-1}) or sinusoidally (0.4 Hz). Smooth pursuit is initiated when a target moves across the visual field. The pursuit system attempts to stabilize the image of the target on the fovea by matching eye velocity to target velocity. The better the match between eye velocity and target velocity, the closer the ratio of these two values, or closed loop gain, is to 1.0. The more the eyes are moving too slowly and lag behind the target, the lower the gain. Two types of fast eye movements, or saccades, occur during pursuit. Compensatory saccades correct for pursuit that falls behind (catch-up saccades) or gets ahead (back-up saccades) of the target. Thus, low gain is typically associated with an increase in the number (and sometimes the size) of catch-up saccades. Intrusive saccades, on the other hand, are not corrective and are ordinarily inhibited during pursuit. The two most common types of intrusive saccades found in psychiatric populations are square wave jerks and anticipatory saccades. Both kinds of saccades take the eyes off the target. Anticipatory saccades are generally larger than 5° in amplitude and move the eyes ahead of the target, where the eyes either wait for it, or make a back-up saccade, before resuming pursuit. Square wave jerks are pairs of small amplitude (up to 5°) saccades separated by 130–450 ms, during which pursuit continues; the first intrusive saccade takes the eyes off the target and the second saccade repositions the eyes on the target.

Numerous studies have evaluated eye tracking using these quantitative measures of performance. ETD in schizophrenia seems to reflect two processes. The predominant pattern is reduced gain and increased

Figure 1 Eye tracking patterns in normal and abnormal pursuit: (a) 0.4 Hz sinusoidal target, (b) qualitatively normal eye tracking of target in (a, c) qualitatively abnormal eye tracking of target in (a).

rates of catch-up saccades (see Figure 1(c)), implicating a disturbance in the smooth pursuit system involving slowed eye velocity accompanied by increased compensatory catch-up saccades. Some evidence suggests that schizophrenics may also have an increased tolerance for position error. This results in sluggishness to initiate catch-up saccades, which increases their amplitude. An increased frequency of square wave jerks and anticipatory saccades also contribute to ETD, but to a lesser extent, and implicate disinhibition of the saccadic system.

Specificity

Numerous studies have reported that ETD is specific to schizophrenia and is not characteristic of nonschizophrenic psychiatric disorders. ETD appears to be a trait in schizophrenia. ETD is stable, and it is independent of medication effects or changes in clinical state. ETD is also present from the onset of the illness. Consistent with the data supporting the specificity of ETD for schizophrenia, some studies have reported that ETD is not characteristic of first-episode mood disorder patients. Moreover, ETD occurs in a significant proportion of clinically unaffected first-degree biological relatives of schizophrenic patients (~45%) but is atypical in relatives of nonschizophrenic patients. ETD is also found in childhood-onset schizophrenics, and a similar pattern of impaired pursuit (low gain and increased catch-up saccades) has been reported in their biological relatives, supporting the notion that childhood- and adult-onset forms of schizophrenia exist along a continuum.

Other studies, however, have found ETD in bipolar disorder (manic-depressive illness) and major depressive disorder as well as in nonpsychotic disorders such as obsessive–compulsive disorder and autism. For example, pursuit deficits of equivalent severity to those seen in schizophrenic patients have been reported in some samples of never-medicated first-episode affective disorder patients. The state–trait issue has not been examined extensively in relation to nonschizophrenic disorders. Some evidence indicates that ETD in bipolar disorder and major depressive disorder may be state-related. For example, certain pharmacological treatments can induce ETD in patients with affective disorders. Lithium carbonate has been shown to induce ETD in bipolar patients, and the monoamine oxidase inhibitor medication, phenelzine, causes pursuit abnormalities in patients with major depressive disorder. Conversely, ETD has been reported to improve following electroconvulsive therapy. Although ETD is clearly not treatment-induced when it occurs in first-episode never-medicated patients, it remains unclear whether it is stable in nonschizophrenic patients or normalizes as a function of some treatments. Whether such changes reflect the primary effects of the treatment intervention or secondary effects of clinical improvement remains unclear. Longitudinal studies are necessary to determine whether the nonspecificity of ETD in some samples is restricted to the acute phase of the illness or is a more enduring trait. As with many biological findings in psychiatry, abnormalities that are relatively specific to one disorder are often seen in more modest form and less frequently in other disorders. This seems to be the case with ETD as well, and may provide important clues to issues of heterogeneity and the boundaries between mental disorders.

Psychotropic Medications

Most studies addressing the issue of medication effects were carried out when first-generation antipsychotic drugs (e.g., haloperidol and fluphenazine) were the primary pharmacological treatment for schizophrenia. These antipsychotic medications are potent blockers of D2 dopamine receptors in the basal ganglia, resulting in extrapyramidal side effects resembling the motor disturbances seen in Parkinson's disease. The presence of impaired pursuit in individuals with idiopathic Parkinson's disease raised the possibility that ETD in schizophrenic patients could in part be a secondary effect of treatment with these medications.

Several lines of evidence indicate that ETD is not caused by treatment with antipsychotic medications. First, ETD (as well as low gain and increased catch-up

saccades) is found in schizophrenic patients who have never been exposed to antipsychotic medication. Second, performance is stable in never-before-medicated first-episode patients who are followed longitudinally while receiving drug treatment. Third, normal pursuit occurs in medicated schizophrenics, indicating that drug treatment does not sufficiently account for ETD. Fourth, indices of performance do not differ in first-episode patients who have never received antipsychotic drug treatment, unmedicated chronic schizophrenics with prior drug exposure, and currently medicated patients. Fifth, the dose of antipsychotic medication is generally not correlated with indices of performance. Sixth, eye tracking tends to be stable, despite changes in clinical state and medication status. Seventh, ETD is found at an elevated prevalence in nonschizophrenic individuals with schizotypal traits (e.g., perceptual aberrations and magical thinking) who are not treated with antipsychotic medication. Of particular importance, ETD occurs in a substantial proportion of the clinically well relatives of schizophrenics who have never been exposed to antipsychotic drugs. The latter two findings provide especially strong support for the conclusion that ETD occurs independently of a schizophrenic psychosis or its treatment. Thus, antipsychotic medications do not seem to affect ETD in a robust consistent manner.

Although current or past treatment with antipsychotic medication is not a necessary condition for the presence of ETD, several caveats warrant recognition. Drug-withdrawal periods in studies of chronic patients tend to be relatively short compared with the length of prior exposure. Most of the information about medication effects is based on first-generation antipsychotics, and much less data are available on patients treated with the second generation, or atypical, antipsychotics. In some studies, but not others, currently unmedicated schizophrenics with prior exposure to antipsychotics have worse eye tracking than never-medicated patients. It is unclear whether this difference reflects an effect of chronic prior drug exposure on the smooth pursuit system *per se* or heightened sensitivity to the effects of medication withdrawal on attentional functioning in patients with a protracted history of drug treatment. Of particular relevance in this regard, antipsychotic drug treatment improves certain aspects of performance, perhaps by improving attentional engagement in the task. This effect is most evident in reduced anticipatory saccades, but can also be manifested in decreased catch-up saccade amplitude, indicating more efficient correction of position error. Thus, the data are most robust in excluding acute rather than chronic effects of typical antipsychotic medications as a cause of ETD.

Genetic Studies – Familial Aggregation, Twin Studies, and Linkage Studies

ETD occurs in first-degree biological relatives of schizophrenics at a rate (~45%) that is much higher than that of the general population (~8%); this finding has been replicated numerous times. The increased prevalence of ETD in relatives of schizophrenics suggests that ETD may be genetically transmitted. Studies of psychiatrically healthy twins as well as of twins discordant for schizophrenia are consistent with genetic control of eye-tracking performance. In two samples of twins discordant for schizophrenia, eye-tracking concordance was 0.77 in monozygotic twins and 0.39 in dizygotic twins. These figures are approximately 80% of those expected for traits under genetic control. The primary features of ETD in relatives are the same as those seen in patients – decreased gain and increased catch-up saccades. In contrast, relatives of patients with nonschizophrenic disorders do not show elevated rates of ETD. Thus, although patients with some other psychiatric disorders may have ETD, ETD does not seem to be familial in nonschizophrenic disorders.

ETD in a schizophrenic patient usually coincides with ETD in at least one first-degree relative. However, there are exceptions. In some instances, normal eye tracking is found in both the patient and in family members. In other cases, patients have normal eye tracking but family member(s) have ETD. The Mendelian latent trait model was developed in order to account for three observations: (1) ETD and schizophrenia frequently occur together in patients, (2) the two traits are occasionally dissociated in patients and are usually dissociated in relatives, and (3) ETD occurs in relatives of schizophrenics at a significantly higher prevalence than does schizophrenia. The empirical distribution of schizophrenia and ETD (in schizophrenia families) is consistent with the proposition that schizophrenia and ETD are independent manifestations of a latent trait that is transmitted by a single autosomal dominant gene. The latent trait has a much higher probability of being expressed as ETD than as schizophrenia. Thus, even though the genetic data on schizophrenia are not consistent with single-gene transmission, a single autosomal dominant gene can account for the distribution of ETD, schizophrenia, or both in schizophrenia families.

ETD has a much higher recurrence risk than schizophrenia (~6.5%) among first-degree relatives of schizophrenics. This observation raises the possibility that ETD is a more penetrant expression of a schizophrenia susceptibility gene than the clinical disorder. In that case, a gene would have a higher probability of being detected through its expression as ETD than

through its expression as schizophrenia – a locus that is one of several for schizophrenia (i.e., oligogenic) can also be a major gene for ETD. The advantages of incorporating highly penetrant disease-related traits, or endophenotypes, into linkage studies has led to the successful identification of genes for genetically complex nonpsychiatric disorders (e.g., long QT cardiac syndrome and juvenile myoclonic epilepsy). The endophenotype strategy has also yielded promising results in linkage studies of schizophrenia. ETD has been linked to loci on chromosome 6p in two independent studies. Another endophenotype, P50 inhibition deficits, has been linked to the α-7 nicotinic receptor gene on chromosome 15q14.

Pathophysiology

The importance of the finding of ETD in schizophrenia is strengthened by the fact that abnormal smooth pursuit can result from a wide range of pathology affecting diverse regions of the central nervous system. This includes the middle temporal and medial superior temporal areas, the frontal eye fields, posterior parietal cortex, parts of the cerebellum, the pontine nuclei, basal ganglia, and brain stem regions, all of which play a role in generating smooth pursuit eye movements. Much of what is known about the cortical processing of moving targets comes from single-cell recording and lesion studies of nonhuman primates and humans with neurological damage in these brain regions. Different regions optimize specific parameters of pursuit (and saccades). Therefore, the pattern of oculomotor deficits and/or normal function provides localizing information about the involvement of specific brain regions. In lesions of striate and extrastriate areas, for example, the accuracy of visual motion information is compromised, resulting in effects on both the pursuit and saccadic systems. Pursuit initiation is slowed and saccades to moving targets are hypometric. Effects on steady-state gain are more modest, presumably because the frontal eye fields and posterior parietal cortex use perceptual feedback and extraretinal signals to compensate for faulty sensory input. Damage to the frontal eye fields, on the other hand, affects pursuit initiation and steady-state gain, but has little effect on the accuracy of saccades to moving targets, indicating that processing of early sensory motion information is intact.

In order to localize the brain regions involved in ETD in schizophrenia, three complementary strategies have been used. The first uses functional brain imaging (positron emission tomography and functional magnetic resonance imaging) to identify different patterns of regional brain activation in schizophrenics and controls while performing an eye-tracking task. The second capitalizes on the availability of experimental paradigms that provide localizing information about the role of specific brain regions in subserving the different components of pursuit and saccadic responses. The third employs psychophysical methods to parse ETD into simpler components.

Brain Imaging

The results of brain imaging studies of schizophrenic patients consistently implicate a disturbance in a frontotemporal network in individuals with ETD. Smooth pursuit deficits have been associated with hyperactivation of the posterior hippocampus and right fusiform gyrus as well as lower activation of the frontal eye fields, cingulate gyrus, and occipital cortex. Consistent with this finding, ETD is associated with reduced resting frontostriatal glucose metabolism and reduced blood flow in the frontal cortex. Moreover, the magnitude of activation in the right dorsal frontal eye fields is significantly correlated with pursuit gain in clinically unaffected relatives of schizophrenics. Schizophrenics also show reduced activation in the frontal eye fields and supplementary eye fields, medial superior temporal cortex, and anterior cingulate and increased, possibly compensatory, activation in medial occipitotemporal cortex. Neuronal activity in motion sensitive area V5 is also abnormal in schizophrenics during pursuit. The involvement of frontal regions in pursuit deficits is consistent with the finding that ETD is correlated with performance on tasks (e.g., spatial working memory) that are thought to depend on the functional integrity of more rostral frontal lobe regions. Thus, widely distributed brain abnormalities appear to contribute to the manifestation of ETD.

Oculomotor Paradigms

Most studies of ETD have used targets that moved sinusoidally or at constant velocities. Such targets can establish that an eye-tracking abnormality is present. However, because target movement is highly predictable, the relative contributions of early sensorimotor (e.g., visual motion information mediated in V5 and the human homologs of the middle temporal and medial superior temporal areas in the monkey) and later higher cortical areas (e.g., frontal eye fields and posterior parietal cortex) to pursuit dysfunction cannot be distinguished. Several recent studies of schizophrenic patients have employed oculomotor paradigms that are less dependent on predictive inputs and that can better separate the early sensory processing of motion signals from later higher-order cortical involvement. The results showed

that sensory input is not effectively used by the pursuit system, as seen in reduced open-loop gain and delayed initiation of pursuit. Closed-loop gain was also reduced but not as much as open-loop gain, suggesting that extraretinal information and perceptual feedback can partially compensate for the faulty use of motion input by the pursuit system. In contrast, saccade latency and accuracy to moving targets were normal, indicating that the saccadic system receives accurate sensory information. This dissociation has been interpreted to suggest that the processing of motion signals is intact at the early stage but that higher-order cortical areas (e.g., frontal eye fields and posterior parietal cortex) are impaired in making optimal use of retinal and extraretinal input for generating accurate pursuit eye movements. Related work suggests that schizophrenic patients and their relatives use retinal error signals excessively to compensate for a deficit in processing extraretinal signals.

Psychophysical Methods

The possibility that a deficit in motion processing contributes to ETD was suggested by three findings. First, lesions of the motion-sensitive areas of the brain (the middle temporal and medial superior temporal areas of the parietal lobe) result in smooth pursuit dysfunction, deficits in detection of coherent motion, reduced open-loop acceleration and impaired ability to use motion cues. Second, open-loop acceleration during pursuit initiation, a response based solely on visual motion signals, is significantly reduced in schizophrenics. Third, reduced steady-state pursuit gain in schizophrenics suggests that impaired velocity detection may be a factor in ETD. In light of these considerations, several studies have examined various aspects of motion processing. Schizophrenics (and their relatives) have increased velocity sensitivity thresholds, but perform normally on visual tasks that do not involve the detection of motion (e.g., contrast sensitivity and orientation). This diminished velocity discrimination is significantly correlated with difficulty generating smooth pursuit as reflected in decreased open-loop acceleration. Moreover, schizophrenics use nonmotion cues to compensate for diminished velocity discrimination and have elevated thresholds for detecting the direction of coherent motion, implicating a deficit in processing global motion. The results of these studies implicate a disturbance in early posterior cortical sensory processing in ETD, whereas the findings of studies that used oculomotor paradigms came to the opposite conclusion. One potential way to resolve this inconsistency would be to examine the same subjects on both kinds of tasks. It is possible, for example, that pursuit initiation deficits may be related to a visual motion processing deficit but that the impairment in steady-state pursuit may be caused by other deficits in the generation or use of extraretinal signals.

In summary, ETD appears to reflect dysfunction in multiple brain regions, although recent research suggests that disturbances in specific brain systems, and the cognitive processes they subserve, may contribute in separate ways to visual tracking deficits. Future research is needed to better localize the neural substrate of ETD in patients and unaffected relatives using functional imaging and to link those regional disturbances to the genotypes related to ETD. In so doing, we can further extend the use of ETD as a window into brain abnormalities in schizophrenia and the genetics of the disorder.

Eyeblink Conditioning

K M Christian, National Institute of Mental Health, Bethesda, MD, USA
R F Thompson, University of Southern California, Los Angeles, CA, USA

Published by Elsevier Ltd.

Classical Conditioning of the Eyeblink Response

Eyeblink conditioning is the most widely studied form of basic associative learning in mammals. In standard delay conditioning, a tone or a light conditioned stimulus (CS) precedes and coterminates with a reflex-eliciting unconditioned stimulus (US), such as periorbital shock or a puff of air to the cornea. Classical conditioning of the eyeblink response is a form of procedural learning and results in the formation of associative memory. Extensive investigation into the neural substrates of this associative memory has resulted in perhaps the most complete description of mammalian memory formation to date.

The Nature of the Eyeblink Unconditioned and Conditioned Responses

Isidore Gormezano showed some years ago in studies of the rabbit that in response to corneal air puff or periorbital shock, the reflex eyeblink response includes eyeball retraction, nictitating membrane (NM) extension, and external eyelid closure, all with essentially identical acquisition functions (NM extension is a largely passive response to eyeball retraction). Simultaneous recording of NM extension and external eyelid closure (electromyogram (EMG) recordings from orbicularis oculi) during acquisition and extinction showed that they were, in essence, perfectly correlated, both within trials and during training. Substantial learning-induced increases in neuronal unit activity that correlate very closely with the conditioned NM extension response have been reported in several motor nuclei: oculomotor, trochlear, motor trigeminal, abducens, accessory abducens, and facial. Coordinated activity in these nuclei and associated muscles contribute to the same global conditioned response (CR), of which the NM extension response is but one component. The suggestion that different motor nuclei might somehow exhibit different CRs in the eyeblink-conditioning paradigm is not supported by evidence.

The CR and the unconditioned response (UR) are similar in eyeblink conditioning in the sense that to a large extent the same muscles and motor nuclei are engaged. However, the CR and the UR differ fundamentally in a number of respects. The minimum onset latency of the CR to a tone CS in well-trained rabbits, measured as NM extension, is about 90–100 ms; the minimum onset latency of the NM extension UR to a 3 psi corneal air puff US in the rabbit is about 25–40 ms. Perhaps most important, the variables that determine the topographies of the UR and CR are quite different. The topography of the UR is under the control of the properties of the US: for example, stimulus intensity, rise time, and duration. In marked contrast, the topography of the CR is substantially independent of the properties of the US and is determined primarily by the interstimulus interval (the CS–US onset interval), with the CR peaking at about the onset of the US over a wide range of effective CS–US onset intervals. This key property of the CR cannot be derived from the properties of the US or the UR. The CR and the UR also differ in that certain components of the UR can be elicited separately by appropriate peripheral stimuli, but the CR always occurs as a global coordinated response. Another important difference is that the CR exhibits much greater plasticity in recovery from lesions of the motor nuclei that impair performance of the UR than does the UR itself. Lesions of the interpositus successful in abolishing the CR have at most only a transient depressive effect on UR amplitude. Numerous parameters of the UR, including amplitude, rise time, frequency, and latency, have been investigated, and there are no significant lasting effects of interpositus lesions in any of these properties.

In sum, the conditioned eyeblink response involves highly coordinated activity in a number of motor nuclei and muscles; it is one global defensive response that is conditioned to a neutral stimulus as a result of associative training. Electrical stimulation of the small critical region of the cerebellar interpositus nucleus (see below) elicits this full complement of coordinated behaviors; it is a 'higher motor program.' The very small lesion of interpositus nucleus which is effective in completely and permanently abolishing the conditioned NM extension response also completely and permanently abolishes all other components of the CR that have been studied – eyeball retraction, external eyelid closure, and orbicularis oculi EMG – without producing any impairment in performance of the reflex response.

Brain Systems Involved in Eyeblink Conditioning

Electrophysiological recordings of neural activity in eyeblink conditioning indicate that, in addition to the motor nuclei described above, a number of brain areas and systems become engaged, most prominently the hippocampus and the cerebellum. In all these

systems, neuronal activity in the CS period increases over the course of learning and precedes the onset of the behavioral CR within trials. Indeed, this increased pattern of action potential discharges in the hippocampus and cerebellum predicts the occurrence and the actual temporal form of the CR (but not the reflex response). In standard delay conditioning, when the CS and the US overlap, lesion studies show that the cerebellar system is critical but the hippocampal system is not. This article focuses on basic delay conditioning and the cerebellum. Within the cerebellar system, the following regions develop the predictive neuronal response: relevant motor nuclei, a region of the fifth nucleus, various reticular brain stem regions, the cerebellar cortex (ansiform and anterior lobes), the cerebellar interpositus nucleus, the pontine nuclei, and the red nucleus.

Cerebellar System: The Pathways

A large literature is in general agreement in identifying the essential circuitry for classical conditioning of eyeblink and other discrete responses (see Figure 1). This circuitry follows closely the well-established anatomy of the cerebellar system and is in general accord with classical theories of cerebellar learning. A brief summary of this work follows.

The UR Pathways

In terms of the reflex pathways, there are direct projections from neurons in regions of the trigeminal nucleus to the accessory abducens (and abducens) nuclei and to the facial nucleus, as well as indirect projections relaying via the brain stem reticular formation, at least to the facial nucleus.

The CR Pathway

Neurons in a localized region of the interpositus nucleus ipsilateral to the trained eye develop a neuronal model of the learned behavioral CR; lesions of this region selectively abolish the CR with no effect in the UR; electrical stimulation of this region evokes the eyeblink response before training (as noted above).

Figure 1 Simplified schematic (most interneurons omitted) of the putative essential circuitry for delay classical conditioning of eyeblink (and other discrete responses) learned with an aversive unconditioned stimulus (US). The reflex US–unconditioned response (UR) pathway involves direct and indirect projections from the trigeminal nucleus to the motor nuclei (for the eyeblink UR and conditioned response (CR) primarily accessory 6 and 7). The tone conditioned stimulus (CS) pathway projects from auditory nuclei to the pontine nuclei and to the cerebellum as mossy fibers. The US pathway includes projections from the trigeminal to the inferior olive and to the cerebellum as climbing fibers. The CR pathway projects from the interpositus to the red nucleus and on to premotor and motor nuclei. There is also a direct γ-aminobutyricacidergic inhibitory projection from the interpositus to the inferior olive. Omitted from this diagram are feedback projections from the cerebellum to several afferent structures. These projections have generally been described physiologically, not anatomically, and may well be involved in some aspect of CR modulation. See article for discussion. Solid cell bodies and bar terminals indicate inhibitory neurons, open cell bodies and fork terminals indicate excitatory neurons. Stars indicate sites of plasticity based on current evidence. NV, trigeminal nucleus. Adapted from Thompson RF (1986) The neurobiology of learning and memory. *Science* 233: 941–947.

This region of the interpositus projects via the superior cerebellar peduncle to a region of the contralateral magnocellular red nucleus. Lesions of the peduncle abolish the CR, as do lesions of the key region of the red nucleus, where neurons also show a model of the learned response. Stimulation of this rubral region also elicits the eyeblink response. The descending rubral pathways project contralaterally to premotor and motor nuclei, seventh for external eyelid closure, accessory sixth and sixth for NM extension. Overwhelming evidence identifies this circuit as the efferent CR pathway for the conditioned eyeblink response. A similar pathway projecting to the spinal cord subserves classical conditioning of the limb flexion response in cat.

The CS Pathway

The pontine nuclei send axons as mossy fibers directly to the cerebellar cortex and interpositus nucleus, mostly contralaterally. The pontine nuclei in turn receive projections from auditory, visual, somatosensory, and association systems, both cortical and subcortical. A wide range of evidence identifies the pontine nuclei–mossy fibers as the essential CS pathway.

The US Pathway

Neurons in the inferior olive (IO) send climbing fiber projections contralaterally directly to cerebellar cortex and interpositus nucleus. The critical region of the IO for eyeblink conditioning is the dorsal accessory olive (DAO), which receives somatosensory and nociceptive input from the spinal cord and appropriate cranial nuclei. Lesions of the critical region of the IO, the face representation in the DAO, completely prevent learning if made before training and result in extinction of the CR if made after training. Neurons in this critical DAO region do not respond to auditory stimuli (CS), respond only to US onset, and show no learning-related activity, and the US-evoked response decreases as animals learn. Electrical microstimulation of this region serves as a very effective US. All these data argue that the DAO–climbing fibers system is the essential US reinforcing pathway for the learning of discrete responses.

The interpositus nucleus sends direct γ-aminobutyricacidergic (GABAergic) projections to the DAO. Hence, as learning-induced increases in interpositus neuron activity develop, inhibition of the DAO neurons will increase. This accounts for the fact that US-evoked activity in the DAO decreases as learning develops, consistent with the classical conditioning model proposed by Robert Rescorla and Allan Wagner. This also appears to serve as a part of the neural circuit essential for the behavioral learning phenomenon of 'blocking,' in which prior training to one CS, such as tone, prevents subsequent learning to a light CS when it is then presented together with the tone in paired compound stimulus training. Infusion of picrotoxin in the DAO to block GABA inhibition from the interpositus during compound stimulus training completely prevents the development of behavioral blocking.

Conjoint Activation of CS and US Pathways

If the above hypotheses concerning the identities of the CS and US pathways are correct, it should be possible to train behavioral CRs by conjoint stimulation of these pathways, which is indeed the case. Stimulation of the pontine nuclei mossy fibers as the CS (below movement threshold) and DAO-climbing fibers as a US results in effective conditioning. Stimulus (US)-elicited movements including eyeblink, head turn, and limb flexion were learned to the mossy fiber stimulation CS just as was the case for peripheral CSs. In an even more reduced preparation, successful conditioning was achieved when parallel fibers were stimulated through a cortical surface electrode as the CS and stimulation of the white matter directly beneath the surface electrode served as the US.

The Cerebellar System: Interpositus Nucleus

Lesions

The initial discovery of the key role of the cerebellum in eyeblink conditioning involved both large aspiration lesions including cerebellar cortex and nuclei and electrolytic lesions of the dentate-interpositus nuclear region. The key nuclear region is the anterior lateral interpositus nucleus ipsilateral to the trained eye. If this region is lesioned before training, learning is completely prevented. These lesions have no effect at all on performance of the UR. Selective abolition of the CR with no effect on the UR following interpositus lesion or inactivation has now been reported in more than 20 studies on several species of mammals. It is important to note that lesion of the interpositus 1 month after training also completely abolishes the eyeblink CR – the interpositus nucleus appears to be the site of long-term storage for the memory.

Kainic acid lesions of the interpositus as small as about 1 mm^3 in the anterior lateral region of the nucleus abolish the CR, indicating extreme localization of the critical region and ruling out the possibility that fibers of passage are involved. Finally, lesions of the output of the cerebellar nuclei, the superior

cerebellar peduncle (scp), abolish the behavioral CR with no effect on the UR. It is important to emphasize that the cerebellar interpositus nucleus is essential for the learning of all discrete movements trained with an aversive US: eyeblink, limb flexion, head turn, and so forth. To the extent tested, the memory traces for all these learned movements are stored (at separate loci) in the interpositus nucleus. Eyeblink conditioning has simply been the most widely studied, although there is also considerable evidence for limb flexion conditioning.

Results of clinical studies of eyeblink conditioning in humans with brain damage are strikingly parallel to the infrahuman animal literature. Appropriate cerebellar lesions markedly impair or completely prevent learning of the standard delay eyeblink-conditioning task; if the cerebellar damage is unilateral, only the ipsilateral eye is affected. In general, effective lesions are large, including damage to cerebellar cortical regions and nuclei, although exact extent of damage is difficult to determine from the brain scans.

Recordings

In a number of studies to date in several species of mammals, recordings of multiple and single neuronal unit activity from the interpositus nucleus during eyeblink conditioning revealed populations of cells in the critical region of the nucleus that, as a result of training, discharged prior to the execution of the learned eyeblink response and fired in a pattern of increased frequency of response that predicted the temporal form of the behavioral CR (the 'neuronal model' of the CR). It is compelling that multiple and single unit activity recorded from the critical interpositus region is appropriately timed to effect the downstream motor pathway and culminate in the well-timed CR. A tight causal chain has been demonstrated from the interpositus to the conditioned eyeblink response (see Figure 2).

Figure 2 Neuronal model of learned eyeblink response recorded from the cerebellar interpositus nucleus. Each graph shows nictitating membrane (nm) movement (top trace) and a histogram of multiple unit activity (bottom trace). Animals that received explicitly unpaired presentations of the conditioning stimuli (cs) do not develop altered patterns of neuronal activity (left column). Trained animals develop a neuronal model of the learned behavior, as shown by an increase in unit activity prior to the US onset (right column). Total trace duration, 750 ms. us, unconditioned stimulus. From McCormick DA and Thompson RF (1984) Cerebellum: Essential involvement in the classically conditioned eyelid response. *Science* 223(4633): 296–299.

Cerebellar System: Reversible Inactivation

Although the evidence cited above is consistent with the interpositus nucleus as the locus of the conditioned eyeblink memory trace, it does not prove this hypothesis. Predictive neuronal models of the CR develop in the interpositus nucleus, the red nucleus, and the motor nuclei, as noted. Further, lesions of the interpositus, of the scp (containing all the output from the interpositus), and of the red nucleus all abolish the CR with no effect on the UR. Lesions of the motor nuclei of course abolish both the CR and the UR. The technique of reversible inactivation was used to determine where within the circuit the memory trace was formed and stored. Muscimol, a $GABA_A$ agonist, was used to inactivate neuron somas, as was cooling, and tetradotoxin was used to inactivate axons.

Inactivation of the scp, the red nucleus, and the motor nuclei during training all prevent expression of the CR (and the UR with motor nuclei inactivation). However, in postinactivation testing/training, the CR has been learned to asymptote; therefore none of these areas contains the memory trace. However, inactivation of the anterior interpositus nucleus, which also prevents expression of the CR, completely prevents learning. Hence the memory trace is established in the interpositus nucleus. If any portion of the trace were established efferent from the interpositus, learning would be incomplete following inactivation of the scp, but it is not. If any portion of the trace were established afferent to the interpositus, then interpositus inactivation would not completely prevent learning, but it does.

Cerebellar System: Cerebellar Cortex

The morphology of cortical neurons is remarkably distinct, and the cortex itself is structurally homogeneous. It is important to note, however, that the

cortex does not share the discrete somatotopy of the deep nuclei, in which damage to a single cubic millimeter of the anterior lateral interpositus will abolish a specific learned behavior, that is, the conditioned eyeblink. Although the spatial distribution of the mossy fiber and climbing fiber afferents, pathways carrying CS and US information, respectively, is not understood fully, data from anatomical and microstimulation studies suggest a strict topographical relationship between the cortex, deep nuclei, and IO. Although this relationship appears to be preserved among these structures, multiple cortical regions are associated with the conditioned eyeblink circuitry. To date, three regions have received the bulk of attention because of reported anatomical connections with the critical region of the interpositus: Larsell's hemispheric lobule VI (HVI), the anterior lobe, and the C1 and C3 zones – parasagittal regions encompassing portions of both HVI and anterior lobe.

Lesions

In the first study to address the role of the cortex in eyeblink conditioning explicitly, aspiration lesions of ansiform or ansiform and paramedian lobules in well-trained rabbits resulted in the expression of short-latency, small amplitude CRs. The most significant aspect of this early finding was the implication that the CR consists of separable elements related to frequency, magnitude, and timing. While there is currently much support for this hypothesis, there remains considerable disagreement as to the extent of cortical involvement and the anatomical loci that may contribute to the acquisition and maintenance of each of these elements.

Early studies suggested that selective lesions of HVI or HVI and the ansiform lobule completely block expression of the CR in well-trained animals. Subsequent attempts to replicate this result have proven unsuccessful, however. Instead, these latter studies have shown consistently that unilateral lesions of HVI and adjacent regions in well-trained animals result in a transient decrease in conditioned responding but that reacquisition to prelesion levels of CR frequency and amplitude can be achieved with additional training. It is important to note that animals showed significant savings during reacquisition, requiring fewer trials to reach criterion than during initial acquisition, which suggests that the cortical lesions did not eliminate the memory trace. Pretraining lesions of HVI and HVIIa lobules and significant portions of the anterior lobe were shown to significantly impair the rate of learning. However, animals were able to achieve significant levels of conditioned responding in the absence of HVI. Response latencies following targeted disruptions of the HVI region have either not been reported or were not statistically different from prelesion latencies.

Selective modification of CR timing, frequency, and magnitude have been observed following aspiration lesions in which frequency of conditioned responding correlated with lesion size whereas latency and amplitude of the CR were only affected by the most extensive lesions that included the anterior lobe. There are now several reports indicating that the anterior lobe may play a critical role in normal development of well-timed CRs. Although it has been claimed that this region is also necessary for the acquisition and extinction of CRs, acquisition in naïve animals with anterior lobe lesions has yet to be tested directly.

Inactivation

Temporary inactivation of the ventral HVI lobule via infusions of the $GABA_A$ receptor agonist muscimol has no effect on the rate of acquisition or the quality of the CRs. Extensive cortical inactivation encompassing both HVI and portions of the anterior lobe significantly impairs but does not prevent acquisition and has no effect on the CR performance once the animal reaches asymptotic levels of conditioned responding. Similarly, reversible inactivation of the HVI region achieved with a cortical cooling probe significantly decreased the learning rate but did not disrupt CR expression in well-trained animals. If there are multiple and noncontiguous regions within the cerebellar cortex that receive appropriate sensory information to influence the conditioned eyeblink response, then selective lesions and inactivation may not affect all critical cortical regions.

Complete Cortical Elimination

Circumventing these complications, several attempts have been made to investigate the effects of functionally inactivating the entire cerebellar cortex. Mutant mice (pcd mice), in which Purkinje cells degenerate approximately 2 weeks postnatally, show significant deficits in both the rate of acquisition and the asymptotic level of conditioning. Nevertheless, pcd mice express significant levels of learning and extinction in the absence of cortical input to the interpositus. Peak latencies of the CRs in the mutants were significantly decreased compared with wild-type mice. A later study confirmed that the interpositus was responsible for the residual learning by demonstrating that bilateral lesions of the interpositus in the pcd mice completely block acquisition. Recently, it was shown that widespread ablation of Purkinje cells via intraventricular infusions of the immunotoxin

OX7-saporin disrupts retention and expression of previously acquired CRs. Reacquisition of the CR following this treatment occurred at a slower rate than did original acquisition.

Functional and reversible lesions of the entire cerebellar cortex can also be achieved through a targeted disruption of the afferent inhibitory input of Purkinje cells at the level of the interpositus through sequential infusions of muscimol and picrotoxin. Muscimol first blocks the synaptic transmission from the cortex, and the baseline level of excitability in the interpositus neurons is restored through application of the GABA receptor antagonist picrotoxin. With this procedure, onset and peak latencies were decreased in well-trained animals, CR amplitudes were increased, and no effects (i.e., no CRs) were observed in naïve animals.

In contrast to the clear and compelling evidence confirming the essential role of the interpositus in the acquisition and expression of the conditioned eyeblink response, reports of cerebellar cortical involvement have proven more difficult to interpret. The absence of savings following inactivation of the interpositus during acquisition argues against the formation of an interpositus-independent memory trace established in the cerebellar cortex. This result does not, however, eliminate the possibility of interpositus-dependent memory trace formation in the cortex or interpositus-independent cortical modulation of the conditioned response in intact animals.

Recordings

Any direct cortical modulation of the CR must be mediated through the Purkinje cell, which serves as the sole efferent pathway innervating the interpositus. Purkinje neurons are inhibitory and have high spontaneous firing rates (~25–60 Hz), and thus it may be likely that the primary influence on the interpositus results from a well-timed disinhibition. If this hypothesis is correct, then an appropriately timed decrease in Purkinje cell activity should develop over the course of learning. Several studies have shown that Purkinje cells in HVI, the adjacent paramedian lobule, the C3 microzone, and the anterior lobe do exhibit learning-related decreases in firing. However, there is also evidence of learning-related increases in Purkinje cell firing during the CS period. The functional significance of the increase in simple spike activity has not been determined, but it has been suggested that an increased inhibition of a subset of interpositus neurons may suppress non-eyeblink-related movements. Multiple-unit activity recorded from the cerebellar cortex exhibits the same temporal model of the behavioral response observed in other brain structures (interpositus, red nucleus, hippocampus, etc.) and is likewise dependent on the interpositus. It is interesting that if the interpositus is lesioned in trained animals, the timing of learning-related activity in single Purkinje cells is also altered. These results suggest that the interpositus may play a critical role in the timing of the cortical plasticity and that the reciprocal connections between the two structures are involved in the development of the well-timed response.

Mechanisms of Memory Storage in the Interpositus

Several studies report that GABA antagonists prevent both learning and expression of the CR, but blocking the *N*-methyl-D-aspartate receptors in the interpositus prevents learning but not expression of the CR. Hence both GABAergic and glutamate transmitter systems are involved. Protein synthesis inhibitors infused in the interpositus prevent learning but not expression of the CR. Recently, subsets of genes have been identified that are differentially regulated during conditioning – an important step in understanding the molecular basis of the learning-induced changes in the interpositus. All these results argue for the formation of neuronal/synaptic plasticity, a memory trace in the interpositus nucleus.

Extremely important direct evidence for a strengthening of the mossy fiber–interpositus neuron synapses comes from the observation of a highly significant increase in the number of excitatory synapses in the interpositus nucleus (likely from mossy fibers) but no change in inhibitory synapses (from Purkinje neurons) following eyeblink conditioning. This increase appears to be a result of associative learning as this synaptic modification did not occur in unpaired stimulation control animals.

In sum, the evidence is now very strong from behavioral, physiological, pharmacological, anatomical, and reversible inactivation studies that the basic associative memory trace in eyeblink conditioning is established in the interpositus nucleus. The next step is to elucidate the causal chain from behavioral training to increased synaptic efficacy and synapse formation.

Mechanisms of Memory Storage in the Cerebellar Cortex

Although the nature of cortical involvement in classical conditioning is not yet fully understood, it is

clear from lesion, inactivation, and genetic ablation studies that the cerebellar cortex does contribute substantially to the development of the CR under normal conditions. Whereas the interpositus was empirically demonstrated to be essential for the acquisition of the conditioned eyeblink prior to an understanding of the underlying cellular mechanisms, empirical studies of the cortex have largely been designed and interpreted with respect to existing cerebellar learning theory. Specifically, it was predicted that parallel fibers encode contextual information associated with the CS and that the climbing fibers encode US information that serves to signal movement error. The discovery of long-term depression at the parallel fiber–Purkinje cell synapse induced by conjunctive activation of parallel and climbing fibers was interpreted as strong support for these key predictions of cerebellar motor skill learning based on cortical organization. Evidence suggesting a functional role for cortical LTD in eyeblink conditioning has emerged from behavioral assays of mutant mice with deficits in LTD expression. Activation of glutamate receptors on the Purkinje cell dendrites is necessary for the induction of LTD, and mutant mice in which these receptors or downstream signaling pathways are disrupted have shown deficient LTD and impaired eyeblink conditioning. The behavioral impairment seen in these mutants is similar to that observed in pcd mice, in which both the acquisition rate and the asymptotic levels of responding are compromised, with no significant effect on either the timing or the extinction of the CR. Additional evidence for a functional role of cortical LTD in the generation of learned behavior comes from the observation that the temporal and spatial parameters of afferent activity eliciting this plasticity mirror the parameters governing stimulus presentation in eyeblink conditioning. It has been shown that LTD induced by sparse stimulation is most significant if parallel fiber activation precedes climbing fiber activation by 50 to 200 ms, a temporal range close to the optimal interstimulus interval for eyeblink conditioning. Furthermore, synaptic changes in Purkinje cell morphology consistent with the induction of LTD have been observed in trained animals. A significant decrease in α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) binding, consistent with LTD-mediated endocytosis of the AMPA receptors, was reported in the ipsilateral cortex of trained animals compared with controls receiving unpaired presentations of the stimuli. Insofar as cerebellar cortex is concerned, most evidence supports LTD as a mechanism of synaptic plasticity underlying eyeblink conditioning. However, the evidence is indirect, in marked contrast to the more direct evidence of synapse formation in the interpositus nucleus.

Conclusion

It is now established beyond reasonable doubt that the cerebellum and its associated circuitry are the essential (necessary and sufficient) brain system for delay classical conditioning of eyeblink and other discrete responses learned with effective USs. Furthermore, it is clear that the interpositus nucleus is necessary for acquisition and expression of this associative memory. While much work remains to be done to elucidate the molecular and cellular events that contribute to this learned behavior, investigation of the classically conditioned eyeblink response has resulted in perhaps the most striking and complete example of a localized memory trace in the mammalian brain.

Facial Expression in Primate Communication

L A Parr, Yerkes National Primate Research Center, Atlanta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

Faces Are Salient Social Stimuli

Faces are one of the most important classes of stimuli involved in social communication. They provide viewers with a wealth of information, including individual identity, age, sex, and even emotion. Much of the important information from faces is registered quickly by perceivers, without any need for prolonged exposure or scrutiny. A quick glance at a photograph can tell you whether the face is of a man or woman, someone you know or a stranger, as well as the person's general age and race. Important information is also provided by short-term, dynamic changes in expression, head orientation, and gaze that are essential components of ongoing social interactions. For example, studies have shown distinct coding of gaze and emotion from facial expressions in the monkey amygdala using functional magnetic resonance imaging, highlighting the important and dissociable qualities of these two sources of information from the face. Finally, some of the information in faces changes over a much longer timescale and would not be apparent if a person was only encountered once. These life history characteristics include appearance changes due to normal aging and general information about health status.

Faces are also highly memorable. Although general information such as identity, age, and sex are processed without conscious effort, many additional details, such as general affective state, attractiveness, or physical details about a person, can be easily drawn from memory. The phrase 'one never forgets a familiar face' appropriately highlights the salience of faces. Even a brief encounter with an unfamiliar individual might, on the surface, seem quite unremarkable, but when asked later to provide more detail about the person (i.e., if the person seemed in good health and whether he or she was happy or not), these questions could be answered with ease. Therefore, faces carry a rich array of information that not only helps to structure an ongoing interaction but also can provide more details about the encounter at a later time. This article reviews some of the important information that is transmitted from the face. This is divided into two main themes – information transmitted from static faces, such as individual identity, and information transmitted from dynamic faces, such as expression. These sources of information are not mutually exclusive, and although there is a wealth of information about the specialized nature of these processes in humans, this article focuses primarily on the evolution of these skills by drawing on comparative data from nonhuman primates, hereafter referred to as primates.

Static Faces

Individual Identity

Human faces are recognized primarily using the configurational arrangement of facial features. The configuration refers to the spatial arrangement of features on the face (i.e., their gestalt). Two types of configural information are present in faces. First-order relational properties refer to the relative arrangement of facial features which is similar in every face; that is, the eyes are laterally displaced above the nose, which is above the mouth, etc. This type of configural information provides the means for recognizing faces from other categories of visual stimuli, and attraction to these basic configural patters appears to be present from birth. Second-order relational properties refer to the relative size and spatial arrangement of inner facial features with regard to one another; that is, the spacing between the eyes, nose, and mouth, which is more or less unique to every face and enables us to remember specific individuals from facial cues alone. Thus, whereas first-order relational properties enable the identification of faces at a basic categorical level, second-order relational properties provide the information necessary to form subordinate-level classifications of faces (i.e., the ability to distinguish among different individuals such as Mary vs. Jane).

One of the main tests for configural processing is the inversion effect, the finding that faces are difficult to recognize when turned upside down because the configural arrangement of facial features is orientation dependent. The face inversion effect has become one of the main tests for configural processing in both humans and nonhuman primates and provides a simple, but elegant, method for comparing face recognition processes across species. However, studies of the face inversion effect in nonhuman primates have revealed very inconsistent results. There are some reports confirming evidence of the inversion effect in monkeys and apes, including cotton-top tamarins, pigtail macaques, chimpanzees, Japanese

macaques, and rhesus monkeys, whereas many studies have failed to find differences for discriminations between upright and inverted faces in longtail macaques, rhesus monkeys, and cotton-top tamarins. One potential explanation for these differences is that a number of different methodological procedures for testing face recognition skills have been used, ranging from the use of viewing preferences to discriminations of a pair of stimuli based on whether they are the same or different. These different tasks may tap different cognitive and perceptual processes, revealing inconsistent results. Moreover, the stimuli used in these studies are primarily images of conspecifics' faces; however, the quality and presentation of these images differ considerably across studies, including line drawing/schematics of primate faces, a heterogeneous assortment of primate pictures, real photographs versus computer images, and restricted sets of human photos. Therefore, although the inconsistencies are numerous, the methodologies are also quite diverse.

Face Expertise

Much of the research on face recognition in primates has focused on whether some kinds of faces are recognized better than others. For example, studies have demonstrated that monkeys prefer to view pictures of their own species compared to pictures of other species. These findings have been used to support the idea that monkeys are specialized for viewing their own species' faces and preferentially attend to these images because they provide the most salient social information. Among humans, this phenomenon is functionally similar to what is known as the 'other-race' effect and suggests that people develop an expertise for processing faces of their own race, compared to other races, which leads to encoding biases for same-race faces. This preference for own-race faces develops quite early, having been observed in infants as young as 3 month of age. Moreover, it has been suggested that the other-race encoding bias stems from a greater reliance on configural cues when processing same-race faces, as evidenced by greater inversion effects found for same-race versus other-race faces. Moreover, these biases are dependent on the level of expertise with the race of the faces presented. One test of face expertise is the parts-to-wholes test, a measure of configural processing that predicts better recognition of facial features when they are embedded within a face (holistic processing) compared to when they are isolated. Using this test, Caucasian subjects show greater holistic processing for own-race faces compared to Asian faces, but no differences in the parts-to-wholes test were found for Asian subjects who had been living in the United States for some time, suggesting an equal reliance on holistic information for Asian and Caucasian faces.

The issue of expertise and configural processing in face recognition is extremely important for several reasons. First, face expertise enables humans to remember and differentiate between many different individuals over a lifetime. Therefore, individual recognition skills are integrally associated with expertise in face processing. Second, developmentally, face expertise takes many years to acquire – some suggest as long as 10 years – and this expertise has been linked directly to the ability to detect subtle differences in the spacing of facial features, or sensitivity to second-order relational features. Moreover, sensitivity to second-order relational features and individuation of faces activates a region of the fusiform gyrus referred to as the fusiform face area (FFA). The FFA is believed to be a brain region specialized for processing faces, or at the very least it is a brain region that is sensitive to the type of learned subordinate-level classifications that are inherently necessary for human face processing. Interestingly, discriminations involving the second-order relational properties of faces, the spacing between internal features compared to discriminations of face identity, selectively activate a region just adjacent to the FFA. Again, this suggests a causal relationship between face expertise and the ability to detect second-order configural cues.

Studies of Face Expertise in Primates

Several studies have demonstrated greater reliance on configural cues in chimpanzees when discriminating faces of species for which they have considerable expertise (human and conspecific faces) but not the faces of unfamiliar species (capuchin monkeys) or nonface objects such as clip art. Chimpanzees, for example, show the inversion effect for the expert face categories but not the nonexpert or nonface categories. Although this was not specifically a test of the other-race effect, it was the first demonstration of face expertise for processing an 'other-race' category in a nonhuman primate and, moreover, the expertise was dependent on configural processing. Findings on the inversion effect in rhesus monkeys have revealed a quite different picture. Monkeys tested using the same procedures have shown significant inversion effects for discriminations of conspecifics' faces but also unfamiliar face categories, including capuchin monkey faces, and nonface categories, including automobiles; however, no inversion effects were observed for the familiar category of human faces or clip art objects. These findings have been replicated in

subsequent groups of rhesus monkeys in which again there was a failure to find any effect of expertise during tasks requiring monkeys to discriminate upright and inverted faces (i.e., conspecifics' faces, chimpanzee faces, and human faces) compared to houses and clip art objects. Monkeys in this study showed a general inversion effect for all face categories, regardless of their familiarity. This finding is similar to those of other studies that have failed to find evidence for species expertise in Japanese monkeys viewing upright and inverted pictures of rhesus monkeys and conspecifics' faces, despite finding an overall effect of orientation. Therefore, prominent species differences exist between the face processing skills of chimpanzees and rhesus monkeys using an identical methodology and stimulus set, leading to a general conclusion that rhesus monkeys lack the kind of face expertise that is characterized by chimpanzee and human face processing.

Studies on chimpanzees and rhesus monkeys have expanded the question of configural face processing and expertise to examine the role of first- and second-order relational features. Three types of configural manipulations were performed (Figure 1). The inner part of the face was extracted, preserving both first- and second-order relational features. The features were split apart, or fractured, disrupting only second-order relational features. Finally, the faces were fractured and some features were rearranged, disrupting both first- and second-order relational features. The chimpanzees were only significantly impaired when discriminating the fractured and rearranged faces – those that contained manipulations of both first- and second-order relational features. Using the same configural manipulations seen in Figure 1 but applied to conspecific faces, rhesus monkeys were impaired for all of the discriminations, with no preferential sensitivity to second-order relational cues. Therefore, comparative studies of monkeys and apes suggest differences in the use of configural cues when processing the faces of familiar and unfamiliar species, suggesting a lack of face expertise in the monkeys, whereas chimpanzees showed behavioral evidence of face expertise on a level that is comparable to adult humans.

Faces as Dynamic Signals

Ritualization and Signal Form

Almost any behavior is capable of conveying information and thus functioning as a signal. Even if referential communication is not the primary function, an observant animal may derive information from behaviors performed by other individuals; providing this information is relatively easy to identify (perceptual consistency) and corresponds to some predicted outcome (functional consistency). Behavior patterns that convey information in this 'incidental' fashion are referred to as unritualized signals and are contrasted with behaviors that have been specialized, or ritualized, through evolution to convey particular information in specific ways. Ritualization refers to the process by which a formerly adaptive, unspecialized behavior becomes divorced from this original, adaptive function to take on a different meaning. An action of tongue protrusion to repel noxious food from the mouth, for example, may have led to the display of disgust. As a result of this ritualization, communicative signals become highly stereotypical and conspicuous so that they will be easily recognized by receivers and their messages/meanings will have little ambiguity. Another example is the silent pout, a facial expression made by chimpanzees, particularly infants and juveniles. When infant chimpanzees suckle, they pucker their lips around their mother's nipple, forming a pout face. When used outside the context of suckling, the pout is seem most often when an individual is denied access to something, is socially ignored or rejected, during

Figure 1 Manipulations of first- and second-order relational features. (Left to right) An unaltered face, inner features, split/fractured features, and fractured/rearranged features. Images were paired in a matching to sample format so that the manipulated image was the sample, the unaltered image was the correct choice, and an unaltered image of a second individual was the nonmatch. Adapted from Parr LA, Heintz M, and Akamagwuna U (2006) Three studies of configural face processing by chimpanzees. *Brain and Cognition* 62: 30–42.

begging, or when startled. Thus, its unritualized function was for feeding, but its ritualized function is to express want or dejection.

The chimpanzee has a set of prototypical, highly ritualized facial expressions, including the bared-teeth display, scream face, pout, stretch-pout whimper, pant-hoot, play face, and bulging lip face (Figure 2). However, with the exception of excellent studies on the structure and function of primate vocalizations, very little is known about how primates discriminate among these important nonverbal signals, and even less is understood about how these signals function within different social contexts, their associated emotional meaning, and, potentially, their altered meaning when used in combination with other signals. A few studies have been undertaken by the author requiring chimpanzees to discriminate pairs of photographs showing different individuals making the same facial expression, from either a neutral face or photographs of other facial expressions. In these studies, chimpanzees perform very well, categorizing the most prototypical example of their facial expressions. Therefore, specific features unique to particular expression categories, such as the upper and lower teeth showing in the bared-teeth display, or unique combinations/configurations of features were likely used by subjects when performing these categorization tasks. There is considerable debate in the human literature as to how facial expressions are processed. Some studies support the role of configural cues in expression categorization, where similar types of tasks have been used as those described for face identity, including the inversion effect. However, other studies have clearly shown that altering a single feature, such as the wrinkling around the eye corners, can change the interpretation of a facial expression such as smiling. Smiling faces that did not contain the crow's feet eye wrinkles were judged less happy than faces that did contain the wrinkles. Thus, although configural cues are important for facial expression categorization in humans, altering individual component features can have a significant impact on the emotional judgment of the entire configuration.

The Social Meaning of Graded and Blended Signals

The facial expressions of nonhuman primates, particularly the great apes, are best described as graded signals because rarely are they observed in their peak-intensity prototypical form, as shown in Figure 2. Similar issues are known for human facial expressions, and it should be noted that most of the work on the meaning of human facial expressions has been done in a

Figure 2 Prototypical chimpanzee facial expressions, verified according to component movements using ChimpFACS. The unique action unit configurations are listed beneath the expression names. These categories are abbreviated from a more complete ethogram. Reproduced from Vick SJ, Waller BM, Parr LA, Pasqualini-Smith M, and Bard KA (2007) A cross species comparison of facial morphology and movement in humans and chimpanzees using FACS. *Journal of Nonverbal Behavior* 31: 1–20.

laboratory setting using either highly standardized, posed expressions or facial expressions represented only as peak-intensity displays. Their graded nature makes it extremely difficult to characterize facial expressions during ongoing social interaction in both chimpanzees and humans and challenges our ability to understand their form, preferred context of use, and social meaning or function. Moreover, there are two dimensions on which signals may be graded: They may vary quantitatively in terms of intensity level and/or qualitatively by forming intermediates with other signals. In an effort to understand the relationship between chimpanzee facial expressions and social behavior, observational studies have recorded in what social contexts specific expressions are made. Prototypical facial expressions were associated most often with a single social context; for example, the relaxed open-mouth face (or play face) was observed to occur almost exclusively within the social context of play. However, there was also considerable overlap in the contexts that gave rise to many of the other facial expressions present in the chimpanzee repertoire. Some facial expressions, for example, appear to share features in common with two or more prototypical categories; thus, they seem to be blended between two parent groups. Figure 3 illustrates one example, the stretch-pout whimper, which is an expression blend because it shares prominent features in common with both the bared-teeth display and the pout, and it was as likely to be expressed in the contexts associated with both of the parent expressions. Thus, it was both a morphological/structural blend and a functional blend. In most cases, however, the expression blends were only blended in visual appearance, not in terms of their context of use, because they were used in a manner similar to only one of the parent expressions that they were blended between.

Some variation in facial expression can also occur as a result of the accompanying vocalization. Although not all facial expressions have an accompanying vocalization, it is obvious that all vocalizations will have some changes in facial appearance. Whether these changes provide information in the visual domain, as opposed to being exclusively auditory signals, is not clear. A multimodal information-processing experiment was conducted in which videos of various facial expressions were presented with either their congruent vocalization (i.e., scream faces with scream vocalizations) or an incongruent vocalization (i.e., a scream face paired with a vocalization of another facial expression category, such as a pant-hoot). The chimpanzees were presented with the choice of matching the incongruent videos by selecting a facial expression photograph that depicted either the auditory cue (i.e., the pant-hoot) or the visual cue (i.e., the scream face). Results showed clear preferences for auditory modality for some expressions (pant-hoots and play faces (laughter)) but the visual modality for others (i.e., the scream). Other authors have shown that rhesus monkeys will orient to the visual display of one of two vocalizations, either a coo or a threat call, when they hear that corresponding vocalization, suggesting an important convergence between the auditory and visual components of multimodal facial signals.

Thus, the communication system among some primates, such as humans, appears to be highly varied in terms of signal appearance (graded and blended facial expressions), the ability to integrate multimodal cues, and in the varied use of facial expressions across a range of social contexts. This presents unique cognitive challenges for primates, particularly chimpanzees, that must know/learn how to use these varied signals as well as interpret their meaning in multiple contexts. The rules for this are unclear, but they may be simple in that specific facial expressions garner different meaning depending on their context of use, as has been suggested in some monkey species, although it was not studied how subtle differences in the form and/or temporal patterning of these signals may also have contributed to their differential interpretation. This type of redundancy may minimize the need to develop a completely new signal to express the same message in different contexts, but it raises the awareness that social context plays

Figure 3 Graded and blended facial expressions in chimpanzees. The leftmost photograph shows a silent pout and the rightmost photograph shows a silent bared-teeth display. The middle photograph is a blended expression, the stretch-pout whimper, and the remaining photographs are graded variations between these phototypes. Reproduced from Parr LA, Cohen M, and de Waal FBM (2005) The influence of social context on the use of blended and graded facial displays in chimpanzees (*Pan troglodytes*). *International Journal of Primatology* 26: 73–103.

as important a role in signal meaning as signal type. This is also quite similar to how human facial expressions are interpreted, since both context and the identity of the performer help to interpret the meaning of expression.

Alternatively, the rules may be quite complex because the range of potential meanings that are possible when different forms of a signal are used in different social contexts, and perhaps even by different age/sex class individuals, grows exponentially large. In this latter case, the meaning conveyed by a specific signal may be a simple heuristic, as opposed to having a specific/referential meaning. Consider the bared-teeth face. This expression in the chimpanzee has been shown to be structurally homologous to the smile in humans: These expressions look very similar and probably share a similar evolutionary history. The bared-teeth expression is also used by chimpanzees in a wide range of social contexts and by all individuals in a social group. In contrast, this signal is highly ritualized in macaques in both form and context, being expressed unidirectionally from subordinate to dominant. Among rhesus monkeys, this has led to its label as a formal signal of dominance because it can be used to reliably predict dominance within a social group. It has also received a functional label drawing on its proposed emotional meaning, referred to by some as the 'fear grin' or 'grimace.' However, the relationship between this signal and the emotion 'fear' is unclear, and often this interpretation does not accurately describe the situation because the bared teeth may be used in unthreatening or nonconflict situations in which there is little risk to the sender. Among chimpanzees, the bared-teeth display appears to mean something much more general, and it is used across a wide variety of social contexts, including during play, with no predicted directionality between sender and receiver. It has been proposed that the bared-teeth display functions to indicate a general state of benign intent (i.e., "I mean you no harm"), which enables individuals to reduce proximity and potentially socially interact in a wide variety of situations. Its use in these situations can result in more grooming between individuals and improved quality of their social relationship. Further studies are needed before researchers will more fully understand how these facial expressions function during chimpanzee social interactions. The final section describes a new comparative research tool, ChimpFACS, which was developed from the human Facial Action Coding System (FACS) to aid in identifying homologous facial movements between chimpanzees and humans and to aid in the classification of graded signals.

Deconstructing Facial Expressions into Component Movements

ChimpFACS is an anatomically based coding system for measuring and describing facial movement according to the action of the underlying facial muscles. It was developed, in part, to provide a standardized (i.e., certification is required) observational coding scheme for describing facial expressions in chimpanzees that would be comparable across users and also to make possible direct comparisons between the facial expressions of chimpanzees and humans by identifying the homologous muscular bases of facial movement. Similar to the human FACS, each component facial movement is based on the action of an individual muscle or, in some cases, a combination of muscles. Therefore, prior to the development of ChimpFACS, detailed dissections of chimpanzee facial muscles were undertaken from cadavers and all of the 23 mimetic facial muscles described in humans were confirmed in the chimpanzee. These component movements were then given numerical codes called action units (AUs), similar to the human FACS. ChimpFACS identifies the muscular basis, appearance changes, and minimum coding criteria necessary for describing a total of 43 AUs (Table 1).

With this tool in hand, several initial studies were undertaken to determine whether this bottom-up approach could validate the previous classification of chimpanzee facial expressions (i.e., those shown in Figure 2, among others) or to provide any new information about the categorization of these highly graded signals through the identification of common underlying movements. Using a discriminant functions analysis (DFA), we validated most of the existing categories of chimpanzee facial expressions by reporting high agreement between the AU configurations coded by ChimpFACS experts and the *a priori* classifications given to facial expressions by me based on experience. Therefore, ChimpFACS was accurately and objectively able to classify prototypical categories of facial expressions according to their component movements. The DFA also enabled researchers to identify the most prototypical combination, or configuration, of facial movements for each expression. The expressions shown in Figure 2 illustrate these prototypes with their unique AU configurations. These configurations will be very useful in future studies on expression categorization because they can confirm the categories used and provide a measure to standardize the best examples. Moreover, this approach will enable more detailed studies to examine whether configuration

or component features are most important for chimpanzee expression categorization and compare the result to recent findings in humans.

Conclusion

The primate face provides a rich source of information pertaining to individual characteristics and social communication. Static information in faces, such as facial configuration, provides the details necessary for individual recognition, but the face can also convey information regarding an individual's age, sex, health status, attractiveness, and race. Humans and chimpanzees have developed an expertise for processing faces of familiar species, particularly own-race faces, which enables the individuation of faces using unique configural features. The current data do not support such an expertise in rhesus monkeys. The face also provides a rich source of socioemotional information via dynamic movement, or facial expression. Although researchers are in the early stages of understanding the comparative nature of expressive communication across primates, comparative tools such as the ChimpFACS will be invaluable in understanding the homologous basis of expressive communication.

Fatigue

R M Enoka, University of Colorado, Boulder, CO, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In common usage, the term fatigue is used to denote a variety of conditions that range from an exercise-induced impairment of motor performance through to the sensations of tiredness and weakness that accompany some neurological disorders. Although convenient for casual conversation, such broad usage precludes the systematic study of the underlying mechanisms. Accordingly, many investigators who study the physiology of fatigue prefer a more restricted definition that considers fatigue to be an exercise-induced reduction in the ability of muscle to produce force or power. With this definition, the amount of fatigue caused by a bout of exercise can be quantified as either the reduction in the peak force achieved during a maximal voluntary contraction or the peak power produced during a single contraction or a series of contractions.

Sites of Impairment

Since the seminal work of Mosso, the typical strategy used by experimentalists in the study of fatigue has been to determine whether the mechanism responsible for fatigue was located in the exercising muscle or in the nervous system. The strategy has been to distinguish between an impairment of contractile protein function and a decrease in the magnitude of the activation signal. This work has demonstrated that the function of the contractile proteins and the capacity of the myofibrils to produce force can be impaired by a decline in the efficacy of excitation–contraction coupling, metabolic changes that influence the supply of adenosine triphosphate and impede the function of the cross-bridges, and an inadequate perfusion of the active muscles. In contrast, activation of the contractile proteins can be reduced by a decline in neuromuscular propagation and the inward spread of action potentials down the transverse tubules, a reduction in the motor output from the spinal cord, a decline in the afferent support of motor neuron discharge, an increase in afferent feedback that reduces motor neuron excitability, a decrease in the activation of the motor unit population by descending inputs, and an insufficient drive to the neurons in the motor cortex (Figure 1).

The experimental models that have been used to identify the sites of impairment range from *in vitro* measurements on isolated muscle fibers through the evaluation of a motor performance by a human participant. Each model has its strengths and weaknesses. To identify the metabolic factors that impair cross-bridge function, for example, it is necessary to use a reduced preparation that permits the assessment of contractile protein function. To examine the changes that occur in the descending drive to the motor neurons during a voluntary contraction, however, it is necessary to measure evoked responses in humans as they perform a prescribed task.

A common technique used to distinguish impairments of contractile function and the activation signal in humans is to superimpose electrical stimulation on maximal voluntary contractions performed during a fatigue protocol. This method is known as the twitch interpolation technique and typically involves superimposing from two to ten stimuli at a high frequency to determine whether additional force can be evoked from a test muscle when an individual attempts to activate it maximally. Any increment in force is normalized to the force that can be elicited by the same stimulus when the muscle is at rest, and the ratio is expressed as an index of voluntary activation. A number of studies have found that voluntary activation is often less than 100% and that the deficit can increase during a fatiguing contraction.

One approach to identify the locus of the deficit in voluntary activation is to evoke muscle contractions with stimuli delivered at various locations along the pathway from the motor cortex to the muscle. For example, studies on the fatigue experienced by the elbow flexor muscles can involve a comparison of responses evoked by transcranial stimulation of the motor cortex, stimulation of the corticospinal tract at the level of the cervicomedullary junction (transmastoid processes), stimulation of the brachial plexus at the supraclavicular fossa, and stimulation of the intramuscular branches of the motor nerve (Figure 2). Stimulation of the motor cortex, corticospinal tract, and brachial plexus evoke both electromyographic and force responses that can be measured, whereas stimulation applied over the muscle elicits only a force response. Because transcranial magnetic stimulation generates action potentials in the axons of cortical neurons that impinge on the output neurons of the motor cortex, a difference in the responses evoked by cortical and corticospinal stimulation provides information on changes in the motor cortical neurons. Similarly, a difference in the responses between the corticospinal and brachial plexus stimulation informs the investigator about changes in the excitability of the motor neurons. These comparisons have indicated that

Figure 1 The decline in force or power that occurs during a fatiguing contraction can be caused by an impairment of one or many of the physiological processes associated with transforming the motor command into a contractile force. From Enoka RM (2008) *Neuromechanics of Human Movement.* Champaign, IL: Human Kinetics.

Figure 2 Changes that occur in the pathway from the motor cortex to the muscle fibers of the elbow flexor muscles can be examined by comparing responses evoked by stimulation of the motor cortex (transcranial stimulation), the corticospinal tract (transmastoid stimulation), the peripheral nerve (brachial plexus), and the intramuscular branches of the motor axons.

group III and IV afferents sensitive to ischemia do not mediate depression of the responses to motor cortical or corticospinal stimulation after fatiguing exercise and that the depression of voluntary activation when exercise is performed in hyperthermic conditions is not related to a decrease in the response evoked by motor cortical stimulation.

Another approach to examining the changes that occur in the pathways that provide activation of the muscle fibers is to measure the adjustments in reflex responses, such as changes in the electromyogram evoked by a stimulus that activates afferent fibers: for example, the measurement of changes in short- and long-latency reflexes evoked by applying either a brief electrical stimulation to the group Ia fibers that arise from muscle spindles or a quick stretch of the muscle to activate the muscle spindle afferents. The short-latency component largely comprises monosynaptic input to the spinal motor neurons, whereas the long-latency component involves transmission of the elicited activity traveling to supraspinal centers before being received by the motor

neurons. Comparison of short- and long-latency components can distinguish the involvement of spinal and supraspinal pathways in the fatiguing contraction, particularly in the upper limbs. Such studies have indicated that adjustments during fatiguing contractions typically involve a change in the balance of excitation and inhibition delivered from spinal and supraspinal sources to the motor neuron pool.

A few studies that have examined changes in the responses evoked by transcranial magnetic stimulation have concluded that some of the deficit in voluntary activation can be attributed to reduction in the net excitation of the neurons that contribute to the descending pathways. Although the origin of this limitation is uncertain, some exercise conditions have adverse effects on cerebral function. For example, the hypoglycemia that is caused by a failure of hepatic glucose production to satisfy the increased demands for glucose during exercise can impair the ability of the brain to provide an adequate descending drive to the spinal motor neurons during a fatiguing contraction. Nybo found that when participants sustained a maximal contraction for 2 min, the decline in force exerted by the knee extensor muscles was greater when the task was preceded by 3 h of exercise without glucose supplementation (placebo) than when the same task was performed with glucose supplementation. Furthermore, the greater rate of force decline for the placebo condition was accompanied by a greater impairment of voluntary activation (Figure 3). These findings, along with others, suggest that the fatigue associated with hypoglycemia is largely related to the decrease in energy turnover in the brain. This effect, which is similar to one produced by hyperthermia, depends on the intensity and mode of exercise.

Although a few pioneers in this field did appreciate that fatigue could result from the failure to sustain an adequate activation, the classical approach to the study of muscle fatigue has been to associate the decline in force capacity with the intramuscular accumulation of various substances (e.g., lactate, phosphate, and ammonia), a disturbance of the Na^+–K^+ balance, changes in intracellular pH, an accumulation of free radical species, alterations in intracellular Ca^{2+} handling or sensitivity, or impaired energy metabolism due to the depletion of substrates such as glucose and the intermediates for the tricarboxylic acid cycle. For example, the accumulation of inorganic phosphate due to the breakdown of creatine phosphate has been shown to evoke at least two major effects that could contribute to fatigue: (1) reduction of the maximal cross-bridge force, either by impeding the transition of the cross-bridge from the low-force state to the high-force state or by decreasing the sensitivity of the myofibrils to calcium; and (2) interference with the handling of calcium by the sarcoplasmic reticulum, such as by increasing the probability of calcium channels' opening, inhibiting the uptake of calcium, and augmenting the precipitation of inorganic phosphate and calcium within the sarcoplasmic reticulum. Similarly, disturbances in the Na^+ and K^+ gradients across the muscle fiber membrane due to an inability of Na^+–K^+pumps to restore ionic gradients during intense exercise can depress the excitability of the membrane and contribute to a decline in muscle fiber force. These studies, which are performed on skinned muscle fibers, have also shown that acidosis has a negligible direct effect on muscle function at physiological temperatures.

Figure 3 The force exerted by the knee extensor muscles (top) and the associated levels of voluntary activation (bottom) during maximal contractions that were sustained for 120 s. Three conditions were examined: baseline (filled triangles), placebo trial (filled circles), and glucose trial (open circles). The baseline condition represents the decreases in force and voluntary activation when the task was performed after a 15 min warm-up. The placebo and glucose trials were performed after 3 h of cycling, either with (glucose trial) or without (placebo trial) glucose supplementation. The force data (top) are reported as a percentage of the peak values recorded during a maximal voluntary contraction. $^*p < 0.05$ compared with the baseline and glucose trial. Mean ± SE. Data from Nybo L (2003) CNS fatigue and prolonged exercise: Effect of glucose supplementation. *Medicine & Science in Sports & Exercise* 35: 589–594.

In intact muscles, the release of calcium from the sarcoplasmic reticulum in response to the propagation of action potentials down the transverse tubules can be impaired during fatiguing contractions. The effect of the impairment is a reduction in the quantity of calcium released in response to a single action potential. As a consequence, the intracellular calcium concentration required to achieve maximal activation of the contractile proteins can be achieved only with high rates of activation. Because this deficit in excitation–contraction coupling is apparent only at low frequencies of activation, it is referred to as low-frequency fatigue. Low-frequency fatigue is more common after voluntary contractions sustained at low forces for long duration or contraction evoked by low frequencies of stimulation. Recovery from low-frequency fatigue can take up to 24 h. Because the force depression is exhibited by stimulation rates that encompass the typical discharge rates of motor units, it is presumed that low-frequency fatigue represents a functionally significant phenomenon.

Despite the observations derived from experiments on single muscle fibers that the decline in force capacity can be caused by an accumulation of some metabolites, other studies have found that such effects can occur even in the absence of an increase in the intracellular concentrations of these metabolites. For example, some of the properties of single fibers that were chemically skinned after performing a fatigue protocol differed from those of resting fibers. Because the process of chemical skinning replaces the sarcoplasm of the fiber with control levels of the intracellular milieu, the difference in myofibrillar sensitivity to calcium and rate of calcium uptake were attributed to changes intrinsic to the myofibrils and sarcoplasmic reticulum.

Taken together, the single-fiber experiments provide evidence that changes within the muscle fiber can contribute to the decline in force associated with fatigue. However, the relative significance of these mechanisms *in vivo* remains uncertain. Nonetheless, it does seem likely the force produced by single muscle fibers does decrease during a fatiguing contraction. The increase in motor unit recruitment during a sustained submaximal contraction, for example, presumably represents an attempt to maintain the desired force in the presence of a declining contribution from the previously active muscle fibers. Despite the many candidate mechanisms that could cause the decline in muscle fiber force, there is no consensus on the primary mechanism.

Task Dependency

One principal conclusion from a century of work on the sites of impairment is that fatigue can be caused by a decrease in the efficacy of multiple physiological processes. It is important to note that the dominant mechanism depends on the characteristics of the task being performed. The task details that influence the contributing mechanisms include the type and intensity of exercise, the muscle groups involved in the activity, and the physical environment in which the task is performed. These findings have led to a principle known as the task dependency of muscle fatigue: There is no single cause of muscle fatigue, and the dominant mechanism depends on the details of the task being performed. Furthermore, some of these observations on task-dependent effects also indicate that the decline in force during a fatiguing contraction often involves multiple mechanisms.

Variation in the dominant mechanism across tasks has confused the literature on muscle fatigue. For example, compare the results of two studies that attempted to determine if old adults are more fatigable than young adults. Baudry and colleagues had young and old adults perform a series of maximal shortening and lengthening contractions with the dorsiflexor muscles. The decline in peak torque during both types of contractions was greater for the old adults, which indicated that they were more fatigable than the young adults. In contrast, Hunter and colleagues found that old men could sustain an isometric contraction with the elbow flexor muscles at a force that was 20% of maximum for a longer duration than young men could. At the conclusion of the submaximal contraction, the two groups of men exhibited a similar amount of fatigue, as indicated by equivalent declines in the maximal force that they could exert. Hence, the old men were less fatigable when they performed this task. This comparison indicates that the influence of age on muscle fatigue depends on the task that is being performed.

Task Failure

Given the task dependency of muscle fatigue, an alternative to searching for an omnipresent fatigue mechanism is to identify the mechanisms that limit the ability of individuals to perform specific tasks. Rather than simply quantifying the amount of fatigue as indicated by the decline in peak force or power, however, recent work has focused on the mechanisms that limit the duration the task can be sustained. Such an approach emphasizes the functional significance of the changes that occur during fatiguing contractions. The relative role of the adjustments that occur during fatiguing contractions can be assessed by identifying those changes that are associated with differences in the time to failure of two performances. Comparisons can include, for example, one group of participants

performing two similar tasks, two groups of participants sustaining the same task, and one group of participants performing the same task before and after an intervention.

One approach has been to compare how varying the type of load influences the duration that a submaximal contraction can be sustained. For example, one could compare two tasks that both involved sustained isometric contractions and required the same submaximal net muscle torque and joint angle yet differed in the type of feedback provided to the participant and the type of load supported by the muscles. In one such task, referred to as the force task, the limb was attached to a restraint, and the participant was required to maintain a constant force for as long as possible while viewing force feedback on a monitor. In the other task, referred to as the position task, the participant supported an inertial load that was equivalent to the force exerted during the force task and was required to maintain a constant joint angle for as long as possible while viewing position feedback on a monitor. The time to failure of the position task was briefer when the two tasks were performed by a hand muscle in the position shown in Figure 4(a). The difference in the time to failure was caused by a more rapid recruitment of the motor unit pool during the position task. Because the net muscle torque exerted by each participant was similar for the two tasks, the load on the muscle fibers did not differ, at least initially. As the fatiguing contractions progressed, however, the more rapid recruitment of motor units during the position task should have reduced the load experienced by the active muscle fibers. Consequently, the more rapid recruitment of motor units during the position task was not caused by a more substantial decrease in the force produced by the active muscle fibers, which suggests that the difference in recruitment rate was a consequence of the control strategy used by the central nervous system. To underscore this interpretation, there was no difference in the time to failure or the rate of motor unit recruitment for the force and position tasks when the target force exceeded the upper limit of motor unit recruitment for the muscle.

When the force and position tasks are performed with the elbow flexor muscles in the position shown in Figure 4(b), the difference in the time to task failure is greater than that for the hand muscle. This suggests that another factor besides the control strategy influences the duration that the position task can be sustained by the elbow flexor muscles. When the two tasks were performed with the elbow flexor muscles in the position shown in Figure 4(c), the difference in the time to failure between the two tasks was much less

Figure 4 Selected models that have been used to compare the time to failure of the force and position tasks. Top, the position task with the first dorsal interosseus muscle. Middle, the force task with the elbow flexor muscles and with the upper arm vertical and the forearm in a neutral position. Bottom, the force task with the elbow flexor muscles and with the upper arm horizontal and the forearm supinated. From Maluf KS and Enoka RM (2005) Task failure during fatiguing contractions performed by humans. *Journal of Applied Physiology* 99: 389–396.

than when the forearm was horizontal (Figure 4(b)). Hence, some factor related to the posture of the arm also contributed to the briefer time to failure of the position task when the forearm was horizontal. The additional factor was the demand on the muscles around the shoulder joint (rotator cuff and deltoid muscles) to maintain the position of the arm. The rate of increase in the electromyographic activity of the shoulder muscles was more rapid during the position task when the forearm was horizontal compared with the force task with the arm in the same position and with both tasks when the forearm was vertical. This observation indicates that the demands experienced by the postural muscles can limit the duration a task can be sustained, which has implications for the exercises that are prescribed during rehabilitation and for the ergonomic design of work stations.

These initial studies with the task failure approach suggest that it provides a strategy to identify the functional significance of the physiological adjustments that occur during fatiguing contractions. It is important to note that the approach should provide a foundation for the systematic evaluation of the task dependency of muscle fatigue and the extent to which the limiting factors generalize across muscles, postures, types of contractions, and individuals in health and disease.

Fear Conditioning and Synaptic Plasticity

J M Levenson, K P Mangan, P S Mukhopadhyay, and K J O'Riordan, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Changes in synaptic efficacy potentially represent a major mechanism whereby information is stored in the nervous system. Many studies have since characterized the mechanisms that underlie induction and expression of synaptic plasticity. However, surprisingly little direct evidence exists that directly implicates synaptic plasticity in memory formation in the nervous system.

Pavlovian fear conditioning is one of the most widely used behavioral paradigms for the study of the cellular and molecular bases of long-term memory formation. Fear conditioning is an attractive model system for the study of long-term memory formation, as the training session is brief, the behavioral expression of fear is robust and easy to quantify, and the circuitry that underlies the acquisition, storage, and expression of conditioned fear memory has been well characterized both anatomically and functionally. Moreover, the advent of modern molecular biology and molecular genetics has provided a plethora of information regarding the molecular and biochemical bases for conditioned fear memory. These properties make fear conditioning an ideal behavioral and neuroanatomical paradigm to investigate the hypothesis that synaptic plasticity is an important cellular mechanism for information storage in the nervous system. In the following sections we review the evidence that synaptic plasticity plays a role in storage of conditioned fear memories *in vivo*.

Pavlovian Fear Conditioning

Fear conditioning refers to training procedures whereby organisms learn to associate previously neutral stimuli with noxious or unpleasant events. Fear conditioning is based on the pioneering work of Ivan Pavlov, who demonstrated that neutral stimuli could acquire affective properties in general. During fear conditioning, stimuli that normally elicit no behavioral response are transformed to elicit robust fear responses. Fear in rodents is most commonly measured as either freezing behavior or potentiated startle reflexes. Fear conditioning begins by presenting an animal to a new environment and/or a neutral stimulus such as a tone or light. These neutral stimuli are referred to as the conditioned stimulus (CS). A noxious stimulus (shock, malaise-inducing chemical), the unconditioned stimulus (US), is then delivered coincident with the end of presentation of the CS. Close temporal association of the CS and US facilitates formation of an association between these two stimuli and a conditioned fear memory. Quantification of conditioned fear memory is performed by exposure of animals to the CS and measurement of stereotypic fear behaviors.

Anatomical Basis of Conditioned Fear

Conditioned fear has been used as a paradigm to study the cellular and molecular bases of memory formation for over 30 years. During this time, several classic experiments involving lesions, inactivation, track-tracing, and functional imaging have allowed for a thorough characterization of the neural circuitry that underlies acquisition and storage of conditioned fear memories. The amygdala and hippocampus are the primary regions of the brain involved in processing and storage of conditioned fear memory (Figure 1). The hippocampus receives information regarding the environmental context of conditioning and transmits this information into the basal (B) and accessory basal (AB) nuclei of the amygdala. The lateral nucleus of the amygdala (LA) receives input from the auditory cortex and auditory thalamus regarding auditory-based CS. The LA nucleus receives context information from inputs via the visual cortex. US information is transmitted to the LA, central (CE), and AB nuclei via distinct pathways. Behavioral and physiologic responses to fear are relayed from the amygdala to various target nuclei via the CE nucleus. Thus, the amygdala is critical for integration of US and CS, and the subsequent effect on behavior. The hippocampus is necessary for formation of context representations, but does not directly elicit fear-motivated responses. Collectively, these observations indicate that cellular and molecular events associated with formation of conditioned fear memory should occur in both the amygdala and hippocampus.

Molecular Mechanisms of Conditioned Fear

Molecular Fingerprint of Synaptic Plasticity

Synaptic plasticity refers generally to any change in the efficacy of a given synapse. That basic description covers a number of different types of plasticity, each with different durations and distinct mechanisms. A number of advances in our understanding of the molecular basis of synaptic plasticity have been made

Figure 1 Anatomical basis of fear conditioning. Formation of conditioned fear memory requires the function of the amygdala. The hippocampus is required only for association of context with fearful stimuli. The amygdala serves to receive and integrate information regarding the conditioned stimulus (CS) and unconditioned stimulus (US), and then mediates the behavioral and physiologic response through outputs from the central (CE) nucleus. The hippocampus receives information regarding environmental context through the visual cortex and then transmits this information to the amygdala through several pathways into the basal (B) and accessory basal (AB) nuclei. Although not explicitly shown, many of the pathways contain reciprocal connections. LA, lateral nuclei of the amygdala; subfields of hippocampus – CA1, area CA1; CA3, area CA3; DG, dentate gyrus; SUB, subiculum; EC, entorhinal cortex; regions receiving CE afferents – BNST, bed nucleus of the stria terminalis; PVN, paraventricular nucleus of the hypothalamus; LH, lateral hypothalamus; PAG, periaqueductal gray of the brain stem; HIPP, hippocampus.

in the past 20 years. Studies of the molecular mechanisms that underlie synaptic plasticity have served two important purposes. First, they have elucidated novel mechanisms involved in all aspects of neuronal function. Second, they have provided a molecular signature that can be used to probe whether synaptic plasticity has occurred *in vivo*. For brevity, a schematic of many of the signaling pathways and molecules engaged during induction of synaptic plasticity has been included (Figure 2).

If synaptic plasticity mediates storage of conditioned fear memories, then the mechanisms responsible for induction and expression of plasticity should also be engaged in the amygdala and hippocampus during storage of conditioned fear memory. In this section we trace the molecular pathways implicated in synaptic plasticity (Figure 2) and review what is known regarding conditioned fear memory. When we refer to the hippocampus in this section, it is implied that we are specifically referring to processes involved in contextual fear conditioning.

Glutamate Receptors

Glutamate is the predominant excitatory neurotransmitter in the mammalian brain. Therefore, induction and expression of many forms of synaptic plasticity in the amygdala and hippocampus begin with activation of ionotropic glutamate receptors. The α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPA-R) is responsible for a majority of the basal excitatory synaptic transmission that occurs in the amygdala and hippocampus. Activation of the AMPA-R is the first step in the induction of synaptic plasticity, and subsequent regulation of AMPA-R expression and function represents key processes involved in expression plasticity. Pharmacologic enhancement of AMPA-R function increases the rate of conditioned fear learning but not the capacity, indicating that AMPA-Rs play a critical role in acquisition of memory. Interestingly, direct application of AMPA-R antagonists prior to testing blocks expression of conditioned fear memory, suggesting that

Figure 2 Molecular mechanisms implicated in both synaptic plasticity and conditioned fear memory. A schematic indicating the signaling pathways and molecular processes implicated in induction of synaptic plasticity and formation of long-term memory. The process begins at the postsynaptic membrane where *N*-methyl-D-aspartate receptor (NMDA-R) activation results in Ca^{2+} influx. The rise in intracellular Ca^{2+} results in activation of several parallel signaling pathways that ultimately converge on the mitogen-activated protein extracellular kinase–extracellular signal-regulated kinase (MEK–ERK) signaling pathway. Activation of ERK engages a complex cascade of events, including protein synthesis, kinases, and transcription factors, which results in a coordinated pattern of gene expression necessary for maintenance of long-term changes in synaptic efficacy. In parallel to NMDA-R-mediated events, activation of mGluRs results in recruitment of phosphatidylinositol 3-kinase (PI3K) and the p38–mitogen-activated protein kinase (MAPK) pathway. All molecules in bold have been directly implicated in conditioned fear memory. See text for discussion of other molecules.

AMPA-Rs also play a role in expression of memory. In support of a role for AMPA-Rs in expression of memory, work in several laboratories has documented an increase in surface expression of AMPA-Rs in the amygdala and hippocampus in response to conditioned fear training. Moreover, electrophysiologic recordings of tissue slices containing the medial geniculate nucleus–lateral nucleus of the amygdala (MGN–LA) synapse *in vitro* indicate that fear conditioning results in an increase in AMPA-R-mediated synaptic transmission. Collectively, these results indicate that AMPA-R-mediated function is necessary for both acquisition and expression of conditioned fear.

A critical step in induction of many forms of activity-dependent synaptic plasticity is activation of a unique class of ionotropic glutamate receptors, the *N*-methyl-D-aspartate receptor (NMDA-R). Formation of conditioned fear memory requires NMDA-R function both in the amygdala and the hippocampus. Pharmacologic inhibition of NMDA-R function in the amygdala prior to training completely blocks acquisition of conditioned fear. Blockade of NMDA-Rs in the hippocampus prevents acquisition of contextual, but not cued, conditioned fear. Pharmacologic inhibition of NMDA-Rs after training has no effect on expression or maintenance of conditioned fear,

indicating that NMDA-Rs specifically function in acquisition of memory. Recent experiments using genetically modified mice demonstrated that overexpression of NMDA-Rs in the forebrain enhances formation of conditioned fear memory. Collectively, these results indicate that NMDA-Rs are necessary for formation of conditioned fear memory and that these receptors are strictly involved in acquisition, but not expression, of conditioned fear.

Metabotropic glutamate receptors (mGluRs) are a final class of glutamate receptor that functions in synaptic plasticity. Activation of mGluRs has been implicated in induction of numerous forms of synaptic plasticity. Interestingly, both pharmacologic inhibition and activation of mGluRs in the amygdala and hippocampus interfere with acquisition of conditioned fear memory. Genetically modified animals that contain either gain or loss of function in specific isoforms of mGluRs exhibit similar phenotypes when acquisition of conditioned fear memory is significantly impaired. These results suggest that mGluRs function *in vivo* in acquisition of conditioned fear memory.

Brain-Derived Neurotrophic Factor

Growth factors play a critical role in several aspects of brain function, and several studies indicate that proper expression and function of growth factors and their associated receptors is necessary for transcription-dependent, long-term forms of synaptic plasticity. Brain-derived neurotrophic factor (BDNF) appears to play a unique role in activity-dependent synaptic plasticity. BDNF mRNA and protein, and the associated receptor, the tyrosine kinase receptor B (TrkB), are expressed in relatively high levels in the hippocampus and basolateral amygdaloid nucleus (BLA). BDNF mRNA is significantly increased in the hippocampus and BLA after fear conditioning. Overexpression of TrkB facilitates acquisition of conditioned fear memory. Pharmacologic and genetic disruptions of TrkB expression and function significantly attenuate conditioned fear learning. Extinction studies suggest that the BDNF/TrkB system is essential for consolidation, but not acquisition, of long-term conditioned fear memory. These studies indicate that the BDNF/TrkB system is engaged during consolidation of conditioned fear memory and represents another molecular correlate suggesting that synaptic plasticity occurs in the hippocampus and amygdala during consolidation of conditioned fear memory.

Signaling Pathways

The role of any membrane receptor is to transduce extracellular stimuli into intracellular signaling events. A great deal is known regarding the signaling pathways engaged during induction of synaptic plasticity. These signaling pathways provide another molecular signature that can be used to determine whether synaptic plasticity has occurred *in vivo* during acquisition and consolidation of conditioned fear memory.

The primary trigger of plasticity-associated signaling is an influx of Ca^{2+} through the NMDA-R (**Figure 2**). As reviewed previously, many studies indicate that NMDA-R function is critical for acquisition of conditioned fear memory. In addition, Ca^{2+} flux can also occur through voltage-gated Ca^{2+} channels (VGCCs). VGCCs have been implicated in both expression and consolidation of conditioned fear memory. After intracellular Ca^{2+} levels are increased, several signaling cascades are engaged to mediate expression and consolidation of conditioned fear memory. The activities of several signaling molecules increase in response to fear conditioning in both the amygdala and the hippocampus, including Ca^{2+}/calmodulin-dependent protein kinase II (CamKII), protein kinase A (PKA), protein kinase C (PKC), and extracellular signal-regulated kinase (ERK). Pharmacologic disruptions of CamKII, PKA, PKC, and mitogen-activated protein extracellular kinase (MEK) in either the amygdala or hippocampus inhibit acquisition of conditioned fear. Genetic disruptions of function, either through knockout or expression of a dominant negative enzyme, of CamKII, PKA, PKC, ras, and MEK all diminish or inhibit formation of conditioned fear memory. Enhancement of cAMP–PKA signaling pharmacologically or genetically increases acquisition of conditioned fear memory. Thus, many of the Ca^{2+}-dependent signaling pathways that are engaged during induction of synaptic plasticity are also activated in response to acquisition of conditioned fear memory.

Plasticity-associated signaling also occurs through non-Ca^{2+}-dependent pathways. For example, signaling through TrkB and mGluRs is necessary for induction of synaptic plasticity. Two major targets of TrkB and mGluR signaling are phospholipase C (PLC) and phosphatidylinositol 3-kinase (PI3K). The β and γ isoforms of PLC are activated by fear conditioning and can be found complexed with ERK-2. Overexpression of TrkB receptors results in enhanced PLC-γ signaling and memory formation. Infusion of a PI3K inhibitor into the hippocampus inhibits formation of contextual fear conditioning. Infusion into the hippocampus of phosphorylated growth factor receptor fragments that activate PI3K facilitates formation of contextual fear conditioning. Indirect evidence suggests that Akt, a kinase that is activated in response to PI3K signaling, is activated in the amygdala by fear conditioning. Considered together with the preceding observations, these studies indicate that

a significant overlap exists between the signaling pathways activated during induction of synaptic plasticity and formation of conditioned fear memory.

Transcription

One of the consequences of engagement of the plasticity-associated signaling pathways is regulation of gene expression. Early studies of long-term memory formation observed that direct injection of RNA synthesis inhibitors into the brain resulted in selective loss of long-term memory, indicating that gene expression was a critical component of long-term memory consolidation. These studies also indicated that mechanistically, memory formation was similar to synaptic plasticity in that short-term memories did not require synthesis of new macromolecules, but long-term memory required *de novo* protein and RNA synthesis. Using a candidate-based approach, initial studies of gene expression during memory consolidation identified several transcripts, the expression of which changes in the amygdala and hippocampus after fear conditioning, including the immediate-early genes c-*fos* and *egr-1*. Contemporary studies using a combination of molecular genetics and high-density oligonucleotide arrays have confirmed these early studies and extended them to include several additional genes, including those for BDNF, tissue plasminogen activator (tPA), activity-regulated cytoskeletal-associated protein (Arc), postsynaptic density-95 protein (PSD-95), and homer. Comprehensive characterization of gene expression during memory formation has revealed the involvement of several transcription factor families including cAMP response element-binding protein (CREB), CCAAT/enhancer-binding protein (C/EBP), and nuclear factor-kappa B (NF-κB). Notably, mouse models that contain either loss or gain of function for these transcription factors have been made and indicate that all of their genes are important for formation of conditioned fear memory. Expression of any one gene can be influenced by literally hundreds of different transcription factors. Thus, the significant degree of overlap between the patterns of gene expression observed after induction of synaptic plasticity and consolidation of conditioned fear memory strongly suggests that synaptic plasticity occurs *in vivo* during consolidation of conditioned fear memory.

Translation

One endpoint of gene expression is protein synthesis. Classic studies have demonstrated that infusion of protein synthesis inhibitors into the brain inhibits consolidation of conditioned fear memory. Several recent studies have discovered some of the molecules that are involved in regulation of protein synthesis during induction of synaptic plasticity. Fragile X mental retardation is an X-linked cognitive disease that is due to loss of function in one of several fragile X mental retardation (FMR) genes. All FMR genes are mRNA-binding proteins, act to transport mRNA to dendritic spines, and have been implicated in the transcription-dependent, late-phase of long-term potentiation (L-LTP). Loss of *FMR1* and *FMR2* results in a diminution of conditioned fear. Moreover, loss of the translational repressors 4E-BP2 and GCN2, which results in loss of L-LTP, inhibits consolidation of conditioned fear memory. Thus, several molecules implicated in protein synthesis and synaptic plasticity are necessary for formation of conditioned fear.

Direct Measures of Synaptic Plasticity during Conditioned Fear

Experiments into the molecular and cellular bases of formation of conditioned fear memory are suggestive, but demonstration of a change in synaptic efficacy *in vivo* would provide the most compelling evidence that synaptic plasticity mediates or at least contributes to storage of memory. At its core, synaptic plasticity is a change in the efficiency of communication at a particular synapse. One of the major mechanisms that underlies both LTP and long-term depression (LTD) is a redistribution in the complement of AMPA-Rs in the postsynaptic density (PSD). Induction of LTP results in an increase in AMPA-Rs, while LTD results in a decrease. Therefore, the relative level of AMPA-Rs in the PSD is a molecular correlate of synaptic efficacy. Several studies have demonstrated that levels of AMPA-Rs in the PSD increase after conditioned fear training in both the LA nucleus and area CA1 of the hippocampus, suggesting that plasticity occurs in these areas of the brain in response to formation of conditioned fear memories.

Induction of synaptic plasticity results in persistent physiologic changes in neurons. Input/output curves in area CA1 of the hippocampus were increased up to 7 days after fear conditioning, suggesting either synaptic transmission and/or neuronal excitability were increased. Efferents from the amygdala appear to be necessary for at least some of the conditioned fear-induced modulation of neuronal excitability in the hippocampus. Interestingly, several studies indicate that either conditioned fear modulates induction of synaptic plasticity, or that induction of synaptic plasticity modulates sensory-evoked potentials. In the hippocampus, conditioned fear occludes induction of LTP in slices *in vitro*. Slices isolated immediately after training exhibit impaired early-phase LTP (E-LTP), while slices isolated 24 h after training exhibit normal E-LTP but impaired L-LTP. Occlusion of LTP suggests that fear conditioning results in

induction of LTP in the hippocampus that prevents further potentiation of slices *in vitro*. In the amygdala, induction of LTP in the MGN–LA pathway results in enhancement of auditory-evoked potentials in this pathway, indicating that the endogenous systems for information processing share at least some mechanisms with synaptic plasticity.

Perhaps the most compelling evidence for synaptic plasticity in conditioned fear memory formation comes from a series of studies measuring changes in electrophysiology of the amygdala and hippocampus. Fear conditioning results in increases in synaptic efficacy in the MGN–LA pathway of the amygdala and the Schaffer-collateral pathway of the hippocampus. Implantation of electrodes *in vivo* has revealed that auditory fear conditioning enhances synaptically evoked potentials in the LA in a manner similar to what occurs when LTP is induced in this same pathway. Moreover, a hippocampus-dependent passive avoidance task increases evoked potentials in the Schaffer-collateral pathway of the hippocampus. In both the amygdala and the hippocampus, fear-induced increases in synaptic potentials occlude the effect of tetanus-induced LTP, suggesting that fear conditioning results in LTP-like changes in synaptic efficacy. Moreover, E-LTP induced in the dentate gyrus *in vivo* can be transformed to L-LTP by exposure of individuals to either an emotionally motivated experience or a hippocampus-dependent learning task, providing direct evidence of significant overlap in the molecular mechanisms used to consolidate long-term memory and long-term synaptic plasticity.

Summary and Conclusions

A significant portion of research into the cellular basis of information storage in the nervous system has focused on the synapse. A great deal has been learned about the mechanisms governing synaptic function and the processes that underlie synaptic plasticity. The convergence of cellular, molecular, and physiologic research on the mechanisms underlying synaptic plasticity have provided a comprehensive description of the processes involved in this phenomenon. This research has provided the necessary tools to test the hypothesis that synaptic plasticity occurs *in vivo* during memory formation. Indeed, several lines of compelling evidence exist that strongly suggest that synaptic plasticity occurs in response to formation of conditioned fear memory. However, all of the research presented thus far is correlative in nature; changes in synaptic responses mimic changes induced by artificial induction of LTP. No study to date has demonstrated that specific patterns of synaptic activity that mimic LTP or LTD induction occur *in vivo* during conditioned fear training and that these firing patterns are followed by long-term changes in synaptic efficacy. Moreover, no study has been able to artificially induce a fear memory through induction of synaptic plasticity in either the amygdala or the hippocampus. Thus, while there is still no direct evidence that synaptic plasticity is involved in memory formation, all indications are that synaptic plasticity is an important part of conditioned fear memory.

Fetal Alcohol Syndrome

E P Riley, S N Mattson, and J D Thomas, San Diego State University, San Diego, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Fetal alcohol syndrome (FAS) was first described by Kenneth Lyons Jones and David Smith in 1973 as a constellation of abnormalities resulting from heavy *in utero* alcohol exposure involving growth retardation, central nervous system (CNS) dysfunction, and distinct facial characteristics. Research during the three decades since that report has demonstrated that FAS is only one outcome on a continuum of effects resulting from prenatal exposure to alcohol. Considering the full range of possible outcomes resulting from prenatal alcohol exposure, FAS and its associated conditions represent a major public health problem and one that is entirely preventable. Herein, we review FAS, the effects of prenatal alcohol exposure on brain and behavior, possible mechanisms of damage, and recent attempts to mitigate these outcomes.

Fetal Alcohol Syndrome

FAS is the most physically apparent consequence of heavy gestational alcohol exposure, and while there are differences between the various diagnostic schemas, in general, anomalies are required in three distinct areas. Centers for Disease Control and Prevention (CDC) guidelines for the diagnosis of FAS require evidence of facial dysmorphology, growth problems, and evidence of CNS abnormalities. The facial dysmorphology consists of the presence of a smooth philtrum, a thin vermilion border, and small palpebral fissures ($\leq$10th centile) (Figure 1). Prenatal or postnatal growth retardation ($\leq$10th centile after adjustment for age, sex, gestational age, and race or ethnicity) is also required. The CNS abnormalities can be structural (significant anomalies as seen on imaging or a head circumference $\leq$10th centile), neurological, or functional. Functional anomalies are defined as global cognitive or intellectual deficits in multiple domains below the 3rd centile or deficits on three or more specific domains (e.g., executive or motor functioning, attention and hyperactivity, social skills, language, developmental deficits). As mentioned, other diagnostic schemas differ slightly. For example, a clarification of the Institute of Medicine (IOM) criteria for a diagnosis of FAS requires only two of the three facial features, but is more restrictive in terms of the CNS abnormality. In addition, this clarification suggests criteria for the diagnosis of partial FAS, alcohol-related birth defects (ARBDs), and alcohol-related neurodevelopmental disorders (ARNDs). Both the CDC and revised IOM guidelines allow the diagnosis of FAS to be made in the absence of information on maternal alcohol consumption. It is important to note that individuals with other syndromes (e.g., velocardiofacial, Williams, and de Lange syndromes) can display some of the characteristic facial features of FAS and therefore partial phenocopies should be ruled out prior to diagnosing FAS.

Although estimates of the prevalence of FAS vary depending upon the population under study and the type of ascertainment used, estimates generally run between 0.5 and 2 cases per 1000 births. However, in some areas, such as the Western Cape of South Africa, rates as high as 70/1000 are reported. Furthermore, FAS is only one outcome on a continuum of effects resulting from prenatal alcohol exposure, and the designation 'fetal alcohol spectrum disorders' (FASDs) is now used as an umbrella term for all possible outcomes resulting from prenatal alcohol exposure. Importantly, as suggested by the use of the term FASDs, both ARBDs and ARNDs can occur in the absence of FAS. Considering the full range of FASDs, physical and behavioral effects resulting from prenatal alcohol exposure may occur in as many as 1 in 100 births.

Animal models of FASDs have been developed that show a great deal of concordance with human findings. These models have helped to demonstrate the behavioral teratogenecity of alcohol, as confounding factors that may be present in clinical populations – such as polydrug use, nutritional factors, and poor prenatal care – can be controlled. Moreover, these models allow mechanisms to be assessed and potential interventions tested. For example, virtually all of the facial characteristics seen in FAS have been produced in mouse embryos by inducing apoptotic cell death in select cell populations in the anterior neural ridge, by exposing the embryos to alcohol during the equivalent of the third week of human gestation.

Effects of Alcohol on the Brain

The most deleterious consequence resulting from gestational alcohol exposure is the effect of alcohol on brain development and the impact that the brain changes have on behavior and cognition. Overwhelming evidence from both human and animal studies indicates that prenatal alcohol exposure can produce permanent changes in brain structure and function.

Figure 1 Features of fetal alcohol syndrome. Reproduced from Streissguth AP (1994) A long-term perspective of FAS. *Alcohol Health and Research World* 18(1): 74–81.

Early autopsy studies indicated a wide range of damage, including microcephaly, neuroglial heterotopias, agenesis of the corpus callosum, and cerebellar hypoplasia. Although one of the most consistent findings is that alcohol produces a reduction in brain volume, the brain is not uniformly vulnerable to a developmental alcohol insult.

One brain region particularly sensitive to developmental alcohol exposure is the cerebellum. Animal studies indicate that perinatal alcohol exposure reduces the number of cerebellar Purkinje and granule cells and alters cerebellar glial cells. These studies demonstrate that the cerebellum is particularly vulnerable during the equivalent of the human early third trimester, with lobules I–V and IX–X of the vermis being most sensitive. Consistent with these reports, magnetic resonance imaging (MRI) studies find about a 15% reduction in cerebellar volume in children with FAS and smaller volume reductions in those without FAS but with histories of heavy prenatal alcohol exposure. Reductions are more apparent in the anterior (lobules I–V) compared to the posterior cerebellar vermis. Thus, within the cerebellum there may be regional differences in sensitivity to alcohol-induced cell loss. Besides these size reductions, the anterior vermis and posterior-inferior vermis are spatially displaced in alcohol-exposed individuals. The degree of displacement of the anterior vermis is 1–3 mm and is most prominent on the anterior and superior edges. Interestingly, the degree of anterior vermis displacement is related to verbal learning and memory deficits.

Studies in children with FASDs suggest regional sensitivity to alcohol in the cortex. Analysis of the overall shape of the brain indicates narrowing in the inferior parietal/perisylvian region, as well as reduced growth in the inferior frontal region. Density mapping of gray and white matter in brain also supports abnormalities in the temporal–parietal regions, where increased gray matter and decreased white matter are apparent, particularly in the left hemisphere. Two small single-photon computed tomography (SPECT) studies support alcohol's effects in this brain region: one demonstrated mild hypoperfusion of the left hemisphere in the parietal–occipital regions and the other noted blood flow reductions in the temporal region.

Human MRI and animal studies indicate that the basal ganglia and, in particular, the caudate nucleus are disproportionately reduced in volume following heavy prenatal alcohol exposure. These results are supported by brain metabolism studies in both humans and animals showing reductions in activity in the thalamus and basal ganglia. Thus, both volumetric and metabolic changes support regional vulnerability in the teratogenic effects of alcohol. These effects on the caudate may be related to executive function and other cognitive deficits in FASDs.

The hippocampus is another subcortical structure affected by developmental alcohol exposure. Animal studies report that such exposure leads to cell loss in the hippocampus and lower dendritic spine density on pyramidal neurons, as well as aberrant mossy fiber projections. This exposure also alters synaptic activity in hippocampal brain slices. Human MRI data on a limited number of individuals indicate that while the hippocampus is smaller than in controls, it is unclear if these reductions are simply proportionate to overall brain size. Hippocampal changes could influence learning and memory in individuals with FASDs, given the significant role of the hippocampus in these cognitive domains.

Finally, abnormalities in the corpus callosum are reported in autopsy, imaging, and animal studies. In fact, it has been suggested that prenatal alcohol exposure is the most common cause of agenesis of the

Figure 2 Magnetic resonance images of a 9-year-old girl with fetal alcohol syndrome. These sagittal images illustrate agenesis of the corpus callosum (left) and colpocephaly (right) present in this child. Reproduced from Mattson SN and Riley EP (1995) Prenatal exposure to alcohol: What the images reveal. *Alcohol Health and Research World* 19(4): 273–278.

Figure 3 Average outlines of the corpus callosum (the major connection between the two hemispheres) in controls, children with fetal alcohol syndrome (FAS), and nondysmorphic children exposed to alcohol prenatally. The children in this last group were exposed to large amounts of alcohol prenatally, but they do not have the facial characteristics required for the FAS diagnosis. Notice that the corpus callosum of the two alcohol groups is displaced, with the greatest displacement occurring in the isthmus and splenium at the back of the corpus callosum. Also note that the nondysmorphic group is somewhat between the FAS and control groups. The corpus callosum is oriented so that the face would be on the left and the back of the head would be on the right. Reproduced from Sowell ER, Mattson SN, Thompson PM, Jernigan TL, Riley EP, and Toga AW (2001) Mapping callosal morphology and cognitive correlates: Effects of heavy prenatal alcohol exposure. *Neurology* 57(2): 235–244.

corpus callosum (Figure 2). Morphometric studies indicate that it is reduced in size and is spatially displaced. Specifically, the posterior corpus callosum in alcohol-exposed individuals is located more anterior and inferior than in controls (Figure 3). Verbal, but not nonverbal, learning/memory deficits are related to the degree of callosal displacement. In addition, new research suggests that assessment of callosal shape, via neonatal cranial ultrasound, may assist in the early identification of FAS. The integrity of the corpus callosum was recently investigated using diffusion tensor imaging in a sample of adults with FAS. Differences were noted in the diffusion fractional anisotropy and the apparent diffusion coefficient between alcohol-exposed and nonexposed young adults, supporting changes in white-matter integrity. Animal studies also report reductions in corpus callosum size, again most prominent in the posterior region. These reductions may be due to alcohol's effect on the development and function of oligodendrocytes, leading to a reduction or delay in myelin production, or to fewer neurons crossing within the corpus callosum.

It has been suggested that high levels of prenatal alcohol exposure may result in the mild end of holoprosencephaly spectrum malformation. Altered craniofacial development, ocular anomalies, and forebrain deficiencies, including hypoplasia of the corpus callosum, basal ganglia, and hippocampus, are consistent with this suggestion. Exposure to alcohol during a

discrete period of development may lead to deficiencies in the development of midline brain structures.

In addition to these structural changes, prenatal alcohol exposure alters the development and function of several neurotransmitter systems. For example, animal studies show that developmental alcohol exposure retards migration, reduces fiber density, and reduces the number of serotonergic neurons in various areas, including the midline raphe nuclei. Prenatal alcohol exposure also reduces glutamate–*N*-methyl-D-aspartate (NMDA) receptor number and activity in the hippocampus and cortex. Given the role glutamate plays in neuronal plasticity, long-lasting changes in glutamatergic signaling could contribute to learning deficits associated with developmental alcohol exposure. Such deficits could also be influenced by disruptions in cholinergic functioning. Alcohol exposure during development reduces the number of cholinergic neurons, reduces levels of choline acetyltransferase (ChAT), and alters the number of muscarinic receptors in regions such as the cortex and hippocampus. Reduced behavioral responsivity to cholinergic drug challenges provides further support for cholinergic hypofunctioning.

Dopaminergic activity is reduced by prenatal alcohol exposure, although the specific effects depend on timing and dose of alcohol. Alterations in dopaminergic functioning may contribute to the attention deficits observed in children with FASDs. Finally, although less well studied, prenatal alcohol also leads to alterations in noradrenergic, histaminergic, and γ-aminobutyric acid (GABA)ergic systems.

Neuroendocrine function is also affected by prenatal alcohol exposure, either indirectly by influencing maternal–fetal hormonal interactions or directly by altering the hormonal balance of the developing fetus. Animal studies demonstrate that prenatal alcohol exposure alters functioning of the hypothalamic–pituitary–adrenal (HPA) axis, the hypothalamic–pituitary–thyroid axis, and hypothalamic–pituitary–gonadal axis, which may influence stress and metabolic and reproductive function. Animals exposed to alcohol prenatally exhibit augmented responses to stress and take longer to return to baseline levels, although these effects may interact with sex. Hyperactivity of the HPA axis may also contribute to immune dysfunction, and limited data suggest that immune function is compromised following prenatal alcohol exposure.

Behavioral and Cognitive Effects in FASDs

Behavioral and cognitive changes related to prenatal alcohol exposure include deficits in sensory and motor function, attention, and learning as well as developmental delays, hyperactivity, and altered social behaviors. Recent research has focused on defining a profile of relative strengths and weaknesses in this population.

IQ Deficits

Probably the most devastating consequence of prenatal alcohol exposure is intellectual impairment. The mean IQ in FAS is in the low 70s, but the range is rather broad and includes functioning in the average range. In individuals with histories of heavy prenatal alcohol exposure, but without the facial characteristics of FAS, the average IQ is in the 80s, but again the range is rather broad. While frequently noted as one of the most common causes of mental retardation, the majority of individuals with FAS are not mentally retarded.

Motor Dysfunction

Given the cerebellar alterations, it is not surprising that prenatal alcohol exposure has been linked with problems in balance, motor coordination, and gait. The ability to maintain balance can be affected in children and adults with FASDs and, importantly, as the mechanisms involved in balance (e.g., visual, vestibular, and somatosensory cues) are challenged, deficits become more obvious. Animal studies have also demonstrated effects on gait, balance, and coordination. Moreover, balance deficits and motor incoordination following perinatal alcohol are correlated with the severity of cerebellar Purkinje cell loss.

Learning and Memory Impairments

Multiple studies have suggested that perinatal alcohol exposure leads to deficits in learning and memory. In humans, these include verbal learning deficits and nonverbal learning and memory deficits. The pervasiveness of the nonverbal deficits may be related to visuospatial dysfunction. For example, recent studies utilizing a virtual Morris maze show deficits in place but not cued navigation in children with FASDs. Animal studies also demonstrate deficits in Morris maze spatial learning that are likely related to alcohol-induced hippocampal or frontal lobe dysfunction. Additional learning deficits have been noted in human and animal studies using a classically conditioned eyeblink response, a task that engages neural circuitry in the cerebellum and brain stem. In animals, these delay conditioning deficits have been related to alterations in interpositus nucleus activity in the cerebellum and have been correlated with the loss of cerebellar deep nuclear cells, which are reduced by about 50% in alcohol-exposed animals. In one human study, children exposed to alcohol prenatally were compared to children with

either dyslexia or attention-deficit/hyperactivity disorder (ADHD), but no history of alcohol exposure. Both alcohol-exposed and dyslexic children failed to learn the conditioned eyeblink response.

Executive Function Deficits

Another pervasive characterization in this population is one of executive function deficits. Weaknesses in planning, response inhibition, verbal and nonverbal fluency, set-shifting, and reversal learning have all been documented in individuals with FASDs. Executive function deficits have been related to the frontal-subcortical system, which is affected by prenatal alcohol exposure. Although preliminary, a recent functional MRI (fMRI) study in individuals with FASDs reported increased functional activation in the inferior and middle frontal cortices on a fairly simple spatial working memory task, another domain of executive functioning. Among findings in animal models of FASDs are deficits in response inhibition and reversal learning. For example, rodents perinatally exposed to alcohol typically perform worse than do controls on tasks requiring successive reversals. In one study, impaired reversal learning was associated with cell loss in the medial prefrontal cortex. Executive functioning deficits may cause profound and disabling difficulties in everyday life and may account for the problems in social, legal, alcohol use, and mental health domains in individuals with histories of heavy prenatal alcohol exposure.

Activity Levels

Deficits in response inhibition may also be expressed as changes in activity level. Since the development of animal models of FASDs in the late 1970s, increased activity and exploration behaviors in the open field are among the most common findings. Although empirical data from clinical populations regarding activity level is limited, children with FASDs have been described as hyperactive and fidgety, characteristics that may also be related to deficits in attention.

Attention Deficits

Children with prenatal alcohol exposure are commonly diagnosed with ADHD. A case-control study of psychiatric inpatients revealed that cases with ADHD were 2.5 times more likely to have been exposed to alcohol compared to control cases, and this was independent of other important risk factors for ADHD, such as smoking or familial factors. Although prenatal alcohol exposure as a risk factor for ADHD has not been universally supported, examination of attention in FASDs suggests that this domain represents a core deficit in this population. However, these attention deficits are not global in nature; visual attention deficits are pervasive whereas auditory deficits are dependent on task demands. Research comparing children with heavy prenatal alcohol exposure to children with ADHD but no history of alcohol exposure is limited, but there is some suggestion that the two groups can be distinguished from each other based upon differences in performance on tests of vigilance and visual spatial reasoning, and in the eyeblink conditioning study mentioned previously.

Psychiatric Comorbidity

In addition to ADHD, other psychiatric disorders are frequently mentioned in conjunction with FASDs. Rates of depression between 27% and 44% have been noted in individuals with histories of prenatal alcohol exposure, and 25% of a sample of adults with FASDs had attempted suicide. Importantly, there is evidence that the level of depression in children with prenatal exposure histories cannot be explained by maternal depression or level of current drinking in the home. Higher rates of disruptive, anxiety, and substance use disorders have also been reported.

Risk Factors

One obvious risk factor for FASDs is the level of alcohol exposure. Alcohol's adverse effects on development are dose dependent, and heavier maternal consumption is associated with more severe outcomes. However, there are data suggesting that even low levels of alcohol may damage the developing fetus. In addition to alcohol dose, pattern of consumption is an important factor. For example, animal models have shown that binge drinking results in more severe neuropathology and behavioral alterations than does more chronic exposure. Clinical studies also suggest that maternal binge drinking places the fetus at higher risk for FASDs. Developmental timing of exposure is another factor. For example, using a mouse model, it was demonstrated that facial features associated with FAS are related to alcohol exposure during a discrete period early in gestation, and that a difference in the day of exposure (gestation day 7 vs. 8) could cause different outcomes in terms of facial characteristics.

Maternal and/or fetal genetic factors also interact with alcohol exposure and affect the relative risk for FASDs. For example, different alleles for the *ADH1B* gene may play a role in the etiology of FAS. Maternal *ADH1B*2* and possibly *ADH1B*3* alleles, which are associated with more rapid alcohol metabolism, reduce the risk of FAS. Using crosses of selectively

bred lines, it has been shown that maternal genotype related to functional alcohol sensitivity influences the outcome in the offspring, regardless of the offspring's genotype. Prenatal care, nutritional factors, maternal age, parity, and use of other drugs of abuse may also interact with prenatal alcohol exposure in determining outcomes.

Mechanisms of Damage and Potential Interventions

Alcohol disrupts brain development via a number of mechanisms and affects many stages of neuronal and glial development, including proliferation, migration, differentiation, and cell survival. Moreover, the mechanisms of damage depend on the developmental timing of alcohol exposure and characteristics of various cellular populations. For example, alcohol alters the cell cycle during proliferation, alters radial glial cells and neuronal responses to cell adhesion molecules, alters neurite outgrowth and dendritic branching, and leads to both apoptotic and necrotic cell death. Several putative mechanisms have been investigated using animal model systems.

Based upon similarities in neuropathology between children with FAS and those with mutations in the L1 cell adhesion molecule, it is hypothesized that alcohol might interfere with normal cell adhesion. *In vitro* studies have shown that ethanol impairs neuronal responses to L1 cell adhesion molecules, which are important for neurite extension and neuronal migration (**Figure 4**). Likewise, coadministration of compounds that antagonize ethanol's inhibition of the L1 molecule should protect against alcohol's teratogenicity. For example, octanol inhibits ethanol's effects on L1, and when coadministered with ethanol inhibits toxicity to the embryo (**Figure 5**).

Another possible teratogenic mechanism is oxidative stress, which leads to cellular damage and death. Perinatal alcohol exposure increases the production of destructive reactive oxygen species and disrupts intracellular antioxidant capacity. Consistent with this mechanism, administration of antioxidants, such as vitamin E, during ethanol exposure can reduce oxidative stress and protect against ethanol-related hippocampal and cerebellar cell death, although the functional significance of this has yet to be established. Administration of a synthetic superoxide dismutase and catalase mimetic antioxidant, EUK-134, reduces ethanol-induced apoptotic cell death and limb malformations in whole mouse embryos. The success of antioxidant treatment may depend on the particular antioxidant agent used and the cell population studied, as well as timing and dosing of alcohol exposure.

The neuroactive small peptide fragments NAPVSIPQ (NAP) and SALLRSIPA (SAL) have antioxidant properties as well as other neuroprotective actions. Treatment with these peptides prior to or shortly after prenatal ethanol exposure reduces alcohol-induced fetal death, growth retardation, and neuropathology. Whether these peptides are effective because of their antioxidant properties, ability to block ethanol's effects on L1 cell adhesion molecules, or another protective mechanism is unknown. Recently, it was reported that nicotinamide administration shortly after perinatal alcohol exposure in the mouse significantly attenuated activation of caspase-3, apoptotic cell death, and behavioral deficits. Nicotinamide is a novel neuroprotective agent that can protect against various insults, such as oxidative stress.

Ethanol also disrupts the production or response to a variety of growth factors, disruptions that may reduce cell proliferation as well as survival. Furthermore, given that some neurotransmitters exert trophic effects during development, alcohol-related reductions in neurotransmitter levels can augment ethanol's teratogenic effects. For example, serotonin exhibits neurotrophic effects during development primarily by activating both neuronal and glial serotonin ($5\text{-}HT_{1A}$) receptors, and alcohol-related reductions in serotonergic activity could alter the development of a number of neuronal populations, including forebrain structures. Concurrent administration of serotonin $5\text{-}HT_{1A}$ agonists, buspirone and ispaspirone, can prevent alcohol's damaging effects on developing serotonergic and other rhombencephalic neurons.

Ethanol may also disrupt development by acting on receptors and ion channels. For example, perinatal alcohol exposure leads to widespread apoptotic cell death and this may be related, in part, to ethanol-induced blockade of NMDA receptors and stimulation of $GABA_A$ receptors. In addition, blockade of NMDA receptors with the antagonists MK-801 or eliprodil during perinatal ethanol withdrawal protects against some ethanol-related behavioral alterations. These results suggest that neurocompensatory overactivity of NMDA receptors may lead to excitotoxicity. Thus, both the acute action and withdrawal from alcohol may be damaging to the developing brain.

Indirectly, prenatal ethanol exposure can also disrupt nutrient absorption and maternal–fetal blood flow. Moreover, acetaldehyde, a metabolite of ethanol, is also teratogenic. Other factors that may contribute to alcohol-related damage include retinoic acid deficiencies, altered regulation of gene expression, and endocrine-related mechanisms. Thus, alcohol disrupts brain development via numerous and complex mechanisms. Elucidation of these mechanisms may lead to the identification of effective treatments.

Figure 4 Ethanol seems to alter cell responses to molecules that regulate neuronal proliferation, migration, and differentiation. One interesting mechanism involves L1 and other cell adhesion molecules. These are essential for normal human nervous system development. L1 and other cell adhesion molecules guide neuronal migration and tract formation during nervous system development, and mutations in the gene for L1 result in brain malformations. Scientists recently recognized that children born with L1 mutations exhibit mental retardation, spastic gait, and a variety of brain malformations, including enlarged ventricles (hydrocephalus), and agenesis of the corpus callosum. Noting that retardation, hydrocephalus, and agenesis of the corpus callosum also occur in fetal alcohol syndrome, Michael Charness and colleagues asked whether alcohol inhibits the adhesiveness of cells bearing the L1 molecule. L cells (mouse fibroblasts) were engineered to express the human gene for the cell adhesion molecule L1 (see the three slides labeled 'L1-transfected'). The cells were allowed to aggregate by gentle shaking for 30 min. Control cells (left slide) form few clusters of adherent cells. Cells transfected with human L1 cell adhesion molecules aggregate much more than do control cells. Of the L1-transfected cells, the first slide (0 mM) shows this aggregation (white clumps) when alcohol is not added to the system. The slides showing the two other L1-transfected cells (5 and 25 mM) show a dose-dependent decrease in aggregation when ethanol is added to the medium. This increase in cell adhesion is inhibited by ethanol in a dose-dependent manner. Ethanol seems to alter cell responses to molecules that regulate neuronal proliferation, migration, and differentiation. Reproduced from Ramanathan R, Wilkemeyer MF, Mittal B, et al. (1996) Alcohol exhibits cell–cell adhesion mediated by human L1. *Journal of Cell Biology* 133(2): 381–390.

Figure 5 Representative morphology of cultured control and alcohol-exposed C57BL/6J mouse embryos at gestational day 8. The embryos in the middle and right panels were exposed to 100 mM alcohol (EtOH) and 100 mM EtOH + 3 μM 1-octanol (OCT), respectively; administration of octanol significantly reduced the severity of alcohol-related teratogenicity. Reproduced from Chen S-Y, Wilkemeycer MF, Sulik KK, and Charness ME (2001) Octanol antagonism of ethanol teratogenesis. *FASEB Journal* 15(9): 1649–1651.

In hopes of intervening in affected individuals with FASDs, factors known to positively influence brain structure and function have been applied to animal models of FASDs. For example, rearing in an enriched environment, motor learning rehabilitation, and exercise improve outcomes in animals exposed to alcohol perinatally. Motor rehabilitation initiated in adulthood increases synaptic connections in the cerebellum and improves motor coordination in subjects exposed to alcohol during development. More recent evidence suggests that even exercise alone can increase hippocampal plasticity and increase neurogenesis in adult animals exposed to alcohol during development. Finally, dietary treatments may also be effective. For example, choline supplementation can reduce the severity of overactivity and learning deficits associated with developmental alcohol exposure even when administered after ethanol treatment has ceased. Treatments that are relatively safe to administer may hold promise for translation into the clinical population.

Summary

FASDs are a devastating, yet preventable, public health concern that span the physical, neurological, behavioral, cognitive, and social domains. Following

heavy prenatal alcohol exposure, both structural and functional changes in the brain are documented. These changes are permanent and are seen in children with FAS and in those that have fewer or none of the facial characteristics of the syndrome. Because they occur in both dysmorphic and nondysmorphic individuals, identification of the full spectrum can be challenging. Efforts to define a behavioral and cognitive profile may assist in more accurate identification of children affected by prenatal alcohol exposure and thus provide the basis for interventions that are desperately needed in this population. Research using animal model systems has both supported and provided impetus for clinical studies. Alcohol-related changes in brain structure, neurochemistry, and resulting behavior have all been documented. Importantly, research using animal model systems has recently identified several promising interventions that may lead to either prevention or treatment of FASDs. Given that women continue to drink alcohol during pregnancy, identification of safe and effective treatments is among the most important challenges.

Finger Movements: Control

A M Smith, Université de Montréal, Montréal, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

A Brief History

Since at least the latter half of the nineteenth century, the motor cortex has been considered the most important brain region controlling the hand. The clinical link between small lesions of the motor cortex and contralateral paresis, particularly those restricted to the hand, was taken by Hughlings-Jackson, Ferrier, and Charcot as persuasive evidence in favor of cortical localization. For these early pioneers of neurology, the motor cortex also included what today is known as the primary somatosensory cortex. However, research during the first half of the twentieth century using better anatomical and physiological methods demonstrated that although both the motor and somatosensory cortical areas contribute corticospinal axons to the pyramidal tract, the axons of the primary somatosensory cortex terminate in the dorsal horn and do not seem to affect movement directly. The electrical stimulation studies of Penfield and Woolsey demonstrated a clearer picture of the somatotopography of the motor cortex and the disproportionately large motor representation of the regions controlling the face and hand. These and other studies showed that several regions in the frontal lobe, collectively called premotor areas, also had somatotopically organized body representations.

Using staining techniques for visualizing degenerating axonal terminals, Hans Kuypers was the first to compare spinal terminations of the pyramidal tract with those of the brain stem motor pathways. In order to produce the necessary corticospinal degeneration, Kuypers sectioned one side of the medullary pyramid and found that approximately 80% of the fibers crossed the midline to descend the cord in the lateral funiculus. The uncrossed remaining 20% of fibers descended in the anterior funiculus. Knowing myotopic organization of the ventral horn and intermediate zone, Kuypers inferred that the uncrossed fibers act on proximal and axial muscles, whereas the crossed fibers act on the more distal limb muscles. Kuypers further demonstrated that in Old World monkeys and apes, a select number of corticospinal axons originating from the motor cortex terminate directly on the dorsolateral motor neurons of lower cervical cord innervating the muscles of the hand.

In subsequent behavioral studies, Kuypers and his colleagues, Lawrence and Hopkins, studied the effects of bilateral bulbar pyramidotomy. They found that the monkeys recovered remarkably well, in contrast to the near permanent hemiplegia neurologists have long associated with infarctions of the motor cortex and internal capsule. However, the investigators made the interesting observation that destruction of the corticospinal tract, whether in the infant or the adult monkey, led to a loss of manual dexterity, ostensibly due to a loss of relatively independent finger movements. That is, the monkeys recovered whole-hand grasping and the ability to use the hand for climbing but were unable to use a single finger to winkle out pieces of food from narrow food wells. Nevertheless, Weisendanger and Hepp-Reymond found that monkeys could still perform a thumb–forefinger precision grip after bilateral pyramidotomy although both their reaction times and their force-building times were significantly increased.

At about the same time, Charles Phillips's electrophysiological studies demonstrated strong monosynaptic connections between the motor cortex and the motor neurons of both intrinsic and extrinsic wrist and finger muscles in the baboon. Also about this time, Edward Evarts took the bold step of recording from single identified pyramidal tract cells in awake monkeys trained to perform specific wrist movements. These studies confirmed that many pyramidal tract neurons discharged prior to voluntary hand movements, a finding consistent with a causal relationship. Evarts went on to show that the discharge frequency of at least some pyramidal tract neurons was directly related to wrist muscle force. Movements produced by external forces such as gravity were not associated with pyramidal tract activity, thereby demonstrating that neither movement direction nor final position was directly encoded by the discharge frequency of motor cortical neurons. Subsequent experiments by Georgopoulos and collaborators suggested that the activity of each neuron might be thought of as having a 'preferred direction' – and that populations of coactive motor cortical cells produce a 'population vector' – that determines the resultant movement direction of a limb.

These general observations remain both valid and relevant today, although a number of more recent discoveries have added considerably to our understanding of how the motor cortex controls finger movements. Brodmann's area 4 is no longer seen as the singular final common path to the motor areas of the spinal cord, and motor areas of the cortex must include the dorsal premotor area (PMd), the ventral premotor (PMv) area, and the supplementary motor area (SMA) and three cingulate motor

areas on the medial wall of the hemisphere. The digit representation in Brodmann's area 4, which is commonly accepted as the primary motor cortex (M1), receives direct input from six separate cortical areas. Dum and Strick showed that each of these premotor areas also has substantial direct projections to the spinal cord that terminate in the motor regions of the intermediate zone. Additional anatomical studies found that the PMv and the PMd have individual digit representations, identified by movements evoked by microstimulation, and that both regions are densely interconnected with M1. It was unexpected that the projections from the SMA were stronger to the PMd and PMv than those with M1.

In general, the current anatomical data do not support the belief that the motor functions of the cerebral cortex are strictly hierarchically organized. Single cell recording studies in the behaving monkey have substantiated that each of these areas is active during voluntary hand movements, although the distinct contribution of each of these areas to hand function is still unknown.

Corticomotor Neuronal Connections

As one might expect, the direct corticomotor (CM) neuronal connections have received the most attention with respect to hand function because of the initial association with independent finger movements. However, as the Weisendanger and Hepp-Reymond studies have shown, this is probably not an exclusive or unique function of the CM neurons. Initially the CM–neuron projections were demonstrated with intracellular recordings of monosynaptic excitatory postsynaptic potentials (EPSPs) in cervical motor neurons in anesthetized monkeys. However, another method, called spike-triggered averaging, has been used to identify these neurons in awake, behaving monkeys. This method, initially implemented by Fetz and Cheney, is based on the supposition that individual EPSPs generated by CM cells in target motor neurons should increase the probability of discharge in motor units at a fixed latency. By averaging the electromyographic (EMG) activity immediately following each action potential from a putative CM cell, the appearance of time-locked postspike facilitation can be demonstrated after averaging hundreds or thousands of times. Another version of the method uses stimulus-triggered averaging, in which an intracortical microelectrode applies single pulses to activate a small region of CM cells. Studies employing these methods have shown that single CM neurons act on the motor neurons of distal muscles, that is, both the extrinsic and intrinsic muscles of the wrist and fingers. However, recent evidence suggests that shoulder and elbow muscles may also have CM connections and the same site may cofacilitate muscles acting at contiguous joints synergistically. Furthermore, CM neurons generally establish synaptic contacts with the motor neurons of more than one muscle, and a single cortical CM cell can excite the motor neurons of as many as four or five muscles. In general, these synaptic contacts are found on muscles that tend to be coactive as opposed to mechanically opposing antagonists. In fact, at a slightly longer latency, postspike suppression of the electromyogram has also been reported in some antagonist muscles.

A recent study by Rathelot and Strick has introduced a new anatomical method for studying CM connections, and this has revealed a number of new and important findings. Rathelot and Strick were able to inject a small group of intrinsic and extrinsic hand muscles in monkeys with rabies virus and use the transsynaptic retrograde transport of the virus to trace the origin of CM cells in the motor cortex. They injected three thumb and finger muscles and showed that the origin of the CM cells projecting to these muscles was widespread, extending medially well beyond the finger representation area into a region that evoked shoulder movements when stimulated. The CM cells originated mainly from area 4, deep within the rostral bank of the central sulcus, and also from area 3a, that part of what was traditionally considered the somatosensory cortex receiving input from primary muscle spindles. Very few CM cells were found on the more rostral precentral convexity. In general, there was no evidence for separate anatomically segregated representations of each digit or each digit muscle in the motor cortex. Instead the hand muscles appear to be represented by multiple colonies spread over broad territories within M1, as suggested by Phillips many years earlier.

Sensory Afferents to the Motor Cortex Hand Area

It has long been known that the motor cortex, like the somatosensory cortex, receives afferents from skin and deeper tissues such as muscles, tendons, and joints. Overall, the locations of afferent sensory receptive fields match the target of motor output. However, the anatomical route of the sensory input to the motor cortex is still uncertain. In addition, the topography of this input–output relationship is not quite the 'finely graded mosaic' of input–output relations that Asanuma proposed in 1981. The discovery of CM neurons with output connections to hand muscle motor neurons in the shoulder regions of the motor cortex increases the likelihood that synergies of the shoulder, elbow, and hand muscles

may be mediated by single cortical neurons. Also hand-related neurons in motor cortex with receptive fields split between the hand and mouth are not uncommon. Consequently, finger muscle activity may be influenced by other selected regions of the body, such as the mouth or shoulder. Whether this receptive field organization is a reflection of a genetically determined inherent connectivity or whether it is the product of use-dependent plasticity is at present unknown. Several studies indicate that both the receptive fields and the hand movements evoked by electrical stimulation can be modified by experience. These use-dependent plastic changes are mediated in part by local inhibitory circuits within the cortex as opposed to the growth of new connections within the spinal cord.

Strick and Preston demonstrated that in the squirrel monkey, the motor cortex contained two distinct representations of the wrist and fingers, one rostral and the other caudal bordering on area 3a. On the output side, the two representations appeared to be identical in terms of the movements and EMG activity evoked by microstimulation, but the two zones differed markedly on the afferent side. Neurons receiving input from deep tissue were located in the rostral zone, whereas neurons receiving input mainly from glabrous skin on the volar surface of the hand were located in the caudal region bordering on area 3a. A similar organization was reported by Picard and Smith in unanesthetized fascicularis monkeys. These findings, taken together with the location of CM cells deep within the rostral bank of the central sulcus, imply that the majority of CM neurons receive cutaneous afferents from the glabrous skin of the hand. Picard and Smith also found that although some motor cortex neurons with cutaneous receptive fields increased activity with the strength of the grip force, a substantial number of neurons increased their discharge rate in response to abrupt shear forces and slip of a handheld object.

There has been a long-standing debate as to whether somatosensory afferents are transmitted to motor cortex through a separate thalamic relay channel or whether they arrive over corticocortical pathways from the postcentral parietal cortex and the second somatosensory cortex (SII) or both. Recent evidence using transsynaptic virus tracers indicates that thalamic neurons receiving input from the spinothalamic tract do not project to motor cortex. Nevertheless, there is still the possibility that some lemniscal afferents project to motor cortex through the rostral ventral posterior lateral thalamic nucleus. However, it is known that the hand area of the motor cortex of monkeys receives abundant projections from the corresponding regions of areas 1, 2, and 5. These, in addition to projections from SII, are perhaps the most likely source of cutaneous afferents to motor cortex. Moreover, temporary inactivation of the somatosensory cortex by direct injections of the γ-aminobutyric acid agonist muscimol produces clear deficits in hand dexterity that are strikingly similar to the hand dysfunction seen after local anesthesia of the fingers or numbness produced by extreme cold. The cutaneous afferents from the fingertips are particularly important for sensing the direction of pressure vectors required for the dexterous handling of small objects.

Although reports of responses to visual stimuli in the monkey motor cortex have been relatively rare, Wannier and collaborators described such responses unrelated to EMG activity throughout the hand area of area 4. In general, responses to moving visual stimuli are more firmly established neurons in the cat than in the monkey. In contrast, visual motion-related responses have been frequently reported for the hand representation region of the ventral premotor area (PMv). Similarly, auditory evoked responses have been recorded in the cat but not in the hand representation area of the primate.

Force Control and Object Manipulation

The discharge frequency of many motor cortical neurons, including CM cells recorded during static holding, is related to pinch force, or the rate of force increment. However, some neurons actually decrease activity with higher grip force, and these are generally neurons with cutaneous receptive fields. This is not surprising in that the manipulation of a delicate object requires the application of a sufficient grip force to prevent the object from slipping but not so excessive as to either crush the object or expend energy unnecessarily. In addition, the discharge of cutaneous finger-related motor cortical cells increases with the friction or surface roughness of the object against the fingers as well as dynamic changes in the shear force or slip of hand-held objects. During object holding a shear force increase or slip will trigger an increase in motor cortex activity in less than 50 ms on average. As yet the role of motor cortex during tactile exploration has not been examined, but it is likely that the cutaneous motor cortex plays an important role in deploying the contact and sliding forces that optimize the mechanical sensitivity of the fingertip skin as well.

Motor Cortex and Relatively Independent Finger Movements

Although the motor cortex has long been acknowledged to play an important role in the execution of

voluntary independent finger movements, there has been some controversy over the degree of independence in finger movements and whether each finger has its own segregated representation territory within the cortex. This question has been most intensively studied by Scheiber and his colleagues, who trained monkeys to execute flexion and extension movements with each of the five digits. Although thumb flexion and extension was performed without movement of the other digits, the movements of the other four digits were not nearly as autonomous. Single motor cortical neurons were active with movements of each of the different fingers. However, the neurons that discharged during movements of different fingers overlapped extensively, suggesting that finger movement is achieved by a population of neurons distributed rather widely in the hand area rather than by a somatotopically segregated population. This arrangement agrees well with Rathelot and Strick's wide distribution of CM cells within the cortex. Subsequent studies of individual finger movements in patients with well-defined vascular infarcts of the motor cortex or its efferents have demonstrated that movements of the thumb were the least impaired, whereas digits 3, 4, and 5 lost their ability to move separately from one another.

Bimanual Coordination

Many, if not most, skilled hand movements involve the coordinated use of both hands together. Wiesendanger and collaborators have studied a number of bimanual tasks in an attempt to elucidate the particular brain mechanisms responsible for two-handed dexterity. Surprisingly, the primary motor cortices of each hemisphere have few callosal connections between the hand representations although the proximal arm regions are well interconnected. In contrast, the hand areas of the two SMAs are reciprocally connected, and neurons with bimanual-related activity have been found there. Although neurons with activity related to the movement of both arms have been clearly demonstrated, unilateral lesions of the primary motor cortex apparently do not disrupt bimanual coordination as such. Specific deficits in bimanual coordination are more frequently seen in the various forms of apraxia associated with posterior parietal lesions of the nondominant hemisphere.

Cortical Synchronous Activity, Hand Muscles, and Prehension

A number of studies by Lemon and collaborators, in both monkey and humans, have demonstrated synchronous oscillatory activity in motor cortex and in hand muscles during prehensile activity. This oscillatory coherence within a 15–30-Hz band is not confined to the motor cortex and has been reported in both somatosensory cortex and cerebellum. In motor cortex the synchronous activity involves CM cells as well as other corticospinal neurons. The coherence is greater during the steady state holding in a precision grip task than during dynamic grasping or release. What is most intriguing is that the degree of coherence covaries with the degree of compliance of the grasped object and appears to be independent of the grip force or the rate of force change. Coherence was considerably reduced when an isometric grip was exerted on a solid, noncompliant object. At present, the physiological significance of the synchrony is unknown. Nevertheless, maintaining a steady force on a compliant object requires constant monitoring of cutaneous and proprioceptive afferents. Given the spatial segregation of these afferents in the motor cortex mentioned above, the synchronous activity may serve to coordinate and unite their actions on spinal neurons and the muscles of the hand.

Mental Imagery, Cortical Excitability, and Hand Orientation

There seems little doubt that mental imagery, or imagining a hand movement, can increase the excitability of corticospinal neurons. Transcranial magnetic stimulation of the motor cortex has been used to evoke motor-evoked potentials (MEPs) in muscles related to opening or closing the hand as participants were imagining these gestures. The MEPs were larger when an imagined movement involved the muscle as an agonist than when the imagined movement involved the same muscle as an antagonist. Numerous studies have also indicated that the observation of actions done by others (called the mirror neuron system by Rizzolatti and Craighero) activates a number of cortical areas including the motor cortex. How these changes in corticospinal excitability result from observing complex actions of the hand is difficult to assess. However, it appears that observation increases neuronal discharge in the posterior parietal regions and in the PMv that ultimately contributes to increases in corticospinal excitability, as shown by transcranial magnetic stimulation.

It is somewhat easier to understand that the sight of a familiar object evokes a mental image of how it is to be grasped even though the neurons activated in this context are not technically 'mirror neurons.' That is, an object's shape and size dictate the degree of wrist rotation and the shaping of the fingers in

preparation for grasping. Current evidence suggests that the visual preparation for grasping is organized in the posterior parietal area and that the reach-to-grasp commands are relayed through PMv to the motor cortex.

Taste Processing in the Primate Brain

Pathways

This article describes how taste, olfactory, and somatosensory inputs are brought together in the cortex to represent food flavor, and how these representations are influenced by visual and even cognitive inputs. To make the results relevant to understanding these processes and the control of food intake in humans, complementary evidence is provided by neurophysiological studies in nonhuman primates, and by functional neuroimaging studies in humans.

The taste and related olfactory, somatosensory, and visual pathways in primates are shown in Figure 1. Of particular interest is that in primates there is a direct projection from the rostral part of the nucleus of the solitary tract (NTS) to the taste thalamus and thus to the primary taste cortex in the frontal operculum and adjoining insula, with no pontine taste area and associated subcortical projections as in rodents. This emphasis on cortical processing of taste in primates may be related to the great development of the cerebral cortex in primates, with sophisticated processing of each sensory modality before unimodal representations are brought together in multimodal areas to form multimodal representations of objects, such as food.

The Primary Taste Cortex

The primary taste cortex in the primate anterior insula and adjoining frontal operculum contains not only taste neurons tuned to sweet, salt, bitter, sour, and umami as exemplified by monosodium glutamate, but also other neurons that encode oral somatosensory stimuli, including viscosity, fat texture, temperature, and capsaicin. Some neurons in the primary taste cortex respond to particular combinations of taste and oral texture stimuli, but do not respond to olfactory stimuli or visual stimuli such as the sight of food. Neurons in the primary taste cortex do not represent the reward value of taste, that is, the appetite for a food, in that their firing is not decreased to zero by feeding the taste to satiety. Corresponding areas are activated by taste and oral texture in humans.

The Secondary Taste Cortex

A secondary cortical taste area in primates was discovered in the orbitofrontal cortex (OFC), extending several millimeters in front of the primary taste cortex. In addition to neurons responding to the same taste and oral somatosensory stimuli, including viscosity, fat texture, temperature, and capsaicin, as in the primary taste cortex, some OFC neurons respond to water in the mouth, and others to the somatosensory stimuli astringency as exemplified by tannic acid, and to capsaicin. In the OFC, it has been shown in monkeys that responses of the neurons to the taste of glucose decreased to zero while the monkey ate glucose to satiety, during the course of which the feeding behavior of the monkey changed from avid acceptance to active rejection. These OFC neurons thus have activity related to the reward value of food.

Representation of Flavor: Convergence of Olfactory and Taste Inputs

At some stage in taste processing, it is likely that taste representations are brought together with inputs from different modalities, for example, with olfactory inputs to form a representation of flavor (see Figure 1). In the OFC, some neurons are unimodal for taste, olfactory, or visual inputs, but others respond to combinations of these inputs. Some of the multimodal single neurons had corresponding sensitivities in the two modalities, in that they responded best to sweet tastes (e.g., 1 M glucose) and also responded more in a visual discrimination task to the visual stimulus which signified sweet fruit juice than to that which signified saline, or responded to sweet taste and in an olfactory discrimination task to fruit odor.

Olfactory inputs become associated with taste inputs to represent flavor by olfactory-to-taste association learning. This has been shown by reversing the taste with which an odor is associated, and this has been found to produce slow changes of the odor to which a neuron responds, taking typically 40 trials in primates, as illustrated in Figure 2. Thus flavor, represented by taste–olfactory convergence, is relatively stable. Thus for some neurons in the OFC the neuronal response to the odor depends on the taste with which it is associated and does not depend primarily on the physicochemical structure of the odor. These findings demonstrate directly a coding principle in primate olfaction whereby the responses of some OFC olfactory neurons are modified by, and depend upon, the taste with which the odor is associated. This convergence can be detected in human functional magnetic resonance imaging (fMRI) studies by supralinear responses to a flavor compound (such as sweet taste and strawberry odor), compared to the sum of the components presented separately. Similarly, Small and colleagues also found supradditive interactions between

Figure 1 Schematic diagram of the taste and olfactory pathways in primates, showing how they converge with each other and with visual pathways. The gate functions shown refer to the finding that the responses of taste neurons in the orbitofrontal cortex and the lateral hypothalamus are modulated by hunger. VPMpc, ventral posteromedial thalamic nucleus; VPL, ventral posterolateral thalamic nucleus; V1, V2, and V4, visual cortical areas.

congruent taste and smell stimuli in areas including the caudal OFC and anterior cingulate cortex (ACC).

In humans, in addition to activation of the pyriform (olfactory) cortex, there is strong and consistent activation of the OFC by olfactory stimuli. In an investigation of where the pleasantness of olfactory stimuli might be represented in humans, O'Doherty and colleagues showed that the activation of an area of the OFC by banana odor was decreased (relative to a control vanilla odor) after bananas were eaten to satiety. Thus activity in a part of the human OFC olfactory area is related to sensory-specific satiety, and this is one brain region where the pleasantness of odor is represented.

An important issue is whether there are separate regions of the brain, discriminable with fMRI, that represent pleasant and unpleasant odors. To investigate this, we measured the brain activations produced by three pleasant and three unpleasant odors. The pleasant odors chosen were linalyl acetate (floral, sweet), geranyl acetate (floral), and α-ionone (woody, slightly food-related). (Chiral substances were used as racemates.) The unpleasant odors chosen were hexanoic acid, octanol, and isovaleric acid. We found that they activated dissociable parts of the human brain. Pleasant but not unpleasant odors were found to activate a medial region of the rostral OFC. Further, there was a correlation between the subjective pleasantness ratings of the six odors and activation of a medial region of the rostral OFC. In contrast, a correlation between the subjective unpleasantness ratings of the six odors was found in regions of the left and more lateral OFC.

Representation of Flavor: Convergence of Visual Inputs with Taste, Olfactory, and Oral Texture Inputs

Visual stimuli such as the sight of food can produce responses in some OFC neurons that have taste or

Figure 2 Orbitofrontal cortex: olfactory to taste association reversal. (a) The activity of a single orbitofrontal olfactory neuron during the performance of a two-odor olfactory discrimination task and its reversal is shown. Each point represents the mean poststimulus activity of the neuron in a 500 ms period on approximately 10 trials of the different odorants. The standard errors of these responses are shown. The odorants were amyl acetate (closed circle) (initially S–, that is, associated with the taste of saline) and cineole (open circle) (initially S+, that is, associated with the taste of glucose). After 80 trials of the task, the reward associations of the stimuli were reversed. This neuron reversed its responses to the odorants following the task reversal. (b) The behavioral responses of the monkey during the performance of the olfactory discrimination task. The number of lick responses to each odorant is plotted as a percentage of the number of trials for that odorant in a block of 20 trials of the task. Rolls ET, Critchley H, Mason R, and Wakeman EA (1996) Orbitofrontal cortex neurons: Role in olfactory and visual association learning. *Journal of Neurophysiology* 75: 1970–1981.

olfactory inputs. The visual inputs are associated by learning with the taste inputs to a neuron, and this learning can be very fast, in as little as one trial. This enables prediction of the taste associated with ingestion of what is seen, and thus in the visual selection of foods. This representation also provides a way for the sight of a food to influence the flavor of a food. Oral temperature, which can also affect the palatability of a food, also influences the responses of OFC neurons, and indeed some of these neurons are tuned to oral temperature.

Representation of the Pleasantness and Reward Value of Flavor in the Brain

The responses of OFC neurons to the taste, olfactory, visual, and/or oral texture components of food flavor all show a reduction that is correlated with the decrease in the reward value of food. This reflects probably an influence of satiety signals, including gastric distension, on the responses of these neurons. An additional effect is a sensory-specific reduction in the responses of these neurons after feeding to satiety with a food, and this is likely to be computed in the orbitofrontal cortex, and to be important in which foods are eaten in a meal and in the control of food intake.

To assess how satiety influences the brain activations to a whole food which produces taste, olfactory, and texture stimulation, we measured brain activation by whole foods before and after the food is eaten to satiety. The aim was to show, using a food that has olfactory, taste, and texture components, the extent of the region that shows decreases when the food becomes less pleasant, in order to identify the different brain areas where the pleasantness of the odor, taste, and texture of food is represented. The foods eaten to satiety were either chocolate milk or tomato juice. A decrease in activation by the food eaten to satiety relative to the other food was found in the OFC but not in the primary taste cortex. This study provided evidence that the pleasantness of the flavor of food, and sensory-specific satiety, are represented in the OFC.

Cognitive Effects on Representations of Food

Brie can smell pleasant. However, the same odor taken out of the context of cheese might be unpleasant. There is evidence that the sight (including color) of a food or wine can influence its flavor. However, what about a more cognitive influence, such as a word? Can this influence the perception and hedonics of food-related stimuli, and if so, how far back down into the sensory system does the cognitive influence reach? To address this, we performed an fMRI investigation in which the delivery of a standard test odor (isovaleric acid combined with cheddar cheese flavor, presented orthonasally using an olfactometer) was paired with a descriptor word on a screen, which on different trials was 'cheddar cheese' or 'body odor.' The subjects rated the pleasantness and the intensity of the odor on every trial. α-Ionone (pleasant, labeled 'flowers') and octanol (unpleasant, labeled 'burned plastic') were used as reference pleasant and unpleasant stimuli for the psychophysics and neuroimaging.

Figure 3 Cognitive influences on olfactory representations in the human brain. Group (random) effects analysis showing the brain regions where the BOLD signal was correlated with pleasantness ratings given to the test odor. The pleasantness ratings were being modulated by the word labels. (a) Activations in the rostral anterior cingulate cortex, in the region adjoining the medial OFC, shown in a sagittal slice. (b) The same activation shown coronally. (c) Bilateral activations in the amygdala. (d) These activations extended anteriorly to the primary olfactory cortex. The image was thresholded at $p < 0.0001$ uncorrected in order to show the extent of the activation. (e) Parametric plots of the data averaged across all subjects, showing that the percentage BOLD change (fitted) correlates with the pleasantness ratings in the region shown in (a) and (b). The parametric plots were very similar for the primary olfactory region shown in (d). PST, poststimulus time (in seconds). (f) Parametric plots for the amygdala region shown in (c). Adapted from de Araujo IET, Rolls ET, Velazco MI, et al. (2005) Cognitive modulation of olfactory processing. *Neuron* 46: 671–679.

Subjects rated the affective value of the test odor as significantly more unpleasant when labeled 'body odor' than when labeled 'cheddar cheese'. We found that the medial OFC/rostral ACC was significantly more activated by the test stimulus labeled 'cheddar cheese' than when labeled 'body odor,' and that these activations were correlated with the pleasantness ratings (see Figure 3). This cognitive modulation was also found in the medial amygdala olfactory area, and this extended toward the olfactory tubercle. Thus cognitive modulation extends into the olfactory system as far down as the secondary olfactory cortex, in the orbitofrontal cortex, and may even influence some parts of the primary olfactory areas, such as the olfactory tubercle. The implication is that cognitive factors can have profound effects on our responses to the hedonic and sensory properties of food, in that these effects are manifest quite far back into sensory processing, so that at least hedonic representations of odors are affected, and even perceptual representations may be modulated.

The Amygdala

These oral sensory properties of food, and also the sight and smell of food, are also represented in the primate amygdala. Interestingly, the responses of these amygdala neurons do not correlate well with the preferences of the macaques for the oral stimuli, and feeding to satiety does not produce the large reduction in the responses of amygdala neurons to food that is typical of OFC neurons. O'Doherty and co-workers showed that the human amygdala was as much activated by the affectively pleasant taste of glucose as by the affectively negative taste of NaCl, and thus provided evidence that the human amygdala is not especially involved in processing aversive as compared to rewarding stimuli.

Conclusions

Food flavors, and the subjective flavor complements, including the consonance of food taste and olfactory components, are represented in primates, including humans, only after several stages of analysis. First the representation of the taste of the food (its identity and intensity) is made explicit in the primary taste cortex. In the pyriform (primary) olfactory cortex, the intensity of an odor, and not its pleasantness or taste, is represented. The OFC is where multimodal representations of food are built, which include taste, texture, olfactory, oral temperature, and visual components.

Although representations of the taste and texture of food are found in the primate (including human) amygdala, the primate OFC is more closely related to the changing affective value of food than the amygdala is, in that the OFC shows responses that decrease to zero as the reward decreases to zero with satiety, and in that the OFC tracks (and probably computes) the changing reward value of stimuli as they are altered by stimulus–reinforcer association learning and reversal.

It is thus becoming possible to start to understand how smell, taste, and other stimuli combine to represent flavor in the brain. Although functional neuroimaging with its spatial resolution of several millimeters shows that some of these representations are close together in the human medial orbitofrontal cortex, the primate neurophysiology provides clear evidence for the exquisitely rich and separate representations of different types of sensory input, because each neuron in this region is tuned to one or to a unique combination of the range of food-related stimuli described here. The information relevant to the control of food intake concerning the sensory properties of foods is thus made explicit in the firing-rate profiles of single neurons and groups of single neurons to the sensory stimuli. It is at the neuron level that brain computations are performed and that the information being transmitted between the computing elements of the brain, the neurons, can be measured by the spiking activity. By making models of the computations taking place in networks of neurons at the spiking neuron level, it is now possible, by integration over the energy required for the activated neurons, to predict signals at a much more global level of functional neuroimaging in humans. By combining information from the neuron and functional imaging level, we are beginning to understand the details of the neuronal operations that underlie the representation of food in the brain, and what makes food pleasant when we are hungry.

The outputs of the OFC reach brain regions such as the striatum, cingulate cortex, and dorsolateral prefrontal cortex, where behavioral responses to food may be elicited because these structures produce behavior that makes the OFC reward neurons fire, as they represent a goal for behavior. At the same time, outputs from the OFC and amygdala, in part via the hypothalamus, may provide for appropriate autonomic and endocrine responses to food to be produced, including the release of hormones such as insulin.

Floor Plate Patterning of Ventral Cell Types: Ventral Patterning

Introduction

Interest in understanding the patterning of the vertebrate neural tube stems from its complex yet highly organized structure and its central role in the life and behavior of animals. Here we concentrate on the strategies and molecular mechanisms by which neuronal subtype identity is assigned in ventral regions of the spinal cord – the region of the central nervous system (CNS) that contains the neurons which control and coordinate motor output. At early stages of embryonic development, five distinct subtypes of neurons can be molecularly identified in the ventral spinal cord; among these are four types of interneurons (V0–V3) and somatic motor neurons (MNs). Each neuronal population arises from blocks of proliferating progenitors that occupy stereotyped locations along the dorsal/ventral axis of the neural tube (Figure 1). These domains of progenitor cells can be distinguished by their expression of distinct molecular markers, including a set of transcription factors, notably homeodomain-containing (HD) proteins and basic helix–loop–helix (bHLH) proteins. The combinatorial expression profile of these proteins delineates five populations of progenitor cells, each of which generates one of the identified neuronal subtypes; consequently, the early spinal cord develops as a dorsal/ventral array of neuronal subtypes. We review the mechanisms involved in the establishment of this pattern of neurogenesis; in particular, we describe the function of the Sonic hedgehog (Shh) signaling pathway, which appears to act as a graded morphogen in the ventral neural tube to control pattern formation.

Evidence That Notochord-Secreted Signals Pattern the Dorsoventral Axis of the Neural Tube

Studies initiated in the 1920s suggested that, rather than containing intrinsic self-organizing capacity, the major determinant of dorsoventral (D/V) polarity is the mesoderm surrounding and underlying the neural tube. From these studies, the notochord was identified as one of the mesodermal structures from which instructive signal(s) emanate that direct D/V patterning of the developing neural tube (Figure 2). In the absence of the notochord, floor plate cells – the characteristic wedge-shaped cells that are generated at the ventral midline of the neural tube – were missing, whereas in embryos containing two notochords a duplication of floor-plate-like structures was evident.

The same principles were reinforced in subsequent experiments using chick embryos, from the 1950s onward. Moreover, these experiments indicated that contact between the notochord and neural tube was essential for floor plate formation. Ensuing experiments in which extra notochords were grafted into chick embryos confirmed the inductive effect on the floor plate, and added an extra dimension; neuroblasts (presumptive motor neurons) were also induced by the notochord but at a distance from the position of the graft (Figure 2(b)). In addition, the floor plate was found to display similar inductive properties to the notochord, indicating that the floor plate also has capacity to promote the generation of both more floor plate cells and MNs. These experiments led to the conclusion that the notochord and floor plate are the source of a signal(s) that induced different cell types and that the distance from the source of this signal(s) determines the cell type generated.

Shh Patterning of the Neural Tube

We now know a considerable amount about the molecules involved in D/V patterning and the understanding of their action relies to a significant degree on the foundation provided by these early embryological experiments. In the search for the signal providing instructive cues to the ventral neural tube, a secreted protein, Sonic hedgehog, was identified. This protein is an ortholog of the *Drosophila* segment polarity gene product, Hedgehog (Hh), a signaling molecule involved in the development of several embryonic tissues. Consistent with this, Shh is expressed in many developing tissues, including the notochord and floor plate. The period when Shh is expressed in these structures corresponds to the time when neural tube polarity is being established. Since the discovery of the Hh family of signaling molecules, much effort has been employed in identifying the components of the signaling pathway, and an understanding of the mechanism of signal transduction is beginning to emerge. Transduction depends on two transmembrane proteins: Patched 1 (Ptc1), the receptor which binds Hh proteins, and Smoothened (Smo), which is responsible for transmitting Hh signals intracellularly (see later).

A range of loss-of-function experiments support the idea that Shh corresponds to the signal that

provides instructive cues to control the generation and arrangement of distinct neuronal populations in the neural tube. In mouse embryos harboring a targeted null allele of Shh, there is a loss of MNs and other ventral interneuron subtypes; concomitantly molecular markers normally restricted to dorsal aspects of the spinal cord expand toward the ventral midline. Furthermore, antibodies raised against Shh that block its ability to bind Ptc1 also disrupt patterning of the ventral neural tube and inhibit the ability of notochord to induce ventral neuronal subtypes. Together, these studies suggest that production of Shh is necessary for correct formation of ventral neuronal subtypes *in vivo*.

Figure 1 Organization of the ventral neural tube: progenitor domains and ventral neuronal cell types and their fates in the spinal cord (schematic of the ventral half of the neural tube). Five progenitor domains are found in stereotyped positions within the ventricular zone of the ventral neural tube, lying dorsal to the floor plate (FP). These progenitor domains – p0, p1, p2, p3, and pMN – will generate the corresponding neuronal cell types – V0 to V3 interneurons and motor neurons (MN) – involved in motor output control.

Experiments carried out *in vitro* using explants of naive neural tissue provided further understanding of the mechanism of Shh activity. These studies indicated that exposure to varying concentrations of Shh protein induced the populations of neurons characteristic of the ventral neural tube. Incremental two- to threefold changes in Shh concentration led to the generation of different neuronal subtypes; moreover, a correlation between the *in vitro* concentration of Shh necessary to induce each neuronal class and their position of generation *in vivo* was apparent (Figure 3). Thus, neurons generated in progressively more ventral regions of the neural tube required correspondingly higher Shh concentrations for their induction. These data indicated that in addition to being necessary for their development, Shh is sufficient to induce ventral interneurons and motor neurons in neural tissue, suggesting that Shh functions in a graded manner to impart positional identity. Thus, cells in the ventral neural tube are exposed to a ventral^{HIGH}–dorsal^{LOW} concentration gradient of Shh, and the concentration of Shh to which a progenitor cells is exposed determines the neuronal subtype generated (Figure 3).

A key prediction of this model is that Shh should operate as a long-range signal, acting directly on cells at a distance from its source. Several lines of evidence indicate that this is indeed the case. First, Shh protein is detectable several cell diameters away from the producing cells of the floor plate (Figure 3). Second, a dominant active version of Smo, a component of the signaling pathway, is sufficient to induce ectopic expression of ventral markers in the neural tube. Third, blockade of Shh signaling, by either cell autonomous removal of Smo or ectopic expression of a mutated version of Ptc1 (the Shh receptor) that acts as a dominant inhibitor of signaling, blocks the generation of ventral neurons, which instead develop

Figure 2 Notochord-secreted signal(s) influence patterning of the neural tube. (a) The notochord (n) is an axial mesodermal structure that underlies the caudal neural tube. The floor plate is formed in the ventral neural tube, close to the notochord, and motor neurons are generated in the ventral horns of the spinal cord, at a distance from the notochord. (b) Grafting an ectopic notochord next to the neural tube induces an ectopic floor plate at a short distance, whereas at a greater distance excess motor neurons are generated. These experiments suggest the existence of an instructive secreted signal(s) from the notochord that can control the patterning of the ventral neural tube.

Figure 3 Sonic hedgehog (Shh) diffuses in the ventral neural tube and controls neuronal cell fate in a concentration-dependent manner. (a) Staining for Shh in E10.5 mouse embryo. Shh protein can diffuse through the ventral half of the neural tube to establish a ventral-to-dorsal gradient (high levels of protein are detected in the Shh-secreting floor plate and lower levels in the intermediate neural tube). (b) Schematic of Shh distribution, illustrating the graded distribution of the protein in the developing neural tube, together with the relative position of newborn ventral neuronal cell types (interneurons, V0–V3; motor neurons, MN). (c) Naive neural plate chick explants can generate the five ventral neuronal cell types, depending on exposure to Shh. Two- to threefold increments in Shh concentration allow the induction of ventral interneurons and motor neurons, suggesting that Shh protein is acting as a morphogen, patterning the ventral neural tube. (a) Reproduced with permission from Gritli-Linde A, Lewis P, McMahon AP, et al. (2001) The whereabouts of a morphogen: Direct evidence for short- and long-range activity of hedgehog signaling peptides. *Developmental Biology* 236: 364–386.

with characteristics of neurons located in the dorsal neural tube. Together, these results suggest that Shh acts directly on cells at a distance through its receptors, rather than indirectly through a relay signal.

A Transcription Factor Code and Neural Cell Fate

The ability of graded Shh signaling to directly control D/V patterning in the ventral neural tube raised the question of how positional identity is imposed on progenitor cells and how this determines neuronal subtype identity. Progenitors respond to Shh signaling by regulating the expression of a series of transcription factors, which, with the exception of the bHLH protein Olig2, are members of the homeodomain protein family, including Pax7, Pax3, Dbx1, Dbx2, Pax6, Nkx2.2, Nkx2.9, Nkx6.1, Nkx6.2, and Irx3. These transcription factors play a crucial part in patterning the ventral neural tube and can be split into two groups according to their response to Shh: class I, the genes of which are repressed by Shh signaling, and class II, the genes of which are activated by Shh (Figure 4(a)). Furthermore, within the same class, genes respond in a concentration-dependent manner to Shh, such that the repression of class I genes with more ventral limits of expression requires higher levels of Shh signaling compared to more dorsally restricted class I genes. Conversely, class II proteins that have a broad domain of expression in the ventral neural tube are induced by lower concentrations of Shh than are class II proteins that have a more ventral limit of expression. In addition, class I and class II genes can be grouped in pairs based on two prerequisites: (1) the ventral limit of expression of a class I protein coincides with the dorsal limit of the paired class II protein and (2) the pair of class I and class II factors display mutual cross-repression.

Graded Shh Controls Class I and Class II Protein Expression

Evidence that graded Shh signaling establishes the transcription factor code emerged from studies of the expression patterns of Nkx2.2 and Pax6. In the developing ventral neural tube, the class I protein Pax6 and the class II protein Nkx2.2 have a mutually exclusive expression pattern, with the most ventral progenitors expressing Nkx2.2, while Pax6 is expressed in progenitors situated dorsal to the boundary of Nkx2.2 (Figure 4(a)). *In vitro* experiments demonstrated that the expression of both of these proteins is regulated by Shh signaling in a concentration-dependent manner. In the absence of Shh, explants express Pax6; exposure to concentrations of Shh above a given threshold results in the repression of Pax6 and the concomitant induction of Nkx2.2. Importantly, the mutually exclusive relationship between Pax6 and Nkx2.2 is

Figure 4 A transcription factor code and patterning of the ventral neural tube. (a) Combinatorial expression of homeodomain-containing (HD) proteins Pax, Irx3, Nkx, and Dbx, together with the basic helix–loop–helix transcription factor Olig2, distinguishes five ventral progenitor domains in the caudal neural tube. HD proteins can be subdivided into two groups according to their response to Sonic hedgehog (Shh) signaling, class I (brown) and class II (orange) proteins, which are inhibited or activated by Shh, respectively. Cross-repression between selected pairs of proteins controls the formation of boundaries between progenitor domains. (b) Cross-repression between pairs of HD proteins controls ventral neural tube patterning. Compared with wild-type embryos (i), in the absence of Pax6 (Sey/Sey; ii), there is a dorsal expansion in Nkx2.2 expression (1) that leads to the inhibition of Olig2 expression (2) and results in the absence of the motor neuron progenitor (pMN) domain and a concomitant expansion of the p3 domain. Conversely, in the absence of Nkx2.2 (iii), there is a ventral expansion of Olig2 (3), but not of Pax6 (4; see text for more details), leading to an expansion of pMN at the expense of p3. Another example of a pair of HD proteins is illustrated with Nkx6.1 and Dbx2 (iv). In double mutants lacking Nkx6.1 and Nkx6.2 (Nkx6$^{-/-}$), there is a ventral expansion of Dbx2 (5) and a downregulation of Olig2 (6). As a consequence, p2, pMN, and p3 domains are lost and p1 progenitors occupy most of the ventral spinal cord. There is also a sporadic expression of Dbx1 (blue circles) in this ectopic p1 domain due to the loss of inhibition by Nkx6.2 (RP, roof plate; pD, dorsal spinal cord domain). Expression patterns of Irx3, Pax6, and Nkx2.2 in these mutants have not been determined.

maintained in these experiments in a cell autonomous manner. Furthermore, addition of anti-Shh antibodies promotes Pax6 expression and inhibits Nkx2.2 expression, even in the presence of Shh. Similar findings have been documented for other class I and class II proteins. Additional signaling molecules have also been implicated in modulating the expression of the progenitor-expressed

transcription factors (see later) and these may act by either influencing the Shh signal transduction pathway or by directly regulating target gene expression.

Cross-Repression between Class I and Class II Proteins Establishes the Mutually Exclusive Expression Profiles

The regulation of class I and class II protein expression by graded Shh signaling is not alone sufficient to explain how the discrete, sharp boundaries of gene expression arise in the neural tube. Gain- and loss-of-function studies indicate that selective cross-repressive interactions between pairs of class I and class II proteins expressed in adjacent domains are important for establishing the all-or-none changes in gene expression that characterize progenitor domain boundaries. This first became apparent for Nkx2.2 and Pax6. Gain-of-function experiments indicate a cross-repressive interaction between Pax6 and Nkx2.2. Moreover, expression of Nkx2.2 expands dorsally in mutant mice lacking Pax6 (Figure 4(b)). This results in a decrease in MN production coupled with an expansion in Nkx2.2-produced V3 neurons. Pax6 is therefore required for accurate positioning of the boundary between MN and V3 progenitors, and for correct production of the neurons from these progenitors. The absence of Pax6 also results in defects in the generation of other ventral neuronal subtypes, in particular V1 and V2 neurons, suggesting that Pax6 has further roles in the control of neuronal subtype identity in the neural tube. Additional studies indicated that in embryos lacking Nkx2.2 there was a loss of V3 neuronal subtype identity, and a ventral shift in the MN progenitor marker Olig2 and subsequently in the generation of MNs (Figure 4(b)). Pax6 expression remained unchanged, however, possibly due to the presence of Nkx2.9, another Nkx family member, which is expressed in a similar domain to Nkx2.2.

Evidence from a second set of class I and class II proteins lends support to the idea of reciprocal cross-repressive interactions. The class II proteins Nkx6.1 and Nkx6.2 adjoin the ventral boundaries of the class I proteins Dbx2 and Dbx1, respectively (Figure 4(a)). In double-knockout embryos lacking both Nkx6 proteins, a ventral expansion of Dbx2 expression was evident (Figure 4(b)). Furthermore, forced expression of Nkx6.1 cell autonomously repressed Dbx2. Conversely misexpression of Dbx2 resulted in the down-regulation of Nkx6.1. A similar relationship between a third pair of proteins, Olig2 and Irx3, is also apparent (Figure 4(a)). With the exception of Pax6, the class I and class II proteins act as transcriptional repressors in neural progenitors, raising the possibility of direct interactions between the proteins and promoters of class I and class II genes.

Control of Neuronal Identity by Graded Shh Signaling

The regulation of class I and class II proteins ultimately leads to the establishment of the progenitor domains p0, p1, p2, pMN, and p3, defined by the expression of distinct combinations of transcription factors, which generate the five neuronal subtypes (Figure 4(a)). Gain- and loss-of-function experiments support the hypothesis that the progenitor transcription factor expression profile specifies the identity of neurons generated from each progenitor domain. The forced expression of a class I or class II protein in the neural tube and targeted inactivation of individual class I or class II proteins change the fate and position of generation of individual neuronal subtypes in a manner predicted by the normal profile of transcription factor expression.

Overall, these studies suggest a model to explain ventral patterning of the neural tube. Crucially, the initial activation or repression of the class I and class II proteins by graded Shh signaling imparts positional identity to progenitor cells. The reciprocal repression between pairs of class I and class II proteins provides a mechanism to convert the gradient of Shh signaling into discrete all-or-none changes in gene expression that may account for the formation of sharp boundaries between adjacent progenitor domains. Each domain then generates a specific neuronal subtype. The repressive interactions between progenitor expressed transcription factors could also serve to consolidate progenitor domain identity, relieving a requirement for a prolonged period of Shh signaling to maintain gene expression domains. Significantly, *Drosophila* orthologs of several of the class I and class II proteins have been demonstrated to play a similar role in allocating regional identity in ventral nerve cord of the developing embryo, raising the possibility that this strategy represents a fundamental feature of nervous system patterning of many extant animals.

Additional Signals Involved in Dorsoventral Patterning of the Neural Tube

Although the evidence confirms the importance of Shh signaling in controlling spatial patterning within the neural tube, other extracellular signals also contribute to correct D/V patterning. During neural induction, progenitors are exposed to fibroblast growth factors (FGFs), originating from the presomitic mesoderm, the regressing node, and the neural plate. FGF signaling acts as an inhibitor of neural differentiation, ensuring cells remain progenitors. FGFs also inhibit the expression of many of the

progenitor transcription factors and it is not until cells have emerged from the influence of FGFs that they mature and begin to express class I and class II proteins. Conversely, retinoic acid (RA) is expressed anteriorly to FGF, in paraxial mesoderm adjacent to the neural tube, and RA is necessary for neural differentiation and progenitor transcription factor expression. RA promotes class I protein expression, therefore counteracting the ventralizing effects of Shh. A third signaling pathway is also implicated in D/V patterning – bone morphogenetic proteins (BMPs). Several members of the BMP family are expressed in the dorsal pole of the neural tube, where they play a role in specifying dorsal neuronal fates. In addition, BMP proteins appear to oppose Shh-mediated ventralization of the neural tube, limiting the dorsal extent of the ventral neural tube. Hence, precise coordination of ventral neural patterning depends on the complex interplay between several signaling pathways, the details of which are only now beginning to be understood.

Formation and Maintenance of Shh Gradient

The central role of graded Shh signaling in the control of D/V patterning in the neural tube has focused attention on how the production and distribution of Shh are regulated. For this, knowledge of the concentration and shape of the gradient is required; parameters such as the rate at which Shh is released from its source, the speed of its spread, and its stability are necessary but difficult to obtain in embryos *in vivo*. Additional complexity to this problem is introduced by the attachment of lipid moieties to Shh and the presence of extracellular proteins that bind to Shh.

Posttranslational Modification and Release of Hedgehog Proteins

The Hh precursor protein is posttranslationally processed to a mature Hh protein by an autocatalytic cleavage that removes the carboxyl (C)-terminus. As part of this reaction, a cholesterol moiety is covalently attached to the C-terminal end of the processed protein. Shh is also acylated on its amino (N)-terminus, for example, by addition of palmitate; the end result is a Shh protein linked to two hydrophobic groups. Although these posttranslational modifications are not absolutely required for Hh activity, as illustrated by the induction of several Hh-target genes with recombinant forms of Shh that lack lipid moieties, the lipid modifications appear to affect the spread and/or activity of Shh in neural tissue. The secretion of cholesterol modified Hh appears to require the transmembrane protein, Dispatched-1 (Disp1), as mutations in this gene result in alterations in neural tube patterning consistent with a lack of Shh released. Palmitoylation of Shh also appears essential in vertebrate neural tissue. Prevention of palmitate addition to Shh protein by mutation of the target cysteine (Shh^{C25S}) leads to a severe deficiency in ventral neural tube patterning, reminiscent of embryos lacking Shh protein. Similar effects are also observed in mice deficient in Skn, the murine ortholog of the product of the *Drosophila ski* gene, which catalyzes Hh palmitoylation. Thus, the hydrophobic modifications of Shh have important and complex effects on Shh function *in vivo*.

Hedgehog-Binding Proteins and Feedback Loops

In addition to lipidation, Hh-binding proteins also modify Hh activity. One important regulatory strategy used by many signaling systems is negative feedback, where signal transduction leads to upregulation of inhibitors of the pathway to attenuate signaling. Hh uses such feedback regulation and inhibition is mediated by several Hh-binding proteins. Among these are Hh receptor Ptc1 and an additional protein, Hh-interacting protein 1 (Hhip1). Both Ptc1 and Hhip1 are upregulated by Shh signaling in the ventral neural tube (**Figures 5(a) and 5(b)**). Evidence that upregulation of Ptc may be involved in limiting the spread of Hh proteins initially came to light in experiments in *Drosophila* which demonstrated an extended range of Hh in the absence of Ptc. Similar observations were later made in the vertebrate neural tube, where a dorsal-to-ventral change in neural fate was noted in cells dorsal to clusters of cells unable to respond to Hh. Elegant studies in mouse subsequently documented the role Ptc1- and Hhip1-mediated Shh sequestration plays in patterning the ventral neural tube (**Figure 5(c)**). In these experiments, a transgenic mouse strain expressing a low basal level of Ptc1 from a heterologous promoter (MtPtc1) was used. This was sufficient to suppress unregulated Smo activity; however, in the absence of endogenous Ptc1 and Hhip1 genes, MtPtc1 failed to restrain the range of Shh signaling, resulting in a ventralization of the neural tube (**Figure 5(c)**). Thus, the upregulation of Ptc1 and Hhip1 in response to Shh signaling normally acts to limit the range over which the ligand can diffuse (**Figure 5(b)**). The appearance of intermediate phenotypes in compound heterozygote mutants for both Ptc1 and Hhip1 indicates that this mechanism utilizes both Ptc1 and Hhip1 in a dose-dependent manner.

Two further transmembrane Hh-binding proteins, Cdo and Boc, have been identified as both targets and regulators of Shh signaling. Both are expressed in the dorsal spinal cord – a domain with low level of Ptc1

Figure 5 Regulation of the Sonic hedgehog (Shh) gradient is important for dorsoventral patterning of the neural tube. (a) Shh is expressed by the notochord (not shown) and the floor plate. Shh-binding proteins are found along the dorsoventral axis of the neural tube; Smoothened (Smo) and Patched1 (Ptc1) are expressed in a ventral-to-dorsal gradient in the spinal cord, together with Hhip1, found in the ventralmost part of the spinal cord. Cdo and Boc are expressed in the dorsal spinal cord; in addition, Cdo is also expressed in the floor plate. (b) Schematic of the control of the Shh gradient by the negative feedback loop triggered by Shh-binding proteins Ptc1 and Hhip1. Shh signaling enhances the expression of its receptors Ptc1 and Hhip1 through Gli transcriptional activators (GliA). The more Shh signaling received by a cell, the more it will increase the expression of Ptc1 and Hhip1. As a result, cells located near the source of Shh express higher levels of Ptc1 and Hhip1 (and also GliA) compared to cells located far away from the Shh source. The two Shh-binding proteins sequester Shh, thus limiting the range of Shh spread. (c) Abrogating the production and posttranslational modifications of Shh results in a dramatic dorsalization of the neural tube as observed in Shh$^{-/-}$ mice or mutants lacking Shh palmitoylation (Shh^{C25S} and Skn$^{-/-}$). In the absence of Ptc1, there is high Shh activity along the dorsoventral axis due to the lack of Smo inhibition. This is not observed in Hhip1$^{-/-}$ embryos. When Ptc1 is ubiquitously expressed at low level under the control of the metallothionein promoter (MtPtc1) and Ptc1/Hhip1 ligand-dependent antagonism is abolished, the distance of Shh spread is increased and consequently ventralization of the spinal cord results. This phenotype is dependent on the quantity of Hhip1, as illustrated by the comparison between MtPtc1;Ptc1$^{-/-}$ with MtPtc1;Ptc1$^{-/-}$;Hhip$^{+/-}$ and MtPtc1;Ptc1$^{-/-}$;Hhip$^{-/-}$. In parallel, this perturbation in Shh gradient decreases the precision in ventral patterning, as the boundary between p3 and pMN is less precise. There is also a lack of precision in the boundary between the floor plate (FP) and the p3 domain in the absence of Cdo, together with a reduction of the FP and a ventral expansion of the p3 domain. RP, roof plate; pD, dorsal spinal cord domain; pMN, motor neuron progenitor.

and Hhip1 – and Cdo is also expressed in the floor plate (Figure 5(a)). Gain- and loss-of-function experiments indicate that Cdo and Boc cell autonomously enhance Hh signaling. Given their expression profiles, it is possible that Cdo increases Shh signaling where the highest Shh signaling levels are required (e.g., in the floor plate). Conversely, at the fringes of the Hh target field (e.g., in intermediate and dorsal regions of the neural tube), where Ptc1 and Hhip1 levels are expected to be low, Cdo and Boc may sensitize cells to even low levels of Shh protein. Ectopic expression of Cdo and Boc led to a non-cell autonomous expansion of dorsal genes in cells lying dorsal to expressing cells, consistent with the idea that these proteins bind Shh, impeding its ability to spread further through tissue. Together, these data begin to indicate that the extracellular spread of Shh is the subject of finely controlled regulation which establishes the appropriate distribution of Shh that ensures the accurate supply of positional information to progenitors residing in the ventral neural tube.

Intracellular Mediators of Shh-Dependent Neural Tube Patterning: A Major Role of Gli Proteins

In receiving cells, intracellular signal transmission depends on two transmembrane proteins: Patched 1 (Ptc1), as already mentioned, the receptor which binds Hh proteins, and Smoothened (Smo), which is responsible for transducing Hh signals intracellularly (Figure 6(a)). In the absence of Shh, Ptc1 inhibits Smo activity, and binding of Shh to Ptc1 releases this inhibition, allowing intracellular signal transduction. Although the exact mechanism of signal transmission downstream of Smo is still the subject of study, several key components of the pathway have been identified. In vertebrates, Suppressor of Fused (Sufu) has a central role in Shh signaling, as gene disruption of Sufu in mice leads to potent ligand-independent activation of the Hh pathway, mimicking the defect in neural tube patterning observed in Ptc1 mutant embryos. Several other factors, including Rab23 (a vesicle transport family protein) and a number of factors involved in the assembly and/or function of a cell's primary cilium, have also been implicated in Shh signal transduction.

Gli Proteins and Dorsoventral Patterning

Although the mechanism of signal transduction remains to be clarified, the evidence suggests that the signal culminates in the regulation of a family of zinc finger-containing transcriptional effectors known, in vertebrates, as the Gli transcriptional regulators (Gli1, 2, and 3). These control target gene expression. All three Gli genes are expressed in the neural tube and several studies have begun to examine the regulation of Gli gene activity and the roles they play in neural tube patterning. Gli1 is expressed in the ventralmost neural tube, and its expression is dependent on Shh signaling. Gli1 appears to act solely as a transcriptional activator. In contrast, Gli2 and Gli3 are expressed in neural tissue prior to neural tube closure; later on, the expression pattern of Gli3 becomes confined to intermediate and dorsal spinal cord regions (Figure 6(b)). Analogous to the regulation of the *Drosophila* Gli ortholog, Cubitus interruptus (Ci), Shh signaling appears to control the transcriptional activity of Gli2 and Gli3. The C-terminally deleted versions of Gli2 and Gli3 proteins are transcriptional repressors, and in the absence of Shh signaling Gli3 is processed to this transcriptional repressor form. On Shh binding to Ptc1, the formation of Gli3 repressor is blocked and the transcriptional activation potential of Gli3 is revealed. In the case of Gli2, exactly how Shh controls transcriptional activity remains unclear, but may involve regulation of Gli2 stability or transcriptional potency by posttranslational modification.

In the mouse, targeted deletion of Gli2 leads to a failure in the generation of floor plate and the adjacent p3 domain and a concomitant ventral expansion in the production of MNs (Figure 6(c)). Cell types located dorsal to the pMN are, however, unaffected. This suggests that Gli2 is required for specifying the cell types that require the highest levels of Shh signaling; in support of this, analysis of mutants for Gli2 crossed with Ptc1 mutants indicates that expansion of the floor plate observed in the absence of Ptc1 is abolished when Gli2 is also absent. Surprisingly, although ectopic Gli1 expression is able to induce ventral cell types, no neural defects have been detected in Gli1 mutant mice. However, a compound mutant lacking both Gli1 and Gli2 has more severe defects than do $Gli2^{-/-}$ mutants. Moreover, the neural tube defects seen in Gli2 mutant embryos can be rescued by replacing Gli2 with Gli1.

On the other hand, Gli3 has been proposed to function primarily as an inhibitor of Shh signaling in the neural tube. Supporting this idea, in the absence of Gli3, progenitor domains located in the intermediate region of the neural tube expand dorsally, concomitant with a switch in the identity of the neurons generated in this region. This phenotype can be corrected by a truncated form of Gli3, corresponding to the processed Gli3, suggesting that the repressor form of Gli3 is responsible for patterning in the intermediate neural tube. However, Gli3 can act as a transcriptional activator, as illustrated by its ability to partially

Figure 6 Gli proteins are involved in dorsoventral patterning of the neural tube. (a) In the absence of Sonic hedgehog (Shh), Patched (Ptc) inhibits the transmembrane protein Smoothened (Smo). Downstream transcriptional effectors, the Gli proteins, are thought to be processed from an activator form (GliA) to a repressor form (GliR). Shh binding to Ptc releases the inhibition of Smo, which inhibits production of inhibitory Gli proteins and promotes their transcriptional activity. (b) Schematic representing the expression of Gli proteins in the developing neural tube. (c) Abolishing Gli1 expression does not affect dorsoventral patterning. Loss of Gli2 (Gli2$^{-/-}$) results in an expansion of the ventral boundary of pMN domain together with a loss of the floor plate (FP) and the p3 domain. These results show that Gli2 is required for the patterning of the ventralmost region of the neural tube. Conversely, null mutants for Gli3 have defects in the patterning of the intermediate region of the neural tube accompanied with a mixing of the cells at the p2/p1 boundary. Double mutants for both Gli2 and Gli3 have a composite phenotype of the single mutants. Whereas Gli2 is acting as a transcriptional activator, Gli3 seems to mainly act as a repressor, as illustrated by the partial rescue of Shh$^{-/-}$ phenotype in the Shh$^{-/-}$;Gli3$^{-/-}$ mutant neural tube. However, Gli3 can also act as a transcriptional activator because it partially complements Gli2 when Gli3 is used to replace Gli2 in transgenic embryos. RP, roof plate; pD, dorsal spinal cord domain; pMN, motor neuron progenitor.

rescue the Gli2 mutant phenotype when expressed from this locus.

Importantly, abolishing Gli3 function in Shh$^{-/-}$ embryos partially rescues the severe defects in ventral neural tube patterning observed in Shh mutant embryos (Figure 6(c)). This confirms the inhibitory role for Gli3 in Shh signaling. It also indicates that although the spatial arrangement of neurogenesis

depends on Shh signaling, the induction of most ventral cell types can take place in the absence of Shh signaling, as long as the repressive activity of Gli3 is removed. Consistent with this, embryos lacking both Gli2 and Gli3 display a D/V pattern similar to that of Shh/Gli3 double mutants.

In zebra fish embryos, although the exact role of individual Gli genes appears to differ from that in the mouse, loss-of-function experiments indicate that the Gli proteins are also required for the reception of Hh signals. Together, these results demonstrate that Gli proteins act downstream of Shh to control ventral patterning through transcriptional regulation of target genes (**Figure 6(c)**). Moreover, the data can be accommodated by a model in which graded Shh signaling establishes a ventral-to-dorsal gradient of Gli activity that reflects the gradient of Shh activity. This Gli gradient corresponds to the sum of the transcriptional activator and repressor forms of all Gli proteins present in a responding cell. In support of this model, gain-of-function experiments in the chick suggest a tight correlation between progenitor cell fate and the level of Gli activity within a progenitor cell; furthermore, different levels of Gli activity are sufficient to emulate different levels of Shh signaling *in vivo*.

Perspective

Numerous studies show that Shh, emanating from the notochord and floor plate, patterns the ventral neural tube by controlling cell fate in a concentration-dependent manner. Several major issues remain to be resolved, including understanding how the Shh signaling pathway regulates Gli activity and how this controls the differential expression of class I and class II protein expression. Moreover, how other extracellular signals modulate and cross-talk with Shh signaling requires further investigation. In addition, the integration of D/V patterning with the anterior–posterior differences and temporal changes in neural cell fate remains to be explained. Finally, the evidence suggests that Shh signaling also controls the proliferation, adhesive properties, and survival of cells in the neural tube. The downstream targets of Shh signaling involved in these processes are not well defined, nor how these cell behaviors are coordinated with and contribute to the control of D/V patterning. Nevertheless, the progress that has been made provides a framework to understand fundamental aspects of the mechanism by which positional cues control the arrangement of distinct neuronal subtypes in the ventral neural tube.

Introduction

Disorders of body fluids are among the most commonly encountered problems in clinical medicine. This is because many different disease states can potentially disrupt the finely balanced mechanisms that control the intake and output of water and solutes. Although solute and water homeostasis mechanisms are closely linked, clinical disorders of body fluids are generally divided into disorders of water homeostasis and disorders of solute homeostasis. Since body water is the primary determinant of the osmolality of the extracellular fluid (ECF), disorders of water homeostasis can be broadly divided into hypoosmolar disorders, in which there is an excess of body water relative to body solute, and hyperosmolar disorders, in which there is a deficiency of body water relative to body solute. Because sodium is the main constituent of plasma osmolality, these disorders are typically characterized by hyponatremia and hypernatremia, respectively. After disorders of water metabolism, abnormalities of sodium balance are the next most common cause of body fluid disorders in clinical practice. Since body sodium is the primary determinant of the volume of the ECF, disorders of sodium metabolism can be broadly divided into hypovolemic disorders, in which there is a deficiency of ECF and plasma volume, and hypervolemic disorders, in which there is an excess of ECF and plasma volume. Depending on the relative balance between body sodium and water, these disorders can also be associated with either hyponatremia or hypernatremia.

Disorders of Hypoosmolality

Hypoosmolality indicates excess water relative to solute in the ECF; because water moves freely between the ECF and the intracellular fluid (ICF), this also indicates an excess of total body water relative to total body solute. Imbalances between body water and solute can be generated either by depletion of body solute greater than depletion of body water, or by dilution of body solute from increases in body water greater than increases in than body solute (Table 1). This is an oversimplification of complex physiology, and most hypoosmolar states include components of both solute depletion and water retention. Nonetheless, this general concept has proved to be useful because it provides a simple framework for understanding the basic etiologies of hypoosmolar disorders.

Definitive identification of the etiology of hypoosmolality is not always possible at the time of presentation, but categorization according to the patient's ECF volume status represents the first step in ascertaining the underlying cause of the disorder.

Decreased ECF Volume (Hypovolemia)

Clinically detectable hypovolemia indicates some degree of solute depletion. Even isotonic or hypotonic fluid losses can cause hypoosmolality if water or hypotonic fluids are subsequently ingested or infused. A low urine sodium concentration (U_{Na}) suggests a nonrenal cause of solute depletion, whereas a high U_{Na} suggests renal causes of solute depletion. Diuretic use is the most common cause of hypovolemic hypoosmolality. Many such patients do not manifest clinical evidence of hypovolemia, in part because ingested water has been retained in response to nonosmotically stimulated arginine vasopressin (AVP) secretion, which occurs in all disorders of solute depletion as an attempt to maintain volume homeostasis. Most etiologies of solute losses causing hypovolemic hypoosmolality will be clinically apparent, although some salt-wasting nephropathies and mineralocorticoid deficiency may be difficult to diagnose during early phases of these diseases.

Normal ECF Volume (Euvolemia)

Virtually any disorder causing hypoosmolality can present with a volume status that appears normal by standard methods of clinical evaluation. Because clinical assessment of volume status is not very sensitive, normal or low blood urea nitrogen and uric acid concentrations are helpful laboratory correlates of relatively normal ECF volume. In these cases, a low U_{Na} ($<30\,\mathrm{mmol\,l^{-1}}$) suggests depletional hypoosmolality secondary to ECF losses, with subsequent volume replacement by water or other hypotonic fluids; as discussed earlier, such patients may appear euvolemic by the usual clinical parameters used to assess hydration status. Hypoosmolar disorders caused primarily by dilution (Table 1) are less likely with a low U_{Na}, although this can occur in hypothyroidism or in the syndrome of inappropriate antidiuretic hormone secretion (SIADH) with superimposed hypovolemia. A high U_{Na} ($>30\,\mathrm{mmol\,l^{-1}}$) generally indicates a dilutional hypoosmolality such as SIADH, the most common cause of euvolemic hypoosmolality. The clinical criteria necessary to diagnose SIADH remain as initially defined by Bartter and Schwartz in 1967. Many different

Table 1 Pathogenesis of hypoosmolar disorders

Solute depletion (primary decreases in total body solute + secondary water retention)[a]
Renal solute loss
Diuretic use
Solute diuresis (glucose, mannitol)
Salt-wasting nephropathy
Mineralocorticoid deficiency
Nonrenal solute loss
Gastrointestinal (diarrhea, vomiting, pancreatitis, bowel obstruction)
Cutaneous (sweating, burns)
Blood loss
Solute dilution (primary increases in total body water + secondary solute depletion)[a]
Impaired renal free water excretion
Increased proximal nephron reabsorption
Congestive heart failure
Cirrhosis
Nephrotic syndrome
Hypothyroidism
Impaired distal nephron dilution
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
Glucocorticoid deficiency
Excess water intake
Primary polydipsia

[a]Virtually all disorders of solute depletion are accompanied by some degree of secondary retention of water by the kidneys in response to the resulting hypovolemia; this mechanism can lead to hypoosmolality even when the solute depletion occurs via hypotonic or isotonic body fluid losses. Disorders of water retention can cause hypoosmolality in the absence of any solute losses, but often some secondary solute losses occur in response to the resulting hypervolemia, and this can then further aggravate the dilutional hypoosmolality.

disorders are associated with SIADH, which can be divided into four major etiologic groups: tumors, central nervous system disorders, drug effects, and pulmonary diseases.

Increased ECF Volume (Hypervolemia)

Clinically detectable hypervolemia indicates whole-body sodium excess, and hypoosmolality in such cases suggests a relatively decreased intravascular volume and/or pressure leading to water retention as a result of elevated plasma AVP levels and decreased distal delivery of glomerular filtrate to the kidneys. Patients with these findings usually have a low U_{Na} because of secondary hyperaldosteronism, but under certain conditions the U_{Na} may be elevated (e.g., diuretic therapy). Hyponatremia generally does not occur until relatively advanced stages of congestive heart failure, cirrhosis, or the nephrotic syndrome, by which time diagnosis is usually not difficult. Renal failure can also cause retention of both sodium and water, but in this case the factor limiting excretion of excess body fluid is not decreased effective circulating volume, but rather decreased renal glomerular filtration.

Clinical Manifestations of Hyponatremia

The clinical manifestations of hyponatremia are largely neurological and primarily reflect brain edema resulting from osmotic water shifts into the brain. These range from nonspecific symptoms such as headache and confusion, to more severe manifestations such as decreased sensorium, coma, seizures, and death. Significant central nervous system (CNS) symptoms generally do not occur until the serum sodium concentration ($[Na^+]$) falls below $125\,mmol\,l^{-1}$, and the severity of symptoms can be roughly correlated with the degree of hypoosmolality. Individual variability is marked, and for any patient the level of serum $[Na^+]$ at which symptoms will appear cannot be accurately predicted. Several factors other than the severity of the hypoosmolality also affect the degree of neurological dysfunction. The most important is the time course over which hypoosmolality develops. Rapid development of severe hypoosmolality frequently causes marked neurological symptoms, whereas gradual development over several days or weeks is often associated with relatively mild symptomatology despite profound degrees of hypoosmolality. This is because the brain counteracts osmotic swelling by extruding extracellular and intracellular solutes, including potassium and a variety of small organic molecules (amino acids, polyols, and methylamines) called organic osmolytes. Since this is a time-dependent process, rapid development of hypoosmolality can result in brain edema before this adaptation occurs, but, with slower development of the same degree of hypoosmolality, brain cells can lose solute sufficiently rapidly to prevent cell swelling, brain edema, and

neurological dysfunction. Underlying neurological disease also affects the level of hypoosmolality at which CNS symptoms appear; moderate hypoosmolality is of little concern in an otherwise healthy patient, but can cause morbidity in a patient with an underlying seizure disorder. Nonneurological metabolic disorders (hypoxia, hypercapnia, acidosis, hypercalcemia, etc.) similarly can affect the level of plasma osmolality at which CNS symptoms occur. Recent clinical studies have suggested that menstruating females and young children may be particularly susceptible to the development of neurological morbidity and mortality during hyponatremia, especially in the acute postoperative setting.

Disorders of Hyperosmolality

Hyperosmolality indicates a deficiency of water relative to solute in the ECF. Because water moves freely between the ICF and ECF, this also indicates a deficiency of total body water relative to total body solute. Although hypernatremia can be caused by an excess of body sodium, the vast majority of cases are due to losses of body water in excess of body solutes, caused by either insufficient water intake or excessive water excretion. Consequently, most of the disorders causing hyperosmolality are those associated with inadequate water intake and/or deficient pituitary AVP secretion (Table 2). Although hyperosmolality from inadequate water intake is seen frequently in clinical practice, this is usually not due to an underlying defect in thirst but rather results from a generalized incapacity to obtain and/or ingest fluids, often stemming from a depressed sensorium.

Evaluation of the patient's ECF volume status is important as a guide to fluid replacement therapy, but is not as useful for differential diagnosis since most hyperosmolar patients will manifest some degree of hypovolemia. Rather, assessment of urinary concentrating ability provides the most useful data with regard to the type of disorder present. Using this approach, disorders of hyperosmolality can be categorized as those in which renal water conservation mechanisms are intact but are unable to compensate for inadequately replaced losses of hypotonic fluids from other sources, or those in which renal concentrating defects are a contributing factor to the deficiency of body water. Most cases of CNS-associated hyperosmolality are due to deficits of pituitary AVP secretion.

Diabetes Insipidus

Diabetes insipidus (DI) can result from either inadequate AVP secretion (central or neurogenic DI) or inadequate renal response to AVP (nephrogenic DI).

Table 2 Pathogenesis of hyperosmolar disorders

Water depletion (decreases in total body water in excess of body solute)
Insufficient water intake
Unavailability of water
Hypodipsia (osmoreceptor dysfunction, age)
Neurological deficits (cognitive dysfunction, motor impairments)
Hypotonic fluid loss[a]
Renal: diabetes insipidus (DI)
Insufficient AVP secretion (central DI, osmoreceptor dysfunction)
Insufficient AVP effect (nephrogenic DI)
Renal: other fluid loss
Osmotic diuresis (hyperglycemia, mannitol)
Diuretic drugs (furosemide, ethacrynic acid, thiazides)
Postobstructive diuresis
Diuretic phase of acute tubular necrosis
Nonrenal fluid loss
Gastrointestinal (vomiting, diarrhea, nasogastric suction)
Cutaneous (sweating, burns)
Pulmonary (hyperventilation)
Peritoneal dialysis
Solute excess (increases in total body solute in excess of body water)
Sodium
Excess Na^+ administration (NaCl, $NaHCO_3$)
Sea water drowning
Other
Hyperalimentation (intravenous, parenteral)

[a]Most hypotonic fluid losses will not produce hyperosmolality unless insufficient free water is ingested or infused to replace the ongoing losses, so these disorders also usually involve some component of insufficient water intake.

Central DI is caused by a variety of acquired or congenital anatomic lesions that disrupt the neurohypophysis, including pituitary surgery, tumors, trauma,hemorrhage, thrombosis, infarction, or granulomatous disease. Severe nephrogenic DI is most commonly congenital due to defects in the gene for the AVP V_2 receptor (X-linked recessive pattern of inheritance) or in the gene for the aquaporin-2 water channel (autosomal recessive pattern of inheritance), but relief of chronic urinary obstruction or therapy with drugs such as lithium can cause an acquired form sufficient to warrant treatment. Short-lived nephrogenic DI can result from hypokalemia or hypercalcemia, but the mild concentrating defect generally does not by itself cause hypertonicity, and responds to correction of the underlying disorder. Regardless of the etiology of the DI, the end result is a water diuresis due to an inability to concentrate urine appropriately.

Because patients with DI do not have impaired urine Na^+ conservation, the ECF volume is generally not markedly decreased and regulatory mechanisms for maintenance of osmotic homeostasis are primarily activated: stimulation of thirst and pituitary AVP secretion (to whatever degree the neurohypophysis is still able to secrete AVP). In cases in which AVP secretion is totally absent (complete DI), patients are dependent entirely on water intake for maintenance of water balance. Although untreated DI can lead to both hyperosmolality and volume depletion, until the water losses become severe, volume depletion is minimized by osmotic shifts of water from the ICF into the more osmotically concentrated ECF.

Osmoreceptor Dysfunction

There is an extensive literature on animal studies indicating that the primary osmoreceptors that control AVP secretion and thirst are located in the anterior hypothalamus. Lesions of this region in animals cause hyperosmolality through a combination of impairments of thirst and of osmotically stimulated AVP secretion. Initial reports in humans described this syndrome as 'essential hypernatremia,' and subsequent studies used the term 'adipsic hypernatremia' in recognition of the profound thirst deficits found in most of the patients. All of these syndromes are now grouped together as disorders of osmoreceptor function. Most of the cases reported to date have represented various degrees of osmoreceptor destruction associated with different brain lesions. In contrast to lesions causing central DI, these lesions usually occur more rostrally in the hypothalamus, consistent with the anterior hypothalamic location of the primary osmoreceptor cells. For all cases of osmoreceptor dysfunction it is important to remember that afferent pathways from the brain stem to the hypothalamus generally remain intact; therefore, the patients will usually have normal AVP and renal concentrating responses to baroreceptor-mediated stimuli such as hypovolemia and hypotension.

Clinical Manifestations of Hyperosmolality

The clinical manifestations of hyperosmolality can be divided into the signs and symptoms produced by dehydration, which are largely cardiovascular, those caused by the hyperosmolality itself, which are predominantly neurological and reflect brain dehydration as a result of osmotic water shifts out of the central nervous system, and those secondary to excessive renal water losses in patients with DI. Cardiovascular manifestations of hypertonic dehydration include hypotension, kidney failure secondary to decreased renal perfusion, acute tubular necrosis or rhabdomyolysis, and, in severe cases, hypotensive shock. Neurological manifestations range from nonspecific symptoms such as irritability and decreased sensorium to more severe manifestations such as chorea, seizures, coma, focal neurological deficits, and cerebral infarction. The severity of symptoms can be roughly correlated with the degree of hyperosmolality, but individual variability is marked, and for any single patient the level of serum $[Na^+]$ at which symptoms will appear cannot be predicted. Similar to hypoosmolar syndromes, the length of time over which hyperosmolality develops can markedly affect clinical symptomatology. Rapid development of severe hyperosmolality is frequently associated with marked neurological symptoms, whereas gradual development over several days or weeks generally causes milder symptoms. In this case the brain counteracts osmotic shrinkage by increasing intracellular content of solutes. These include electrolytes, such as potassium, and organic osmolytes, which previously had been called 'idiogenic osmoles' (for the most part, these are the same organic osmolytes that are lost from the brain during adaptation to hypoosmolality, discussed previously). The net effect of this process is to protect the brain against excessive shrinkage during sustained hypertonicity. However, once the brain has adapted by increasing its solute content, rapid correction of the hyperosmolality can cause brain edema, since it takes a finite time (24–48 h in animal studies) to dissipate the accumulated solutes, and until this process has been completed the brain will accumulate excess water as the plasma osmolality is normalized. This effect is most often seen in dehydrated pediatric patients, who can develop seizures as a result of rapid rehydration.

Disorders of Hypovolemia

It is important to distinguish dehydration, which indicates a relative deficiency of body water, from hypovolemia, which indicates insufficient extracellular fluid to maintain blood volume within normal ranges and almost always requires a deficiency of body sodium. Since dehydration often occurs in association with hypovolemia, these terms are frequently used interchangeably but inappropriately. Although water loss or inadequate intake also can produce hypovolemia, to a large degree the ECF volume deficits will be reduced by osmotic water shifts out of the ICF space. The degrees of hyperosmolality that can be achieved in dehydrated patients with relatively small effects on circulating blood volume and pressure are striking. Clinically significant hypovolemia develops much more quickly, and to a much more pathological degree, when water losses occur in conjunction with solute losses. In this case, sodium balance is critically important for maintenance of body fluid homeostasis. Because of a relative absence of regulated sodium intake in humans, renal sodium conservation represents the main defense for maintenance of volume homeostasis during hypovolemic conditions.

Hypovolemic states are generally classified into those in which solute is lost through extrarenal causes but renal function is unimpaired, and those in which an impairment of renal sodium conservation mechanisms either causes or exacerbates the hypovolemia (Table 3).

Table 3 Pathogenesis of hypovolemic disorders

Extrarenal solute and water depletion
Blood loss
Hemorrhage
Severe anemia
Gastrointestinal fluid losses
Diarrhea
Vomiting
Nasogastric suctioning
Pancreatitis
Bowel obstruction
Cutaneous fluid losses
Sweating
Burns
Renal solute and water depletion
Mineralocorticoid deficiency
Addison's disease
Salt-wasting nephropathy
Chronic interstitial nephropathy
Polycystic kidney disease
Medullary cystic disease
Obstructive uropathy
Bartter's syndrome
Drugs
Diuretic agents
Solute diuresis
Glucose
Mannitol

Solute Losses by Extrarenal Pathways

The presence of a low U_{Na} in a patient with clinical manifestations of hypovolemia generally indicates an extrarenal cause. This can occur via a variety of etiologies. In most cases the source of the sodium and water losses (sweating, diarrhea, hemorrhage, etc.) will be readily apparent. In some patients the loss of water is disproportionately greater than the loss of sodium. When primarily water is lost, as in DI, then intracellular dehydration will be more marked than hypovolemia, as described earlier, and osmotic homeostatic mechanisms will be activated to a greater degree than are the renal mechanisms that act to preserve volume homeostasis. In contrast, isotonic hypovolemia, as produced by large amounts of blood loss from hemorrhage, represents a situation in which the regulatory mechanisms for water and sodium balance that are activated will be primarily those that protect volume homeostasis, without much contribution from osmotic regulatory systems. Most body fluid losses, whether from excessive sweating, gastrointestinal excretions, or diuretic use, result in losses of both water and sodium, but the fluid lost in such situations is generally in the range of 75 mM, or half-isotonic. As a result, both hypovolemia and hyperosmolality occur, and volume homeostatic mechanisms will be activated more than in cases of pure water losses, such as diabetes insipidus. Consequently, renal sodium conservation, as reflected by a low U_{Na}, occurs prominently in hypovolemic patients with normal kidney function.

Renal Solute Losses

The presence of an elevated U_{Na} in a patient with clinical manifestations of hypovolemia generally indicates a renal cause of hypovolemia. This can occur via several different etiologies. Adrenal insufficiency (Addison's disease) is caused by bilateral destruction of the adrenal glands. Because the adrenal glands are the site of synthesis of aldosterone in addition to glucocorticoids, patients with Addison's disease have impaired renal sodium conservation. This leads to renal sodium wasting in excess of the sodium losses observed with other forms of hypovolemia, resulting in both hypoosmolality and hypovolemia. The net effect on sodium balance will be to activate mechanisms for both sodium intake and renal sodium conservation. However, because aldosterone acts on the more distal part of the nephron, proximal renal sodium-conserving mechanisms cannot adequately compensate for the sodium wasting in this case. Analogous to

primary adrenal insufficiency, other primary disorders of renal sodium wasting also predispose patients to the development of clinical hypovolemia. These include chronic interstitial nephropathy, polycystic kidney disease, medullary cystic disease, obstructive uropathy, Bartter's syndrome, and drugs such as cisplatinum. However, the sodium losses in these diseases are usually relatively mild and only rarely cause clinically significant hypovolemia, since dietary sodium intakes are generally more than sufficient to replace daily urinary sodium losses even when these are fairly large.

Therapy with diuretic drugs is one of the most common causes of hyponatremia. Although the resulting sodium losses often induce some degree of hypovolemia as well, the magnitude of ECF volume reduction is generally mild. In contrast, obligatory solute diureses, particularly those associated with glucosuria, can cause substantially greater urinary sodium losses and severe hypovolemia relatively quickly, primarily because of the ongoing natriuresis and diuresis. One manifestation of this is the circulatory collapse that represents a major cause of early mortality in patients with uncontrolled diabetic ketoacidosis.

Clinical Manifestations of Hypovolemia

The hallmarks of hypovolemia are clinical signs of inadequate ECF and plasma volume, most of which reflect increased activity of the sympathetic nervous system to maintain mean arterial pressure via release of norepinephrine from nerve terminals and epinephrine from the adrenal medulla. Associated symptoms are those of orthostatic dizziness, dry mucus membranes, and thirst. The last symptom is a crucial part of compensatory mechanisms that maintain ECF volume. However, the absence of increased sodium appetite in response to hypovolemia limits the effectiveness of thirst to restore ECF volume and contributes to the production of hypoosmolality as a result of ingestion of hypotonic fluids. In addition, age-related changes appear to impair some of the compensatory homeostatic responses to hypovolemia. Elderly patients are known to be particularly prone to hypovolemia, regardless of the cause. This suggests the presence of defects in the mechanisms that regulate osmotic and volume homeostasis. Studies in elderly humans have consistently demonstrated intact or enhanced AVP secretion in response to osmotic stimuli. Although elderly patients generally have a decreased renal response to AVP, given the nature of the urine volume–urine osmolality relationship shown in Figure 1, a small decrease in urinary concentrating ability will not cause markedly increased urine volume losses under most conditions. The most significant defect in the elderly appears to be a decreased sensation of thirst. After 24 h of fluid deprivation, elderly individuals report less subjective thirst than do younger individuals, which can lead to less spontaneous drinking in response to periods of water deprivation.

Disorders of Hypervolemia

Hypervolemia results from excess ECF and plasma volume. Because water distributes across all body fluid compartments, excess sodium is much more effective at producing ECF and plasma volume expansion because of its more restricted extracellular distribution. However, hyperosmolality from an excess of other solutes does not invariably lead to volume expansion. Patients with renal failure have high levels of blood urea that often increase total plasma osmolality by as much as 20–30 mOsm kg^{-1} H_2O, yet this causes neither intracellular dehydration nor ECF and plasma volume expansion. This is because urea is a nonpolar solute that freely permeates cell membranes. Only increases in concentrations of impermeable solutes are accompanied by ECF volume expansion, and such clinical disorders are caused almost exclusively by sodium retention.

Most clinical disorders characterized by increased total body sodium and fluid are the result of a perceived deficit in the 'effective' ECF volume. Thus, in diseases such as congestive heart failure (CHF) and cirrhosis, the kidney avidly retains sodium and water despite a total body surfeit of both of these substances. Although many questions about specific disease processes remain to be answered, evidence over the past decade has supported the concept that the critical component of the ECF volume that is the primary determinant of renal sodium retention is the effective arterial blood volume (EABV), which represents only approximately 15% of the blood volume, or about 0.5–0.7 l in a 70 kg human.

Blood volume is sensed in the arterial and venous circulations by baroreceptors that alter their electrical output according to the degree of stretch of the blood vessel wall. In arteries this is predominantly a function of the blood pressure (mean arterial pressure as well as dynamic changes in pulse pressure) and of the intrinsic tensile properties of the arterial wall, whereas in veins the stretch is mainly a function of the volume of blood within the vessel. Consequently, under normal conditions the major determinant of arterial baroreceptor activity is the pressure in the large vessels of the arterial circulation, primarily the aorta and carotid arteries, and the major determinant of venous baroreceptor activity is the circulating blood volume. The arterial pressure is primarily determined by two factors, cardiac output and peripheral arterial resistance. Similarly, renal perfusion pressure

Figure 1 Schematic representation of normal physiological relationships between plasma osmolality, plasma arginine vasopressin (AVP) concentrations, urine osmolality, and urine volume in humans. Note particularly the inverse nature of the relation between urine osmolality and urine volume, resulting in disproportionate effects of small changes in plasma AVP concentrations on urine volume at lower AVP levels. Adapted from Robinson AG (1985) Disorders of antidiuretic hormone secretion. *Journal of Clinical Endocrinology & Metabolism* 4: 55–88.

determines the activity of the baroreceptors of the renal afferent arterioles that control renin secretion from the juxtaglomerular apparatus. Acute decreases in either variable are interpreted as a decreased EABV: in CHF this occurs as a result of the decrease in cardiac output (and possibly pulse pressure) as myocardial function is compromised, and in cirrhosis as a result of the decrease in peripheral arterial resistance due to arteriovenous shunting and circulating vasodilators. In response to either of these factors, the activity of arterial and renal afferent arteriolar baroreceptors is increased and a cascade of neural and humoral responses is activated to increase arterial pressure back to normal ranges. These include (1) activation of the sympathetic nervous system (both norepinephrine release from sympathetic nerve terminals and epinephrine release from the adrenal medulla), which increases peripheral arteriolar resistance and stimulates renin production by the kidney; (2) suppression of brain stem vagal efferent output to the heart, which causes a reflex tachycardia; (3) activation of the renin–angiotensin system, which promotes renal sodium conservation via angiotensin-stimulated aldosterone secretion; and (4) stimulation of pituitary AVP secretion, which promotes renal water retention. If these compensatory responses are sufficient to allow the EABV to return to normal, then cardiac output and mean arterial pressure will return toward normal too, but this is only because they are now being supported by the secondary effects set in motion as a result of the initial decrease in EABV. Thus, a new steady state is achieved in which an increase in total body sodium and water supports the maintenance of EABV at acceptable levels.

Table 4 Pathogenesis of hypervolemic disorders

Primary renal sodium retention
Renal failure
Primary hyperaldosteronism
Adrenal adenoma
Adrenal hyperplasia
Exogenous mineralocorticoid therapy
Secondary renal sodium retention
Congestive heart failure
Cirrhosis
Nephrotic syndrome

Hypervolemic states can be broadly divided into those in which pathological sodium and water retention occurs as a result of primary renal or adrenal disease and independently of the ECF volume status, and those in which renal sodium and water retention occurs secondarily to stimuli that signal an insufficiency of EABV (Table 4).

Primary Renal Sodium Retention (Baroreceptor Suppression)

Diseases of primary renal sodium retention produce an expansion of all components of the ECF, including the circulating arterial volume. As a result, these disorders are characterized by suppression of most of the neural and humoral mechanisms that act to maintain EABV. Acute and chronic renal failure represent the quintessential examples of primary renal sodium retention. As the glomerular filtration rate deceases, the kidney eventually becomes unable to excrete sufficient sodium and water to equal ongoing fluid and sodium intake. At what stage of renal failure clinically significant fluid retention and edema occur depends on the patient's salt and water intakes as well as their degree of renal impairment. Because all ECF compartments are expanded, the renin–angiotensin–aldosterone system and the sympathetic nervous system are suppressed via the effects of baroreceptor activation. Hyperaldosteronism is another example of primary sodium retention with subsequent ECF volume expansion. Although the kidneys are normal and the disease is secondary to elevated mineralocorticoid activity, because this process occurs independently of the ECF volume status it falls into the category of primary renal sodium retention. High levels of plasma mineralocorticoid activity can result from an adrenal tumor or hyperplasia (primary hyperaldosteronism) or from pharmacological therapy with synthetic mineralocorticoids. Regardless of the etiology, the net effect is sodium retention.

Secondary Renal Sodium Retention (Baroreceptor Activation)

In diseases of secondary renal sodium retention, high plasma aldosterone levels are produced by angiotensin II stimulation of adrenal aldosterone secretion. Normally, activation of the renin–angiotensin system occurs under physiological conditions of hypovolemia to promote renal sodium conservation; however, when this cascade is activated in response to a perceived decrease in EABV, then pathological sodium and fluid retention results. Many different pathophysiological states can cause sodium retention and its sequelae. Congestive heart failure is the best known cause of hypervolemia. Although the pathophysiology seems straightforward, because the disease evolves slowly over long periods of time, many of the clinical manifestations with regard to sodium and fluid balance depend on the point in the disease process at which the patient is evaluated. As cardiac output continues to decrease, more defense mechanisms will be called into play to support EABV.

The pathophysiology underlying the fluid and electrolyte abnormalities of cirrhosis remains unsettled. The sodium and fluid retention are clearly not the result of a primary renal defect, but rather are secondary to a perceived decreased EABV, since all of the regulatory systems for maintenance of EABV are activated as they are in CHF. However, the cause of the decreased EABV is less certain. It has been proposed that a key factor in the pathophysiology is decreased peripheral vascular resistance, as a result of both the arteriovenous shunting in the gastrointestinal and other vascular beds in this disease, as well as from the decreased metabolism and clearance of a variety of vasoactive agents that accumulate during hepatic insufficiency. However, other pathogenetic factors are likely involved in this very complex disease as well.

Clinical Manifestations of Hypervolemia

The clinical manifestations of hypervolemia depend on the underlying disease process. Patients with primary aldosteronism generally have mild hypernatremia and hypokalemia, and manifest varying degrees of hypertension but less frequently subcutaneous edema. When the serum $[K^+]$ is $<3\,\mathrm{mmol\,l^{-1}}$, symptoms of hypokalemia, such as muscle weakness, can predominate. Patients with hyperaldosteronism secondary to perceived reduced EABV, such as congestive heart failure and cirrhosis, generally do not have hypertension but tend to have greater degrees of edema, reflecting more sodium and water retention,

because they cannot escape the effects of elevated aldosterone levels due to their decreased renal perfusion. This produces greater amounts of subcutaneous edema and, in later stages of the diseases, accumulations of excess retained fluid in the peritoneal cavity (ascites) and lungs (pulmonary edema) and whole body swelling (anasarca).

Photoluminescence Phenomena

Fluorescence and phosphorescence belong to the class of physical events called photoluminescence; many chemical substances emit light of a particular wavelength (perceived by the human eye as a particular color) very shortly after being hit by light of another wavelength. Based on the delay between the absorption and emission of light, photoluminescence events are called fluorescence (very short delay; around 10^{-6}–10^{-8} s) or phosphorescence (delay 10^{-6} s and longer). Substances that fluoresce are called fluorochromes.

High-energy electromagnetic radiation has a wavelength shorter than that of visible light. With decreasing energy contents this wavelength becomes increasingly longer. For instance, the wavelength of X-rays is measured in angstrom units while the wavelength of visible light is suitably expressed in nanometers (1 nm = 10 Å units). The relationship between energy and wavelength is understandable if one is familiar with Max Planck's mathematical equation:

$$E = h\nu$$

where E is energy, h is Planck's constant, and ν is frequency.

In the color spectrum, the wavelength of the emitted light is always longer than that of the absorbed light (the so-called Stokes shift). Thus, ultraviolet (UV) light causes a suitable fluorochrome to fluoresce blue light, blue light causes a suitable fluorochrome to fluoresce green, green light causes red fluorescence, and red light causes infrared fluorescence. Fluorescence and the wavelength shift between excitation light and emission light were first scientifically described by the English physicist George Gabriel Stokes in 1852.

What Is Light?

Light can be considered as an electromagnetic waveform or as a stream of quanta of energy, photons. The quantum theory explanation of fluorescence is as follows. Fluorochrome molecules in their ground state of energy absorb photons. The energy contained by the photons is transferred to the fluorochrome molecule, which enters a higher energy state (called the excited state). A split-second later, the excited fluorochrome molecule returns to the ground state while emitting the excess energy as a photon in the visible light band of the electromagnetic spectrum. The quantum physics underlying excitation and emission is known as the Franck–Condon principle. This principle also explains the Stokes wavelength shift.

Design of the Fluorescence Microscope

The construction most often applied in modern fluorescence microscopes follows the principle of epifluorescence (Figure 1). In short, high-intensity light is projected via a mirror placed in the optic path, an excitation filter, and the objective lens, onto the section or other object of study. The excitation filter is necessary to select light with the appropriate excitation wavelength (see section on Filters). Fluorescence emitted by fluorochrome molecules inside or attached to the specimen passes through the objective lens and also hits the mirror. This mirror is the construction's centerpiece. It is covered with a suitable coating that reflects the high-intensity excitation light from the light source toward the objective lens and the specimen, while at the same time it reflects away from the observer's eye the excess excitation light reflected back from the specimen into the microscope via the objective lens. Most important is that the mirror does not reflect the fluorescence emitted by the specimen. As a consequence, the light that has emerged from the object as fluorescence passes the mirror unreflected, passes an extra filter (the emission filter), and reaches the observer's eye, the camera, or some detector. The characteristic that this mirror separates the excitation light from the fluorescence light is basic to its name: dichroic mirror. Sometimes this mirror is referred to as the 'beam splitter.' In some microscope designs the excitation light first passes a so-called barrier filter to limit the wavelength band and then passes through the excitation filter.

Thus, the epifluorescence microscope is designed in such a way that only fluorescence light reaches (via the ocular lens the eye of the observer) the camera or other imaging device, while the excitation light does not. Every major manufacturer of optical instruments carries a line of fluorescence microscopes, both upright and inverted models and nearly always based on the epifluorescence principle.

Fluorochromes: Absorption and Emission Spectra

The effectiveness of a specific fluorochrome for a particular staining purpose depends on several characteristics. In this respect the associated absorption

Figure 1 Principle of epifluorescence microscopy involving a dichroic mirror. Excitation light is reflected, emitted light (fluorescence) is not.

Figure 2 Typical excitation and emission spectra for Alexa Fluor 488. Note the shift toward longer wavelengths of the emission spectrum compared with the excitation spectrum (Stokes shift). The excitation spectrum of Alexa Fluor 488 has a peak at 492 nm; the emission spectrum has a maximum at 520 nm.

and emission spectra take a high priority on the list. The absorption spectrum (also called excitation spectrum) is a graph in which the intensity of the emission is plotted against the wavelength of the light used to excite the fluorochrome (Figure 2). From this graph the user decides which 'color' light (which excitation wavelength) should preferably be used to get the maximum fluorescence out of the fluorochrome.

The emission spectrum is a graph that shows the intensity of the emitted fluorescent light plotted against the wavelength of the emitted fluorescence (Figure 2). This graph informs the user with which filter or detector settings the highest yield or best signal of the fluorescence output can be obtained. Note that because of the Stokes wavelength shift, the emission spectrum of any fluorochrome always has a peak at a longer wavelength, compared to the peak that occurs in the excitation spectrum.

Polychromatic and Monochromatic Light

The conventional mercury and xenon light sources applied in fluorescence microscopes provide white light – that is, a mixture of light of all colors of the rainbow. This type of light is called polychromatic. Also, the novel metal halide illumination systems produce white light. The intensity of the light from these light sources can be plotted against the wavelength. In xenon and metal halide illumination systems this plot shows a more or less linear or flat graph. In mercury illumination the intensity–wavelength plot shows typical peaks in intensity. These peaks are called 'mercury lines.' Fluorescence detection systems have traditionally been designed around such 'lines' – for example, the 365 nm or the 436 nm lines provided by an HBO lightbulb (more details later). As a consequence of the polychromatism of these sources of excitation light there is the necessity for appropriate filtering to select a narrow excitation wavelength band. Only a laser provides monochromatic light with a single color (i.e., an extremely narrow wavelength band).

High Quantum Efficiency with a Laser Excitation System

Because fluorescence-based laser scanning image acquisition systems have become widely available, we will, for the sake of simplicity, further deal with monochromatic light. An example is when an excitation spectrum shows a peak at, say, 488 nm: in this case, 488 nm light (blue light) is the best wavelength

to excite this fluorochrome. Excitation with light of this wavelength (blue) will get the maximum amount of fluorescence out of the fluorochrome (green light). Excitation of this fluorochrome with light of a different wavelength – for instance, red light (600 nm) – will not bring about much fluorescence. Thus, in order to make maximal use of a particular fluorochrome it is necessary to be familiar with its excitation spectrum. In general, the sharper and narrower the peak of its excitation spectrum, the better a fluorochrome fits its purpose. This especially holds for multicolor fluorescence applications and in the extreme for laser scanning fluorescence microscopy. In the latter application, excitation light is per definition monochromatic and because of this the laser wavelength should ideally match the peak in the absorption spectrum of the fluorochrome. If the laser light wavelength does not match this peak, most fluorochrome molecules will simply not be excited and weak or no fluorescence will appear. In this context the term 'quantum efficiency' is used. A quantum efficiency of 100% means 'one excitation photon in, one fluorescent photon out,' or, in other words, the maximal fluorescence output obtainable with an excitation light input with a given wavelength is close to 100% quantum efficiency.

Importance of Absorption and Emission Spectra in Double-Fluorescence Studies

Anyone interested in the simultaneous visualization of two fluorochromes – for instance, in a double-immunofluorescence procedure designed to test whether a given substance A is present in cells also containing substance B (so-called co-localization) – should be concerned about the spectral characteristics of the two selected fluorochromes to be associated with A and B. The excitation spectrum of fluorochrome A should not overlap that of fluorochrome B. If it does, then fluorochrome B may be excited and produce a signal in response to the light meant to excite fluorochrome A. The effect in this case is false positivity (cells with substance B erroneously observed as containing A). Similarly, the emission spectra of fluorochromes A and B should not overlap. When they do, A and B will appear with the same color and it will be impossible to discriminate between cells expressing A, cells expressing B, or cells containing both A and B.

The occurrence of observable fluorescence of fluorochrome B with the illumination and the filter set designed to highlight A, and, vice versa, of observable fluorescence of fluorochrome A with the illumination and the filter set designed to highlight B, is called cross-talk, bleeding through, or shining through. A notorious example of bleeding through occurs in many routine fluorescence microscopes when some fluorescence emitted by tetramethylrhodamine isothiocyanate (TRITC; red fluorescence) bleeds through the filter set used to observe fluorescein isothiocyanate (FITC; green fluorescence). One reason, apart from poorly designed filter sets, is that the excitation spectrum of FITC is quite wide. When it is absolutely necessary to avoid bleeding through, FITC could be replaced by a fluorochrome with a better (i.e., narrower) excitation spectrum. Alternatively or simultaneously, TRITC could be replaced by a fluorochrome with a peak in its excitation spectrum at a longer wavelength. Usually, FITC is replaced by Cy2 or Alexa Fluor 488. TRITC can be replaced by Texas Red or Alexa Fluor 594. An alternative way to reduce bleeding through is to 'play' with the filter sets or to use a special microscope (i.e., the confocal laser scanning microscope) that is equipped with one or more monochromatic light sources.

Shortpass, Bandpass, and Longpass Filters

With the exception of the confocal laser scanning microscope with its monochromatic lasers, the illumination light source in most fluorescence microscopes is a mercury lamp. This light source produces light ranging from UV to infrared (the lamp becomes extremely hot!). The emission spectrum of this light has several wavelength peaks that are referred to as 'excitation lines' (see earlier): 280, 313, 334, 365, 405, 435, 546, 577, and 579 nm. Some of these lines are exploited by filter manufacturers to design filter sets that optimally match the excitation spectrum of a particular fluorochrome. For instance, filter sets that employ the 546 nm line are used to excite TRITC, and filter sets that employ the 577 and 578 nm lines are used to excite Texas Red or Alexa Fluor 594. Note here that if one considers the purchase of a particular filter set, one should inform the manufacturer which lamp is used as the illumination source. Xenon metal halide and other metal halide lamps have emission spectra that area quite different than the mercury lamp emission spectra, and for this reason might yield disappointing results with a filter set designed around a specific mercury excitation line.

Filters may be used to filter away unwanted excitation wavelengths from the mercury lamp's light (such a filter is also called a 'barrier filter'), or they may be used to pass a selected portion of the emitted light to the eyes of the observer or to his camera. In everyday practice an excitation filter is always complemented with an associated emission filter. Filters that allow

Figure 3 Depiction of shortpass, bandpass, and longpass filters. This fluorochrome (curve) reveals most of its fluorescence in the wavelength area covered by the bandpass filter.

Figure 4 Cutoff wavelengths of a fluorescence filter, in this case a longpass filter. The black curve shows the cutoff of a nearly ideal filter, whereas the red curve belongs to a filter with poor cutoff characteristics. The latter filter allows passage of traces of fluorescence of wavelengths shorter than the official cutoff wavelength.

the light of the short-wavelength portion of an excitation (or emission) spectrum to pass, but block light of longer wavelengths, are called shortpass filters (Figure 3). Conversely, filters that block light of the short-wavelength portion of an excitation (or emission) spectrum and that allow light of the remaining, longer wavelengths to pass are called longpass filters (Figure 3). Filters that allow only a specific part of the light in a given spectrum to pass, blocking light with wavelengths shorter than a particular short wavelength and light with wavelengths longer than a particular long wavelength, are called bandpass filters (Figure 3). A typical and appropriate wavelength referred to in bandpass filters is the center wavelength, which defines the center of the wavelength band of light allowed to pass the filter. Another important parameter in bandpass filters is the bandwidth. Filter manufacturers provide tables that inform researchers about the wavelengths that matter for a particular filter set that is made for use with a particular fluorochrome (for instance, the wavelength at which a longpass filter begins transmitting light). Note that this wavelength, referred to as the cutoff wavelength, is in fact a short-wavelength trajectory, and the better (and often more expensive) the filter (Figure 4), the narrower this trajectory and the steeper the transmission curve in the cutoff trajectory.

There are several principles according to which filters can be manufactured, but this is outside the scope of this article.

Multiple-Bandpass Filters

A relatively new development is the appearance on the market of filter sets designed such that they allow the simultaneous observation of the fluorescence emitted by two or three different fluorochromes: these double- and triple-bandpass filters are also called combination filters. These filter sets can be very handy to screen quickly whether and where co-localization of fluorochromes occurs in tissues or cells. The classical method to study co-localization of fluorescent markers is to inspect an object switching back and forth between two different filter sets (each set specific for one of the fluorochromes). The disadvantage of the combination filter sets is that their design is always a compromise between specific demands set by the excitation/emission spectra of each of the individual fluorochromes. In fact, these are filters that allow a certain amount of cross-talk! Also, if for some reason fluorochrome A shines brighter than fluorochrome B, the fluorescence emitted by B might become overwhelmed by that of fluorochrome A.

Suitable Fluorochromes

In the past 30 years ever better fluorochromes have been developed, and each year new fluorochromes reach the market. The most recent catalog published by the leading company (see section on 'Relevant Websites'), currently in its tenth version, contains more than 3000 products, the majority of which are fluorescent substances. The basic demands underlying these developments are the quest for stable and specific fluorochromes that have a high photon efficiency, yet can be combined with bioactive molecules. Fluorochromes should comply with the following demands: chemical stability, photostability, sensitivity, high quantum yield at a particular excitation wavelength, a narrow excitation spectrum, and nontoxicity. They should possess the ability to be combined with antibodies, nucleic acids, agonists, or other reporter molecules used in fluorescence detection systems in biomedical applications. Some of the currently available fluorochromes are provided in Table 1. A detailed description of nearly all commercially available fluorochromes for cell biological purposes can be found in the catalog published on the Internet or in print by Invitrogen/Molecular Probes. The first fluorochrome to be applied in immunofluorescence, FITC, has long been surpassed by fluorescing substances with much better optical and chemical characteristics. FITC is so entrenched, however, notably in some pathology applications, that it is still being used.

Table 1 Excitation/emission peak wavelength of widely used fluorochromes

Traditional dyes

Quenching and Antiquenching Measures

Although fluorescence is a cyclical process, fluorochromes have a limited lifetime due to, for instance, chemical interaction of the fluorochrome with molecules in the immediate vicinity, exposure to light, or both. Anyone working with fluorescence is familiar with deterioration of fluorescence in the tissue while the material is being examined in the fluorescence

microscope. This phenomenon is referred to as quenching, photobleaching, or fading. Quenching may occur through exposure to daylight and can be accelerated by an increase in the temperature of the environment. Because of this, most researchers at least store their fluorescence material in the dark. The more prudent researcher stores the precious material in a refrigerator or a freezer. In our experience, the fluorescence in brain sections immunostained and detected with secondary antibodies or avidin conjugated to Cy-fluorochromes or Alexa Fluor fluorochromes, dehydrated, coverslipped, and stored in a freezer at –20 °C has remained remarkably stable over at least 5 years.

Manufacturers of fluorescence microscopes equip their top models with electronic shutters to limit the exposure of the specimen to high-intensity excitation light. Quenching can be abated by the addition to the mounting medium of antiquenching agents, such as *p*-phenylenediamine, or of a commercial antifading product.

Background and Autofluorescence

Unwanted, nonspecific fluorescence surrounding fluorescence-stained structures is usually referred to as background fluorescence. Causes of background staining might be, for instance, the unspecific binding of the fluorochrome or its vehicle to tissue components. A particular source of background is autofluorescence, which is the characteristic of biological tissue to fluoresce 'spontaneously' at wavelengths in the green visible light range (up to 500 nm excitation). Notorious autofluorescence is produced by pigment particles (e.g., lipofuscin). Autofluorescence can be aggravated by fixatives containing glutaraldehyde. Remedies can be to use fluorochromes that can be operated at higher wavelengths (e.g., Texas Red and Carbocyanine 5), or through the use of more specific secondary antibodies, improvements of the signal-to-noise ratio by signal enhancement, checking the pH of the mounting medium (the intensity of fluorescence is pH dependent), the omission of glutaraldehyde, and, finally, the use of the thinnest sections manageable. Lipofuscin autofluorescence can be reduced by specific measures.

First Success

The first great success of a fluorescence-based method in neuroscience occurred after the discovery that catecholamines in dried sections of brain tissue, when exposed to formaldehyde vapor, propagate the deposition of a fluorescing, cyclic product in cells and fibers. This treatment of brain tissue, known as the formaldehyde-induced fluorescence technique (FIF), named the Falck–Hillarp technique after its discoverers, offered neuroscientists for the first time in history an instrument to study brain neuronal systems belonging to a particular chemical family, the catecholaminergic neuron. The discovery that neurons in the substantia nigra are responsible for the dopaminergic innervation of the striatum is largely based on observations on FIF-treated brain sections. Thus, the FIF technique marks for the neuroanatomical field the beginning of the transition from purely descriptive neuroanatomy to the current era of function-related chemical and molecular neuroscience. Improvements further refined this method into a fluorescence tool that dominated neuroscience research until the advent of more sensitive methods based on immunofluorescence. Because of its limited sensitivity and its inability to distinguish among various monoamines, the FIF technique no longer plays a major role in neuroscience research.

Genetic Engineering

If it were possible to have available tissue in which cells of interest are intrinsically labeled with a fluorescent marker, while the remaining cells are not, then all attempts to stain with fluorochromes would be unnecessary or could be aimed at other interesting but non-autofluorescent cells. Such tissue can indeed be created by genetic engineering. Organisms (or cell cultures) exist into which a gene that codes for green fluorescent protein (GFP; a photostable autofluorescent protein from the jellyfish, *Aequorea victoria*) has been transfected into the genome of particular cells. As a consequence, these cells metabolize and accumulate GFP that fluoresces 'spontaneously' when the cells are illuminated with light of the excitation wavelength.

The excitation spectrum of GFP has an excitation peak at 498 nm. GFP is reportedly extremely photostable. Since the introduction of GFP, a whole range of GFP–look-alikes has been introduced, each with its own specific excitation/emission characteristics: there is yellow-GFP, cyan-GFP, and wild-type (wt)-GFP, and so forth (see Table 1). Specific types of neurons exclusively expressing GFP can be of great help to the anatomist for the unraveling of neuronal networks (Figure 5).

Applications

Applications of fluorescence in neuroscience are numerous, and the reader is encouraged to consult a vast literature on this subject. We mention here only some broad areas of application. In fixed tissue, immunofluorescence allows detection of neuroactive substances, neurofilaments, cell proteins, and gene

Figure 5 GFP expressing a medium-size spiny neuron in the striatum of a genetically engineered mouse. (a) Fluorescence image in a 125-µm-thick slice. Note that all cell components and processes contain GFP. Visualization with 488 nm excitation in a confocal laser scanning microscope. (b) A three-dimensional computer reconstruction of the same cell. The presence of such cells as isolated neurons in mouse strains has greatly facilitated anatomical neuronal network analysis. Mouse material was a gift by Christiaan Levelt (University of Amsterdam).

products (by a technique named fluorescence *in situ* hybridization (FISH)). Detection of tracers incorporated in tissue before the tissue was fixed (i.e., by the living organism, via introduced markers and transfected fluorescent markers) is another approach. In living tissue and cells, voltage-sensitive dyes, calcium imaging, uptake and transport phenomena, and photobleaching experiments (fluorescence resonance energy transfer (FRET)) may be used.

The Fluorescence Microscope

Long before fluorescence imaging become an essential tool in neurobiology, shaping the way we think about neurons and the brain, Camillo Golgi, Santiago Ramon y Cajal, and others used light-absorbing tissue stains coupled with bright-field microscopy to visualize the brain's architecture. Their ability to observe the elements of the nervous system led to the early development of modern neuroscience. The field of neuroscience is still shaped by our ability to visualize the structures and cells of the nervous system. Modern microscopes far exceed the design specifications of those made prior to the mid-1900s. Modern glass formulations are vastly improved, enabling greater correction for optical aberration than ever before, and synthetic antiglare lens coatings are now very advanced. Integrated circuit technology has allowed manufacturers to produce smart microscopes that incorporate microprocessors into the microscope stand. Today's microscopes incorporate multiple illuminators, analyzers and polarizers, differential interference contrast (DIC) prisms, fluorescence attachments, and phase-contrast capabilities. When combined with the existing array of fluorochromes, a fluorescence microscope can be used to identify cells and submicroscopic cellular components with a high degree of specificity amid nonfluorescing material (Figure 1). In fact, at its highest resolution, the fluorescence microscope is capable of revealing the presence of a single molecule. Through the use of multiple fluorescence labeling, different probes can simultaneously identify several target molecules. Although the fluorescence microscope cannot provide a spatial resolution below the diffraction limit of specific specimen features, the detection of fluorescing molecules below such limits is readily achieved. In this section, we briefly described the microscopy equipment regularly found in the laboratory of a neuroscientist.

Fundamentals of Excitation and Emission

Epifluorescence illumination is the overwhelming choice of techniques in modern microscopy. The basic function of a fluorescence microscope is to irradiate the specimen with a desired and specific band of wavelengths and then to separate the much weaker-emitted fluorescence from the excitation light. In a properly configured microscope, only the emission light should reach the eye or detector so that the resulting fluorescent structures are superimposed with high contrast against a very dark background. The limits of detection are generally governed by the darkness of the background, and the excitation light is typically several hundred thousand to a million times brighter than the emitted fluorescence.

The effective separation and detection of excitation and emission wavelengths are achieved in fluorescence microscopy through the proper selection of filters to block or pass specific wavelength bands in the ultraviolet, visible, and near-infrared spectral regions. Epifluorescence microscopes feature a vertical illuminator interposed between the observation viewing tubes and the nosepiece housing the objectives and have the light source positioned at one end and the filter cube turret at the other. The illuminator is designed to direct light on to the specimen by first passing the excitation light through the microscope objective on the way to the specimen and then using that same objective to capture the emitted fluorescence. For fluorescence microscopy, the light of a specific wavelength (or defined band of wavelengths), often in the ultraviolet, blue, or green regions of the visible spectrum, is produced by passing multispectral light from an arc-discharge lamp (usually a mercury or xenon burner) or other source through a wavelength-selective excitation filter. Wavelengths passed by the excitation filter reflect from the surface of a dichromatic mirror, through the microscope objective to bathe the specimen with intense light. The light that emits from the fluorescing specimen radiates spherically in all directions, regardless of the excitation light source direction. Some of the emitted light is gathered by the objective and is sent back to the dichromatic mirror. Because the emitted light consists of longer wavelengths than the excitation illumination, it is able to pass through the dichromatic mirror and up toward the observation tubes or electronic detector. Most of the scattered excitation light reaching the dichromatic mirror is reflected back toward the light source. Before the emitted fluorescence can reach the eyepiece or detector, it first passes through the emission filter. This filter blocks any residual excitation light and passes the desired longer emission wavelengths. The excitation and emission filters can either be placed in front of the light source and capture device (or eyepiece), respectively, or they can be incorporated into the filter cube that houses the dichromatic mirror.

As already discussed, the fluorophore emission intensity peak is usually lower in frequency and

Figure 1 Using fluorescent microscopy to visualize cultured neurons. The dendrites of maturing primary rat hippocampal neurons in culture were imaged using a mouse anti-microtubule-associated protein (MAP)2 antibody and a goat antimouse secondary antibody conjugated to Alexa 488. The inset image is a higher magnification of synaptic proteins (green is synaptophysin; and red is postsynaptic density protein (PSD) 95) in mature cultured hippocampal neurons. Scale bar = 10 μm.

magnitude than that exhibited by the excitation peak. In addition, the emission spectral profile is often a mirror image (or nearly so) of the excitation curve but shifted to longer wavelengths. In order to achieve maximum fluorescence intensity, a fluorophore (often termed a dye) is usually excited at wavelengths near or at the peak of the excitation curve, and the widest possible range of emission wavelengths that include the emission peak are selected for detection. Perhaps the most important criteria, in view of relatively low fluorescence emission intensities, are that (1) the light source used for excitation be of sufficient brightness so that the weak emission light can be maximized and (2) the fluorochromes possess adequate absorption properties and emission quantum yields.

Fading: Photobleaching and Quenching

A wide spectrum of conditions often comes into play that ultimately affects the reradiation of fluorescence emission and thus reduces the intensity. The general term for a reduction of fluorescence emission intensity is fading, a catch-all category that is usually further subdivided into quenching and photobleaching phenomena. The excited state relaxation process of quenching results in reduced fluorescence intensity through a variety of mechanisms involving nonradiative energy loss and frequently occurs as a result of oxidizing agents or the presence of salts or heavy metals or halogen compounds. Photobleaching, on the other hand, is the irreversible decomposition of the fluorescent molecules in the excited state because of their interaction with molecular oxygen before emission.

Fluorescence Light Sources

An unfortunate consequence of low emission levels in most fluorescence microscopy applications is that the number of photons that reach the eye or camera detector is also very low. In most cases, the collection efficiency of optical microscopes is less than 30% and the concentration of many fluorophores in the optical path is in the micromolar or nanomolar range. In order to generate sufficient excitation light intensity to produce detectable emission, powerful compact light sources, such as high-energy short arc-discharge lamps, are necessary. The most common lamps are mercury burners, ranging in wattage from 50 to 200 W, and xenon burners, ranging from 75 to 150 W. These light sources are usually powered by an external direct current supply, furnishing enough startup power to ignite the burner through the ionization of the gaseous vapor and to keep it burning with a minimum of flicker for approximately 200–300 h. The mercury burners do not provide even intensity across the spectrum from ultraviolet to infrared, and much of the intensity of the lamp is expended in the near ultraviolet. Prominent peaks of intensity occur at 313, 334, 365, 406, 435, 546, and 578 nm. At other wavelengths in the visible light region, the intensity is steady, although not nearly so bright (but still usable in most applications). In considering illumination efficiency, mere lamp wattage is not the prime consideration. Instead, the mean luminance must be considered, which takes into account the source brightness, arc geometry, and the angular spread of emission.

In the past few years, optical microscopy has experienced an increase in the application of laser light sources, particularly the argon ion, argon–krypton ion, and a variety of helium–neon lasers. These lasers have the virtues of small source size, low divergence, near-monochromicity, and high mean luminance. Lasers have become essential for the development of certain techniques, such as scanning confocal microscopy, and a great deal of effort has been expended on developing new solid-state devices to replace the older gas lasers.

Objectives

Microscope objectives are perhaps the most important components of an optical microscope because they are responsible for primary image formation and play a central role in determining the quality of images that the microscope is capable of producing. Objectives are also instrumental in determining the

magnification of a particular specimen and the resolution under which fine specimen detail can be observed in the microscope. Modern objectives, composed of numerous internal glass lens elements, have reached a high state of quality and performance, with the extent of correction for aberrations and flatness of field determining the usefulness and cost of an objective. Construction techniques and materials used to manufacture objectives have greatly improved over the course of the past 100 years. Today, objectives are designed with the assistance of computer-aided-design systems, using advanced rare-element glass formulations of uniform composition and quality and having highly specific refractive indices. The enhanced performance that is demonstrated using these advanced techniques has allowed manufacturers to produce objectives that are very low in dispersion and corrected for most of the common optical artifacts such as coma, astigmatism, geometrical distortion, field curvature, and spherical and chromatic aberration. Not only are microscope objectives now corrected for more aberrations over wider fields, but image flare has been dramatically reduced with a substantial increase in light transmission, yielding images that are remarkably bright, sharp, and crisp.

Microscope Stage

Modern microscope stages are precisely manufactured and very durable. They are cast from iron, composite ceramics, or aluminum and machine finished to accurate tolerances. Translation mechanisms are usually rack-and-pinion styles, machined from aluminum, brass, or synthetic polymers. There are a wide variety of microscope stages that are designed for specific purposes. These include stages equipped with auxiliary equipment for manipulating samples during observation, measuring systems that allow precise measurements to be made over very small distances, universal stages that allow measurements over many specimen angles, and other specialized stages that perform a myriad of unique functions.

Microscope stages are classified according to design and functionality. In the simplest case, the plain stage consists of a rectangular or square design containing several clips to hold the specimen slide. Although manual movement of a specimen is very useful for quick examination of specimens, it is very difficult to use with higher-power objectives (above 20×). At high magnification, small translations of the specimen slide will usually throw the features of interest completely out of the view field, and attempting to relocate them can lead to frustration. Therefore, most stages can be fitted with the added feature of a specimen-slide translational control device, commonly referred to as a mechanical stage. Mechanical stages contain controls that allow the movement of the specimen slide in both the *X* (right and left) and *Y* (back and forth) directions in minute distances, making it easier for the microscopist to find specific areas on the slide.

Our ability to electronically control mechanical stages has improved tremendously over the last 15 years. These advances have been crucial in the development of the high-magnification measuring systems used in quantitative microscopy. The stages on these systems are equipped with electronically controlled micrometer-style translational devices that allow for very accurate and controlled movements of the stage and specimen, give accurate digital readouts of the stage position, and can be programmed for precise stage movements in a sequence of steps. There are a wide variety of designs for these specialized stages and many after-market manufacturers are capable of supplying custom-configured stages built to the customer's specifications.

Data Collection

Almost all microscopists, at some point, have the need or desire to record the images seen through the microscope. The use of photography to capture images in a microscope dates back to the invention of the photographic process. Early photomicrographs were remarkable for their quality, but the techniques were laborious and burdened with long exposures and a difficult process for developing emulsion plates and films. The primary medium for photomicrography was film until the past decade, when improvements in electronic camera and computer technology made digital imaging cheaper and easier to use than conventional photography. The imaging device is one of the most critical components in fluorescence microscopy because it determines at what level specimen fluorescence may be detected, the relevant structures resolved, and/or the dynamics of a process visualized and recorded. The problems of photodestruction of fluorochromes in the presence of oxygen (photobleaching) and limitations on the numbers of fluorochromes that can be involved in a single region make it essential that a sensitive electronic detector is used in fluorescence microscopy. In addition, only approximately 5–10% of the emitted light from an excited fluorochrome is collected and transferred to the sensor in a typical epifluorescence microscope. There are two approaches to capturing as much of this limited light flux as possible: integration by a slow-scan charge-coupled device (CCD) and image intensification and capture on a video-rate or progressive-scan CCD camera. The general finding is

that a cooled, slow-scan CCD camera always produces a higher signal-to-noise ratio than an intensified CCD, provided sufficient integration time is available. The CCD is presently the most widely used detector for fluorescence microscopy. Emerging electron-multiplying CCD technology is opening the door to even more sensitive detectors and may become a primary component in the microscopist's toolbox in the next few years.

Fluorescent Probes

Many fluorescent probes are constructed around synthetic aromatic organic chemicals designed to bind with a biological macromolecule (e.g., a protein or nucleic acid) or to localize within a specific structural region, such as the cytoskeleton, mitochondria, Golgi apparatus, endoplasmic reticulum, or nucleus. Other probes, both synthetic and those derived from naturally occurring proteins, are employed to monitor dynamic processes and localized environmental variables, including concentrations of inorganic metallic ions, pH, reactive oxygen species, and membrane potential. Fluorescent dyes are also useful in monitoring cellular integrity (live vs. dead and apoptosis), endocytosis, exocytosis, membrane fluidity, protein trafficking, signal transduction, and enzymatic activity. As such, the investigation of living and fixed neurons has benefited greatly from the evolution of fluorescent biomarkers. Although many of the available fluorescent reagents are used in the study of neurons, we describe here only the major groups.

Classic Synthetic Fluorescent Probes

Fluorochromes have been of great value in the study of both neurons in culture and tissue. These stains (also termed fluorophores) are excited by specific wavelengths of irradiating light and emit light of defined and useful intensity. Importantly, modern fluorochromes have a significant quantum yield (the ratio of photon absorption to emission). Fluorochromes were introduced to microscopy in the early twentieth century as vital stains for bacteria, protozoa, and trypanosomes, but did not see widespread use until the 1920s when fluorescence microscopy was first used to study dye binding in fixed tissues and living cells. Although these reagents proved to be useful, it was not until the early 1940s that Albert Coons developed a technique for labeling antibodies with fluorescent dyes, which gave rise to the field of immunofluorescence. Over the past 60 years, advances in immunology and molecular biology have produced a wide spectrum of secondary antibodies and provided insights into the molecular design of fluorescent probes targeted at specific regions within macromolecular complexes. Surprisingly, the advances made in fluorescent dye synthesis during the past few decades have provided very little insight into molecular design rules for developing new fluorochromes.

Many of the classic fluorescent probes, including fluorescein isothiocyanate, Lissamine rhodamine, and Texas red, have been successfully used to investigate neurons for many years in wide-field fluorescence. Although some of these fluorochromes (especially fluorescein isothiocynate) have been replaced with newly developed synthetic analogs, others, such as tetramethyl rhodamine and the isothiocyanate derivative, are still frequently employed in multiple-labeling investigations in microscopy due to their efficient excitation by the 546 nm spectral line from mercury arc-discharge lamps and 543 nm gas lasers.

The Birth of a New Generation of Synthetic Fluorescent Probes

The dramatic advances in modern fluorophore technology are exemplified by the Alexa Fluor dyes introduced by Molecular Probes. These sulfonated rhodamine derivatives exhibit higher quantum yields for more intense fluorescence emission than spectrally similar probes, and they have several additional improved features, including enhanced photostability, absorption spectra matched to common laser lines, pH insensitivity, and a high degree of water solubility.

The popular family of cyanine dyes, Cy2, Cy3, Cy5, Cy7, and their derivatives, exhibit fluorescence excitation and emission profiles that are similar to many of the traditional dyes, such as fluorescein and tetramethylrhodamine, but with enhanced water solubility, photostability, and higher quantum yields. Most of the cyanine dyes are more environmentally stable than their traditional counterparts, rendering their fluorescence emission intensity less sensitive to pH and organic mounting media. In a manner similar to the Alexa Fluors, the excitation wavelengths of the Cy series of synthetic dyes are tuned specifically for use with common laser and arc-discharge sources, and the fluorescence emission can be detected with traditional filter combinations.

In addition to the new generation of fluorochromes just described, nanometer-size crystals of purified semiconductors, principally cadmium selenide, known as quantum dots, are emerging as a potentially useful fluorescent labeling agent for living and fixed neurons in both traditional wide-field and laser scanning confocal fluorescence microscopy. Recently introduced techniques enable the purified tiny semiconductor crystals to be coated with a hydrophilic polymer shell and conjugated to antibodies or

other biologically active peptides and carbohydrates for application in many of the classic immunocytochemistry protocols, as well as tracking agents in live-cell imaging. These probes have significant benefits over organic dyes and fluorescent proteins, including long-term photostability, high fluorescence-intensity levels, and multiple colors with single-wavelength excitation for all emission profiles. In addition, the fluorescence emission intensity is confined to a symmetrical peak with a maximum wavelength that is dependent on the dot size but independent of the excitation wavelength. As a result, the same emission profile is observed regardless of whether the quantum dot is excited at 300, 400, 500, or 600 nm, but the fluorescence intensity increases dramatically at shorter excitation wavelengths.

Directly Targeted Fluorophores

DNA and chromatin in neurons can be stained with dyes that bind externally to the double helix. The most popular fluorochromes in this category are 4′,6-diamidino-2-phenylindole and the bisbenzimide Hoechst dyes that are designated by the numbers 33 258, 33 342, and 34 580. These probes are quite water-soluble and bind externally to AT-rich base pair clusters in the minor groove of double-stranded DNA with a dramatic increase in fluorescence intensity.

Fluorophores targeted at specific intracellular organelles, such as the mitochondria, lysosomes, Golgi apparatus, and endoplasmic reticulum, are useful for monitoring a variety of biological processes in living and fixed neurons. In general, organelle probes consist of a fluorochrome nucleus attached to a target-specific moiety that assists in localizing the fluorophore through covalent, electrostatic, hydrophobic, or similar types of bonds. Many of the fluorescent probes designed for selecting organelles are able to permeate or sequester within the cell membrane (and, therefore, are useful in living cells), whereas others must be installed using monoclonal antibodies with traditional immunocytochemistry techniques.

Fluorophores Used to Sense the Intracellular Neuronal Environment

Fluorophores designed to probe the internal environment of living neurons have been widely examined by a number of investigators, and many hundreds have been developed to monitor effects such as localized concentrations of alkali and alkaline earth metals, heavy metals (employed biochemically as enzyme cofactors), inorganic ions, thiols and sulfides, and nitrite; pH, solvent polarity, and membrane potential. Ca^{2+} is a metabolically important ion in neurons that plays a vital role in cellular response to many forms of external stimuli. Because transient fluctuations in Ca^{2+} ion concentration are typically involved when cells undergo a response, fluorophores must be designed not only to measure localized concentrations within segregated compartments but also to produce quantitative changes when flux density waves progress throughout the entire cytoplasm. Many of the synthetic molecules designed to measure Ca^{2+} levels are based on the nonfluorescent chelation agents ethylene glycol tetraacetic acid (EGTA) and 1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid (BAPTA), which have been used for years to sequester Ca^{2+} ions in buffer solutions. Several of the most common Ca^{2+} probes are the ratiometric indicators fura-2, fluo-3, and indo-1. Important fluorescence monitors for intracellular pH include a pyrene derivative known as 8-hydroxypyrene-1,3,6-trisulfonic acid, trisodium salt (HPTS) or pyranine; the fluorescein derivative (2-carboxy ethyl)-5-(and 6)-carboxy fluorescein (BCECF); and another substituted xanthene termed carboxy seminaphtorhodafluor (SNARF)-1.

Fluorescent Proteins

Fluorescent probe technology and cell biology (including neurobiology) have been dramatically altered over the past few years by the discovery and development of naturally occurring fluorescent proteins (Table 1). Mutated derivatives of these proteins have rapidly advanced to center stage in the investigation of a wide range of intracellular processes in living organisms. These biological probes have provided scientists with the ability to visualize, monitor, and track individual molecules with high spatial and temporal resolution in both steady-state and kinetic experiments. A variety of marine organisms have been the source of more than 100 fluorescent proteins and their analogs, which arm the investigator with a balanced palette of noninvasive biological probes for single-, dual-, and multispectral fluorescence analysis. Among the advantages of fluorescent proteins over the traditional organic and new semiconductor probes already described is their response to a wider variety of biological events and signals. Coupled with their ability to specifically target fluorescent probes to subcellular compartments, their extremely low or absent photodynamic toxicity, and their widespread compatibility with tissues and intact organisms, these biological macromolecules offer an exciting new frontier in live-cell imaging.

The first member of this series to be discovered, green fluorescent protein (GFP), was isolated from the North Atlantic jellyfish, *Aequorea victoria*, and found to exhibit a high degree of fluorescence without

Along with the common name and/or acronym for each fluorescent protein, the peak excitation (Ex) and emission (Em) wavelengths, molar extinction coefficient (EC), quantum yield (QY), relative brightness, and *in vivo* structural associations are listed (*signifies a weak dimer). The computed brightness values were derived from the product of the molar extinction coefficient and quantum yield, divided by the value for EGFP. This listing was created from scientific and commercial literature resources and is not intended to be comprehensive, but instead represents fluorescent protein derivatives that have received considerable attention in the literature and may prove valuable in research efforts. The excitation and emission peak values listed may vary in published reports due to the broad spectral profiles. In actual fluorescence microscopy investigations, spectral profiles and wavelength maxima are influenced by environmental effects, such as pH, ionic concentration, and solvent polarity, as well as fluctuations in localized probe concentration. Therefore, the listed extinction coefficients and quantum yields may differ from those actually observed under experimental conditions.

the aid of additional substrates or coenzymes. In native GFP, the fluorescent moiety is a cyclized tripeptide derivative of serine, tyrosine, and glycine that requires molecular oxygen for activation, but no additional cofactors or enzymes. Subsequent investigations revealed that the GFP gene could be expressed in other organisms, including mammals, to yield fully functional analogs that display no adverse biological effects. In fact, fluorescent proteins can be fused to virtually any protein in living cells using recombinant complementary DNA cloning technology, and the resulting fusion protein gene product can be expressed in cultured neurons and transgenic animals. Lack of a need for cell-specific activation cofactors renders the fluorescent proteins much more useful as generalized probes than other biological macromolecules, such as the phycobiliproteins, which require the insertion of accessory pigments in order to produce fluorescence.

Mutagenesis experiments with GFP have produced a large number of variants with improved folding and expression characteristics, which have eliminated wild-type dimerization artifacts and fine-tuned the absorption and fluorescence properties. These studies have uncovered GFP variants that exhibit a variety of absorption and emission characteristics across the entire visible spectral region, which has enabled researchers to develop probe combinations for simultaneous observation of two or more distinct fluorescent proteins in a single organism. Several of these derivatives, known as biosensors, are useful in resonance energy-transfer experiments and other investigations that rely on multicolor fluorescence imaging.

Attempts to shift the absorption and emission spectra of *Aequorea victoria* fluorescent proteins to wavelengths in the orange and red regions of the spectrum have met with little success. However, fluorescent proteins from other marine species have enabled investigators to extend the available spectral regions to well within the red and near-infrared wavelength range. Newly developed photoactivation fluorescent proteins, including photoactivatable GFP, Kaede, and Eos, exhibit dramatic emission wavelength shifts on irradiation with ultraviolet light. These probes should prove useful in live-cell neuron imaging studies involving selective irradiation of specific target regions and the subsequent kinetic analysis of diffusional mobility and compartmental residency time of fusion proteins.

An emerging set of tools for the neuroscientist's fluorescent probe palette is hybrid systems designed around small molecules that can be covalently targeted to genetically specified proteins within or on the surface of living cells. The most promising system is a tetracysteine-biarsenical system that requires modification of the target protein using a 12-residue peptide sequence containing four cysteine residues. When membrane-permeable biarsenical molecules, known as FlAsH and ReAsH, interact with the modified target, fluorescence can be detected at picomolar levels.

Advanced Microscopy Techniques

Neurons are polarized cells that have three morphologically and biochemically distinct compartments: the soma, axon, and dendrites. It is the existence of these subregions and their unique characteristics that make studying protein synthesis, assembly, trafficking, and function in neurons using some of the more traditional approaches difficult. Therefore, neuroscientists have taken advantage of advanced microscopy techniques to perform biochemical-like studies in subneuronal compartments. In this section, we discuss the techniques that make this possible.

Fluorescence Recovery after Photobleaching

The phenomenon of photobleaching is exploited in a technique known as fluorescence recovery after photobleaching (FRAP), a very useful mechanism for investigating the diffusion and motion of biological macromolecules. The method is based on photobleaching a fluorescently tagged molecule in a precisely defined region of the specimen by an intense burst of laser light, accompanied by the subsequent observation of the rates and pattern of fluorescence recovery in the photobleached area. A related technique, known as fluorescence loss in photobleaching (FLIP), is employed to monitor the decrease of fluorescence in a defined region lying adjacent to a photobleached area. Similar to FRAP, this technique is useful in the investigation of molecular mobility and dynamics in living cells.

Fluorescence Resonance Energy Transfer

In some cases, fluorescence quenching results from the transfer of energy to another molecule (termed the acceptor; e.g., EYFP), which resides physically close to the excited fluorophore (the donor; e.g., ECFP), a phenomenon known as fluorescence resonance energy transfer (FRET). This particular mechanism has become the basis for a useful technique involving the study of molecular interactions and associations at distances far below the lateral resolution of the optical microscope. FRET is useful for obtaining quantitative temporal and spatial information about the binding and interactions of proteins, lipids, enzymes, and nucleic acids in living cells. The technique is performed using either steady-state or time-resolved

methodology, but time-resolved FRET imaging has the advantage of more accurately mapping the donor–acceptor distance.

Optical Highlighter Fluorescent Proteins

Protein chromophores that can be activated to initiate fluorescence emission from a quiescent state (a process known as photoactivation) or that are capable of being optically converted from one fluorescence emission bandwidth to another (photoconversion) represent perhaps the most promising approach to the *in vivo* investigation of protein lifetimes, transport, and turnover rates in neurons. Appropriately termed molecular or optical highlighters, photoactivated fluorescent proteins generally display little or no initial fluorescence under excitation at the imaging wavelength, but dramatically increase their fluorescence intensity after activation by irradiation at a different (usually lower) wavelength. Photoconversion optical highlighters, on the other hand, undergo a change in the fluorescence emission bandwidth profile on optically induced changes to the chromophore. These effects result in the direct and controlled highlighting of distinct molecular pools within the cell.

The ability to selectively initiate or alter fluorescence emission profiles in photoconversion optical highlighter proteins renders these probes excellent tools for exploring protein behavior in living cells. Because the fluorescence intensity (or color spectrum) of highlighters occurs only after photon-mediated conversion, newly synthesized non-photo-activated protein pools remain unobserved and do not complicate experimental results. This signal independence from new protein synthesis could potentially enable the study of protein degradation kinetics in tagged molecules by techniques such as optical pulse labeling and monitoring of the fluorescence over time. Additional quantitative techniques, including fluorescence-correlation spectroscopy, should prove useful in measuring the mobility of photoactivated optical highlighters in small numbers, even down to the single-molecule level.

Photoactivation and photoconversion of optical highlighters are generally rapid and produce stable fluorescence signals. Therefore, these probes can be used to examine a variety of kinetic properties of tagged proteins, such as their diffusion coefficients, fractional mobility, compartmental residency time, and exchange rates. In many cases, photoconversion offers greater flexibility than the traditional photobleaching techniques of FRAP and FLIP. In addition, cell lineage or translocation in developing organisms can be easily monitored by imaging the fluorescence dispersion after photoactivation of a single cell or subpopulation of cells. In these regards, optical highlighters demonstrate remarkable promise to complement and extend the range of present fluorescent protein-imaging applications.

Fluorescence Deconvolution Microscopy

An intrinsic problem exists in wide-field fluorescence microscopy – blur arising from fluorescently stained structures removed from the point of focus hinders the visualization of information in the focal plane. Deconvolution is the computational process that reduces out-of-focus blur. Deconvolution microscopy has become the preferred method for imaging weak signals, particularly in live imaging of events in culture cells, because CCDs have much higher quantum efficiency than the photomultipliers used in confocal microscopy. The reason why this technique is usually limited to imaging culture cells and relatively thin tissue specimens is because all the algorithms used to perform deconvolution have the potential to amplify input signal noise. However, when used correctly, the application of deconvolution algorithms to image stacks made up of several consecutive *Z*-axis image planes results in images that have substantially improved contrast and resolution.

Confocal Microscopy

Laser scanning confocal microscopy represents one of the most significant advances in optical microscopy ever developed, primarily because the technique enables visualization deep within both living and fixed cells and tissues and because it affords the ability to collect sharply defined optical sections from which three-dimensional renderings can be created (Figure 2). Confocal microscopy offers several advantages over conventional wide-field optical microscopy, including the ability to control depth of field, the elimination or reduction of background information away from the focal plane (that leads to image degradation), and the capability of collecting serial optical sections from thick specimens. The basic key to the confocal approach is the use of spatial filtering techniques to eliminate out-of-focus light or glare in specimens whose thickness exceeds the immediate plane of focus. There has been a tremendous explosion in the popularity of confocal microscopy in recent years, due in part to the relative ease with which extremely high-quality images can be obtained from specimens prepared for conventional fluorescence microscopy and to the growing number of applications in cell biology that rely on imaging both fixed and living cells and tissues. In fact, confocal technology is proving to be one of the most important advances ever achieved in optical microscopy.

Figure 2 Rat brain hippocampus section (30 μm thick): (a) wide-field fluorescence image; (b) laser scanning confocal image. The tissue was stained with triple immunofluorescence using primary antibodies to histones (cyan), heavy neurofilaments (green), and glial fibrillary acidic protein (GFAP; red).

In modern confocal microscopes, two fundamentally different techniques for beam scanning have been developed. Single-beam scanning, one of the more popular methods employed in a majority of the commercial laser scanning microscopes, uses a pair of computer-controlled galvanometer mirrors to scan the specimen in a raster pattern at a rate of approximately one frame per second. Faster scanning rates (to near video speed) can be achieved using acousto-optic devices or oscillating mirrors. In contrast, multiple-beam scanning confocal microscopes are equipped with a spinning disk containing an array of slits or pinholes coupled to microlenses. These instruments often use arc-discharge lamps for illumination, instead of lasers, to reduce specimen damage and enhance the detection of low fluorescence levels during real-time image collection. Another important feature of the multiple-beam microscopes is their ability to readily capture images with an array detector, such as a CCD camera system.

The broad range of applications available to laser scanning and spinning-disk confocal microscopy includes a wide variety of studies in neuroanatomy and neurophysiology, as well as morphological studies of a wide spectrum of cells and tissues. In addition, the growing use of new fluorescent proteins is rapidly expanding the number of original research reports coupling these useful tools to modern microscopic investigations. Other applications include resonance energy transfer, stem-cell research, photobleaching studies, lifetime imaging, multiphoton microscopy, total internal reflection, DNA hybridization, membrane and ion probes, bioluminescent proteins, and epitope tagging.

Multiphoton Fluorescence Microscopy

Multiphoton fluorescence microscopy is a powerful research tool that combines the advanced optical techniques of laser scanning microscopy with long-wavelength nonlinear multiphoton fluorescence excitation to capture high-resolution, three-dimensional images of specimens tagged with highly specific fluorophores.

The methodology is particularly useful to neurobiologists who endeavor to study dynamic processes in living brain tissues without inflicting significant, and often lethal, damage to the specimen. Excitation in multiphoton microscopy occurs only at the focal point of a diffraction-limited microscope, providing the ability to optically section thick biological specimens to obtain three-dimensional resolution. Because the position of the focal point can be accurately determined and controlled, multiphoton fluorescence is useful for probing selected regions beneath the specimen surface. The highly localized excitation energy serves to minimize the photobleaching of fluorophores attached to the specimen and to reduce photodamage, which increases cell viability and the subsequent duration of experiments that investigate the properties of living cells. In addition, the application of near-infrared excitation wavelengths permit deeper penetration into biological materials and reduces the high degree of light scattering that is observed at shorter wavelengths. These advantages enable researchers to conduct experiments on thick living-tissue samples, such as brain slices and developing embryos, that would be difficult, if not impossible, to image with other microscopy techniques.

A major impediment to research in multiphoton microscopy is the high cost of the equipment, in particular the necessary mode-locked pulsed laser systems that are required for two-photon and three-photon excitation. Typically, Ti:sapphire lasers, which have a wavelength tunability of 700–1100 nm, are used for multiphoton imaging of fluorescent probes. As newer, cheaper, and user-friendly lasers are introduced into this competitive market, more commercial multiphoton

microscope systems will be introduced at a cheaper price. This availability, coupled to the fact that there are no physical limitations on the implementation of multiphoton fluorescence, will encourage the widespread application of this technique throughout the biological sciences.

Detecting Single Molecules Using Total Internal Reflection Microscopy

Under ideal conditions, it is often possible to detect the fluorescence emission from a single molecule, provided that the optical background and detector noise are sufficiently low. A single fluorescein molecule emits as many as 300 000 photons before it is destroyed by photobleaching. Assuming a 20% collection and detection efficiency, approximately 60 000 photons would be detected. Using avalanche photodiode or electron-multiplying CCD detectors for these experiments, investigators have been able to monitor the behavior of single molecules for many seconds and even minutes. The major problem is adequate suppression of the optical background noise. Fluorescence microscopy techniques using total internal reflection provide the desired combination of low background and high excitation light flux.

Total internal reflection fluorescence microscopy (TIRFM) takes advantage of the evanescent wave that is developed when light is totally internally reflected at the interface between two media having dissimilar refractive indices. In this technique, a beam of light (usually an expanded laser beam) is directed through a prism of high refractive index, such as glass or sapphire, which abuts a lower refractive index medium of glass or aqueous solution. If the light is directed into the prism at a higher than the critical angle, the beam will be totally internally reflected at the interface. The reflection phenomenon develops an evanescent wave at the interface by the generation of an electromagnetic field that permeates approximately 200 nm into the lower refractive index space. The light intensity in the evanescent wave is sufficiently high to excite the fluorophores within it, but because of its shallow depth, the volume excited is very small. The result is an extremely low-level background because so little of the specimen is exposed to the excitation light.

TIRFM can also be conducted through a modification of the epi-illumination approach used in wide-field techniques. This method requires a very high numerical aperture objective (at least 1.4, but preferably 1.45–1.6) and partial illumination of the microscope field from one side by a small sport or more uniform illumination by a thin annulus. High-refractive-index lens immersion medium and microscope cover glass are required to achieve the illumination angle resulting in total internal reflection. Light rays exiting the objective front lens element at an angle less than the critical angle are transmitted away from the microscope. When the angle is increased to or beyond the critical angle, total internal reflection results.

Figure 3 The newly developed up/down microscope. This advanced microscope is capable of simultaneously performing both total internal reflection fluorescence microscopy and epifluorescence or confocal microscopy. The upper part of the system is equipped with an Olympus digital server unit confocal, a Hamamatsu ORCA II ERG camera, a QICAM-IR, and a Hamamatsu electron-multiplying charge-coupled device camera. The bottom half of the system is a multi-laser-line total internal reflection fluorescence microscope equipped with a Hamamatsu ORCA II ERG camera. Because two different microscope heads are used, equipped with independent Z-axis motors, simultaneous imaging can be performed on the exact same focal plane or on different planes: distinctive *Z*-axis, *XY*-plane, or both positions.

Other popular advanced fluorescence techniques, such as FRET and FRAP, are often combined with TIRFM to achieve additional information. In addition, microscopes that are capable of simultaneously performing both TIRFM and epifluorescence or confocal microscopy are now being developed (Figure 3). The result is a very powerful tool for the study of individual fluorophores and fluorescently labeled molecules. The advantages resulting from the study of the properties of single molecules are only beginning to be appreciated.

Conclusion

The modern fluorescence microscope combines the power of high-performance optical components with computerized control of the instrument and digital image acquisition to achieve a level of sophistication

that far exceeds that of simple observation by the human eye. Microscopy now depends heavily on electronic imaging to rapidly acquire information at low light levels or at visually undetectable wavelengths. These technical improvements are not mere window dressing but, rather, are essential components of the light microscope as a system.

The era when optical microscopy was purely a descriptive instrument or an intellectual toy is past. At present, optical image formation is only the first step toward data analysis. The microscope accomplishes this first step in conjunction with electronic detectors, image processors, and display devices that can be viewed as extensions of the imaging system. Computerized control of focus, stage position, optical components, shutters, filters, and detectors is in widespread use and enables experimental manipulations that were not humanly possible with mechanical microscopes. The increasing application of electro-optics in fluorescence microscopy has led to the development of optical tweezers capable of manipulating subcellular structures or particles, the imaging of single molecules, and a wide range of sophisticated spectroscopic applications. In conclusion, the current range of optical microscopy now extends from the single molecule to the entire animal.

fMRI: BOLD Contrast

S A Huettel, Duke University Medical Center, Durham, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Many neuroscience techniques provide information about human brain function. Perhaps the most influential in recent years has been functional magnetic resonance imaging (fMRI). The success of fMRI can be traced to several factors. Whereas its predecessor positron emission tomography requires injection of some radioactively labeled metabolite, fMRI measures naturally occurring blood oxygenation level-dependent (BOLD) contrast. Data can be acquired using standard clinical magnetic resonance imaging (MRI) scanners (Figure 1), of which there are more than 10 000 in North America alone. The broad availability of these machines has made fMRI accessible to thousands of researchers, many originally from fields outside of neuroscience. Also, the measurements obtained using fMRI allow study of many cognitive processes. The spatial resolution of fMRI is on the order of a few millimeters, allowing researchers to identify areas of distinct function. The temporal resolution of fMRI is on the order of 1 s, which is much slower than measurements of brain electrophysiology but fast enough for many types of experiments.

The advantages of fMRI over other neuroimaging techniques have resulted in remarkable growth. No longer restricted to a handful of institutions, fMRI has become the central research technique in hundreds of laboratories. During the year prior to the publication of this edition of the encyclopedia, more than 1500 peer-reviewed scientific articles (by a conservative count) cited fMRI in their abstracts or titles. Yet, with growth should come caution. Like any other neuroscience technique, fMRI can be readily used to conduct confusing, meaningless, and uninterpretable experiments. Although a complete discussion of fMRI is beyond its scope, this article provides a broad overview to the basic principles of fMRI, from physics and neurophysiology to experimental design and analysis.

Physical Principles of MRI

The process of MRI scanning can be partitioned into three components (Figure 2), corresponding roughly to the three parts of that abbreviation: magnetization, resonance, and image formation. First, a large superconducting solenoid coil generates a very strong magnetic field that induces magnetization in tissue protons. Second, an excitation coil sends radiowaves into the tissue; by calibrating this coil to a particular, resonant frequency of the magnetized protons, energy from the radio waves will be absorbed by the protons and later reemitted as the MR signal. Third, a set of gradient coils are used to strengthen or weaken the magnetic field very slightly across space, which provides spatial variation in the signal that is received. Depending on the particular pattern (or pulse sequence) of radio waves and magnetic gradients, images can be acquired that are sensitive to brain structure or function.

Magnetization

Atomic nuclei whose characteristics can be measured by MRI are often referred to as 'spins,' reflecting that under normal conditions, thermal energy causes the nucleus to spin about itself. The most common MRI-visible nucleus in the human body is that of hydrogen within water molecules, and the processes described in the remainder of this article involve creating images of the properties of hydrogen protons. One can think of these protons as analogous to spinning bar magnets (like tops or gyroscopes), each described by the frequency and the orientation of its spinning.

In the absence of any strong magnetic field, the hydrogen protons are oriented randomly and thus their magnetic moments tend to cancel each other out. However, when the spins enter the MRI scanner, their axes of spinning tend to become aligned either parallel or antiparallel to its strong magnetic field (Figure 3). Protons in the parallel state have a lower energy level, whereas protons in the antiparallel state have a higher energy level. At room temperature in a standard 1.5 T MRI scanner, roughly equal numbers of protons are in the parallel (approximately 50.002%) and antiparallel (approximately 49.998%) energy states. This difference, although proportionally very small, results in a net magnetization. We can think of the net magnetization as a vector with two components: (1) a longitudinal component that is either parallel or antiparallel to the magnetic field and (2) a transverse component that is perpendicular to the magnetic field.

Because of their angular momentum, protons in a magnetic field initiate a gyroscopic motion known as precession. The precession frequency is proportional to the strength of the field (i.e., approximately 42.58 MHz/T). Within even the smallest quantity of tissue, there are an enormous number of protons, each precessing with different phase.

Figure 1 A modern MRI scanner. Machines such as this 1.5 T scanner can be used for both structural MRI measurements and fMRI studies. The subject lies down on the table at the front of the scanner and places his or her head inside the volume coil at the center of the image. Surrounding the central bore of the scanner are the coils that generate the strong static magnetic field and weaker gradient magnetic fields; these two sets of coils are hidden behind the plastic cowling in this image. Reproduced from Huettel SA, Song AW, and McCarthy G (2004) *Functional Magnetic Resonance Imaging*. Sunderland, MA: Sinauer, with permission.

Thus, the transverse components of their magnetization will tend to cancel out under normal conditions, leaving only a net magnetization that is precessing in parallel with the main magnetic field.

Resonance

Spins in the low-energy state (parallel) can jump to the high-energy state (antiparallel) by absorbing electromagnetic energy (i.e., photons). Yet, because the net magnetization rotates around the magnetic field axis many millions of times per second, a single pulse of energy would have little effect. Instead, protons absorb energy when it is applied at a particular frequency for an extended period of time. As an analogy, imagine a backyard swing set. By continually applying energy at the swing's natural (or resonant) frequency, a series of very small pushes contributes energy to the system and increases the velocity of the swinging. Similarly, MRI scanners use specialized coils to transmit electromagnetic energy at the precession frequency of the hydrogen protons within the magnetic field, whereupon some spins in the low-energy state absorb this energy and change to the high-energy state. This process is known as excitation (Figure 4(a) and 4(b)).

After excitation, some protons will move back to the low-energy state, emitting energy in the process. During this period, the net magnetization gains a significant transverse component – oscillating at the resonant frequency of the precessing spins – that can be measured in detector coils as the MR signal (Figure 4(c)). This process is known as reception. Since the frequencies of excitation and reception are identical, the same radiofrequency coil can be used for both. The MR signal, which is the coherent part of the transverse magnetization, decays quickly over time because of spin–spin interactions, generally within a few tens of milliseconds – a process known as transverse relaxation. The time constant that characterizes this decay process is T2. Simultaneously over a period of several seconds, some of the individual spins move back to the low-energy state in a process known as longitudinal recovery (of the net magnetization). The time constant that characterizes this recovery process is T1.

An additional, extrinsic cause of MR signal decay is the presence of inhomogeneity in the external magnetic field. Because each spin precesses at a frequency proportional to the magnetic field it experiences, spatial variations in field strength cause variation in precession frequency, also leading to the loss of coherent MR signal. Because field inhomogeneity has an additive effect on top of T2 spin interactions, the combined effects of these two factors are characterized by a third time constant, T2*. This final time constant forms the basis of the BOLD contrast used in nearly all fMRI studies.

Image Formation

In the context of MRI, an image is a map that depicts the spatial distribution of some spin property – for example, how many spins there are, how those spins move, or the spins' relaxation constants such as T1 or T2. The fundamental concept underlying image formation in MRI is that of the magnetic gradient, or spatially varying magnetic field. By superimposing a second magnetic field that varies linearly across space, the scanner causes spins at different locations to precess at different frequencies. In most forms of MRI, including fMRI, several gradients are used in succession. Following an initial spatial gradient along one direction (e.g., from the top to bottom of the brain), an electromagnetic (or excitation) pulse is applied at a frequency designed to excite spins within a single two-dimensional slice of tissue. Then, magnetic gradients in the other two directions are rapidly cycled on and off in prescribed patterns, depending on how the image is to be collected. The particular combination of radiofrequency excitation pulse(s) and patterned changes in magnetic gradients used for collection of a particular image is known as a pulse sequence.

Figure 2 A schematic overview of the hardware required for fMRI research. The scanner is controlled by electronics that generate the pulse sequences used in fMRI experiments. Key components include amplifiers that create spatial gradients in three directions and a radiofrequency amplifier which controls the output of the head coil. The MR signal is measured in that same head coil and then transmitted back to the scanner console room for subsequent reconstruction. For fMRI experiments, additional systems are necessary for displaying stimuli, recording behavior, and storing and analyzing the data. Reproduced from Huettel SA, Song AW, and McCarthy G (2004) *Functional Magnetic Resonance Imaging*. Sunderland, MA: Sinauer, with permission.

How changing magnetic gradients can be used to create an image may be the most complex aspect of MRI. To understand the underlying concepts, it is important to recognize that any image can be mathematically represented as either a map of intensity values (normal space) or a map of spatial frequency values (*k*-space). For MRI, each point in *k*-space reflects the accumulated changes in phase based on the spatial gradients that have been presented following excitation. For example, if positive horizontal and positive vertical gradients were together applied for a few milliseconds, any signal then recorded would be considered to come from the upper right quadrant of *k*-space. At the center of *k*-space are low spatial frequency components, reflecting only small net exposures to gradients. These correspond to the overall intensity and coarse features of the normal space image. The periphery of *k*-space contains high spatial frequency components; these provide information about fine details of the sample.

Most pulse sequences manipulate spatial gradients to collect data from all parts of *k*-space following one excitation pulse. In echo-planar imaging, which is the most commonly used approach to fMRI, horizontal and vertical gradients are alternated to fill *k*-space in a back-and-forth pattern. Spiral imaging sequences use a different approach: simultaneously using both gradients to move from the center of *k*-space outward (or from the periphery inward) in a whirlpool pattern. Regardless of the pulse sequence, two parameters are

Figure 3 Net magnetization. In the strong magnetic field of the MRI scanner, slightly more than half of the protons align their axis of precession parallel to the magnetic field, whereas slightly less than half are antiparallel. This difference results in a net magnetization, labeled M, along the direction of the magnetic field. Reproduced from Huettel SA, Song AW, and McCarthy G (2004) *Functional Magnetic Resonance Imaging*. Sunderland, MA: Sinauer, with permission.

important. The echo time (or TE) is the time between the excitation pulse and the recording of data from the center of *k*-space; to give maximal T2* contrast for fMRI, TE values are typically a few tens of milliseconds. The time between successive excitations, known as repetition time (TR), depends on how many slices are to be collected and the characteristics of the pulse sequence, including TE. In most fMRI studies that sample the entire brain, often using 20 or more individual slices, TR is between 1 and 3 s.

In summary, standard MRI scanners can collect, every few seconds, an image of the brain that is sensitive to magnetic field inhomogeneities. As described in the following section, one consequence of neuronal activity is changes in blood oxygenation that cause exactly that – spatially specific inhomogeneities in the local magnetic field.

Physiological Principles of fMRI

Although constituting only approximately 2% or 3% of the body's mass, the human brain uses approximately 20% of the body's energy. This enormous energy budget supports the integrative (dendritic) and signaling (axonal) activity of neurons. Both forms of neuronal activity do not require external sources of energy because the associated changes in electrical potential are caused by movements of ions along concentration gradients. Energy must be supplied, however, for the restoration of membrane potentials following neuronal activity. It has been estimated that for humans and higher primates, the restoration of

Figure 4 A schematic representation of excitation and reception. (a) When protons are placed in an external magnetic field, often labeled B_0, more will be at the low-energy state (orange) than at the high-energy state (blue). (b) If an excitation pulse is applied at the resonant frequency of the protons, some will absorb that energy and jump to the high-energy state. (c) However, after the excitation pulse is turned off, some of the protons in the high-energy state will return to the low-energy state, releasing the energy they earlier absorbed. Reproduced from Huettel SA, Song AW, and McCarthy G (2004) *Functional Magnetic Resonance Imaging*. Sunderland, MA: Sinauer, with permission.

these potentials requires the lion's share of energy expenditure, perhaps 80% or more of all ATP consumption in the brain.

To meet this energy demand, the vascular system supplies two important metabolites: glucose and oxygen. It has long been speculated that regional blood flow – and thus delivery of these metabolites – depends on the local activity of neurons. In a famous passage, the nineteenth-century British physiologists Roy and Sherrington argued that blood flow might depend on function: "We are of opinion that an automatic mechanism . . . is well fitted to provide for a local variation of the blood supply in accordance with local variations of the functional activity" (1890, p. 105).

Recent studies have demonstrated that neuronal stimulation leads to increases in blood flow in arterioles near the area of stimulation, consistent with Roy and Sherrington's predictions. However, the increased blood flow is imperfectly coupled to the increased metabolic demands of neurons, both in spatial specificity and in quantity. Even if only a small population of neurons are active, there are increases in arteriole diameter several millimeters or more from the active neurons. The arterial system supplies more oxygen than can be extracted within the capillary bed. Thus, following neuronal activity, there is an increase in the amount of oxygenated hemoglobin and a decrease in the amount of deoxygenated hemoglobin in venous blood. These changes in blood flow and especially blood oxygenation suggest potential markers for brain function.

BOLD fMRI

In the early 1980s, Thulborn and colleagues found that the relative oxygenation of blood (*in vitro*) influenced its T2* decay constant. Later that decade, Seiji Ogawa and colleagues examined whether manipulating the proportion of blood oxygen would affect the visibility of neural blood vessels on T2*-weighted images. They found that when their rodent subjects breathed pure oxygen, MR images revealed structural differences but not blood vessels. However, when the rodents breathed normal air, blood vessels became visible on the images as thin, dark lines. Ogawa and colleagues concluded that these thin lines represented magnetic susceptibility effects caused by the presence of paramagnetic deoxygenated hemoglobin. A summary of the BOLD effect is presented in Figure 5.

The effect discovered by Ogawa came to be labeled blood oxygenation level-dependent contrast, or often simply BOLD contrast. Soon after his initial reports, several groups began to explore whether this endogenous contrast could be used to create images of brain function. (Note that, at the same time, several fMRI studies used exogenous contrast agents, typically based on the injection of compounds containing the element gadolinium. The use of contrast agents remains important for many clinical uses of fMRI, but it has become superseded by BOLD contrast because of its invasive nature.) The first papers using BOLD fMRI, which were published in 1992, provided proof that this new technique could provide images of activation in primary motor and visual cortices. Throughout subsequent years, researchers extended the reach of BOLD fMRI to more cognitive applications, using it to map the neural substrates supporting attention, memory, decision making, and other complex functions.

Only recently has there been significant progress toward understanding the neurobiological origins of the BOLD signal. Recall that the energy demands of the brain are primarily attributable to neuronal activity, specifically the restoration of membrane potentials. However, it was long unclear whether BOLD changes tracked axonal action potentials, dendritic postsynaptic potentials, both, or neither. Simultaneous measurements of fMRI BOLD signal and electrophysiological activity – originally in monkeys and recently in humans – have indicated that BOLD signal contrast arises primarily from postsynaptic potentials, not action potentials. In particular, synchronized dendritic activity across populations of neurons seems to be a key contributor to BOLD amplitude.

fMRI Experimental Design and Analysis

The physical and physiological properties described in the previous sections establish important constraints on the design and analysis of fMRI experiments. Underlying most fMRI experiments is the linear systems framework, which suggests that the measured MR signal arises from the linear convolution of a set of impulses representing neuronal activity with a standardized hemodynamic response function. This framework implies that one can determine whether a brain region exhibited a hypothesized pattern of neuronal activity by statistical evaluation of its BOLD time course. In general, fMRI designs (and subsequent analyses) are created to answer two types of questions: detection, or "What brain regions showed task-related neuronal activity?" and estimation, or "How did the BOLD response change over time in a particular brain region?"

Experimental Design

Considered broadly, fMRI experimental designs take blocked or event-related forms. The former tends to have superior detection power, whereas the latter

Figure 5 Blood oxygenation level-dependent (BOLD) contrast. Under normal conditions, oxygenated hemoglobin is converted to deoxygenated hemoglobin within the capillary bed, resulting in a darkening of T2* images (a). However, when neurons become active, there is an increase in the supply of oxygenated hemoglobin. This causes a decrease in the amount of deoxygenated hemoglobin, which in turn results in brightening on T2* images (b). Reproduced from Huettel SA, Song AW, and McCarthy G (2004) *Functional Magnetic Resonance Imaging*. Sunderland, MA: Sinauer, with permission.

tends to have better estimation power. In recent years, optimized event-related designs that provide both excellent detection and good estimation have become increasingly common. Mixed approaches which combine features of both types of design are also used to examine both transient and sustained processes. The choice of design depends not only on the experimental goals but also on the constraints of the tasks. For example, some types of experiments (e.g., detecting an infrequent target) can only be presented in an event-related form, whereas others (e.g., performing a sustained attention task) are more reasonably conducted in blocked form.

Blocked designs present stimuli or tasks for prolonged intervals (or blocks), with the goal of evoking an extended period of steady-state neuronal activity. The central challenge for blocked designs is matching the different blocks on all factors except the main independent variable. Blocks that involve no experimental task (i.e., resting) are not absent of mental processes. Instead, they contain particular types of processes associated with reflection, daydreaming, self-assessment, bodily attention, and emotion. Thus, certain brain regions repeatedly show up as deactivations (i.e., exhibiting greater activation on control than task blocks) across a wide variety of tasks. Although well-controlled blocked designs have maximal detection power, they provide almost no information about the timing of neuronal activity or about the shape of the evoked BOLD response.

Event-related designs present stimuli or tasks in discrete, punctate fashion. In most such designs, different conditions of the independent variables are associated with different event types. Unlike blocked designs, the different events are usually presented in either a random or a temporally jittered order to maximize the ability to distinguish among their BOLD contributions. Without such steps, the BOLD signal would saturate to some maximal value with repeated events. The greatest advantage of event-related designs is their flexibility: any property could be used to define different classes of events. In memory

studies, for example, a common approach is to present a series of words to be encoded into memory. These words are sorted into event categories not based on what the subject does within the scanner but, rather, based on whether or not a word is remembered at a subsequent testing session hours (or even days) later.

Finally, mixed designs combine the basic elements of the previous two types. They present stimuli in discrete and regular blocks, each containing multiple types of events. The task blocks are assumed to evoke sustained changes in task-strategy, attention, or other cognitive processes, and blocked analyses measure state-related processes. The individual events are assumed to evoke transient activation associated with the particular task demands. Event-related analyses would therefore measure item-related processes. Mixed designs are preferable over either of the two basic design types when both sustained and transient aspects of cognition are of interest.

Preprocessing

Once collected, fMRI data are usually subjected to a series of steps known as preprocessing to measure and remove unwanted variability. These steps are usually undertaken after the *k*-space data have been reconstructed into image space but before engaging in any task-related statistical analyses. Initial temporal and spatial preprocessing steps correct for variability both in the timing of slice acquisition and in the spatial position of voxels. The most insidious cause of spatial error is head motion, which is often more easily prevented by physical restrictions than corrected during preprocessing. Although a variety of corrective algorithms are used, the most common are rigid-body transformations that attempt to minimize the error between each volume and a reference volume (e.g., the first in the data set).

To facilitate comparisons across subjects, fMRI data are often normalized into a standard stereotaxic space, usually through a combination of linear and nonlinear transformations. High-resolution anatomical images for each subject are often used as an intermediate step in this normalization process. Depending on the experimental goals, temporal and spatial filtering may also be introduced. Temporal filtering can minimize the contributions of several forms of noise, such as physiological variability (e.g., respiration) or slow, temperature-related changes in the strength of the magnetic field. Spatial filtering (i.e., smoothing) can reduce apparent noise and increase the validity of comparisons across subjects. Finally, quality assurance should be an integral part of any preprocessing. Without rigorous quality assurance testing, unnoticed problems can propagate into the final results of an experiment with potentially disastrous results.

Data Analysis

As for all of science, analyses in fMRI can be either data driven or hypothesis driven. In data-driven analyses, which are only found in a minority of fMRI studies, the researcher identifies regularities present in the experimental data. Common approaches include independent components analysis, partial least squares, and intersubject correlations. Data-driven analyses are largely exploratory in that they are intended to discover systematic and regular changes in BOLD signal. Note that data-driven techniques are often used as a first step before setting up subsequent hypotheses. This combined approach can be extraordinarily powerful, particularly when used to examine interrelations among brain regions.

In contrast, hypothesis-driven analyses are intended to test specific predictions about the relations between an experimental task and evoked BOLD activation. Most hypothesis-driven analyses use a variant of the general linear model to evaluate whether and how different explanatory variables contribute to the observed pattern of activation. The explanatory variables are usually considered to represent particular cognitive processes (or sets of processes), such as encoding an item into memory or deciding between two options. A central challenge of the data analysis, therefore, is identifying when these processes occurred. Then, impulses defined by the timing and estimated duration of the processes are convolved with some representation of the fMRI hemodynamic response; these convolutions generate one or more regressors that predict how BOLD signal would change were that process to occur. All such regressors are entered into a model – often accompanied by nuisance regressors such as head motion parameters – to form a design matrix. A statistical program then calculates what combination of regression weights best predicts the experimental data. Data from different subjects are combined using fixed- or random-effects approaches; for most experiments, random-effects approaches are preferable because they allow extension of the results to the population from which the subject sample is drawn.

Correction for Multiple Comparisons

A typical fMRI data set can contain a few tens of thousands of voxels. Thus, using a conventional threshold (e.g., alpha of 0.05) will result in an enormous number of type I errors (false positives). Conversely, the use of very strict correction factors (e.g., Bonferroni comparison) risks missing many regions

with true activity (e.g., type II errors). A common compromise between these extremes is to adjust the correction factor based on the data's spatial autocorrelation, which can result from many sources: the spatial extent of activity, hemodynamic spread, smoothing during preprocessing, and variability across subjects. For fMRI data, the true number of independent comparisons can be orders of magnitude smaller than the number of voxels. Another, nonexclusive approach is to require clusters of activation to reach a particular size (e.g., ten or more active voxels) to be counted as significant. Finally, other correction metrics can be used, such as the false discovery rate, which controls the type I error rate among voxels labeled as significant.

Displaying and Interpreting fMRI Data

Nearly all neuroscientists (and most of the lay public) have been exposed to images created by fMRI analyses. Images of a high-resolution brain with colored patches can be extraordinarily striking (Figure 6), sometimes leading to the idea that scientists have captured a photograph of the brain in action. The apparent detail of the background MRIs – or three-dimensional renderings – suggests that the research has exquisite spatial resolution. Also, when researchers show an area of activation, it seems like they have discovered the brain area that processes faces, makes decisions, or evaluates numbers. These ideas, though all compelling, are false. The images arising from fMRI experiments are not photographs: they are statistical maps. The resolution of fMRI maps is relatively coarse (i.e., acquired at 3- to 5-mm resolution and then smoothed further during processing) compared to the potentially submillimeter resolution of structural MRI. In addition, the identification of a single active region does not rule out the possibilities that many other regions may contribute or that the experiment may not have sufficient power to identify other effects.

Described plainly, the colors of fMRI activation maps reflect the statistical confidence that a particular brain region expresses a particular function. Bright colors usually indicate regions where there is strong evidence that the experimental manipulation affected the BOLD signal, whereas uncolored regions lacked any significant statistical effect. Like other experiments, fMRI studies are not designed to identify null effects, and a region that is uncolored on a fMRI activation map may still contribute. Furthermore, the meaning of an image depends on the quality of the underlying experimental design, the adherence of the subjects to the expected task, the analyses conducted, and even the threshold chosen. When evaluating fMRI data, it is thus extraordinarily important to look beyond the images to evaluate the underlying methods.

Future Directions

In many ways, fMRI has indeed become a mature technique. Researchers and students can download publicly available (and anonymized) data sets and freely available analysis programs. Dozens of fMRI

Figure 6 fMRI data displayed on a high-resolution rendered brain. Shown are statistical maps derived from a visual search task, displayed on a high-resolution brain that has been rendered into a three-dimensional surface. The colors represent areas of statistically significant activation, with yellow indicating greatest significance. Shown in (a) are areas with positive activation during visual search, whereas in (b) areas with reduced activation during visual search are indicated.

courses are offered throughout the world yearly. Even the collection of fMRI data has become democratized: new MRI scanners, even those for clinical use, come equipped with hardware, pulse sequences, and online analysis for fMRI experiments.

Given this maturity, from where will the next advances in fMRI arise? One possibility is increased field strength. In the early years of fMRI, there was a continual push toward high-field (i.e., >1.5 T) scanning. Now, 3 T and higher field machines are common, both in research and in clinical settings, and further improvements in field strength seem likely to be incremental at best. Another possibility is improved spatial and temporal resolution. Although some new techniques have arisen (e.g., the growth of spiral imaging), current fMRI data acquisition is – to a first approximation – largely similar to that of a decade ago. The stability of fMRI technology does not mean that no future advances are likely. In particular, simultaneous multiple-coil recording promises to allow researchers to reduce the time required to collect fMRI images and, more important, increase image quality. Yet, even this will not revolutionize BOLD fMRI experimentation.

Instead, the main advances in fMRI will come from improved experimental designs, new forms of data analysis, and novel combinations with other techniques. Most early fMRI studies tried to localize particular brain functions to particular locations. As argued by critics, this approach overemphasizes functional specificity but fails to account for how different regions interact to support complex behavior. Although this criticism is still regularly repeated, its validity diminishes with each passing year. Researchers are increasingly likely to relate fMRI activity to specific behavioral measures, such as memory accuracy, decision outcome, perceptual reports, or even individual traits. Likewise, increasingly more studies report interactions between regions, not just a list of activation foci. Combining fMRI with electrophysiological techniques will remain a key area of methodological research because of their posited complementarity of spatial and temporal properties. However, during the next few years, there may be more value in adding transcranial magnetic stimulation to fMRI to better address questions about causality. Regardless of whether some (or all) of these new developments take shape over the coming years, it seems clear that fMRI will continue to be a central technique in the study of the human brain.

Folate Deficiency States

V T Ramaekers, University Hospital Aachen, Aachen, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Since the discovery of folic acid and folate deficiency states, the knowledge from rare inborn errors of folate metabolism and folate transport disorders across placental, intestinal, and blood–central nervous system (CNS) barriers has contributed to our understanding of the origin of neural tube defects, homocysteinemia, and vascular disease, and a range of neuropsychiatric disorders. Herein, we review the most important aspects of prenatal, systemic, and cerebral folate deficiency (CFD), their underlying mechanisms including the role of folate-receptor autoantibodies, the current treatment strategies for folate deficiency states, as well as the effect of the folate food fortification program in North America.

Physiology of Folate Metabolism

Folic acid is a water-soluble vitamin, of which only traces are found in nature. Folic acid is the parent structure of folates, which represent a family of more than 25 structurally related and interconvertible compounds. The basic structure of folic acid consists of a 2-amino-4-hydroxypteridine molecule linked through a methylene carbon to a para-aminobenzoyl group, which is attached to a monoglutamate residue or polyglutamate chain (Figure 1). Reduction of the pteridine ring at the 5,6,7,8 carbon positions results in the reduced folate forms which function as active cofactors in cellular metabolism. These reduced folate forms may carry one-carbon units at three different oxidation levels in the form of methyl, methenyl, or formyl groups, attached to the N-5 and/or N-10 position of tetrahydrofolate, which can enzymatically be interconverted.

The naturally occurring folates in foods are reduced polyglutamyl derivates of mostly L-5-methyltetrahydrofolate (5MTHF), present in leafy green vegetables, citrus fruits, liver, and yeast extracts. After food ingestion, polyglutamyl folates are hydrolyzed to monoglutamyl derivatives by a zinc-dependent pteroylglutamate hydrolase at the brush-border membrane of the jejunum. This is followed by a carrier-mediated transport (reduced folate carrier 1; RFC1) into the intestinal cell where the various monoglutamyl folates are converted to 5MTHF, which exits the cell into the portal circulation for further transport to the liver and peripheral organs. Food-derived folic acid can be reduced to dihydrofolate and L-tetrahydrofolate by the enzyme dihydrofolate reductase (DHFR) and further converted to 5MTHF before leaving the intestinal cell. However, part of the folic acid can also enter directly into the circulation in case of diminished activities of the reducing and interconverting enzymes. Another source of folate is derived from the colonic folate-producing bacterial flora.

The physiological function of the various reduced folate forms subserves the *de novo* synthesis of purines and thymidine, methylation of DNA, conversion of homocysteine to methionine, and the formation of the activated methyl-group donor *S*-adenosylmethionine (SAM).

5MTHF is the physiologically most active and important circulating folate form in blood which passes cellular membranes, placental, and blood–brain barriers. 5MTHF is the precursor of the activated methyl-group donor SAM (Figure 2). SAM is used in more than 100 chemical reactions among which are the methylation of DNA, fatty acids, phospholipids, polysaccharides, and proteins. For example, the methylation of arginine at position 107 within myelin-basic protein is necessary to maintain stability of CNS myelin. In addition, the universal methyl-group donor SAM acts in the catabolism of biogenic monoamines.

An adequate folate pool and metabolism is not only necessary for DNA synthesis and cell growth, but also for normal embryonic development, maturation, and function of the nervous system.

Three different transport mechanisms promote cellular folate uptake and transport across cellular membranes, that is, folate-receptor mediated endocytosis by folate receptor 1 (FR1) and folate receptor 2 (FR2), the RFC1, and an ATP-dependent folate exporter system (Figure 3(a)). FR1 is mainly distributed at epithelial cells such as choroid plexus, lung, thyroid, and renal tubular cells, while FR2 is mainly located within mesenchymal derived cells, like red blood cells. Both FR1 and FR2 are high-affinity proteins which function at the physiological nanomolar range of extracellular folate concentrations. RFC1 is ubiquitously distributed and represents a low-affinity folate-transporting system with bidirectional transport across cellular membranes. The ATP-dependent folate exporter regulates intracellular folate monoglutamate concentrations.

The transport mechanisms across the placental, intestinal, and blood–CNS barriers deliver sufficient folate stores within organs and the CNS (Figure 3(b)).

Figure 1 Structural formula of folic acid. This is composed of an unreduced 2-amino-4-hydroxypteridine molecule linked through methylene (C9-position) to p-aminobenzoylmono-glutamate, while R represents the carried one-carbon group at different oxidation states in the form of methyl, methenyl, or formyl, attached to the N-5 and/or N-10 positions as shown in the drawing. The metabolically active form tetrahydrofolate is reduced at the 5,6,7,8 positions of the pteridine group.

Figure 2 Metabolic pathways showing the interconversion of different folate forms in the brain with major transport of 5-methyl-THF (5MTHF) across the choroid plexus where, in CFD, a nonfunctional FR1 protein is thought to be responsible for reduced folate transport to the CNS. At the upper left the conversion of homocysteine to methionine is shown by the enzyme methionine synthase requiring 5MTHF and vitamin B12. Methionine is converted to the activated methyl-donor SAM, necessary for methylation reactions. The other folate interconversions and metabolic pathways are also shown. SAM, *S*-adenosylmethionine; SAH, *S*-adenosylhomocysteine; 5-methyl-THF, 5-methyl-tetrahydrofolate; Ser, serine; Gly, glycine; THF, tetrahydrofolate; DHF, dihydrofolate; DHFR, dihydrofolate reductase; SHMT, serine hydroxymethyltransferase requiring cofactor B6; MTHFR, methylenetetrahydrofolate reductase; 5-formyl-THF is synonymous with folinic acid or leucovorin.

For passage across the blood–cerebrospinal fluid (CSF) barrier, plasma 5MTHF is bound by the FR1 protein, anchored to choroid epithelial cell membranes by a glycosylphosphatidylinositol (GPI) moiety. This is followed by receptor-mediated endocytosis, storage, and subsequent export. The choroid plexus is the main site of active folate transport to the CNS. Folate transport by FR1 across the choroid plexus is an active ATP-dependent transport leading to an at least twofold higher concentration in CSF compared to plasma. The FR1 is mainly localized at the basolateral surface of choroid epithelial cell membranes, facing the plasma side, where it functions through receptor-mediated endocytosis (Figure 3(b)). After endocytosis and release of folate from its receptor into the cytosol, part of the endocytotic membrane-attached FR1 will recycle to the basolateral choroid cell surface (Figure 4). For normal expression of FR1 on the cell

Figure 3 (a) The three different folate transport mechanisms to and from the cell interior, that is, FR1-mediated endocytosis, RFC1 and the ATP-dependent folate exporter. Folate monoglutamates can also enter mitochondria and will be converted to the folylpolyglutamate form. Folylpolyglutamates can be recoverted to their monoglutamate form by lysosomal gamma-glutamyl-hydrolase (GGH). (b) After intestinal absorption across the intestinal barrier with the use of RFC1, folates enter the circulation and can be transported into mesenchymal tissues, for example, red blood cells (RBC) by the folate receptor 2 (FR2). After entry into the cell, folate monoglutamate can be retained within cells after polyglutamylation by folylpoly-gamma-glutamate synthetase (FPGS), the major part of which will be tightly bound to proteins (F– stands for folylpolyglutamate). After passage across choroid epithelial cells using FR1 receptor-mediated endocytosis, folates will enter the CSF and enter neuronal cells by the RFC1, located at axons and dendrites. Within the neurons, part of the folate pool will be catabolized by oxidation to dihydrofolates (DHF) and folic acid, which can be reconverted to reduced tetrahydrofolate by dihydrofolate reductase (DHFR). However, in the brain of man there is no or virtually absent DHFR activity. *In vitro* experiments indicate that part can be oxidized to form 6-formyltetrahydropterin and para-aminobenzoylglutamate.

membrane surface and proper functioning of this folate-receptor-mediated endocytosis, many cooperating genetic and nongenetic factors have been identified as important determinants, such as intracellular homocysteine concentration, the extent of N-glycosylation of FR1, and the sphingolipid and cholesterol content of membranes. At the apical surface of choroid epithelial cells, RFC1 facilitates the folate export. RFC1 is also located at vessel membranes of the blood–brain barrier, where its contribution to the main bulk of folate transport is of minor importance because it has low folate affinity and will only bind folate concentrations within the micromolar range. At the cellular level, folate concentrations are influenced by folate availability, cellular folate transport efficiency, folate polyglutamylation, and folate turnover which can be influenced by different degrees of folate catabolism. The different folate forms are also known to be highly susceptible to oxidative degradation with the exception of 5-formyltetrahydrofolate (synonyms: folinic acid, calcium folinate), which represents a stable form of folate.

Oxidative degradation of the physiologically active reduced folate compounds within the brain will deplete the active folate pool and its dependent

Figure 4 Active folate transport to the CNS occurs mainly at the choroid plexus epithelial cells, where the folate-binding proteins (FR1), anchored at the plasma side, bind and incorporate 5MTHF through an endocytotic process, after which conversion to folylpolyglutamate takes place by the action of folylpoly-gamma-glutamate synthetase (1). The stored folylpolyglutamate can be converted again to its monoglutamate form by gamma-glutamylhydrolase (2) after which the monoglutamate form of folate can leave the choroid plexus to the spinal fluid compartment. Part of the anchored FR1 will be cleaved from its GPI–peptide anchor and released to the spinal fluid as soluble FR1 (sFR1) without losing its physico-chemical properties. At the apical surface RFC1 facilitates the export of folate monoglutamate. The expression of FR1 is thought to correlate inversely with extracellular folate concentrations.

pathways because of absent activity of the reducing enzyme DHFR in the nervous system of man.

Clinical Features of Folate Deficiency States

Since 1965 folate-deficient states were recognized to be associated with megaloblastic anemia, neural tube defects, and cardiovascular disease. Systemic folate deficiency was suspected to play a role in the pathogenesis of various neuropsychiatric disorders and predispose to cancer. However, in many points, the pathogenesis remained still obscure. In systemic folate deficiency megaloblastic anemia is not always a consistent feature. Laboratory investigations include measurement of serum and red blood cell folate, homocysteine, and amino acids. Because clinical features sometimes mimic vitamin B12 deficiency states, vitamin B12 measurements should be included as well.

Prenatal Folate Deficiency

During pregnancy the daily folate requirements increase. Intrauterine folate deficiency during embryogenesis increases the risk of a pregnancy complicated by neural tube defects, conotruncal heart defects, and craniofacial malformations (Figure 5). Several drugs with an antifolate effect should be avoided during pregnancy (Table 1). Low socioeconomic status was found to be associated with multivitamin deficiencies during pregnancy, thereby increasing the likelihood of a neural tube defect. For this reason women of childbearing age are advised to take extra folate supplements before conception. The most important reason for the folate food fortification program introduced in North America since 1998 was to reduce the overall occurrence of neural tube defects in the population, and it resulted in a significant reduction.

Rare genetic, environmental, and nongenetic predisposing factors affecting folate metabolism and transfer across the placental barrier have been identified to play a role in the origin of neural tube defects. Among the nongenetic factors, the presence of autoantibodies directed against the folate receptor has been identified in the serum of mothers whose pregnancy was complicated by a neural tube defect. These FR autoantibodies in serum of the mothers block folate transfer across the placental barrier from the mother to the fetus, which predisposes to intrauterine folate deficiency at the time of neural tube closure in the embryo.

Systemic Folate Deficiency

Systemic folate deficiency is often the consequence of inadequate dietary folate intake and malabsorption, frequently occurring in patients with alcohol abuse, chronic debilitating diseases, regional intestinal diseases, and celiac disease. A hereditary disorder of congenital folate malabsorption and several rare

- Well-known:
  - megaloblastic anemia
- Assumed:
  - increased rate of neural tube defects (NTD) and other birth deformities (inborn heart failure, deformities of urogenital tract, cleft lip and palate)
  - increased risk of arteriosclerosis (Homocysteine↑)
  - .....
- Risk groups:
  - limited alimentation (alcoholics)
  - increased need (pregnancy)
  - decreased uptake (celiac disease)

Figure 5 Megaloblastic anemia is well known in folate deficiency and should be differentiated from vitamin B12 deficiency. Increased rates of congenital malformations associated with intrauterine folate deficiency are known, while folate deficiency in adults at risk will predispose to homocysteinemia and cardiovascular diseases.

Table 1 Overview of systemic folate depletion and conditions of CFD associated with isolated 5MTHF loss in the CNS

Classification of condition	*Underlying mechanism*
Systemic depletion	
Malnutrition	Folate deficient in the diet or food deprivation
Malabsorption	Reduced folate absorption in the jejenum
Coeliac disease	Gluten enteropathy
Chron and jejunal diseases	Affects folate absorption
Antifolate agents	
Chemotherapy (MTX)	Blocks RFC1 carrier; inhibits dihydrofolate reductase
Isoniazide	Tuberculostatic drug
Sulfonamides	Analogs of para-aminobenzoic acid, interfering with THF synthesis in sensitive bacteria
Anticonvulsant drugs	Interfering with cellular folate uptake
Carbidopa	Inhibits aromatic amino acid decarboxylase with consequent SAM and 5MTHF overconsumption
Congenital folate malabsorption	Hereditary factor involving the RFC1 gene?
Inborn errors of metabolism	
MTHFR deficiency	Depletion of enzymatic product 5MTHF
Formiminotransferase deficiency	Defective histidine derived one-carbon transfer to THF
Cerebral folate deficiency	
Infantile-onset CFD	Serum FR autoantibodies of the blocking type
Low-IQ autism with neurological deficits	Serum FR autoantibodies of the blocking type
Late-onset spastic-ataxic with mental deficits	Serum FR autoantibodies of the blocking type
One-carbon pool deficiencies in the CNS	
3-Phosphoglycerate dehydrogenase def.	Defective serine synthesis affecting one-carbon pool
Inborn errors of metabolism	
Dihydropteridine reductase deficiency	Unproven mechanism
Aromatic L-amino acid decarboxylase def.	Overconsumption of 5MTHF and SAM
Kearns–Sayre syndrome	Disturbed active folate transport at choroid plexus
Mitochondrial encephalopathies	Disturbed active folate transport at choroid plexus
Rett syndrome	FR pseudogene expression due to MECP2 defect?
Aicardi–Goutières syndrome	Variable CFD of unknown origin

inborn errors of folate metabolism are accompanied by megaloblastic anemia and severe neurological features and will be outlined further. An important aspect to be considered in systemic folate deficiency is the antifolate effect of many drugs like isoniazide, sulfonamides, salicylazosulfapyridine, pyrimethamin (Daraprim), methotrexate, carbidopa, and the anticonvulsants phenytoin, primidone, phenobarbital, carbamazepin, and valproate.

Homocysteinemia with an increased risk of thrombosis and thromboembolism, stroke, and cardiovascular disease has been associated with commonly occurring polymorphisms of several genes, like for example homozygosity for the 677C→T mutation of the methylenetetrahydrofolate reductase (MTHFR) gene, that results in the change of an alanine to valine in the catalytic domain of the enzyme leading to a 50–60% decrease in the specific activity of MTHFR. The T allele frequency is around 30% in Europeans and Japanese but is only around 11% in African Americans. Studies have clarified that this polymorphism is only associated with elevated homocysteine levels in patients with low folate intake. The reduced enzyme activity will affect the interconversion of various folate forms and change the folate form distribution. MTHFR polymorphism has been found to play a role in the pathogenesis of homocysteinemia which together with other genetic and environmental factors further increases the risk of thrombosis and thromboembolism, stroke, and cardiovascular disease.

The first reported neuropsychiatric manifestations of systemic folate deficiency were the single occurrence or combinations of polyneuropathy, ataxia, and spastic–ataxic syndromes due to subacute combined degeneration of the spinal cord, already known to occur in cobalamin deficiency. In addition, systemic folate deficiency was reported to be associated with mental retardation, dementia, parkinsonian features, athetosis, seizures, myopathy, and an increased incidence of affective disorders, in particular depression, organic brain syndrome, and schizophrenia-like syndromes. Arguments in support of the etiologic role of folate deficiency were megaloblastic anemia with low serum and red blood cell folate, elevated plasma homocysteine, and clinical improvement after folate administration.

The pathophysiology of CNS dysfunction due to folate deficiency in psychiatric disorders remains obscure but is probably related to derangements of DNA synthesis and gene expression, disturbed methylation processes, and serotonin turnover. Folate-deficient patients with neuropsychiatric phenotypes were found to have low levels of the serotonin end-metabolite 5-hydroxyindole acetic acid (5HIAA) in their CSF, returning to normal after folate administration. Folate-deficient patients without neuropsychiatric abnormalities had normal CSF 5HIAA levels. There appeared to exist a close relationship between folate-responsive neuropsychiatric symptoms and changes of CNS serotonin metabolism.

Neuropathological correlates of folate deficiency described vessel wall lesions and demyelinating lesions of white matter around blood vessels in the brain and spinal cord. The histopathology of demyelinating lesions in the spinal cord showed vacuolization of myelin sheaths of the posterior and lateral columns and often the anterior columns, which has been called subacute combined degeneration. Subacute combined degeneration of the spinal cord has earlier been associated with vitamin B12 deficiency in patients with pernicious anemia (**Figure 6**).

The advent of improved neuroimaging of the nervous system with MRI has revealed white matter demyelinating lesions and leukoencephalopathy in patients with systemic folate deficiency or children suffering from a severely reduced enzyme activity of methylenetetrahydrofolate reductase.

Figure 6 Subacute combined degeneration of the spinal cord is a progressive, degenerative disease involving the posterior (PC) and lateral columns (LC) of the spinal cord. It was first described in pernicious anemia due to vitamin B12 deficiency. In the mid-thoracic region of the spinal cord, there is axis cylinder and medullary sheath degeneration, involving the posterior columns, direct and indirect pyramidal tracts, and direct cerebellar tracts. Clinical signs in adults present insidiously with generalized weakness and vague gastrointestinal discomfort. Most characteristic is a sensation of 'pins and needles' in toes and fingers, with muscular atrophy in arms and legs. Touch, vibration, position, deep pain, and muscle sensibility are steadily impaired, and the Romberg test becomes positive. Pain is uncommon. The gait becomes spastic and ataxic with hyperactive deep reflexes and pathologic toe signs. The sphincters are seldom affected. In the terminal stages flaccid paraplegia, loss of reflexes, and mental changes appear. Spinal fluid studies show normal cells, glucose, and protein content.

Cerebral Folate Deficiency

CFD can be defined as a recognizable neurological syndrome associated with low CSF 5-methyltetrahydrofolate (5MTHF), the active folate metabolite, in the presence of normal folate metabolism outside the nervous system. CFD results from either disturbed folate transport or from increased folate turnover within the CNS.

An infantile-onset CFD syndrome is characterized by the presence of three or more typical features manifesting from the age of 4 to 6 months, starting with marked unrest, irritability, and sleep disturbances followed by psychomotor retardation, cerebellar ataxia, and hypotonia, pyramidal signs in the lower limbs which may ascend to spastic tetraplegia with age, if left untreated. In about one-third of the cases, dyskinesias (choreoathetosis, ballism) and epileptic seizures develop. Most children show deceleration of head growth from the age of 4 to 6 months. Visual disturbances are not invariably present but may start to develop around the age of 3 years. Progressive sensorineural hearing loss may begin to develop from the age of 6 years (Figure 7). Neuroimaging can be normal but in about 50% of the children, atrophy of frontotemporal regions and periventricular demyelination can be noted, and in a minority slowly progressive supra- and infratentorial atrophy can be found.

CSF analysis of the secreted membrane-derived FR protein could identify this protein as a nonfunctional FR protein with normal immunoreactivity but diminished binding to radioactively labeled folate. Because active folate transport to the CNS occurs mainly at the choroid plexus through folate-receptor-mediated endocytosis, the FR1 and FR 2 genes were sequenced and found to be normal. Further investigations have now clarified that the most important mechanism underlying infantile-onset CFD is the presence in serum of circulating autoantibodies, directed against the membrane-attached FR to choroid epithelial cells (Figure 8). These FR autoantibodies were characterized by a high affinity to the FR and were shown to block the binding of folate, thereby preventing its passage into the CSF and nervous tissues. Serum FR autoantibodies were absent among the asymptomatic mothers of the children affected by infantile CFD.

A particular subgroup of infantile-onset CFD patients manifest low-IQ autism, which is mostly associated with part of the neurological deficits described for infantile-onset CFD. In a high number of these autistic children serum FR autoantibodies have been identified.

Later onset spastic–ataxic syndromes followed by stagnation of mental development have been identified to be associated with CFD and also found to be associated with FR autoantibodies. The patients have normal development during the first 12–18 months and show no or only mild cognitive deficits.

The discovery of FR autoimmunity as a major cause of CFD has opened a new window on those neuropsychiatric conditions suspected to be linked to folate deficiency, although folate levels in serum and red blood cells, as well as homocysteine levels remain within the normal range. It may well be that a particular subgroup of patients with depression, schizophrenia-like syndromes, and dementias suffer from CFD. Clinicians should be alerted especially if

Figure 7 The figure displays the age of onset of the main clinical features. Visual and hearing loss are not consistent features.

Figure 8 The FR autoantibodies circulating in serum will block the FRs attached at the basolateral surface of choroid epithelial cells and impair folate transfer to the CSF and from there to nervous tissues. Supplementation with high doses of reduced folates will increase the 5MTHF serum values by more than 100 times the physiological range, so that 5MTHF can pass the blood–CNS barriers through the low-affinity RFC1. The autoantibody against the FR is indicated as a yellow T. The arrow on the right represents the virtually absent dihydrofolate reductase activity in neuronal cells. DHF, sihydrofolate; RFC, reduced folate carrier; FR, folate receptor.

these patients do not respond to the conventional treatment modes and consider the possibility of CFD and FR autoimmunity. However, the prevalence of CFD and serum autoantibodies in these patients awaits further studies.

Genetic Studies and Inborn Errors of Folate Metabolism

Because systemic folate deficiency and the use of antifolate drugs in pregnant mothers was known to lead to congenital malformations, including neural tube defects, gene knockout experiments have been performed in mice to study the specific effects after knockout of the FR1, FR2, and RFC1 genes with respect to prenatal development.

To study whether the FR genes are involved in maternal-to-fetal folate transport, the FR genes in mice were inactivated. Nullizygous FR2−/− embryos developed normally, but FR1−/− embryos had severe morphogenetic abnormalities and died *in utero* by embryonic day 10. Supplementing pregnant FR1+/− dams with folinic acid reversed this phenotype in nullizygous pups. Decreasing the folate dose administered to FR1+/− dams resulted in a wide range of malformations of FR1−/− pups, involving the neural tube, craniofacies, eyes, and abdominal wall. These experiments in mice support the earlier findings that periconceptional folate supplementation reduces the occurrence of several human congenital malformations, including craniofacial, heart, and neural tube defects.

RFC1 knockout experiments also lead to intrauterine lethality in nullizygous mice. Following supplementation of RFC1+/− dams with a daily subcutaneous administration of 1 mg folic acid, near-normal development could be sustained in RFC−/− embryos, of whom 10% went on to live after birth but died within 12 days. These RFC−/− mice showed a marked absence of erythropoiesis in bone marrow, spleen, and liver with lymphoid depletion in the splenic white pulp and thymus. These data indicated that in the absence of RFC1 function, neonatal animals die due to failure of hematopoietic organs.

A hereditary congenital folate malabsorption is a very rare condition with preponderance in females. The patients suffer from an isolated defect in intestinal absorption of folic acid and a defect of its transport across the blood–brain barrier. The clinical manifestations are severe megaloblastic anemia, increased susceptibility to infections, mental retardation, recurrent seizures, movement disorders with ataxia or athetosis, and basal ganglia calcifications of the brain. Laboratory investigations confirm low folate levels in serum, red blood cells, and CSF. The genetic defect has not yet been identified. A number of rare inborn errors of folate metabolism are known to have a genetic basis (see also Table 2).

The most common inborn error of folate metabolism is MTHFR deficiency, a riboflavin-dependent enzyme which reduces the substrate 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which is used for the remethylation of homocysteine to methionine. Deficient enzyme activity leads to homocysteine elevation and low methionine levels in plasma. There is no megaloblastic anemia because 5,10-methylenetetrahydrofolate, present in normal amounts, can still be utilized by thymidylate synthase for the synthesis of thymidine. Clinical severity varies and the age of onset ranges from the neonatal period to adulthood. The patients show features of neurodevelopmental delay, muscular weakness, seizures, gait abnormalities, incoordination, paresthesias, and psychiatric disturbances. There is a high risk of venous thrombosis and thromboembolism with stroke. Neuroimaging shows signs of cerebral atrophy and leukoencephalopathy. This autosomal recessive condition can be caused by different mutations of the MTHFR gene on chromosome 1p36.3.

Other rare inborn errors of folate metabolism are formiminoglutamate transferase deficiency and dihydrofolate reductase deficiency, of which only a few cases have been reported.

Diagnosis and Differential Diagnosis

Several rare conditions are known which are associated with secondary systemic or cerebral folate deficiency and should be considered in the differential diagnosis (Tables 1 and 2).

Autosomal recessive forms of severe methylenetetrahydrofolate reductase deficiency (MTHFR) should be considered, and leucocyte or fibroblast MTHFR activity should be measured in these patients.

The amino acids serine, glycine, and histidine act as the most important one-carbon donors to replenish the pool of unsubstituted tetrahydrofolates. Therefore, hereditary metabolic conditions associated with lowered levels of these amino acids can be expected to reduce secondarily the 5MTHF concentrations and thus the SAM-mediated methylation reactions. A *de novo* disorder of serine synthesis due to 3-phosphoglycerate dehydrogenase deficiency leads to a recognizable clinical entity with microcephaly, intractable seizures, feeding disturbances, and severe neurological disability. The presence of low serine in CSF and the brain will consequently reduce the substrate for the enzyme serine hydroxymethyltransferase in this disorder which will reduce the production of 5,10-methylenetetrahydrofolate, the precursor for 5MTHF and SAM.

Table 2 Congenital folate malabsorption and inborn errors of folate metabolism

Essential clinical features	*Diagnostic investigations*
Congenital folate malabsorption	
Megaloblastic anemia, mental retardation, ataxia, athetosis, seizures, susceptibility to infections, NMR: Basal ganglia calcifications	Intestinal folate malabsorption Megaloblastic anemia Folate deficiency (P, RBC, CSF) Low methionine (P) Correction of anemia after intramuscular folinic acid
Methylenetetrahydrofolate reductase deficiency	
Microcephaly, retardation, muscle weakness and neuropathy, seizures, thromboembolic events	Homocysteinemia and homocystinuria Low to normal plasma methionine Low MTHFR activity in lymphocytes or fibroblasts
Formimino transferase deficiency	
Retardation, convulsions, hypotonia and megaloblastic anaemia	Formimino glutamate excretion ↑(U) Hydantoin-5-propionic acid ↑ (U)
Dihydropteridine reductase (DHPR) deficiency	
Progressive neurological illness with microcephaly, myoclonic seizures, temperature instability, tone fluctuations, choreoathetosis, NMR: Basal ganglia and subcortical calcifications	Phenylketonuria unresponsive to diet CSF HVA↓, 5HIAA↓, 5MTHF↓ Neopterin normal or ↑, biopterin ↑↑ (U,CSF) RBC DHPR activity ↓ (Guthrie card)
3-Phosphoglycerate dehydrogenase deficiency	
Microcephaly, retardation, intractable seizures, feeding difficulties, NMR: Dysmyelination	CSF serine ↓↓, glycine ↓, 5MTHF ↓ Low enzyme activity in fibroblasts
Aromatic amino acid decarboxylase deficiency	
Low blood pressure, psychomotor retardation, oculogyric crises, eyelid ptosis, miosis, hypotonia, sweating, temperature instability, chorea, dystonia	Plasma epinephrine and serotonin ↓ CSF HVA ↓, 5HIAA ↓, L-dopa ↑, 3-*O*-methyl-dopa ↑ and 5-OH-tryptophane ↑ Vanillactic acid ↑ (U) L-Dopa decarboxylase activity ↓↓ (P)

P, plasma; RBCs, red blood cells, U, urine; HVA, homovanillic acid; 5HIAA, 5-hydroxyindoleacetic acid.

Other inborn errors of metabolism associated with secondary CFD include dihydropteridine reductase (DHPR) and aromatic L-amino acid decarboxylase deficiency. Diagnosis depends on a high index of clinical suspicion and typical findings from plasma amino acid levels and CSF amino acid levels, biogenic monoamine, and pterin metabolites.

DHPR deficiency (OMIM # 261630) is an autosomal recessively inherited disorder involving failure of reduction of quinonoid-dihydrobiopterin to tetrahydrobiopterin, the common cofactor of the aromatic amino acid hydroxylases phenylalanine-, tyrosine-, and tryptophane hydroxylases. The resulting enzyme dysfunction leads to elevated serum phenylalanine with reduced synthesis of the neurotransmitters dopamine and serotonin. Serum amino acid analysis will reveal hyperphenylalaninemia, and CSF analysis the reduced end-metabolites of dopamine and serotonin, that is, homovanillic acid and 5-hydroxyindole acetic acid. Children manifest with progressive mental and physical retardation, microcephaly, myoclonic seizures, hypotonia/hypertonia, swallowing difficulties, hypersalivation, choreoathetosis, and temperature instability. MRI and CT brain scans reveal cortical atrophy with subcortical and basal ganglia calcifications. Secondary CFD develops due to a suspected interaction of the accumulated quinonoid-dihydrobiopterin metabolites with folate metabolism resulting in lowered CSF 5MTHF.

Aromatic L-amino acid decarboxylase deficiency (OMIM # 608643) is another autosomal recessive disorder with secondary CFD as a result of increased utilization of 5MTHF and SAM which are required to convert the accumulated L-dopa to 3-ortho-methyldopa. The CSF pattern shows accumulation of the substrates 5-hydroxytryptophan, L-dopa and its converted metabolite 3-ortho-methyldopa together with lowered metabolites of the enzymatic reaction products serotonin and dopamine. The clinical picture manifests soon after birth and is associated with severe signs related to depletion of dopamine, epinephrine, and serotonin.

Recent reports have described secondary CFD to occur in a number of girls with Rett syndrome and patients with a variant or classical Aicardi–Goutières syndrome. Multicenter studies from Europe and Israel now have shown low 5MTHF to be present in CSF among about 50% of all Rett patients, independent of the presence of an MECP2 genotype. Rett patients with low CSF 5MTHF seem to suffer more frequently from epilepsy that is resistant to antiepileptic drugs. Further CSF studies of children with Rett

syndrome have also been performed in North America and were unable to detect low CSF folates in a large number of patients. The contrast between the North American and European studies on Rett syndrome is an interesting finding which might be linked to the folate fortification food program. The exact link between the MECP2 genotype and reduced folate transfer to the CNS remains to be established.

Kearns–Sayre syndrome is associated with clonal expansions of large-scale mitochondrial DNA rearrangements (i.e., partial Δ-mtDNAs and/or dup-mtDNAs) arising in the maternal oocyte or in early fetal life. It has long been known that CSF folate levels are reduced with or without concomitant reduction of plasma folate. The choroid plexus epithelial cells which harbor these mtDNA rearrangements will fail to produce sufficient ATP to transport 5MTHF actively across the blood–CSF barrier. Other mitochondrial encephalopathies are now known to also lead to reductions of active folate transport with resulting CFD, and are amenable to treatment with folinic acid (see **Figure 9**).

Treatment Guidelines and Outcome

Treatment should be adopted according to the origin and causes of the folate-deficiency state. For women of child-bearing age, no consensus exists about the optimal preconceptional daily dosage of folic acid, for which advice ranges from 400 μg up to 5 mg folic acid. The folate food fortification program in North America has achieved a dramatic reduction of the incidence of neural tube defects, whereas European efforts to prescribe folic acid to women on an individual basis have failed due to noncompliance.

In patients with systemic folate-deficiency states, the underlying cause should be clarified first by appropriate investigations, and promptly followed by the administration of currently available and registered folate compounds. The choice of the folate compound depends on the underlying condition. Folinic acid represents a stable form of a metabolically active reduced folate compound in contrast to folic acid, which is an oxidized and metabolically inactive folate form. Paradoxically, treatment with folic acid may further enhance CNS depletion of the metabolically active pool of reduced folates because folic acid has a higher FR1-binding affinity compared to 5MTHF and consequently competes at the FR1 receptor with the transport and storage of reduced folate species. Due to absent DHFR activity in the brain, the folic acid cannot be reduced to the active form of reduced tetrahydrofolate. Hunter et al. have previously described in a study on healthy volunteers that daily administration of extremely high doses of 15 mg folic acid for more than 1 month caused mental changes, sleep disturbances, and irritability. Some became hyperactive, whereas others became depressed and confused and had increasing difficulties with concentration. In addition, Hommes and Obbens reported that intravenous folate at extremely high doses (45–120 mg) caused generalized seizures in rats.

In infantile-onset CFD with or without concomitant FR autoantibodies, treatment is started with a daily oral administration of 0.5–1 mg kg^{-1} body weight folinic acid (calcium folinate), divided into two or three doses. Most children showed excellent tolerance. While treating children with CFD, caution should be exercised to avoid overdosage and neurotoxicity with folinic acid. Abrupt increases of the folinic acid dose by more than 0.5 mg kg^{-1} day^{-1} over a period less than one month must be avoided for safety reasons. Side-effects such as gastrointestinal upset, an increased risk of seizures, transient tics, and agitation have been observed in a minority of children treated with folinic acid; hence, careful clinical and EEG follow-up studies should be performed after 1, 3, and 6 months.

These extremely high folinic acid doses for children with CFD increase the serum 5MTHF values by a factor of more than 100 times the normal physiologic concentration. At these high 5MTHF concentrations in serum, 5MTHF can be bound by RFC1 at the blood–CNS barrier for further transport into the nervous system, and thus bypass the FRs blocked by autoantibodies. Although the group of youngest children with early diagnosis and treatment showed a favorable response with marked neurological recovery and cessation of seizures, the group of older children tended to show a more delayed response with incomplete neurological recovery. Mental deficits, in particular, persist if diagnosis and treatment are started at a later age (**Figure 10**), although folinic acid was still able to prevent further deterioration. In children who did not show any clinical effect or a doubtful effect after treatment during an initial period of 4–6 months at a folinic acid dose of 0.5–1 mg kg^{-1} day^{-1}, a lumbar puncture has been repeated in order to monitor the change of CSF 5MTHF levels. The reason for repeating the spinal fluid analysis after 4–6 months was to detect whether 5MTHF levels in CSF had normalized, remained low, or had become too high with the risk of clinical toxicity. Based upon the initial CSF levels together with the monitored levels during treatment, dose readjustments for folinic acid have been calculated.

Severe MTHFR deficiency is difficult to treat with poor outcome; high betaine doses can be tried to improve methylation and reduce homocysteine levels. Folinic acid treatment has been tried in patients with

Figure 9 From top to bottom on the left, the brain MR imaging (T2-weighted) of a child affected by mitochondrial complex I deficiency with a history of congenital myopathy, psychomotor retardation, and resistant epilepsy, showing a severe leukoencephalopathy at the age of 18 months, involving white matter, brain stem, basal ganglia, and thalamus. Further CSF studies confirmed CFD. Treatment consisted of supplementation with the complex I cofactor Q10, the radical scavengers vitamin C and E, and high doses of folinic acid. After treatment at the age of 4 years, significant reversal of the leukoencephalopathy can be noted on the comparable axial images at the right side.

secondary CFD due to deficient ATP production and failure of active folate transport to the CNS. Kearns–Sayre syndrome has been treated with positive clinical effects and reversal of the leukoencephalopathy. In one patient with a myopathy, seizures, and severe leukoencephalopathy due to reduced activity of mitochondrial complex I, folinic acid therapy was combined with high doses of Q10, riboflavine, and the radical scavengers vitamin C and E (Figure 9). There was mild clinical recovery and a dramatic reversal of the leukoencephalopathy.

The food folate fortification in North America has not only reduced the incidence of neural tube defects, but in Ontario the occurrence of neuroblastoma has now been found to have declined. Future statistical analyses will reveal whether other conditions like

Figure 10 The overall improvement of infantile-onset CFD becomes better the earlier it is diagnosed and treatment started. The figure shows overall improvement in function of the age before which the child is diagnosed, expressed as the percentage of ameliorated signs and symptoms after folinic acid therapy during at least one year. Children treated before the age of 6 years show better results with even better prognosis at earlier ages. The red curve represents the percentage of recovery for mental deficits, which can be noticed to decline sharply between the age of 1 and 2 years. In contrast, control of epilepsy and pyramidal deficits showed more favorable responses after treatment. The critical time window to detect and treat infantile-onset CFD is very short and thus early treatment should be started to prevent persistent mental deficits.

cardiovascular disease, strokes, cancer, major depression, and psychiatric disease have declined since introduction of the folate fortification in food.

Food and Water Intake: Regulation

E M Stricker, University of Pittsburgh, Pittsburgh, PA, USA
S C Woods, University of Cincinnati, Cincinnati, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Water intake and food intake are often discussed in the same chapter in textbooks and in related reviews of ingestive behavior or motivated behavior more generally. This practice reflects obvious similarities in the manifestation and control of the two behaviors, and it implies that analogies and/or overlap in their regulatory circuits are sufficient to consider them together rather than separately. It also reflects the fact that the two behaviors are interdependent, with changes in one often associated with changes in the other. As technology in neuroscience has become increasingly more sophisticated, it is now also recognized that control of the two behaviors involves parallel levels of sensory signals. This article reviews those similarities.

In considering the biological basis of water and food intake, the following general approach has long been taken. Proceeding from the assumption that a critical amount of each nutrient is needed, it was assumed (and sometimes demonstrated) that this amount is regulated by physiological processes, that a deficiency of each nutrient creates a specific excitatory stimulus to ingest the needed nutrient and thereby correct its deficiency, and that removal of the deficiency also removes the excitatory stimulus for the motivation to consume it. This simple negative feedback model reflecting the homeostatic control of ingestive behavior is, in fact, too simple; thirst and the control of water intake are much more complex than the schema suggests, whereas hunger and the control of food intake are not adequately represented by the schema.

Hunger and Food Intake

Because of limited storage capacity, most living cells cannot survive long intervals without an influx of new calories. If the animal is to survive, the sensation of hunger must therefore occur long before there is a generalized lack of calories throughout the body so as to ensure that energy will be available when needed. Thus, a strict depletion–repletion model cannot provide a suitable perspective from which to consider the control of food intake, at least at the organismal level, since hunger and eating generally occur when animals have ample stored nutrients to last over prolonged intervals of fasting.

Three quite different strategies have been proposed throughout the years to account for hunger and eating in animals that already have abundant stored calories. The first posits that critical sensors exist in the brain and elsewhere that are sensitive to local fluxes of nutrients, which herald impending demands on storage depots. The most popular of these models was the glucostatic hypothesis proposed by Jean Mayer 50 years ago, in which sensory cells in the hypothalamus were thought to be sensitive to local glucose. Decreases of glucose signaling in the hypothalamus were hypothesized to act as a bellwether for the organism as a whole and to elicit eating, whereas increases of glucose signaling were posited to stop eating. Consistent with this hypothesis, eating can be initiated by experimentally induced reductions of glucose signaling or glucose metabolism, whether systemically or locally in the hypothalamus, and meals generally end when the use of glucose as a fuel by the body is high. Analogous hypotheses have been proposed based on fluxes of lipid metabolism, of correlates of protein metabolism, and of available intracellular energy in the form of ATP. In every instance, specialized receptor cells were hypothesized to be exquisitely sensitive to small fluctuations and to inform brain areas controlling food intake.

The second strategy posits that the sensation of hunger does not need to be stimulated but is always present, and that animals are constantly stimulated to eat unless they have just eaten, in which case the inhibitory effects of satiation generated from the previous meal are still operative. Such an arrangement presumably evolved because, in the wild, the appearance of food is unpredictable, and animals can take advantage of opportunities to eat whenever they occur. Consistent with this perspective are laboratory findings that (1) it is far more difficult to precipitate eating in satiated rats than to stop eating in hungry rats; (2) the size of spontaneous meals eaten by laboratory rats is unpredictable, but meal sizes do predict how long they wait until they eat again; and (3) food deprivation does not cause a shortage of caloric nutrients in the circulation (in contrast to evidence of water deficiency during water deprivation). Hunger in this model is thought to be initiated by the gradual disappearance of inhibitory satiety stimuli that were generated by the previous meal, in contrast to a gradual increase in an excitatory hunger stimulus.

The third strategy is to dissociate meal initiation from fluxes of nutrients or satiety signals altogether, unless nutrients drop so low that emergency intake is

necessary for survival. Hunger and meal initiation are posited to occur based on learning, habits, and various social and other situations. This arrangement allows animals to take maximal advantage of their environment without having to respond to urgent signals when engaged in other activities. Any biological influence related to nutrient levels or needs is therefore exerted on how many calories are consumed once a meal begins and the fate of the ingested calories.

There are experimental data supporting each of these positions, and they are discussed as appropriate later. Although there is no clear consensus as to the signals that initiate hunger and/or eating, it is generally acknowledged that signals arising during meals contribute to a sense of fullness or satiation. Several types of signals are generated as food passes from the mouth to the stomach to the intestine, and their cumulative effect is to elicit satiation. Signals from the oral cavity (taste, texture, and swallowing stimuli) are not critical in this regard since satiation is not produced by allowing animals to eat (i.e., to taste, chew, and swallow food) but having the ingested food drain from the stomach through an open gastric fistula. This kind of sham eating persists for long intervals in fasted rats with no sign of slowing over several hours. Hence, satiation signals must arise distally to swallowing. One obvious candidate is gastric distension, detected by stretch receptors within the walls of the stomach. A general rule is that the greater the distension, the greater the inhibition of eating. This afferent signal projects to the caudal brain stem via the gastric branch of the vagus nerve, and animals eat larger than normal meals when these vagal fibers are acutely disabled.

Whereas signals from the stomach indicate the volume of ingested material, signals from the small intestine indicate the nutrient content of ingested food. Because the digestion of different macronutrients (carbohydrates, lipids, and proteins) requires different enzymes and cofactors, sensory cells lining the intestinal lumen have the ability to analyze what has been eaten and to initiate the secretion of the appropriate blend of digestive juices from the pancreas, liver, and intestinal cells. These sensory cells secrete peptidergic signals that act locally (paracrine action) or hormonally to orchestrate digestion. Some of these same peptidergic signals convey messages to the brain coding the macronutrient and caloric content of the ingested food, and these are collectively called satiation signals.

The best known satiation signal is cholecystokinin (CCK), a peptide secreted from duodenal I cells in response to lipids in the ingested food. Administration of exogenous CCK reduces meal size and elicits feelings of fullness in humans. Administration of a selective CCK receptor antagonist increases meal size, implying that endogenous CCK normally contributes to limiting meal size. CCK secreted from the duodenum in response to food acts locally on CCK receptors on sensory vagal neurons, and CCK is no longer able to reduce meal size when these neurons are severed or their destination point in the hindbrain is destroyed. Importantly, the same vagal axons that convey the CCK signal have branches that convey the signal indicating stretch from the stomach, and there is evidence that a potentiated signal to the brain is provided by the synergistic interaction of the two signals – one indicating the quantity of food ingested and the other indicating an aspect of the quality. CCK is but one of many satiation peptides secreted from the intestine in response to the contents of a meal. Although specifics of the signaling system vary slightly among them, all have in common the ability to reduce meal size and to converge in the hindbrain where they are integrated and relayed to appropriate circuits that control meal continuation.

Calories can also be detected in the liver, and there is evidence that hepatic signals are relayed to the hindbrain via the vagus nerves. Therefore, as food is eaten and processed there is a continuous wave of information informing the brain as to how much and which nutrients have been consumed. Early signals from the stomach convey mainly volume, and these become integrated with duodenal and other intestinal signals as the meal progresses. At the same time, insulin is secreted from the pancreas into the hepatic portal vein, and there is evidence that it potentiates the hepatic signals. The important point is that the brain receives continuous information and integrates it with other factors to decide when to stop an ongoing meal.

In addition to compensating for short-term fluctuations in metabolism and energy expenditure, food intake also interacts directly with the organism's energy stores. The energy equation states that body weight will change over time if energy intake does not equal energy expenditure. It has been recognized for more than 50 years that body weight is regulated, and that circulating signals tonically inform the brain about how much fat is present in the body and whether more or less food needs be eaten to balance input with expenditure. Adiposity signals include the hormones insulin and leptin. Both insulin, from the pancreatic islets, and leptin, from white adipose tissue, are secreted and circulate in the blood in direct proportion to body fat. Both are transported through the blood–brain barrier directly into the hypothalamus and other brain areas where they interact with specific receptors on neurons. When either insulin or leptin is increased locally in or near the ventral

hypothalamus, animals act as if they have suddenly gained weight; that is, they eat less and lose weight. Conversely, when the insulin or leptin signal is reduced in the hypothalamus, animals eat more and gain weight.

Because insulin levels are more closely related to the amount of visceral fat, and leptin is more closely related to the amount of subcutaneous fat, the brain receives an integrated signal from the two peptide hormones. This combined adiposity signal is then integrated with information from the hindbrain regarding the progress of meals. When the insulin or leptin signal is elevated (indicating more stored energy), animals are more sensitive to satiation signals such as CCK and they eat smaller meals. In contrast, when the insulin or leptin signal is reduced, CCK is less potent and larger meals are consumed. Hence, adiposity signals combine with satiation signals to help maintain fat stores over time.

Satiation signals and adiposity signals act against a background of other factors to determine food intake. These include psychological factors such as learning, habits, the social situation, and stress, as well as physical factors. Among the latter are dehydration and nausea, both of which greatly reduce intake, and phase of the ovarian cycle in females.

In summary, food intake is a complex behavior. Most animals eat in discrete bouts or meals, and there is considerable evidence that the factors that control when meals occur (i.e., meal onset) are quite different than those that control meal size. The amount of food eaten in a given meal is determined by the quantity and quality of the food (via phasic satiation signals), by fluctuations in body fat stores (via tonic adiposity signals), and by myriad other factors. Although the impact of any of these factors may be small in a particular meal, collectively they ensure that energy stores are maintained over time when ample food is available.

Thirst and Water Intake

Water deprivation elicits the sensation of thirst when certain brain cells become dehydrated by as little as 1% or 2% by the osmotic loss of water. Those cells are located in the basal forebrain, just rostral to the third cerebral ventricle. They exist outside the blood–brain barrier and consequently they respond readily to changes in the particulate concentration, or osmolality, of plasma (pOsm). Although they are not uniquely sensitive to dehydration, such as retinal cells that detect only photons, they do have unique synaptic connections to other brain neurons that stimulate thirst. When the 'osmoreceptor cells' are impaired, either by experimental lesions or by brain disease, animals become blind to increases in pOsm and do not experience thirst normally.

This arrangement whereby osmoreceptors cells detect small increases in pOsm and initiate thirst and water intake, which consequently lower pOsm and thereby eliminate the excitatory signal for behavior, allows the possibility that osmoregulation is controlled by a single-loop negative feedback system. However, a major obstacle to this possibility is that ingested water becomes equilibrated with body fluids only after it is emptied from the stomach, and therefore it cannot provide rapid rehydration and negative feedback in the control of water intake. Although this delay would be expected to lead to continued consumption of large volumes of water in excess of amounts needed for rehydration, ample evidence indicates that such overconsumption of water by dehydrated animals does not occur, and that many species, including humans, replace water deficits by drinking large volumes of water very rapidly and then stopping abruptly. Thus, some early signal must inhibit thirst. Actually, an appropriate signal has been identified, which originates in the oropharynx and is derived from the rapid swallowing of liquids. In support of this conclusion are findings that (1) dehydrated dogs reduce thirst well before decreases in systemic pOsm can be observed; (2) the rapid cessation of thirst also occurs both when ingested water drains through an open gastric fistula before reaching the small intestine and when dehydrated dogs drink isotonic saline; and (3) no effect on thirst is found when water is infused directly into the stomach, bypassing the oropharynx, until the administered fluid decreases systemic pOsm. These striking observations collectively provide strong support for the proposal that some component of the act of drinking, such as rapid swallowing, generates an early stimulus that inhibits water intake in dogs.

These seminal findings have been replicated and extended to other species, including monkeys, sheep, and humans. The repeated confirmations implied that volume-dependent oropharyngeal signals were a general feature in the inhibition of thirst in animals. However, most investigations of the central controls of fluid homeostasis now use laboratory rats as experimental subjects, and whereas dehydrated rats also use presystemic signals to modulate thirst, the signals in rats are not oropharyngeal. In addition, in the rodent system early signals can provide both stimulation and inhibition of thirst, and the early signals are associated with both the volume and concentration of ingested fluid.

However, even with the inclusion of presystemic signals, our consideration of thirst is not complete; there are multiple signals of thirst, not just those resulting from osmoregulatory needs. Animals deprived of drinking water lose water from plasma in addition

to water from cells, and the loss of plasma volume (hypovolemia) is itself a stimulus of thirst. Indeed, thirst can be elicited even when no increase in pOsm occurs, such as following hemorrhage. Animals detect deficits in blood volume by stretch receptors embedded in the distensible walls of the inferior vena cava (which delivers much of the venous return to the heart) and of the right atrium. The stretch of the vessels is proportional to the volume contained therein, so when blood volumes are low the sensory neurons send an afferent signal of hypovolemia to the caudal brain stem, which then relays that message to the forebrain for stimulation of thirst.

One problem with this arrangement, however, is that ingested water, when absorbed, does not repair the plasma volume deficits that stimulated thirst. Instead, approximately two-thirds of the water moves by osmosis into cells. That outcome is desirable when thirst is associated with increased pOsm and cellular dehydration but not when plasma volume is diminished and pOsm is not elevated; then, water consumption only causes osmotic dilution without much correction of hypovolemia. Therefore, it should not be surprising that merely 3–5% osmotic dilution provides a potent stimulus for inhibiting thirst even in the presence of marked hypovolemia. This inhibition of hypovolemic thirst by osmotic dilution may be contrasted with the satiation of osmoregulatory thirst that occurs when appropriate amounts of water are consumed.

The inhibition of water intake despite hypovolemia usefully prevents osmotic dilution from becoming severe but it does not repair the plasma volume deficits that stimulated thirst in the first place. To restore those volumes, animals must ingest plasma or an equivalently dilute NaCl solution. Having first drunk water due to thirst, they must then consume salt. In fact, rats have been shown to drink water and concentrated NaCl solution in appropriate amounts, moving back and forth between the two solutions, to create the isotonic NaCl mixture that is ideal for plasma volume restoration. Space does not allow description of the central mechanisms for this control of thirst and salt appetite during hypovolemia, although much of this information is now known.

It is important to note that thirst in response to plasma volume deficits is not eliminated after destruction of the sites in the caudal brain stem that receive neuronal projections from the cardiovascular stretch receptors that detect hypovolemia. This finding indicates that another stimulus of thirst exists during hypovolemia. This signal likely is provided by angiotensin, a peptide hormone formed in the blood after secretion of the enzyme renin from the kidneys. Angiotensin also stimulates salt appetite as well as the hormones that enable the retention of water and sodium in urine, and it is a very potent vasoconstrictor agent as well (thus helping to support blood pressure during hypovolemia). By having so many functionally related actions, angiotensin ensures that diverse behavioral and physiological responses to hypovolemia occur simultaneously. Note that a stimulus of thirst also results from acute decreases in arterial blood pressure, and that mediation of this thirst by angiotensin, once controversial, has been established.

Circulating angiotensin acts in the brain at the subfornical organ, which is located in the dorsal portion of the third cerebral ventricle. Local angiotensin receptors can respond to elevations in systemic levels of the hormone because the subfornical organ lacks a blood–brain barrier, thus allowing angiotensin to diffuse into that region of the brain. Surgical destruction of this brain structure eliminates thirst and salt appetite stimulated by angiotensin. However, it does not abolish these dual effects of hypovolemia, which indicates that redundant mechanisms can be used to detect the loss of plasma volume and activate appropriate behavioral responses. Such redundancy should not be surprising given the great significance of adequate blood volume to life.

Conclusions

Despite the superficial similarity of food and water consumption, the mechanisms by which the two ingestive behaviors are controlled differ greatly from one another. This difference is in accord with other fundamental features of caloric and water homeostasis, which also differ greatly. For example, water deprivation produces cell dehydration and hypovolemia, whereas food deprivation does not compromise cellular metabolism. Water consumed in excess is excreted readily in urine, whereas food consumed in excess is stored in liver and adipose tissue. Evidently, calories are a more precious commodity than water.

Food intake is not likely to be controlled according to a depletion–repletion scheme whereby hunger is generated by caloric deficiencies. As mentioned previously, the autonomic recruitment of stored calories prevents such deficiencies, and normally there are no apparent need-based excitatory signals for hunger. Instead, multiple signals for inhibiting food intake have been identified. Some of these satiation signals are specific to food ingestion (e.g., CCK, postgastric delivery of calories, and leptin), whereas others are nonspecific and disrupt all ingestive behavior (e.g., gastric distension and nausea). Thus, brain mechanisms that control food intake generally respond to inhibitory signals, both neural and blood-borne, some of which are related to recently ingested and stored calories and some that are not.

In contrast, water intake is controlled according to a modified depletion–repletion scheme whereby bodily water loss generates signals that stimulate thirst and water consumption, which ultimately repairs dehydration. Two neural signals of thirst have been identified – one associated with increased plasma osmolality and cellular dehydration in brain osmoreceptor cells and one associated with decreased plasma volume as detected by cardiovascular receptors. A third, humoral signal of thirst, provided by the peptide hormone angiotensin II, arises from the periphery during hypovolemia and arterial hypotension and acts in the brain. Water intake satiates osmoregulatory thirst but inhibits thirst due to hypovolemia or angiotensin II, and salt consumption (also stimulated by hypovolemia and angiotensin) is required to repair plasma volume deficits and thereby satiate thirst. Thus, brain mechanisms respond to excitatory and inhibitory signals, both neural and blood-borne, that integrate thirst and salt appetite.

During the past four decades, numerous studies have sought to define the biological bases of hunger, food intake, and satiation. Two general perspectives on the problem have been recognized. One views food intake in relation to body weight maintenance and the influence of leptin and insulin, whereas the other views food intake in relation to the control of meals and the influence of gastric distension and intestinal nutrients. In other words, one perspective involves systemic signals associated with body fat stores and the other involves presystemic signals that occur during a meal but before ingested nutrients reach the systemic circulation. The presystemic signals allow animals to prepare for storage and utilization of the nutrients by providing information about what has been consumed and in what quantity, and thereby allow the animals to regulate the delivery of nutrients from the stomach to the small intestine (i.e., gastric emptying) and to vary it according to the concentration of gastric nutrients and bodily needs. Analogously, the control of drinking bouts is influenced by systemic signals associated with body fluid stores and derived from the volume, osmolality, and pressure of circulating blood. The same benefits result when thirsty animals are informed of the volume and content of ingested fluid before it reaches the circulation. The animals then modulate fluid consumption and do not drink in excess, and they modulate gastric emptying of ingested fluid; they also modulate secretion of vasopressin in anticipation of changes in blood osmolality and volume that occur once ingested fluid reaches the small intestine, equilibrates osmotically with body fluids, and is absorbed.

Both food and water intake are complemented by secretion of a peptide hormone – insulin and vasopressin, respectively – that conserves glucose and water, respectively. Eating stimulates insulin secretion, as does the ingested food; hence the coexistence of the behavioral and physiological responses. In contrast, many of the same signals that stimulate thirst also stimulate vasopressin secretion; hence the coexistence of the behavioral and physiological responses. In both cases, the absence of the hormone leads to pronounced urinary nutrient loss and compensatory increases in intake (i.e., diabetes insipidus and diabetes mellitus, respectively). Food consumed in excess does not eliminate renal glucose conservation, and in consequence fat stores increase (although large fat stores may diminish further storage). In contrast, water consumed in excess rapidly dilutes body fluids, thereby inhibiting the hormone responsible for renal water conservation and allowing excretion of the excess fluid in urine.

Multiple signals, both excitatory and inhibitory, control food and water intake. In each case, the signals involve various peptide hormones, afferent neural messages, and substrate levels. Hunger can be inhibited by CCK, insulin, and leptin, along with neural signals from the stomach (in response to gastric distension) and liver (in response to the hepatic delivery of utilizable nutrients), whereas hunger can be stimulated by ghrelin and the absence of satiety signals. Conversely, thirst can be stimulated by angiotensin II along with neural signals from cerebral and visceral osmoreceptors (in response to osmotic loads) and from cardiac baroreceptors (in response to hypovolemia), whereas thirst can be inhibited by atrial natriuretic peptide (which blocks angiotensin II receptors) and by neural signals from cerebral and visceral osmoreceptors (in response to osmotic loads), from arterial baroreceptors (in response to acute hypertension), and from presystemic receptors (in response to volume-dependent signals of rapid swallowing (e.g., in dogs and humans) or of gastric and small intestine distension (e.g., in rats).

Integrated central nervous system circuitry has been identified for a dual-control system that responds to excitatory and inhibitory signals in the control of food intake. One feature of such a system is that eating onset depends on the relative magnitude of the collective signals. Thus, a small excitatory signal can be effective in eliciting eating in the presence of even smaller inhibition, whereas great inhibition precludes eating onset. In contrast, the control of water intake is influenced largely by the appearance and disappearance of excitatory signals, with early cessation provided by acute and potent inhibitory signals that are stimulated by drinking. The relevant receptors that generate these signals have been identified, as have most of their anatomical interconnections.

The control of food intake is complex, at least in humans, and involves many factors unrelated to

caloric homeostasis and hunger, such as social pressures, food palatability, food appearance, and mood. Thus, despite the absence of hunger, individuals tend to eat when in a group that is eating, when presented with food that is especially tasty or attractive (e.g., dessert), or when stressed (i.e., the calming effect of eating) or bored (i.e., the stimulating effect of food). The control of water intake is much less complex because it involves few factors other than those related to fluid homeostasis. Nonetheless, in the absence of true thirst, fluid can be consumed for reasons of palatability (e.g., flavored drinks) or to obtain a desired chemical in the beverage (e.g., alcohol and caffeine). It seems likely that much of contemporary human food and fluid ingestion in affluent Western culture is unrelated to homeostatic needs and actually creates imbalances caused by nutrient excess.

Forebrain Development: Holoprosencephaly (HPE)

E S Monuki, University of California at Irvine, Irvine, CA, USA

Published by Elsevier Ltd.

Introduction and Scope

Holoprosencephaly (HPE) has long fascinated clinicians, basic scientists, and the public alike. This fascination results largely from its striking phenotype, which includes features such as a single midline eye (cyclopia) and a single forebrain holosphere rather than two hemispheres (Figure 1(a)). HPE also represents the most common congenital birth defect of the human forebrain (1 in 10 000 live births, 1 in 250 conceptions). Although previously considered to result from defective cleavage (i.e., splitting of the eye and forebrain fields), it is now well appreciated that the forebrain malformation results from primary defects in midline induction. Correspondingly, when factors needed to adopt midline fates are deficient, HPE is commonly observed. HPE, therefore, serves as a central paradigm for understanding how forebrain midline fates are specified.

The focus of this article is to describe forebrain midline development as revealed by studies on the cells and molecules implicated in HPE. After a brief description of HPE, we describe the following as they relate to forebrain midline development: (1) the organizers (signaling centers), (2) the genes and signaling pathways, and (3) the interactions among signaling pathways. Among the highlights are a tidy categorization of causal HPE genes into four well-known signaling pathways and the recent delineation of interactions among these pathways that help to explain longstanding conundrums about HPE phenotypes.

Definition of Holoprosencephaly

Primary midline failure in HPE has myriad secondary effects on forebrain development, which often lead to confusion and error regarding the HPE designation. Morphologically, the brunt of HPE neuropathology occurs at the midline rather than in more lateral structures. This includes marked reduction to total absence of midline tissues and, correspondingly, the failed separation of adjacent forebrain structures that are normally bilateral (Figure 1(b)). (Although often referred to as fusion, the term failed separation is more accurate.) At the molecular level, these morphological defects equate to absence of midline marker expression and aberrant continuity of lateral markers across the midline. This definition helps to exclude disorders such as microencephaly (small brain size), absence of the corpus callosum, hydrocephalus and absence of the septum pellucidum (which give the appearance of fused ventricles), and aprosencephaly/atelencephaly (absence of forebrain/telencephalon).

HPE can be divided into two categories with qualitatively different midline phenotypes: (1) classic and (2) middle interhemispheric (MIH) (Figure 1(a)). Classic HPE is further divided into alobar, semilobar, and lobar subtypes based on the degree of severity, with alobar being the most severe. The feature common to classic HPE subtypes is ventral predominance – that is, the neuropathology is most severe ventrally and then extends variably and in graded fashion to the rostral, dorsal, and posterior domains. In contrast, the MIH form (also known as syntelencephaly) exhibits midline failure that is restricted to the dorsal forebrain, generally affecting the posterior frontal and parietal lobes in humans (Figure 1(a)). Notably, MIH HPE lacks significant pathology away from the dorsal region – that is, the rostral and ventral domains, including the eyes and face, are relatively unaffected.

Organizers in Forebrain Midline Induction

Like other tissues, the development of the forebrain midline is governed by morphogenetic movements and organizers (signaling centers), which are localized groups of cells that produce morphogens. Morphogens are molecules that promote different cell fates at different concentrations. The key signals identified in forebrain midline induction are secreted proteins that are well-known morphogens in development.

Conceptually, induction of the forebrain midline occurs after neural induction, anterior–posterior (AP) patterning, and forebrain specification. Despite this useful conceptual distinction, however, there is significant overlap among these processes in terms of timing and the factors that govern them. For example, many of the signaling centers that govern neural induction, AP patterning, and forebrain specification are located at the embryonic midline, and these same signaling centers regulate forebrain midline induction. Thus, to provide an appropriate and comprehensive framework, we first summarize the earliest stages of forebrain development.

Nonneural Organizers of the Neural Plate

In the early embryo, forebrain development is regulated by organizers that lie outside the developing nervous system (i.e., in nonneural tissues). These
