Figure 1 Holoprosencephaly (HPE): (a) normal forebrain compared to classic and middle interhemispheric (MIH) HPE in human fetuses; (b) HPE histology. In (a), the normal forebrain is composed of two hemispheres separated by an interhemispheric fissure. In severe (alobar) classic HPE, hemispheric separation is undetectable throughout the forebrain. Classic HPE neuropathology is always most severe ventrally, with variable extension to the rostral and dorsal domains. In MIH HPE, the lack of hemispheric separation is restricted to the dorsal regions, with no apparent extension to rostral or ventral domains. In (b), central to all types of HPE is failed midline induction, which results in absent midline structures and the continuity of lateral tissues across the midline. In this example of MIH HPE (following roof plate ablation), mutant mice lack choroid plexus and have a continuous cortex across the dorsal midline. Ventral tissues in (b) removed for visual clarity. (a, right panel) Reproduced from Marcorelles P, Loget P, Fallet-Bianco C, et al. (2002) Unusual varient of holoprosencephaly in monosomy 13q. (a (left, middle), b) Reproduced with permission from the Journal of Neuropathology and Experimental Neurology.

nonneural organizers act before and during gastrulation to induce neural fate and AP patterning and then induce organizers within the forebrain tissue itself. Induction of these local neural organizers is often homeogenetic in nature – the nonneural cells instruct their neural neighbors to adopt a fate similar to its own – with the homeogenetic signals being the morphogens themselves. Important nonneural organizers of the forebrain include the node, anterior visceral endoderm (AVE), epidermal ectoderm, and prechordal plate.

The Node and Anterior Visceral Endoderm: Morphogen Antagonists and Forebrain Specification

Neural induction The node and AVE have primary importance in neural induction in mammals (Figure 2). Despite lingering questions and apparent differences among species, antagonism of bone morphogenetic protein (Bmp) signaling consistently takes center stage in the process of neural induction, and both the node and AVE are rich sources of Bmp antagonists, such as Noggin and Chordin. In some species, Bmp antagonism suffices for neural induction, whereas additional competence signal(s) – most likely fibroblast growth factors (Fgfs) – seem to be required in others.

Forebrain specification The AVE, which eventually underlies the future forebrain after cell movements and rotation (Figure 2(a)), has been shown in mice and chicks to regulate AP patterning of the neural plate. In addition, the AVE is necessary and sufficient for forebrain specification. Multiple AVE-derived

Figure 2 Nonneural organizers of the forebrain: (a) schematic cross section of early embryo; (b) patterning of the anterior neural plate by nonneural organizers (tissue layers separated for visual clarity). In (a), the extraembryonic anterior visceral endoderm (AVE) has rotated to underlie the future forebrain while cells in and around the embryonic node intercalate and migrate rostrally between the ectoderm and endoderm to form the prechordal plate and notochord. In (b), before prechordal plate arrival, the forebrain anlage is adjacent to the AVE (brown) and nonneural ectoderm (purple). AVE-derived morphogen antagonists are involved in AP patterning and forebrain specification. Antagonism of Bmp signaling is central to the earlier process of neural induction, but the roles of ectoderm-derived Bmps at the neural plate stage remain largely undefined. The prechordal plate and associated mesendoderm (blue) intercalate between the AVE and neural plate (neurectoderm). The prechordal plate produces multiple signals (Nodal, Shh, Bmp7) that influence rostral morphogenesis and induction of midline neural tissue. AP, anterior–posterior; Bmp, bone morphogenetic protein; Shh, Sonic hedgehog; Wnt, Wingless-int. (b) Adapted from *Developmental Cell*, vol. 6, Wilson SW and Houart C, Early steps in the development of the forebrain, p. 171, 2004, with permission from Elsevier.

signals mediate these processes, including cerebrus and dickkopf, which antagonize Bmp, Wingless-int (Wnt), and Nodal signaling. Antagonism of multiple morphogens, many of which caudalize neural tissue, is central to AVE function. Thus, AVE-dependent forebrain specification is not instructive *per se* but, instead, involves protecting the forebrain from factors that impart caudal character, such as Wnts, Fgfs, and retinoic acid. This has contributed to the so-called default model in which forebrain fate represents the default state of neural tissue unexposed to patterning signals. Eventually, AVE signaling to neural tissue is altered by the intercalation of mesendoderm during gastrulation (Figure 2(b)).

Role in anterior neural border specification The AVE has been implicated in specifying the anterior neural border (ANB), the local neural organizer at the edge of the rostal neural plate. Removal of the AVE or inactivation of its morphogen antagonists results in the absence of the ANB and telencephalon. In addition to cerebrus and dickkopf, the AVE produces secreted Frizzled-related proteins (sFRPs), which are (Figure 3), Wnt antagonists, and Wnt antagonism is known to be required for ANB formation.

Epidermal Ectoderm: Bmps and Roof Plate Induction

Bmp antagonism in neural induction Continuous with the neural plate is nonneural epidermal ectoderm, the future skin. Prior to and during neural induction, the ectoderm possesses high Bmp signaling levels, and antagonism of this high-level signaling is central to neural induction. Ultimately, high Bmp signaling confers epidermal fate. Epidermal ectoderm-derived Bmps are likely to mediate multiple processes at the rostral and lateral margins of forebrain neural plate, although these functions remain undefined.

Role in roof plate induction In the chick and mouse spinal cord, Bmps from epidermal ectoderm induce the formation of the roof plate (RP), the dorsal midline organizer of the neural tube (Figure 3(a)). (Note that the lateral margins of neural plate become the dorsal midline of neural tube after neurulation.) Because the RP continues to produce Bmps, epidermal ectoderm-dependent RP formation serves as a classic example of homeogenetic induction, and it appears likely that homeogenetic RP induction occurs at all levels of the developing neural tube.

Figure 3 Local neural organizers of the neural plate: (a) rostral morphogenesis of the hypothalamic anlage; (b) signals produced by local neural organizers. In (a), cells of the hypothalamus (ht) originate at or near the node and then move rostrally under the influence of the prechordal plate. This morphogenesis results in the lateral displacement of cells in more rostral fields, particularly the eye field (ef). In (b), Wnt antagonists and Fgfs (most notably Fgf8) are produced at the rostral margin of the neural plate (the anterior neural border). The hypothalamic anlage produces Nodal and Shh, whereas Fgfs and Wnts are produced caudally. d, diencephalon; Fgf, fibroblast growth factor; mb, midbrain; t, telencephalon; Adapted from Wilson SW and Houart C (2004) Early steps in the development of the forebrain. *Developmental Cell* 6: 168, figure 1, with permission from Elsevier.

Prechordal Plate: Nodal, Shh, Bmp, Ventral Midline Induction, and Role in Holoprosencephaly

Prechordal plate formation During gastrulation, mesendodermal cells from the node migrate rostrally along the midline between the ectoderm and endoderm layers. These cells form the tight notochord, which underlies the neural tube up to the midbrain–forebrain boundary and the prechordal plate, a loose cell collection that underlies the emerging forebrain (Figure 2(b)). The prechordal plate shares certain similarities with the notochord, in particular the production of the Sonic hedgehog (Shh) morphogen. Unlike the notochord, however, the prechordal plate also produces several other signaling proteins, including Nodal, Bmp7, and Wnt antagonists.

Regulation of hypothalamic morphogenesis and induction of ventral midline organizers The prechordal plate regulates three different aspects of hypothalamic (HT) development: (1) the rostral migration of future HT cells, (2) HT induction, and (3) HT patterning. The hypothalamus then serves as a local neural organizer caudomedial to the eye field. Prechordal plate signals also induce local organizer function in the ventral telencephalic midline (VTM; preoptic and entopeduncular regions, and then later in the medial ganglionic eminence). Nodal and Shh signals account for these prechordal plate-dependent functions. The prechordal plate has also been implicated in ANB development because Shh is needed to maintain Fgf8 expression in the ANB.

Role in classic holoprosencephaly Among nonneural organizers, only the prechordal plate has been directly implicated in HPE induction, and prechordal plate defects generate classic HPE phenotypes. Manual prechordal plate removal results in a single eye field, failed HT induction, and molecular defects characteristic of classic HPE. In addition, genetic analyses of the Nodal, Shh, and Bmp signaling pathways point to the primary involvement of the prechordal plate in classic HPE induction.

Local Neural Organizers at the Forebrain Midline

Under direction of nonneural organizers, local organizers are established within forebrain tissue itself (Figure 4). This occurs during the period spanning the end of gastrulation and the beginning of neurulation (neural tube formation). Local midline organizers include the hypothalamus and ventral telencephalic midline (VTM) ventrally, the ANB rostrally, and the RP dorsally. Induction of ventral and rostral organizers occurs before that of the RP, which is completed after neurulation. Among these, the RP has been directly implicated in MIH HPE, whereas molecular genetic and transplant studies also suggest direct ANB involvement in classical HPE.

Hypothalamus and Ventral Telencephalic Midline: Nodal, Shh, and Ventral Patterning

Hypothalamic morphogenesis and induction In fish and chicks, HT cells originate near the node, where they are intermingled with floor plate cells. HT cells then migrate rostrally toward the telencephalon, which results in a lateral displacement of forebrain tissue, most notably the eye field (Figure 3(a)). This morphogenesis lags slightly behind that of the prechordal plate (Figure 2(b)), and the prechordal plate regulates HT morphogenesis via Nodal signals. Although less well appreciated than the signaling functions, defects in rostral HT morphogenesis are easy to envision as the culprits of cyclopia and HPE. Prechordal plate signaling via Nodal and Shh signals is then responsible for inducing HT and VTM fates and signaling functions.

Figure 4 Local neural organizers of the rostral neural tube: (a) midline organizers; (b) morphogen expression. In (a), specialized signaling centers are aligned at the midline following neurulation, including at the closed rostral end of the neural tube. In (b), the midline organizers serve as central sites of morphogen production, which then extends beyond the midline to involve additional sites. Dorsally, Bmps and Wnts are produced at the midline and then secondarily at the dorsomedial edges of telencephalon (choroid plexus and cortical hem). Rostral Fgf8 expression extends to involve a domain caudal to the eye field. Conversely, Shh production extends rostrally to involve the ventral telencephalic midline rostral to the eye field. TM, telencephalic midline.

Nodal and Shh expression Following induction, the HT continues to produce Nodal and Shh (Figure 3(b)). Nodal and Shh signals from the prechordal plate and/or produced locally then regulate HT patterning. The VTM is induced to express Shh, but not Nodal, and Shh expression from the VTM eventually extends into the medial ganglionic eminence (MGE) (Figure 4). These ventral Shh sources are probably responsible for inducing and patterning the septum, MGE, and lateral ganglionic eminence (LGE) in the ventral telencephalon.

Roles in patterning and holoprosencephaly pathogenesis Distinguishing the roles of ventral neural organizers from those of the prechordal plate has been difficult due to their common expression of morphogens. Nonetheless, both the hypothalamus and VTM seem certain to be involved in HPE pathogenesis, if not its induction. Based on proximity and timing, the VTM may be directly responsible for the basal ganglia defects (e.g., basal ganglionic fusion) that are frequently seen in classic HPE.

Anterior Neural Border: Wnt Antagonists, Fibroblast Growth Factors, and Telencephalic Specification and Patterning

Anterior neural border induction In addition to the AVE, the prechordal plate and epidermal ectoderm are well positioned to participate in ANB specification. Shh signaling, most likely from prechordal plate, is needed to maintain Fgf8 expression in the ANB, although initial Fgf8 induction can occur in the absence of Shh.

Expression of Wnt antagonists and Fibroblast growth factors Following induction, the ANB expresses two different classes of secreted products: (1) Tlc, a Wnt antagonist of the sFRP family and (2) a number of Fgfs, which vary among species (e.g., Fgf3/8 in fish and Fgf8/15/17/18 in mice) (Figure 3(b)). Fgf8 is particularly important for ANB function. Fgf8 expression does not remain restricted to the ANB, however; it extends caudally into the optic region and then splits. Low-level Fgf8 expression is also detectable in dorsal telencephalic and diencephalic midline regions after neurulation, which may represent continued Fgf8 expression that originated at the lateral margins of neural plate.

Roles in telencephalic specification and patterning Ablation and transplant studies suggest a central role for the ANB in telencephalic specification and patterning. These two functions are mediated by the two different classes of ANB products. Tlc mediates ANB-dependent telencephalic specification by antagonizing caudal Wnt sources. The Fgfs (particularly Fgf8) mediate ANB-dependent telencephalic patterning rather than its initial specification, promoting rostral telencephalic fates over caudal ones.

Potential roles in midline patterning and holoprosencephaly induction ANB tissue rescues midline eye-field fates in Nodal mutants, implicating the ANB in the eye defect of classic HPE. Although Fgf8 expression extends beyond the ANB, genetic analyses suggest a prominent role for the ANB in Fgf8 mutant HPE phenotypes.

Roof Plate: Bmps, Wnts, Dorsal Midline Induction, and Role in Middle Interhemispheric Holoprosencephaly

Roof-plate induction Based on analogy to the spinal cord, nonneural (epidermal) ectoderm probably has a central role in inducing forebrain RP, although this remains unproven.

Expression of Bmps and Wnts Following its formation and induction during neurulation, the RP expresses several Bmps (2/4/5/6/7/12), as well as multiple Wnts.

Bmp4, which is the best-studied Bmp in forebrain development, is expressed in the RP and abuts the Fgf8 domain in the rostral midline (Figure 4(b)).

Roles in dorsal midline induction In addition to minor lineage contributions, the RP governs induction of dorsal fates near the telencephalic midline, most notably the telencephalic choroid plexus epithelium (CPe) and cortical hem (the small CPe–cortex junctional region). The RP also patterns the adjacent dorsal cortical primordium. Based on rescue and gain of function studies, many of these RP-dependent functions are mediated by Bmps. These Bmp-dependent RP functions at the dorsal telencephalic midline parallel those in the dorsal spinal cord and cerebellum.

Role in middle interhemispheric holoprosencephaly In addition to failed dorsal midline induction, genetic RP ablation in mice results in MIH HPE. The ablation phenotype also accurately predicts CPe and hippocampal defects in MIH HPE patients, thus supporting a causal role for the RP in human MIH HPE.

Molecules and Pathways in Forebrain Midline Induction and Holoprosencephaly

With a cellular framework now established, we turn our attention to the individual genes and signaling proteins involved. Although selective molecular expression allows for functional assignment to specific organizers in some cases, individual signals and genes are most often expressed beyond the confines of single organizers (e.g., after homeogenetic induction; Figure 4). However, whether they inform organizer function or not, molecular analyses have illuminated a great deal about midline patterning and HPE. We start by grouping causal HPE genes into defined signaling pathways, then discuss each pathway in turn.

Genes Implicated in Holoprosencephaly

Several HPE genes have been identified from studies in fish, mice, and humans. In humans, nine genes have been identified, with a similar number of genes awaiting identification. Most of the identified genes have known functions in specific morphogen pathways. Some encode transcription factors (e.g., Six3, Zic2, and Tgif) with less certain relationships to individual pathways or organizers, although recent studies have begun to clarify their roles as well (Table 1).

Table 1 Holoprosencephaly genes and signaling pathways[a]

NODAL	*SHH*	*FGF8*	*BMP*
Nodal	SHH	Fgf8	Chordin
Cyclops	PTCH	SIX3	Noggin
Squint	DHCR7		Twsg1
One-eyed pinhead	GLI2		ZIC2
TDGF1/CRIPTO	Smo		
FAST1	Cdo		
	DispA		
	SIX3		

[a]Genes from humans and experimental organisms linked to definitive holoprosencephaly (HPE) phenotypes, grouped by signaling pathway. Human genes are shown in upper case. TGIF may be involved in both Nodal, Bmp, or retinoic acid signaling in the forebrain, although this remains undefined. Megalin may be involved in either Shh or Bmp signaling. SIX3 and ZIC2 may be involved in additional signaling pathways.

Signaling Pathways in Forebrain Midline Induction and Holoprosencephaly

Nodal signaling at the ventral midline

Genetic associations with holoprosencephaly. Defects in several Nodal signaling components lead to HPE phenotypes in fish, mice, and humans. These include Nodal ligands, a receptor subunit (ActRIIA), extracellular cofactors (EGF-CFC family), a transcriptional transducer (Smad2), and a transcriptional cofactor (Tgif). Genetic loss of function yields predictable phenotypes based on the known positive or negative regulation of Nodal signaling by these genes, with the exception of Tgif. (HPE is associated with reduced Nodal signaling and Tgif loss of function, but, as a negative regulator, Tgif loss of function should lead to increased Nodal signaling.)

Nodal sites and functions: Confined expression to ventral tissues. Among its many developmental functions, Nodal signaling is required for the initial specification of the prechordal plate, where Nodal ligands are expressed. Prechordal plate-derived Nodal signals then regulate HT morphogenesis and induction (Figure 2(b)). Nodal signaling is the only pathway known to regulate rostral HT morphogenesis. Later, Nodal is expressed in the hypothalamus itself (Figure 3(b)), but does not extend beyond the ventral midline during this developmental period.

Nodal mutant holoprosencephaly phenotypes: Severe classic holoprosencephaly extending to the dorsal midline. Despite the restriction of Nodal expression to ventral tissues, Nodal mutants have a particularly severe HPE phenotype that extends to involve the rostral and dorsal midlines. This severe classic HPE phenotype is reminiscent of those associated with defects in Shh signaling.

Shh signaling at the ventral midline

Genetic associations with holoprosencephaly. Like Nodal, studies from different organisms implicate several Shh signaling components in ventral midline induction of the forebrain. These include the ligand, its cholesterol-based posttranslational modifications,

Shh release (DispA), receptors (Ptch, Smo), and the coreceptor or trafficking molecule (megalin). By and large, genetic analyses of individual components have led to midline and HPE phenotypes consistent with their known positive or negative effects on Shh signaling.

Shh sites and functions: Confined expression to ventral tissues. Shh is co-expressed in prechordal plate with Nodals (Figure 2(b)). Prechordal plate Shh induces the overlying hypothalamus and VTM (preoptic and anterior entopeduncular regions), which leads to activated Shh expression in these tissues (Figures 3(b) and 4(b)). Although the relative contributions of Shh from prechordal plate, the hypothalamus, and the VTM remain difficult to dissociate, ventral Shh signaling is clearly essential for midline eye-field specification and for excluding laterally expressed genes from the midline. The midline eye-field defects in Shh mutants do not result from aberrant HT morphogenesis, unlike Nodal mutants, and are therefore more clearly due to failed inductive signaling. At later stages, Shh production extends into more lateral regions of the ventral telencephalon (medial ganglionic eminence) (Figure 4(b)). Like Nodal, all Shh sources remain confined to ventral tissues during the HPE inductive period.

Shh mutant holoprosencephaly phenotypes: Severe classic holoprosencephaly extending to the dorsal midline. Like Nodal, Shh signaling defects in mice and humans lead to ventral predominant classical HPE, which typically extend to involve the rostral and dorsal midlines. For example, human HPE phenotypes due to Shh mutations include absence of the interhemispheric fissure, absence of corpus callosum, and failed cortical separation in rostral and dorsal telencephalic domains. At the dorsal midline, Shh null mice exhibit no telencephalic CPe and aberrant expression of lateral cortical markers across the midline. Notably, the absence of CPe and abnormal midline expression of lateral cortical markers mimics the dorsal midline phenotype induced by RP ablation.

Fgf8 signaling at the rostral midline

Genetic association with holoprosencephaly. Although not yet implicated in humans, Fgf signaling from the ANB has been implicated in midline patterning defects in fish (Fgf8 and Fgf3) and mice (Fgf8). Significantly, Fgf8 mutations have recently been shown to result in definitive HPE phenotypes in mice. Other dedicated Fgf signaling components have yet to be implicated in HPE, although Six3 has a critical role in Fgf8 induction.

Fgf8 sites and functions: Anterior neural border with ventral and dorsal extensions. Fgfs are not expressed in nonneural tissues near the forebrain but are, instead, limited to local neural organizers. In the forebrain neural plate, the expression of Fgf8 and other Fgfs (which differ among species) initiates in the ANB at the margin of the telencephalic field (Figure 3(b)). Fgf8 expression eventually extends caudally into the midline eye field and then splits bilaterally (Figure 4 (b)). After neurulation, high-level Fgf8 expression continues at the rostral telencephalic midline, although lower levels also become detectable in the dorsal telencephalic and diencephalic midline regions. Caudally, Fgfs are also expressed in the isthmus organizer, the local neural organizer at the midbrain–hindbrain boundary.

Fgf8 studies and mutant. holoprosencephaly phenotypes: Variable, extending to the dorsal midline Fgf8 mutant phenotypes are variable but include those corresponding to classic HPE. Defects in HT and VTM induction correlate with Fgf8 activity level, based on analysis of hypomorphic Fgf8 mouse mutants. Moreover, ectopic Fgf8 studies in chicks indicate the positive regulation of midline fate (including induction of an ectopic sulcus reminiscent of the interhemispheric fissure). Notably, midline induction failure in Fgf8-dependent HPE can also extend to the dorsal midline. Unlike its consistently positive regulation of ventral midline fates, however, Fgf8 effects on dorsal midline development are nonlinear. Recent studies in the chick midbrain provide a plausible explanation – namely that Fgf8 both promotes RP competence (positive regulation) and inhibits RP differentiation (negative regulation).

Bmp signaling at the ventral and dorsal midlines

Genetic association with holoprosencephaly. Genetic studies on the Bmp antagonists Noggin and Chordin in mice have directly implicated Bmp signaling in HPE. Other dedicated Bmp signaling components have yet to be associated, although a major site of Zic2 action appears to be upstream of the Bmp-producing RP. Tgif (a Smad corepressor) may also act in the Bmp pathway, and Bmp signaling has been implicated in many of the midline defects associated with RP ablation in mice.

Bmp sites and functions: Ventral and dorsal midline tissues. Prior to gastrulation, multiple Bmps are expressed in ectoderm, where the antagonism of Bmp signaling induces neural fate. Following neural induction, Bmps continue to be expressed at high levels in nonneural (epidermal) ectoderm contiguous with the neural plate. Noggin and Chordin are expressed at highest levels in the prechordal plate and notochord from early stages, whereas Bmp7 expression in the prechordal plate begins later (Figure 2(b)). Following neurulation, the RP becomes an epicenter for Bmp expression (Figure 4), although many Bmps maintain expression domains in the overlying ectoderm,

mesenchyme, and elsewhere. Bmp expression is maintained at later stages in two dorsal telencephalic midline tissues derived or induced by the RP: CPe and cortical hem, which is the CPe–cerebral cortex junctional region that serves as a Wnt production epicenter.

Bmp mutant holoprosencephaly phenotypes: Classic and middle interhemispheric forms. The Noggin/Chordin mutant HPE phenotype falls into the ventral-predominant classic HPE category. This correlates with their major site of expression in the forebrain region, the prechordal plate. Bmp signaling has been shown to suppress Shh expression, which probably accounts for the need to antagonize Bmp signaling in the prechordal plate (Figure 2(b)). Bmp-antagonist studies provide additional evidence for the primary role of prechordal plate in classic HPE induction. On the other hand, RP ablation induces MIH HPE, including the absence of CPe and aberrant midline expression of cortical markers (Figure 1(b)). Bmp signaling has been directly implicated in CPe induction and suppression of cortical markers at the midline, and multiple midline defects caused by RP ablation can be rescued by exogenous Bmp4. Thus, Bmp signaling appears to be centrally involved in RP-dependent midline and HPE induction.

Interactions among the Signaling Pathways

Several insights into midline patterning and HPE have come from recent *in vivo* and *in vitro* studies that have determined how the various signaling pathways interact. In addition to these interactions, we discuss how the transcription factors implicated in HPE impact these signaling pathways (Figure 5).

Nodal → Shh Pathway in the Ventral Midline

As previously discussed, Nodal and Shh share not only common expression sites but also similarity in mutant phenotypes. Genetic epistasis experiments provide significant evidence for Nodal being upstream of Shh in the pathway leading to HT induction. For example, Nodal null mutants lack prechordal plate and Shh expression, and exogenous Shh rescues HT and ventral telencephalic Nodal defects. Shh appears sufficient to mediate many, but not all, Nodal-dependent functions (e.g., diencephalic defects in Nodal mutants are not rescued by Shh, suggesting a separate Shh-independent Nodal pathway). Subsequent HT patterning involves parallel pathways for Nodal and Shh (as well as Bmp7), with the two morphogens biasing toward opposing HT fates.

Figure 5 Genetic network in forebrain midline induction: (a) the core morphogen interaction network; (b) additional network components. In (a), The genetic network starts with ventral Nodal, which positively regulates ventral Shh production. Shh then engages in a positive feedback circuit with Fgf8 in the ventral and rostral domains. Fgf8 has both positive and negative influences on the dorsal midline, serving initially as a competence factor for RP induction. Later, Fgf8 acts as an inhibitor of RP maturation and participates in a negative feedback loop with dorsal Bmp4 and other Bmp signals. This core network explains how defects in morphogens expressed exclusively in ventral domains (Nodal and Shh) can spread to involve the rostral and dorsal midlines, which is characteristic of classical HPE. Conversely, this network also explains why primary RP defects that cause MIH HPE do not spread rostrally or ventrally. In (b), Bmp7 produced by the prechordal plate antagonizes Shh production, which accounts for the classic HPE phenotype due to Noggin and Chordin loss. Six3 mutations also cause classic HPE, which is consistent with Six3 involvement in multiple circuits that all serve to promote the Shh → Fgf8 positive feedback loop. Although the mechanism by which Zic2 mutations lead to classic HPE remains uncertain, Zic2 mutation can also result in MIH HPE due to its role in RP induction. HPE, holoprosencephaly; MIH, middle interhemispheric; RP, roof plate.

Shh → Fgf8 Positive Feedback Loop in the Ventral and Rostral Midlines

Evidence for a positive feedback loop Fgf8 expression is almost entirely lost in Shh mutant mice, but Fgf8 expression is dramatically upregulated in mouse mutants with increased Shh signaling (Gli3 mutants), indicating that Shh signaling positively regulates Fgf8 expression. The critical Shh sources at the ventral

midline (whether the prechordal plate, hypothalamus, or VTM) remain to be determined. Interestingly, Shh is not required for Fgf8 induction (based on rescued Fgf8 expression in Shh/Gli3 double null mutants) but, rather, for its maintenance once induced. Conversely, Fgf8 loss in fish and mice leads to decreased Shh expression in the hypothalamus and VTM. Consistent with a positive feedback loop, Fgf8 and Shh expression are consistently co-regulated whenever Bmp signaling is altered, either genetically or with exogenous proteins in chicks and mice. The positive feedback loop between Shh and Fgf8 is similar to that described in limb development.

Convergence of Shh and Fgf8 signaling in the eye field In addition to the positive feedback loop, Shh and Fgf8 signaling cooperatively induce optic stalk fate in the eye field. The eye field is well placed for such convergence, where nearby Shh and Fgf8 expression domains are closely apposed (Figure 4(b)). In cyclopic Shh mutant eyes, exogenous Fgfs or ANB transplants are sufficient to rescue optic stalk fate. In addition, the absence of ventral telencephalic fates in Shh −/− mice is suppressed by Gli3 inactivation, implying the presence of another ventralizing signal. This most likely includes Fgf8, which is dramatically upregulated in Shh/Gli3 compound null mice.

Positive Regulation of the Shh → Fgf8 Loop by Six3

Although Six3 does not fit neatly into a single signaling pathway, it is embedded in two defined positive feedback loops that serve to promote the Shh → Fgf8 loop. Six3 is expressed in the anterior neural plate and ANB, where it is required for forebrain and eye specification. These Six3 functions involve a feedback loop between Six3 and Wnt repression. Six3 is also required for ANB and Fgf8 induction. Following Fgf8 induction, Six3 serves as a competence factor for Fgf8-dependent telencephalic gene expression, resulting in a Six3 → Fgf8 positive feedback loop in the telencephalon. Six3 is also strongly expressed in the eye field and hypothalamus, where it confers competence for Shh-dependent HT fate. Thus, all defined Six3-dependent loops and pathways act to promote the Shh → Fgf8 positive feedback loop.

Negative Regulation of the Shh → Fgf8 Loop by Bmps

As already discussed, several experimental manipulations that alter Bmp signaling (e.g., Bmp and Noggin bead placements in chicks; RP ablations, Chordin/Noggin double knockouts, Noggin electroporations, and exogenous Bmp applications in mice) lead to the same conclusion – namely that Bmp signaling negatively regulates both Fgf8 and Shh expression. As discussed earlier, Bmps in the prechordal plate (Figure 2(b)) probably account for the HPE phenotype seen in Chordin/Noggin compound null mice. Bmps produced in the dorsal midline region may also negatively regulate Fgf8 and Shh because Fgf8 and Shh expression are well maintained (and Fgf8 possibly upregulated) following genetic RP ablation in mice.

Fgf8 → Roof Plate Pathway: Positive and Negative Regulation by Fgf8

Studies in fish and mice indicate that reduced Fgf8 expression can lead to dorsal midline defects and HPE. This indicates that Fgf8 can positively regulate dorsal midline induction. However, until recently, most gain-of-function studies have provided evidence for negative Fgf8 regulation of dorsal midline development. Significantly, analyses of hypomorphic Fgf8 mouse mutants have provided evidence for nonlinear Fgf8 effects (i.e., reduced Fgf8 signaling can have both positive and negative effects on the dorsal midline), and recent studies in chick midbrain provide an explanation for this nonlinearity. These studies identified two different roles for Fgf8 in RP development. Fgf8 first acts as a competence factor for RP induction (e.g., Fgf8 beads can induce an ectopic RP *in vivo*). At later stages, Fgf8 inhibits RP maturation, probably by antagonizing transforming growth factor (TGF)β signals, including Bmps, which positively regulate RP differentiation. Earlier studies in the chick forebrain suggest similar Fgf8 functions in the forebrain, although these remain unproven. The ability of Fgf8 to confer RP competence provides, for the first time, a mechanism accounting for failed dorsal midline development following Fgf8 reduction.

Zic2 → Roof Plate Pathway in the Dorsal Midline

Studies in mice demonstrate Zic2 expression prior to neurulation, followed by preferential Zic2 expression in the dorsal forebrain. Zic2 knockdown in mice leads to defective neurulation kinetics and absence of RP induction, which leads to a dorsal HPE phenotype. Notably, among known HPE genes, only *ZIC2* has been specifically linked to human MIH HPE (single case predicting a hypomorphic 12-amino-acid in-frame deletion), although most human *ZIC2* mutations lead to classic HPE. The classic phenotype could be related to Zic2 expression in ventral midline tissues. Nonetheless, the mouse knockdown studies and hypomorphic human allele suggest that dorsal midline development – and RP induction in particular – are particularly sensitive to reduced Zic2 level. Zic2 expression is well maintained following RP ablation in

mice and is insensitive to exogenous Bmps in explants and dissociated cells, which argues against positive feedback from the RP back to Zic2.

Sufficiency of Morphogen Interactions to Account for Classic and Middle Interhemispheric Holoprosencephaly Phenotypes

As mentioned earlier, how pure ventral signaling defects caused by Shh and Nodal mutations can spread to involve the dorsal midline has been a conundrum that lacked explanation. Studies of the developing spinal cord, which so often serve as the precedent for the developing forebrain, do not help in this regard. For example, Shh loss in the spinal cord leads to ventral expansion of Bmp-regulated genes (as occurs in the forebrain), but it does not lead to RP failure or other dorsal midline defects.

Recent studies, particularly those involving Fgf8 and the RP, provide for a coherent genetic regulatory network that resolves this apparent conundrum and is sufficient to account for both classic and MIH HPE phenotypes (Figure 5). In this network, Fgf8 serves as the key intermediary between ventral Nodal/Shh and dorsal Bmp signaling (via the ANB and rostral midline, which distinguish the anterior neural tube from more caudal regions). The role of Fgf8 as an intermediary results from both its involvement in positive feedback with Shh and its positive regulation of dorsal midline development by providing competence for RP (and dorsal Bmp) induction. Via Fgf8, defects in Nodal and Shh signaling then lead plausibly to failed dorsal midline development, as seen commonly in classic HPE.

Conversely, the RP ablation and Bmp genetic studies help to explain why MIH HPE defects do not spread ventrally. Based on a relatively large number of studies, Bmp signaling acts uniformly to negatively regulate both Fgf8 and Shh expression (Figure 5). Reduction of dorsal Bmp signaling (e.g., due to RP failure), therefore, serves to maintain or upregulate the pathways responsible for patterning the rostral and ventral midlines, thus preserving these domains in MIH HPE. The unidirectionality of spread in HPE (i.e., ventral to dorsal in classic HPE but not vice versa in MIH HPE) is also consistent with the temporal order of differentation, with the induction of ventral and rostral midline signaling centers occurring prior to neurulation and RP induction.

Interestingly, in virtually all cases examined, positive and negative regulation of the involved signaling pathways occurs at the level of individual morphogen mRNAs. Conceivably, regulation of signaling pathways could occur at myriad levels (e.g., extracellular antagonists, extracellular diffusivity, cell surface receptors, intracellular transducers, or degradation), and regulation at multiple levels is likely at the forebrain midline, as it is elsewhere. Thus, it is perhaps remarkable that steady-state mRNA levels of the morphogens alone are sufficient to account for the spectrum of midline patterning defects seen in HPE. Although unproven, we might then predict that regulation at other levels of signaling should occur predominantly in the same positive or negative direction as those for the individual morphogen mRNAs.

Future Directions

Several unanswered questions remain about the pathways involved in forebrain midline induction and HPE. The extent to which the simple morphogen interaction network models the HPE phenotypes requires further testing. In addition, notably absent from most of this article is a detailed discussion of Wnt signaling. Wnts have well-defined roles in AP patterning, including telencephalic specification, but their precise roles in midline patterning remain undefined. Because Six3 and Wnt suppression make up a positive feedback loop central to telencephalic induction, Wnt suppression is at least indirectly involved in promoting competence (via Six3) for Shh- and Fgf8-induced ventral midline fates. Rostral Fgf8 signaling has also been implicated as a negative regulator of dorsal Wnt signaling, although the role of this pathway in HPE pathogenesis is unclear. Another conceivable participant is retinoic acid (RA). RA has been implicated as one of the caudalizing signals whose antagonism is required for forebrain fate specification. Excessive RA signaling can lead to an HPE-like phenotype in mice, which is consistent with its ability to downregulate Shh expression.

The role of Tgif also remains somewhat mysterious. A significant number of human *TGIF* mutations (mostly predicting loss of function) have now been associated with HPE. As a repressor of Nodal and RA signaling, Tgif does not yet fit well into the Nodal–HPE pathway (Tgif loss-of-function mutations should lead to increased rather than decreased Nodal signaling), but it fits with RA (the same mutations mimic excessive RA). However, total Tgif loss in mice does not lead to midline induction failure or HPE. In addition, Tgif expression after neurulation appears preferentially in dorsal domains and is higher in the cortex than the dorsal midline. Maintained Tgif expression is dependent on an intact RP and is positively regulated by exogenous Bmps in culture, which is consistent with a role for Tgif in HPE pathogenesis but not in induction *per se*. Additional basic studies on Tgif function in early forebrain development are needed to clarify its placement in the genetic regulatory network that underlies forebrain midline and HPE induction.

Forebrain Development: Prosomere Model

L Puelles, University of Murcia, Murcia, Spain

© 2009 Elsevier Ltd. All rights reserved.

Definition

The prosomeric model is a segmental structural model of the brain of vertebrates that explicitly holds that the brain is formed by an uninterrupted series of transverse subunits of the neural tube, generally called neuromeres. Among such subunits is a large rostral forebrain unit – the secondary prosencephalon – that encompasses hypothalamus, eyes, and telencephalon, followed by three caudal forebrain or diencephalic neuromeres (i.e., prosomeres), which are regarded as being serially homologous with more-caudal neuromeres, namely, a single midbrain mesomere, 11 hindbrain rhombomeres, and the spinal myelomeres. It is important to note that for descriptive purposes, the model postulates in all vertebrates a morphogenetic bending of the longitudinal axis of the tubular neural primordium, most marked at the cephalic flexure, whose incurvation causes wedge-shaped deformation of the topologically transverse cylindrical neuromeric sectors of the neural tube. These units share a set of fundamental longitudinal zones (due to common dorsoventral (DV) patterning processes) and therefore represent segments, that is, metameric developmental units (anteroposterior (AP) patterning). The common causal background of the longitudinal zones establishes the property of metamery (i.e., serial homology) across all neuromeres, irrespective of their differential molecular identities and individual prospective adult fates and of the variable border properties of the cells found at the interneuromeric boundaries. Therefore, the prosomeric model visualizes all vertebrate brains as segmented structures constructed along the same Bauplan (same set of DV and AP developmental units). Orthogonal intersection of DV and AP boundaries in the neural tube wall defines a checkerboard pattern of domains (histogenetic areas) in which specific properties and finer regionalization phenomena appear (shared or not among vertebrates). This makes the model useful for systematic descriptive neuroembryology, comparative neuroanatomy, and causal analysis of conserved or variant brain morphogenesis.

Characteristics

Why We Use Models

Structural neurobiology studies the form and functional inner structure of brains. This needs a conceptual model in which all sorts of detailed data on form and structure down to cellular aspects can be systematically accumulated, organized, compared, and differentiated one from another in their mutual relationships. The basic model of the vertebrate brain is the concept of the closed neural tube, from which adult brains emerge via differential morpho- and histogenesis. Since we cannot know all from the beginning, morphological models essentially are reasonable and useful conjectures about how many parts there are and how they are patched together. Such models are periodically perfected over time, becoming in the case of brains increasingly complex operational scaffolds based on accumulated data and a number of assumptions. There is always the possibility of constructing better (or worse) models.

A good model in essence should be parsimonious; that is, it should identify a minimal set of characteristic parts or landmarks in the modeled system, which can be generally recognized and seem to encompass, or be able to explain, most if not all available structural data. A good model also may delimit various 'unfilled' conceptual domains, where new data should fit in (as the periodic table of chemical elements did when it was first formulated). Such predictive aspects of models are highly useful because they implicitly indicate which new questions might be meaningful or how best to pose and answer them in practice. Simultaneously, models are instrumental in providing possible significance to any new, unexpected observation. Scientists in principle believe in and use a particular model as long as it seems to accommodate established knowledge, inspire significant research, and allow satisfactory incorporation of emerging sets of new data. Historical periods in which technological improvements produce radically novel sorts of data are particularly critical for the survival of a model.

Models widely shared among a scientific community represent a scientific paradigm. In contrast to hypotheses and theories, paradigms are not meant to be tested, since one must believe in one of them and use it as if it represented the truth, in the very process of testing a hypothesis experimentally. A paradigm comes dangerously close to becoming a dogma, a belief that wholly escapes criticism or doubt and is considered ascientific. Several models may coexist historically, sometimes because each one is perceived to have different advantages, but usually due to lack of awareness that one of them is distinctly better than the others, compounded with the human tendency to persist irrationally in long-held beliefs. Nevertheless, models and paradigms eventually may be perceived as

obsolete and be discarded by newer, less committed generations of scientists, particularly when they are manifestly unable to account for some data and efforts to apply them lead to highly unparsimonious, complicated lines of thought. Continued use of an obsolete model, or mixed-up joint use of elements of different models, tends to obstruct the progress of science.

Some neuroscientists wrongly think that they do not use a neural model. This means they simply are unaware of the model they are using. Frequently, some aspects they mistakenly regard as facts actually are conjectures. Dogmatic conscious or unconscious belief in models is a condition that is prone to poor thinking and poor science. Due to the great complexity of the studied organ, brain science is a field where such interpretive malfunctioning is not uncommon.

Neuromeric Models

The earliest morphological models of the brain were based on the adult form of the human and animal brains. This approach provided over time a rich set of neuroanatomical terms and conjectural meanings, many of which are now obsolete, although some old terms and concepts still persist in textbooks. During the late nineteenth century, and as a result of various important advances such as microscopy, evolutionary theory, and cell theory, comparative anatomical and embryological knowledge of brains advanced enough to allow the initial formulation of developmental brain models generally valid for all vertebrates. Developmental models also appeared for the entire body. The first generally accepted developmental structural paradigm for brains was a segmental model of the neural tube, which appeared hand in hand with a segmental model of the body and head of vertebrates. The axial skeleton was conceived as being segmented into metameric vertebrae (with a number of units fused together in the sacrum and in the cranial basis). The branchial apparatus also seemed segmented into serial branchial arches and slits. The brain and the set of spinal and cranial nerves were postulated to consist of a number of segmental units correlated one to one with the vertebrae and/or branchial arches.

The term 'neuromere' that was soon applied to these transverse neural units was coined by the American scientist Orr, who very ably characterized histologically in lizard embryos the relevant hindbrain, midbrain, and forebrain neuromeric units. He also provided a clear-headed morphological analysis of longitudinal zonation and axial bending of the brain, largely consistent with the present-day prosomeric model (Figure 1). Orr's study is the historic root of the prosomeric model, though previous and subsequent writings by von Kupffer, Hill, His, Neal, Palmgren, Rendahl, Tello, and Vaage, among others, contain less explicit antecedents. A large-scale review of shared neuromeric structural data collected for all vertebrate lineages from agnatha to mammals was published by von Kupffer at the turn of the twentieth century.

Wilhelm His produced an alternative very influential neural model, though he certainly must have known the neuromeric views of von Kupffer and other contemporaries well. His defined the floor, basal, alar, and roof plates, the alar-basal boundary (sulcus limitans of His), the concept of isthmus, and the idea of neural tube morphogenetic deformation due to axial bending. This model was very influential because it underpinned the first Nomina Anatomica in 1895, whose committee was presided over by His. The model was not explicitly neuromeric, though His' concepts of axial bending and longitudinal zonation and most of his transverse boundaries, including those of the isthmus, clearly were consistent with neuromeric models (Figure 2).

Columnar Models

At the height of the prestige of neuromeric brain models, an important unrelated breakthrough resulted from the analysis of functional components in the cranial and spinal nerves. It was discovered that each nerve component (motor or sensory fibers) either originates from or projects on a distinct columnar domain of the hindbrain or spinal cord. Separate columns could be assigned to visceral and somatic nerve components. Afferent fibers usually bifurcate into ascending and descending branches that distribute widely within the corresponding column. In so doing, they do not respect the neuromeric boundaries. These data were widely perceived as important, and they threw doubt on the neuromeric models, at least for application to advanced embryos and adults, since the basic functional organization of the hindbrain and spinal cord seemed to be columnar and not segmental, irrespective of the separate, more or less periodic nerve roots, and the peripheral dermatomes and myotomes. It was increasingly thought that maybe neuromeres were transient early embryonic phenomena without impact in the mature brain, in which a columnar arrangement of functions emerges. While Europe immersed itself in World Wars I and II, a new school of US neuroanatomists bloomed, led by JB Johnston and CJ Herrick, and its members proceeded to explore these new columnar ideas. Already in 1910, Herrick postulated columnar subdivisions in the diencephalon, which he initially thought might be continuous caudally with brain stem columns and extend rostrally into telencephalic ones. This work

Figure 1 Schema of the prosomeric model of Puelles and Rubenstein (2003). The forebrain lies to the left. Note axial bending at cephalic flexure. The longitudinal alarbasal boundary is present throughout the lateral wall of the neural tube, symbolizing all longitudinal components (floor and roof plates not represented); a singularity known as zona limitans (zl) is a transversal spike-like deviation of the general alar-basal boundary. The secondary prosencephalon (Sec.Pros.) is the rostralmost and most complex unit, consisting of telencephalon (Tel), eye and hypothalamus (HT: divided in two parts). Septum (Se), striatum (St), pallidum (Pal), preoptic area (POA), and amygdala (Am) regions are identified within the telencephalon; the pallium lies under the label Tel. Tuberal (Tub) and mammillary (Mam) subregions of the hypothalamus are marked. The caudal forebrain or diencephalon consists of three prosomeres (p1–p3), whose alar regions include the pretectum (PT), the thalamus and habenula (Th–Hab), and the prethalamus and prethalamic eminence (PTh, PThE); a specific tegmental domain corresponds to each of them (under p1–p3 labels). A simplified view of the large mesencephalic alar plate (Mes) divides it into superior colliculus or tectum (Tect) and inferior colliculus or torus semicircularis (TS); 'colliculi' are mammalian terms. The hindbrain or rhombencephalon (Rh) contains 12 neuromeric units, from the isthmus (Ist) and ehombomere 1 (rl) down to rhombomere 11 (r11), which limits with the spinal cord (SC). Note the cerebellum (Cb) forms mainly across isthmus and r1.

originated the prevalent present-day dogma of the structural division of the diencephalon into epithalamus, dorsal thalamus, ventral thalamus, and hypothalamus, considered to be longitudinal columns of the forebrain. This emphasis was accompanied by negation of the cephalic flexure (or simply, not attaching morphological meaning to it).

Soon afterward it was recognized that the postulated diencephalic columns are not continuous with the brain stem and telencephalic ones. As a consequence, each of these sets had to be conceived of as forming independent partial models of the respective brain parts. This left in between three vaguely defined, unmodeled, and badly understood transition areas: isthmus, pretectum, and telencephalic stalk. Efforts to extrapolate to diencephalon and telencephalon the columnar 'functions' of the brain stem and spinal cord (i.e., visceral-somatic sensory and motor functional correlations) were also unproductive. Paradoxically, though the promise of the columnar model stumbled on the forebrain, this did not lead to any doubts about its potency as a paradigm or usefulness as a forebrain model, because by that time it had become a neuroanatomical dogma. For a long time, dogmatic transmission of the columnar Herrick model in research and classroom pushed the alternative neuromeric models nearly to oblivion. Most neuroscientists to this day have been made to believe that the supposedly dorsoventral columnar series of epithalamus–dorsal thalamus–ventral thalamus–hypothalamus is a fact, not a risky conjecture of a hundred years ago.

The fundamental failure of the columnar forebrain model was that it redefined the observable forebrain axis, negating its observable curvature and substituting an arbitrary ideal straight axis which is not supported by any specific data. The columnar straight brain axis crosses from the pontine brain stem into the the 'caudal' hypothalamus, then traverses the hypothalamus and preoptic area 'longitudinally,' to enter the telencephalon and end in the olfactory bulb (this last part is obviously inconsistent with the paired paramedian nature of the olfactory bulbs and telencephalic hemispheres). Herrick curtly explained such pragmatic axial redefinition as "controversial . . . but convenient."

Figure 2 Model of W His (1895). Six transversal units (I–VI) are recognized along the bent neural tube. The alar-basal boundary appears through the entire lateral wall, parallel to the floor and roof plates. Domains I and II correspond to the myelencephalon and metencephalon, respectively. Domain III is the isthmus. Domain IV is the midbrain, and domain V is the 'diencephalon proper.' Domain VI contains part of hypothalamus, the eye, and the telencephalon. Basal plate domains are identified as I (II–VII) and alar plate domains are marked as 2 (I2–VI2). An additional domain VI3 represents the olfactory bulb, and the V3 and V4 domains refer to the metathalamus and habenula, respectively.

In the subsequent era of spectacular experimental neuroanatomical advances (axonal degeneration, axonal transport, electron microscopy, chemical anatomy), which extended up to the recent 1980s, Herrick's columnar model seemed to encompass without problems the accumulating hodological and chemoarchitectonic data on the forebrain. Stereotaxic topographic references for lesions and tracer injections worked well with the idea of a straight axis of the entire brain, which could be naively thought to be reproduced by the length axis of the stereotaxic apparatus. Only isolated embryologists (and then only those who looked at whole mounts and sagittal sections, procedures that curiously fell into disuse) insisted now and then that the brain axis is always curved and therefore topologic transversal and longitudinal dimensions had to be defined in accordance with the specific part of the neural tube considered.

The Rebirth of Neuromeric Models

A fully new set of neuroanatomical developmental data started to accrue during the 1980s and 1990s. These data included observations on the expression domains of neural developmental genes, possible thanks to the new *in situ* hybridization protocol for transcribed messenger RNA (and other correlative molecular biology and genomic advances). This procedure renders visible the cells that are in the process of reading out piecewise the information coded in the genome. Since many of these genes are causally determinant of the structural and histogenetic patterning of the neural tube wall, their expression patterns and the boundaries defined by them are highly relevant for brain models. It was soon discovered that some genes show longitudinal patterns of expression and others show transversal patterns (actually, both aspects usually appear in combination). All efforts to encompass these patterns within the forebrain columnar model have failed or have led to unparsimonious and highly convoluted *ad hoc* interpretations. On the other hand, the hindbrain and spinal cord columnar model does agree significantly with longitudinal gene patterns but highlights at the same time that observed transversal patterns relate specifically to the old neuromeric models. It turns out that neuromeric and columnar patterns coexist in the hindbrain and spinal cord, as predicted long ago by defenders of the segmental approach.

Similar analysis of forebrain gene expression data in the context of a forebrain neuromeric model (using the original bent axis) showed the capacity of this model to encompass and give morphologic significance (developmental function) to the new set of molecular causal data. The apparent rebirth of a neuromeric paradigm in the forebrain and hindbrain (where neuromeres are best visible) pointed the way to the possibility of conceiving a general segmental model of the entire central nervous system, in which longitudinal zones (columns, but different ones in the forebrain than those postulated by Herrick and his followers) and transverse neuromeres combine to interpret and predict the nature of causal phenomena operating in the construction of the brain. This sort of ultimate or synthetic brain model was called the prosomeric model, as developed in several reports and reviews by Puelles and Rubenstein.

Forebrain: Early Development

F Cavodeassi, M Kapsimali, S W Wilson, and R M Young, University College London, London, UK

Key Features of Early Forebrain Development

The forebrain is specified within the anterior neural plate during gastrulation, and by the end of somitogenesis, this territory has established ventrally the hypothalamus and floor plate and dorsally the telencephalon, eye, and diencephalon, which itself is further subdivided in prethalamus, zona limitans intrathalamica (ZLI), thalamus, and pretectum (Figure 1). All forebrain structures arise from a simple sheet of neuroepithelial cells, which undergoes regionalization and dramatic morphogenesis during early developmental stages. The morphology and function of various forebrain structures may be different among vertebrates, but the general organization and early patterning steps are likely conserved.

The initial formation of the forebrain is linked to the specification of neural identity in the embryonic ectoderm. Neural character is induced by gastrula stages through a combination of fibroblast growth factor (FGF) activity and extracellular antagonists of bone morphogenetic proteins (BMPs). The induced neural plate initially has anterior character, as evidenced by expression of genes that later become restricted to prospective forebrain and midbrain regions. Subsequently, the activity of various signaling molecules (including FGFs, Wnts, and retinoic acid) emanating from posterior regions of the embryo leads to caudalization of the neural tissue. These two events, neural induction and caudalization, eventually result in the generation of a nascent central nervous system (CNS) with graded anteroposterior (AP) character.

To acquire and maintain anterior character, the rostral neural plate must avoid exposure to caudalizing factors. Several mechanisms ensure this happens. These vary between species, but there are some common themes. For instance, gastrulation movements shift the anterior neural plate away from the sources of caudalizing signals. In addition, locally secreted signals from a variety of rostral tissues antagonize the activity of the caudalizing factors, protecting the anterior neural plate and ensuring it retains anterior character.

The Wnt/β-catenin pathway is perhaps the most crucial of the signaling cascades critical for early regional AP patterning of the rostral neural plate. Embryos carrying mutations that lead to enhanced Wnt activity in the anterior neural plate lack the telencephalon, rostral hypothalamus, eyes, and prethalamic territories. Thus, specification of the rostral forebrain requires low levels of Wnt/β-catenin activity. Conversely, local suppression of Wnt signaling can lead to the expansion of the rostral at the expense of more caudal forebrain domains.

The gradual regionalization of the neural plate as a consequence of the activity of Wnts and other signals leads to the subdivision of the anterior neural plate (or prospective forebrain) into discrete territories defined by the restricted expression of various transcription factors of the Emx, Irx, Pax, Six, and other families. Some of these transcription factors are likely to be direct effectors of the signals that regionalize the neural plate. For instance, Six family genes are repressed by Wnt signals and consequently expressed only in rostral regions. In turn, Six family proteins suppress Wnt activity, thus establishing a feedback loop that ensures tightly regulated levels of Wnt activity in the prospective forebrain.

One consequence of the initial regionalization of the neural plate is the establishment of groups of cells that function as local signaling centers, orchestrating subsequent neural development at different positions of the neuroepithelium (also called secondary organizers). These organizers influence cellular fate and growth of the adjacent tissues, further refining the initial pattern of the neural plate.

Along the rostrocaudal axis of the forming rostral CNS, cell populations with organizer properties are found at the anterior neural border or anterior neural ridge (ANB or ANR), at the ZLI, and at the midbrain–hindbrain boundary (MHB). The ANB/ANR is a source of signals including Wnt antagonists and FGFs that promote telencephalic fate; the ZLI is established later than the ANB/ANR and the MHB and is a source of sonic hedgehog (Shh) which influences the patterning and growth of surrounding prethalamic and thalamic structures; and the MHB is a source of FGF and Wnt signals that pattern the midbrain and rostral hindbrain and contribute to defining the caudal boundary of the forebrain.

Along the dorsoventral axis, the most prominent cells with signaling properties are ventral midline cells of the floor plate and hypothalamus. These cells produce Hh, Nodal, and other signals and are important for regionalization and neuronal patterning of the ventral forebrain and for splitting of the initially coherent eye field into left and right eyes. Cells along the dorsal midline of the forebrain, including the derivatives of the ANB/ANR and more caudal roof plate tissue, are also the source of various secreted signals, including FGFs, Wnts, and BMPs. The roles for such signals are

Figure 1 (a) Organization of the forebrain territories at neural plate stage. The groups of cells giving rise to each territory are shown in different colors. (b–d) The same color code is used to show the relative positions of the different territories in embryonic brains at a later stage of development, from lateral (b), dorsal (c), and ventral (d) views. ZLI, zona limitans intrathalamica.

perhaps best understood with respect to the regionalization of the mammalian dorsal telencephalon.

The morphogenesis that occurs during transition from the simple sheet of cells that constitutes the anterior neural plate to the complex structures of the mature forebrain and eyes (see Figure 1) is the least understood aspect of early forebrain development. This area is likely to see considerable research activity in the next few years.

Specification and Early Development of Various Forebrain Domains

Hypothalamus

The hypothalamus is the master regulator of neuroendocrine functions in the brain. It is a derivative of the most ventral/rostral regions of the prospective forebrain, and medial (ventral) regions of the hypothalamus are in continuity with floor plate tissue that runs the entire length of the ventral CNS.

During gastrula stages, prospective midline neural plate cells that will form floor plate and hypothalamus are located near the organizer from which they will extend rostrally and caudally along the CNS as convergence and extension movements shape the AP axis of the embryo. Initially, all prospective neural midline may be specified with floor plate character. However, as rostral midline neural tissue progressively extends within the rostral neural plate, it escapes the caudalizing influence of signals from caudal mesendodermal and neural tissues and begins to acquire rostral, hypothalamic identity. Thus by the end of gastrulation, ventral midline tissue of the neural plate is overtly divided into rostral, hypothalamic, and more caudal floor plate domains (Figure 1). The prospective hypothalamic domain is subsequently further subdivided along the AP axis and differentiates as specific territories with different identities and different signaling properties.

The Nodal and Hedgehog (Hh) signaling pathways are implicated in the induction of both hypothalamus and floor plate although their relative contributions to this process vary between classes of vertebrates. In fish, Nodal signaling is essential for induction of medial regions of the floor plate and caudomedial regions of the hypothalamus. Hh signaling is not essential for formation of these domains but is critical for the induction and patterning of ventral tissues adjacent to the most medial floor plate and lateral and rostral to the caudal hypothalamus. Similar distinctions between medial and lateral floor plate and hypothalamic domains probably exist in all other vertebrate classes, but at least in mammals, the Hh pathway plays a more prominent role in the formation of all midline structures.

As with more dorsal regions of the CNS, the level of Wnt/β-catenin signaling influences the rostrocaudal character of the ventral midline and adjacent tissue. Hypothalamic fate specification requires low

levels of Wnt/β-catenin activity, and if Wnt signaling is enhanced, cells with more caudal floor plate character extend further rostrally into the territory normally occupied by hypothalamus. Within the hypothalamus itself, raised Wnt signaling can promote caudal at the expense of rostral hypothalamic identity, suggesting that a low level of Wnt signaling may cooperate with Nodal signals to confer posterior hypothalamic identity. In addition to Nodals and Wnts, BMP and Hh signals are also important in conferring regional hypothalamic character to neurons generated in this portion of the ventral forebrain. For instance, Shh together with BMP7 is sufficient to confer hypothalamic dopaminergic identity to neural progenitor cells *in vitro*.

The various signals that influence hypothalamic development are thought to induce transcription factors that further refine signaling activity and confer regional character and specific neuronal fates on ventral CNS cells. For instance, *six3* expression is suppressed by Wnt signaling and in turn represses Wnt activity whereas, conversely, *irx3* expression is induced by Wnt signaling and itself promotes Wnt signaling. Mutual repressive interactions between Six and Irx family homeodomain proteins therefore contribute to the division of rostral neural tissue into rostral *six3*-expressing and caudal *irx3*-expressing domains. Several of the transcription factors that function downstream of these early regional patterning events to promote the generation of hypothalamic neurons have been characterized and include homeodomain proteins of the Nk2 family and neurogenin subfamily of basic helix–loop–helix proteins.

Telencephalon

The adult telencephalon is the most structurally diverse region of the vertebrate forebrain, but at early stages of development, patterning mechanisms are likely to be conserved across all vertebrates. At these early stages, the telencephalon has two major subdivisions: a dorsal pallial region that gives rise to the neocortex in mammals and analogous structures in other vertebrate classes and a ventral, or subpallial, region that gives rise to basal ganglia or striatopallidal structures.

At the neurula stage, the prospective telencephalon constitutes a band of cells located in the most anterior neural plate, rostral and lateral to the eye field (Figure 1). For the telencephalon to form, Wnt/β-catenin signaling must be suppressed, and several genetic mutations in fish which lead to enhanced Wnt activity in the anterior neural plate lead to transformation of the telencephalon (and eyes) to more caudal forebrain fates. Wnt signaling is suppressed by a variety of antagonists secreted from cells within the prospective telencephalon itself and from adjacent tissues, including underlying mesendoderm. For instance, in fish, cells located in the ANB/ANR express a Wnt antagonist of the secreted frizzled-related protein family, which when overexpressed expands telencephalic territories. Secreted frizzled-related proteins are believed to function by binding Wnt proteins and thus preventing Wnt ligands from interacting with their receptors. Although high levels of Wnt activity at early stages of development can suppress all telencephalic development, graded levels of Wnt activity can also influence regional patterning within the nascent telencephalon, promoting dorsal, pallial fates and suppressing ventral, subpallial identity.

In addition to Wnt antagonists, the ANB/ANR expresses FGF family members, and these signaling proteins play a variety of crucial roles in telencephalic development. It is unclear whether FGF signaling is required for induction of the telencephalon, but subsequent to induction, FGFs regulate regional patterning. Together with Shh, FGF signaling is required for induction of ventral, subpallial telencephalic character. Studies in mouse have revealed that within the dorsal, pallial telencephalon, FGF signaling is a critical regulator of arealization of the cortex. This polarization is mediated by transcription factors that appear to have graded activity across the pallium. For instance, antagonistic interplay between Pax6 and Emx2 influences the caudomedial and rostrolateral character of pallial territories. Thus, Emx2 mutant mice display expanded rostrolateral pallial character at the expense of caudomedial territories, whereas Pax6 mutants display the opposite phenotype.

Eye

The neural retina, pigment epithelium, and optic stalk or nerve are all derivatives of the anterior CNS. Within the neural plate, precursors for these eye structures initially form a coherent field of cells, termed the eye field, which spans the midline. Morphogenetic movements in combination with signals derived from midline tissues subsequently result in cells from the eye field moving laterally and evaginating to form the left and right optic vesicles. Distal cells within the vesicles form the neural and pigmented retina while more proximal and medial cells contribute to the optic stalks or nerves.

During gastrulation, the eye field is defined by the combinatorial expression of various transcription factors including Pax6, Six3, and Rx. Mutations in these genes result in eye malformations in all organisms analyzed, from humans to mice and fish. All these genes, generically known as eye specification genes, are part of a complex cross-regulatory network essential for eye development, and their functions during this process are highly conserved throughout the animal kingdom. It is unclear how the expression of these genes is first

induced, but expression is at least modulated by the same signals that regionalize other domains of the anterior neural plate. Thus, for example, Pax6, Rx3, and Six3 are restricted to anterior regions of the zebra fish neural plate by the activity of the canonical Wnt/β-catenin pathway, and excess Wnt activity can suppress both their expression and subsequent eye formation. The eye field is therefore induced in anterior regions of the prospective forebrain, where high levels of Wnt/β-catenin activity are absent. At least in fish, the eye field is further protected from canonical Wnt signaling by the activation, within the prospective eye field, of a noncanonical Wnt pathway that antagonizes canonical Wnt signaling, thereby promoting the expression of *rx3* and *six3* in this domain.

Both telencephalon and eye field are induced in regions of low or absent Wnt signaling. Although the mechanisms that distinguish prospective telencephalon from eye field are unclear, it is likely that graded BMP signaling is involved in the segregation of these two territories. At least in fish, high levels of BMP signaling encroaching from the margins of the neural plate suppress expression of eye field genes, limiting the lateral extent of eye field specification. Thus, the activation of the eye specification genes is promoted in the region sandwiched between prospective telencephalic and dorsal diencephalic domains that receive high levels of BMP signaling and more caudal diencephalic domains that receive high levels of Wnt signaling. The Rx3 transcription factor is likely to be an effector of the fate choice between telencephalon and eye (in addition to a role in eye morphogenesis), as telencephalic markers are ectopically expressed in the eye field of zebra fish rx3 mutants. It is unclear whether the eye specification genes are under the direct transcriptional control of these signaling pathways; to date, only *six3* has been shown to be transcriptionally regulated by the Wnt signaling pathway.

The eye primordium is specified as a single domain straddling the midline, but two optic vesicles, evaginating from the lateral walls of the neural tube, are established from this single domain. This is accomplished by morphogenetic processes that split the territory in two and lead to lateral evagination of the optic primordia. Do the eye specification genes instruct a specific program of morphogenesis for the eyes, or does this process depend on other, yet to be described, mechanisms? The answer is probably a combination of both. For example, *rx3* mutants in zebra fish and medaka show defects in the evagination of the optic vesicles, but early markers of eye field formation are initially expressed normally, suggesting that *rx3* regulates morphogenesis of the forming optic vesicles. However, the genes and proteins that are the direct effectors of the morphogenetic movements are currently unknown.

Nodal and Hh signals emanating from ventral midline tissues are also involved in the separation of the retinae. Disruption of either of these signals leads to phenotypes in which the retinae remain fused across the midline of the brain and the optic stalks are absent. In these conditions, the hypothalamus also fails to form, and it has been proposed that the absence of this structure, which normally would move anteriorly between the eyes, contributes to the failure of eye field separation. Other mutant conditions affecting the rostral movement of the hypothalamus, such as *silberblick/wnt11* mutant in zebra fish, similarly show varying degrees of cyclopia. Ongoing studies using advanced imaging and transgenic approaches are allowing much better documentation of the morphogenetic processes that accompany eye formation in normal development and in conditions that lead to cyclopia, and new insights into these processes will soon be forthcoming.

Diencephalon

According to the prosomeric model of forebrain organization, its most caudal part is subdivided into prethalamus (previously ventral thalamus), thalamus (previously dorsal thalamus), and pretectum, with the ZLI being located between prethalamus and thalamus (**Figure 1(b)**). Of all the major subdivisions of the forebrain, these domains are the most poorly understood in terms of their early development. For instance, it remains uncertain whether these three subdivisions are already specified at neural plate stages of development or whether they resolve at later stages. The ZLI is considered to be the boundary between prechordal and chordal domains of the brain, and one would expect this position to be defined very early, but as yet no sufficiently detailed fate maps exist to indicate where within the neural plate the cells that constitute the ZLI originate.

Despite this uncertainty, it is generally thought that the ZLI will form at a position defined on the neural plate by the boundary of expression between *six3* in the rostral forebrain and *irx3* in the posterior diencephalon–midbrain at neural plate stages. As discussed in the section titled 'Hypothalamus,' the expression of these genes is regulated by Wnt/β-catenin activity, which activates *irx3* and suppresses *six3*. This implies that a specific level of Wnt/β-catenin activity defines the position at which the ZLI forms and thus the relative size of prospective prethalamus and thalamus.

Later in development, when the embryo has gone through neurulation, the ZLI forms a compartment between the prethalamus and the thalamus. The ZLI expresses Shh and is therefore potentially a secondary organizer in the forebrain. In support of this, studies in mice, chick, and zebra fish suggest that Hh proteins secreted from the ZLI regulate regional patterning and growth of the prethalamus and the thalamus. It is likely that further roles will be found for the ZLI in the near future.

The boundary between the caudalmost forebrain and the midbrain corresponds to the interface between *pax6* expression in the forebrain and *pax2* and *engrailed* expression in the midbrain. Similar to the case with Six3 and Irx3, corepressive interactions between these genes are thought to define the position of the forebrain–midbrain boundary. Midbrain development is promoted by FGF8, and overexpression of *fgf8* is able to expand *en2*, inhibit *pax6* expression, and therefore shift the forebrain–midbrain boundary rostrally.

The dorsal part of the diencephalon is unusual in exhibiting marked asymmetries between left and right sides of the brain. These asymmetries are likely present in all vertebrates but are more prominent in some species than others. Studies in zebra fish are unraveling the mechanisms that establish this asymmetry and determine the directionality and laterality of the asymmetric nuclei.

Anatomy of the Primate Fovea

The 'fovea centralis' is a morphological specialization for high acuity which is found in the central retina of *Tarsius*, Old World monkeys, New World monkeys except *Aotes*, apes, and humans. The human fovea lies on the visual axis of the eye 4 mm temporal and 0.8 mm inferior to the center of the optic disc. Helmholz showed in the early twentieth century that the fovea is the site of maximal visual acuity. It has four anatomical characteristics which distinguish it from the surrounding retina and are modifications to support high acuity:

1. Retinal layers from the outer plexiform to the ganglion cell layer (GCL) are displaced laterally, forming a pit. *Fovea* is Latin for small pit, and it was identified as a characteristic of human retina by the late eighteenth century.
2. The foveal center or 'foveola' contains the highest density of cone photoreceptors in the retina. Cone photoreceptors function in bright light and support high acuity and color vision. Foveolar cone densities average 200 000 mm^{-2} in most primates compared to peripheral cone densities <20 000 mm^{-2}.
3. The most important foveal synaptic circuit is the 'private line' midget circuit which runs from cone to bipolar cell (BP) to GC. This preserves a faithful representation of the high-pixel foveal cone mosaic for transmission to central visual centers.
4. The fovea is free of blood vessels throughout life which has implications for foveal development. Each of these modifications is discussed in more detail below.

The fovea centralis is divided into four concentric circular zones which are shown for a *Macaca* monkey fovea at low magnification in Figure 1. The central retina overlapping the four foveal rings contains a concentration of yellow pigment, so this region is also called the macula lutea or 'yellow spot.' Details of retinal layers and their neurons in a 13-year-old human foveola, fovea, and parafovea are shown at higher magnification in Figure 2. A drawing of the primate fovea is shown in Figure 3 which contains a diagram of foveal cone synaptic circuits.

The 'foveola' is the central 250–300 μm, and represents the central 1°20′ of the visual field. It is slightly more than 100 μm thick and is formed only by cone outer and inner segments, a tightly packed 10–12 deep layer of cone cell bodies (Figures 2(a) and 2(c)), and surrounding Müller glial cell processes. All other layers are displaced peripherally by the pit. The foveola is the region of highest cone density so that foveolar cones are very thin and long and have the longest inner and outer segments in the retina (Figures 2 and 3). Rod photoreceptors are absent. The next ring is the 'fovea,' which extends 750 μm around the foveola. The fovea covers 5.5° of the central visual field. The foveal region contains the pit which is round, about 1000 μm at its widest, and 200–240 μm deep. The walls of the pit form the foveal slope which is characterized histologically by having a GCL which goes from no cells near the foveola to a GCL up to eight cells deep on the edge of the fovea. Cone density is lower than in the foveola, and cones are thicker. Rods are present at low density in the fovea (Figure 2(b), R). The outer plexiform layer appears in the fovea. It contains a thick layer of long cone axons called the fibers of Henle and the synaptic pedicles of the foveolar cones (Figure 2(b), P) which are displaced peripherally during foveal development. A foveal cone midget circuit is drawn in color in Figure 3. Capillaries appear in the inner retina and encircle the foveal slope, where they form a foveal avascular zone (FAZ) about 400–500 μm wide (Figure 3). The third ring is the 'parafovea,' which is ~500 μm wide, and the outermost ring is the 'perifovea,' which is ~1.5 mm wide and extends almost to the optic disc (Figure 1). These zones do not have sharp morphological boundaries. Rods are more numerous in the parafovea (Figure 2(c), R) and cones are thicker and less numerous. In the perifovea rods are the dominant photoreceptor and the GCL decreases to one to two cells thick near the optic disc.

Foveal Pit

Although numerous reasons have been put forth for having a foveal pit, its role in vision is not clear. Blood vessels encircle the foveal slope (Figure 3), forming an FAZ about 500 μm in diameter in humans and monkeys. Snodderly et al. show that vascular coverage or 'screening of light' of the photoreceptor layer by blood vessels is 0 in the FAZ, but then rises rapidly to 30% at 1 mm and 45% at 2 mm. One functional

Figure 1 Photomicrograph of a section through the central retina of an adult *Macaca* monkey. The layers and their abbreviations are used throughout all of the figures. CH, choroid; PE, pigment epithelium; OS, outer segment; IS, inner segment; ONL, outer nuclear or photoreceptor layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. The subdivisions of the foveal region are indicated.

Figure 2 Photomicrographs of a 2 µm plastic section through a 13-year-old human retina. The three retinal regions and their labels are aligned on the outer limiting membrane. In the foveola (a) cone (C), cell bodies form a tightly packed multilayer. These cones have very long and thin OS and IS. Cone pedicles are absent. In the fovea (b), inner retinal layers and the foveal slope or walls of the pit appear. Cone ISs become thicker and a few rods (R) appear under the cone cell bodies. The outer plexiform layer contains many fibers of Henle (FH) ending in cone pedicles (P). These are the pedicles of the foveolar cones which were displaced peripherally during pit formation (see Figure 3). In the parafovea (c), rods are the predominant type of photoreceptor while cones are reduced to a single layer. Inner retinal layers are at their full thickness, although the GCL will become thinner in more peripheral retina.

reason for the FAZ and foveal pit may be to provide an optically clear and stable path to the foveolar cones. A second function of the pit suggested by Springer and Hendrickson may be to facilitate cone packing during foveal development (see below).

Foveal Photoreceptor Distribution

Cones and rods can be identified by their size difference using Nomarski optics as shown in the top row of photographs in Figure 4, or by riboprobes or antisera that recognize cone versus rod opsins. Cone subtypes can be differentiated by antisera that recognize opsin protein in short wavelength-selective or blue cones versus long and medium wavelength-selective or red and green cones. To date, no riboprobes or antisera have been devised that can morphologically differentiate red versus green cone opsin. Cone-selective wavelength absorption combined with adaptive optics for the first time enabled Williams and Roorda to visualize the blue, red, and green cone ratios and mosaics in living human central retina.

Photoreceptor distribution in human retina is shown in Figure 4. The mean number of photoreceptors in a young adult human retina is 4.6 million cones and 92 million rods based on the Curcio et al.

Figure 3 A drawing modified from Polyak of a monkey foveola and fovea. The ticks on the lower bar indicate 100 μm. A midget circuit is drawn on the right side with the foveolar cone in magenta, the midget bipolar cell in cyan, and the midget ganglion cell in yellow. Arrowheads indicate synaptic contacts. On the left, the arrows indicate the centralmost blood vessels on the foveal slope which outline the pit and delineate the foveal avascular zone.

Figure 4 The distribution and density per square millimeter of primate photoreceptors. Cones are in blue and rods in red. The upper band of Nomarski images shows the change in size and ratio of human rods (red) and cones (blue) out to 16 mm from the foveal center. Upper scale bar is for these photographs. Adapted from Curcio CA, Sloan KA, Kalina RE, and Hendrickson AE (1990) Human photoreceptor topography. *Journal of Comparative Neurology* 292: 497–523 and Dennis Dacey.

sample. Using the same counting methods, Packer et al. find that the smaller *Macaca* monkey retina averages 3.1 million cones and 60 million rods. In both primates, rods are absent in the fovea, then their density rises sharply to a peak (Figure 4, red line) of $\sim 150\,000\,\mathrm{mm}^{-2}$ at the eccentricity of the optic disc, and from there rod density decreases slowly across peripheral retina. The rod:cone ratio is

20:1 across much of the human retina. Cone density (Figure 4, blue line) peaks sharply in the foveola and then drops rapidly into the periphery, with a 1:1 rod: cone ratio reaching 500 μm eccentricity. Cone density remains higher along the nasal horizontal meridian so that at the same eccentricity nasal retina has 2–3 times as many cones as temporal retina. The same pattern is found for GC in both human and monkey retinas. In Old World monkeys and humans, red and green cones are around 90% of the cone population with blue cones constituting 8–12%. In humans, blue cones are typically separated from one another by other cones forming a six-sided but random mosaic while some New World monkeys have two to four blue cones in a cluster. Adaptive optical imaging finds that central human red and green cones form little clusters with no regular overall pattern. A surprising finding from these studies is that, although most humans have a ratio averaging 2red:1green, individuals can range from 1red:8green to 9red:1green, yet have normal color vision. By contrast, *Macaca* and baboon Old World monkeys typically have a cone ratio of 1green:1red across the retina.

The fovea is the center of photoreceptor topography and has a circular arrangement in which photoreceptor types systematically drop out. Near the optic disc (Figure 4, 5 mm), cone density is low and rod density is at its peak. Central to this eccentricity, cone density rapidly rises and rod density drops until in the fovea (Figure 4, 1 mm), the density is 40 000 mm^{-2} for each population. In humans, the last significant number of rods is found at 300 μm (Figure 5, black dots) but in *Macaca* monkeys a few rods continue into the foveola. In humans, blue cones (Figure 5, blue dots) are absent in the central 100 μm of the foveola, where only red and green cones (Figure 5, red and green dots) are present. By contrast, in *Macaca* and marmoset monkeys, blue cones continue across the foveola at decreased density. Thus, the primate fovea has subtle differences between humans and monkeys for blue cone and rod distribution.

Foveal cone diameter changes dramatically over the central 5 mm, which is illustrated in Figures 2 and 4 (blue circles). Rods also increase in diameter across the periphery (Figure 4, red circles), although not as dramatically as cones. Foveolar cones are the longest and thinnest in the retina, as well as the most tightly packed. Foveolar and foveal cones have a very long axon or fiber of Henle which ends in a synaptic pedicle which is displaced peripherally (Figure 3, diagram). The overall total length of foveal cones is 500–700 μm. Adult foveal cones measured in plastic sections have outer segments 1.2 μm wide and 40–50 μm long while the slightly tapered inner segments are 3 μm at the outer limiting membrane and 2 μm at their tip and 30–35 μm long. Cone length decreases and cone diameter increases rapidly with increasing distance from the foveal center (Figure 4, top row). For instance, 400 μm outside the foveola center, inner segments are 6 μm wide and 24 μm long. This increase in size is correlated with a drop in cone density from 200 000 mm^{-2} at the foveola to 100 000 mm^{-2} just 150 μm away to 15 000 mm^{-2} at 1.5 mm (Figure 4). Despite the apparent high density, the actual number of cones is only 7000–10 000 in the foveola and 90 000 in the central 2 mm of human retina. Therefore, our highest visual acuity depends on the functional integrity of less than 100 000 cones out of 5 million, emphasizing how critical optimal health of the fovea is for good vision throughout life.

Figure 5 A schematic showing the arrangement of red, green, and blue cones and rods in the central human fovea. The innermost circle is 100 μm wide and depicts the foveolar center which has only red and green cones. The middle circle is 200 μm wide, and here blue cones are added to the red and green cones. Rods (small black dots) appear at 300 μm, and these four photoreceptor types will continue to the retinal edge with rods predominating over peripheral retina.

Foveal Synaptic Circuitry

Stefan Polyak, Brian Boycott, John Dowling, and Helga Kolb used Golgi impregnation for the light and electron microscopic analysis which first revealed the intricate synaptic relationships of primate foveal neurons. These studies concluded that there was a 'private line' synaptic circuit which was called the midget circuit because of the small dendritic trees, cell bodies, and axon terminals found in it. The midget circuit begins with one foveal cone synapsing

Figure 6 Drawing of the neurons involved in the midget circuit. (a) In the fovea, one red or green cone is presynaptic to two midget bipolar cells (BPm). The OFF is excited when the light goes down and the ON is excited when the light goes up. Each BPm receives only from this single cone. In turn, each BPm provides all excitatory input to a midget ganglion cell (GCm), so a pair of GCm signal all of the activity in the visual space covered by a single cone (line above cone). Because only a single cone drives this circuit, it also will transmit either red or green color information. (b) Outside the fovea, cones are thicker and more widely spaced. One red or green cone still is presynaptic to two BPm (only the ON is shown for clarity here); however, both BPm synapse on the same GCm. This means that the GCm receives visual input from the larger area covered by both cones (line above cones), and visual acuity is decreased. If by chance, both cones are red or green, color coding will be retained. If one cone is green and the other red, this will provide mixed input to the GCm and degrade color vision.

onto two midget bipolar cells (BPm) and is diagrammatically shown in magenta and cyan in Figure 3 and in Figure 6(a). Each BPm receives input only from that single cone. The ON BPm is stimulated when light increases and the OFF BPm when light decreases. In turn, each BPm provides all of the synaptic input to the dendritic tree of a midget ganglion cell (GCm; cyan to yellow (Figure 3); Figure 6(a)), so these GCm respond to the same ON or OFF stimulus. Thus, a single cone signals via two BPm to a pair of GCm which transmit centrally all ON and OFF information about the point in visual space covered by this cone (Figure 6(a), horizontal bar). Because cones are the initial receptor, and foveolar cones are packed at the highest density, high-pixel transmission requires a large number of GCm. About half of the 1.1 million GC in human retina are found within 4.5 mm of the foveal center. In turn, each of the GCm needs a set amount of visual cortex to process its information, reflected in that >40% of the primary visual cortex is devoted to processing information arising within the fovea.

Only red or green cones drive the midget circuit. However, it is not necessary to have both red and green color or trichromatic vision to have high acuity and a fovea. New World male marmoset monkeys have only a single red or green functional gene and are dichromatic, yet they have a normal fovea and acuity equal to female marmosets with two functional genes. The same is true of colorblind human males. This indicates that the fovea evolved for high acuity before the separation of New World and Old World primates 30–40 million years ago. Blue cones have a separate retinal circuit in which two to five blue cones synapse onto a single blue BP and several blue BPs synapse onto a blue GC, so even in the human fovea the blue cone circuit is not designed for high acuity. In trichromatic monkey and human retinas, it appears that red and green color processing 'piggybacks' on the midget circuit. Because each foveal cone contains only red or green opsin, this means that the GCm will carry color as well as high acuity information.

Outside of the fovea, GCm receive input from more than one BPm (Figure 6(b)), and this ratio increases into the periphery. This means that a single peripheral GCm is receiving from multiple cones, and therefore the visual space transmitted centrally by this peripheral GCm is the size of the area covered by all of the cones feeding into that GCm (Figure 6(b)). As you move away from the fovea, this causes visual acuity to decrease roughly proportional to the decrease in cone packing and the increase in bipolar:GC ratio. Color vision also declines into the periphery, presumably because of increased mixing of BPm inputs from red and green cones.

Foveal Development

Adult foveal dimensions, peak cone density, and relative position in the temporal retina remain constant across primates, despite an eightfold range of eye and retinal sizes from the tiny marmoset monkey eye to large ape and human eyes. This strongly suggests that the molecular factors and mechanical forces that create a fovea arose early in primate evolution and are localized to a small region. Given the large

amount of visual thalamus and cortex that already is required for processing foveal visual information, having larger foveas may not be possible without enlarging the brain beyond its cranial capacity.

Foveal development is shown in Figure 7 with colored diagrams of a midget circuit overlaid on actual photographs of fetal and neonatal *Macaca* monkey retina. At midgestation in monkey or human retina, the incipient foveal region lies ~3 mm temporal to the optic disc, but lacks many of its adult characteristics. This is a region >2 mm in diameter which has continuous retinal layers superficially like the adult parafovea (Figure 7(a)). A marked difference is that in the central 1.5 mm, the outer nuclear layer consists of a single layer of photoreceptors which are almost entirely cones (pure-cone region). As early as cones and rods can be identified morphologically or with immunomarkers, in humans only red and green cones are present in the center of the pure-cone region; this is the future foveola. Blue cones appear more peripheral and rods are not present until the edge of the pure-cone region. By contrast, in monkey retina, blue cones are found across the wide pure-cone region, but rods are excluded. Thus, in the fetal primate retina, the same three concentric circles of photoreceptor types found in the adult fovea are present, but each fetal circle is much wider. The molecule(s) determining this pattern are not known.

Foveal neurons undergo remarkable remodeling during development. A key point is that synapses form between cones, BP, and GC at an early stage in primate retina. In *Macaca* fovea, cones have quite mature ribbon synapses by Fd70 and BP/GC ribbon synapses at Fd60 which is more than a month before pit formation begins. In humans, synaptic markers are present by fetal week 11 which is 4–5 weeks before opsin is expressed and 3 months before pit formation begins. This early midget synaptic circuit is illustrated by the vertical column of connected neurons in Figure 7(a).

The first evidence of pit formation is seen around Fd100 in *Macaca* monkeys, Fd135 in New World

Figure 7 Sections of fetal monkey fovea at Fd 73 (a), Fd 160 (b), and 7 days after birth (c). The midget circuit is drawn on each photograph with the cone in magenta, BP in cyan, and GC in yellow. (a) At midgestation, the circuit is aligned vertically because all layers are present. (b) In later gestation, the pit forms by displacing the GCL first (arrow); note that the GCL is one cell thick over the pit center while the inner nuclear layer is only slightly thinned. As the GC are displaced, each BP has to elongate its axon to keep synaptic contact which is now more peripheral (arrowhead). A blood vessel is drawn in red to indicate the position of the foveal avascular zone. (c) As the pit becomes deeper around birth, cone cell bodies begin to pack into the foveal center (arrow). This requires the cone to elongate its axon to maintain the cone–BP synapse (upper arrowhead), which has been displaced onto the foveal slope during the later stages of pit formation. The adult midget circuit is shown in Figure 3.

marmoset monkeys, and fetal week 24–26 in humans (Figure 7(b)). Pit formation begins with a slight indentation of the GCL in the center of the pure-cone region, and then over time first the GCL and inner plexiform layer, and then the inner nuclear layer neurons, are displaced peripherally (Figure 7(b), arrow). Pit formation takes a considerable time; in humans, an adult-like pit is not present until 11–15 months postnatal, and in monkeys until 2–4 months postnatal. Because foveal neurons have formed synaptic contacts before pit formation, it is necessary to retain these contacts throughout the ensuing complex displacements. Morphological data suggest that in the early stages of pit formation, BPs elongate their axons to retain contact with GCs, and GCs elongate their dendritic stalks to retain contact with BPs as the GCs move peripherally. This produces the offset of inner retinal neurons shown diagrammatically in Figure 7(b) with the BP to GC synapse marked by an arrowhead.

Significantly, at the same age as pit formation begins, blood vessels and their accompanying astrocytes have vascularized central retina, but are excluded from entering the central 400–500 μm of the foveal GCL. This forms a fetal FAZ indicated by the red blood vessel in Figure 7(b). A two-step mechanical model for pit formation has been proposed by Springer and Hendrickson based on a combination of finite element modeling and quantitative morphology. This model requires interaction between the FAZ and two known mechanical factors within the eye, intraocular pressure and retinal stretch caused by eye growth. The first step is that intraocular pressure acts on the more elastic tissue within the FAZ and slowly indents it. This slowly pushes peripherally the neurons, synapses, and glia within the FAZ, first in the GCL, then in the inner plexiform layer, and finally in the inner nuclear layer. Intraocular pressure creates the narrow relatively deep pit seen in all primates around birth (Figures 7(b) and 7(c)). The second step occurs postnatally, and involves a small amount of stretch within the fovea due to postnatal eye growth. This stretch slowly remodels the fovea into the flatter, wider adult pit (Figures 1 and 3).

Well after pit formation is underway, cones and rods across central retina begin to pack centrally into the fovea (Figure 7(c), arrow). Cone packing is marked by (1) the pure-cone region slowly decreasing in diameter so that over time rods lie within 300 μm of the foveola; (2) foveal cones becoming much longer and thinner, enabling tighter packing of their inner segments and cell bodies; (3) a marked elongation of fibers of Henle on cone and central rods; and (4) a steady rise in foveal cone density. For instance, in humans, cone density rises from 19 000 mm^{-2} at birth to 41 000 mm^{-2} around 1 year to 113 000 mm^{-2} at 4 years, which is in the lower range of adults. Because no new cones are produced during this period, and the number of the cones in the pure-cone region does not change, this density increase is due to cone remodeling which allows packing of a pre-existing population into a smaller space. Elongated thin cones with long fibers of Henle appear as packing commences (Figure 7(c)). The fiber of Henle is formed because foveal cones must retain their synaptic connections with BP cells, and the timing of its appearance suggests that Henle fiber elongation is mainly due to foveolar, foveal, and parafoveal cone cell bodies slowly being displaced centrally. Additional elongation is stimulated by cone synaptic pedicles being displaced more peripherally to where the BP now reside (Figure 7(c), upper arrowhead). The mechanism of cone packing is debatable, but one factor may be the same retinal stretch which flattens the foveal pit. Finite element analysis modeling shows that stretching the pit creates centralward lift forces around the pit which could help pack cones. This is supported by the observation that temporally both the morphological changes in cones and increased cone density strongly correlate with pit flattening in both New and Old World monkeys.

Fragile X Associated Tremor Ataxia Syndrome

Introduction

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a newly discovered neurodegenerative disorder that typically affects men in their fifth or sixth decade. It is characterized by intention tremor, unstable gait, cognitive decline, neuropathy and psychiatric features, along with brain atrophy, white matter disease, and intranuclear inclusions (abnormal protein clusters) in neurons and astrocytes throughout the brain. FXTAS is caused by the premutation of the fragile X mental retardation (*FMR1*) gene and, along with fragile X syndrome (FXS) and premature ovarian failure (POF), is one of three separate disorders that are now associated with this gene. POF, a disorder characterized by the cessation of menses in women younger than 40 years of age, is also caused by a premutation of the *FMR1* gene. FXS is the window by which FXTAS and fragile X-related POF were discovered. FXS is a childhood-onset neurodevelopmental disorder caused by a full mutation of the *FMR1* gene. These disorders are all associated with a mutation on the *FMR1* gene, which is located on the bottom part of the X chromosome. The mutation is characterized by a CGG (trinucleotide repeat) expansion in the front part of the gene that is not translated into protein.

Normal CGG repeat size in the *FMR1* gene is between 5 and 44. The mutation falls into three categories: gray zone, premutation, and full mutation. Repeat size between 45 and 54 CGG repeats is known as the 'gray zone' or 'intermediate' size range. There are no known clinical associations with individuals that carry the gray zone allele; however, this CGG repeat size may be unstable when it passes to the next generation and this instability is difficult to predict based on repeat size alone. The premutation allele is defined as a repeat size of 55–200. The premutation allele is associated with POF and FXTAS, as well as various medical, neurological, psychological, and cognitive deficits including autistic spectrum disorders (ASD) and attention deficit hyperactivity disorders (ADHD). The full mutation allele, characterized as having a repeat number of greater than 200, is associated with FXS. FXS has a broad array of social, cognitive, physical, and psychological abnormalities that present in the affected individual with a wide degree of variability. In order to achieve a better understanding of FXTAS, a discussion of the associated disorder, FXS, as well as clinical implication of carrying the premutation allele, is necessary.

Fragile X Syndrome

FXS is the most common form of inherited mental retardation and one of the known causes of autism and autistic-like characteristics. The prevalence of the full mutation is 1 in 3600 in males and 1 in 6000 in females. It is thus named because in the event of a full mutation, the bottom part of the long arm of the X chromosome where the *FMR1* gene is located (Xq27.3) appears fragile as if it is falling off the chromosome. In the full mutation, the gene becomes methylated at the CpG island (the first part of the CGG repeat) causing transcriptional silencing of the gene and the fragile X mental retardation protein (FMRP) is not produced. FMRP is an RNA-binding protein that is thought to regulate translation at the dendrite in response to glutamatergic neural activation. FMRP is therefore a modulator of synaptic plasticity and dendritic morphology. The absence or deficiency of FMRP results in FXS.

From the first identification of FXS, developmental disabilities and mental impairment have been the hallmarks of the syndrome in both affected males and females. Males with the full mutation may exhibit distinctive physical characteristics such as large and/or protruding ears, high arched palate with rare cleft palate, prominent forehead, macrocephaly (where head circumference is larger than average), and mandibular prognathism (where the lower jaw is more protruded than the upper jaw) (**Figure 1**). Connective tissue abnormalities are common in FXS and include hyperflexible joints, soft velvety skin, flat feet, and mitral valve prolapse (a heart valve abnormality). Genital abnormalities consist of macroorchidism (abnormally enlarged testes). The cognitive effects of the full mutation include developmental delays, learning disabilities, and mental retardation ranging from mild to severe. Behavioral effects include ADHD, hand biting, anxiety, sensory integration disorders, and language delays. Autism occurs in approximately 30% of males and in approximately 10% of females with FXS.

Females with the full mutation typically have milder deficits due to the second X chromosome, which presumably makes FMRP. FMRP production results from only the normal X chromosome, and each cell randomly selects which *FMR1* gene to silence. Individuals with a greater proportion of silenced mutated genes

Figure 1 An adult male with FXS.

will have less of the characteristics of FXS and females with a greater percentage of their mutated *FMR1* alleles remaining active will exhibit more of the characteristics of FXS. Females with a full mutation and a greater proportion of silenced mutated genes will have a normal IQ, whereas females with an unfavorable activation ratio (below 0.5) will have learning disabilities or mental retardation because of an absence or deficiency of FMRP, similar to males with FXS. Typically, intellectual impairment is milder in females than affected males. It is more common for women to have normal IQs; however, most females with a normal IQ have learning disabilities, particularly math difficulties, or emotional problems such as depression, obsessive thinking, social anxiety, impulsivity, or poor eye contact. Approximately 30% of females with the full mutation exhibit the distinctive physical features of prominent ears and hyperextensible finger joints.

Premutation Carriers

The prevalence of the premutation in the general population is approximately 1 in 259 females and 1 in 813 males. Before the discovery of the *FMR1* gene, premutation carriers were thought to be unaffected. For several years after the discovery of the *FMR1* gene, the clinical involvement in the premutation carrier was unknown. POF was identified as a specific phenotype associated with the premutation after discussions at a 1987 FXS conference between families, patients, and clinicians about early menopause. Research studies have estimated that POF affects approximately 15–20% of female premutation carriers (compared to 1.7% of noncarriers). POF is not seen in females with the full mutation, suggesting that specific molecular abnormalities in the premutation are not present in the full mutation.

Within the past few years, there has been a significant change in understanding the clinical and molecular consequences of being a carrier of the premutation. Prior to this, behavioral and cognitive testing were not routinely done. Carriers, in fact, may have mild physical features of FXS, as well as cognitive and behavioral abnormalities including social deficits, attention problems, and ASD. When seen clinically for behavior problems, 73% of males with the premutation who were probands were diagnosed with either ASD or ADHD. Nonproband males with the premutation who were identified by cascade testing (routine testing among family members after a diagnosis is made) are still at a significantly greater risk for ASD (8%) or social deficits but not nearly as high as that for the probands. This rate is also higher than normal for brothers without the premutation. The premutation allele is also associated with an increased risk of obsessive–compulsive behavior, particularly in males, and with an increased prevalence of obsessive–compulsive behavior. The clinical involvement now apparent in carriers of the premutation has clear molecular underpinnings.

It was the discovery of elevated *FMR1* mRNA in males and females with the premutation that confirmed a unique molecular phenotype in carriers. POF and FXTAS, the disorders of premutation carriers, are not associated with FMRP deficit as in FXS but instead with an increased level of *FMR1* mRNA. Individuals with the full mutation do not have elevated levels of mRNA since the gene is silenced, and they do not develop POF or FXTAS later in life. It has been found that *FMR1* mRNA is increased two- to eightfold above normal when compared to that in controls or individuals with the normal *FMR1* gene in peripheral blood leukocytes (white blood cells) in premutation carriers. This is thought to result in mRNA toxicity, whereby proteins bind to the expanded CGG repeat in the mRNA and are sequestered into inclusions seen in the nuclei of neurons and astrocytes. It has been found that as repeat size increases, *FMR1* mRNA levels increase despite mildly decreased levels of FMRP.

Fragile X-Associated Tremor/Ataxia Syndrome

As discussed previously, FXTAS and FXS are mechanistically distinct syndromes. The connection between FXS and its associated disorder, FXTAS, was not

made until 2001. Mother's of children with FXS provided the missing link between FXS, a childhood neurodevelopmental syndrome of carriers of the full mutation, and FXTAS, an adult-onset disorder of carriers of the premutation. Often, mothers would express concern for their fathers, who were carriers of the premutation, whereas their children were being seen for FXS-related problems. They would report that their fathers were experiencing hand tremor, resulting in loss of daily living skills, as well as gait problems, often causing serious falls. These males were then seen clinically. It is now known that approximately one-third of male carriers will develop FXTAS, with varying degrees of symptom progression. Approximately 1 in 800 males carry the premutation in the general population, which means that approximately 1 in 3000 men run the risk of developing FXTAS.

FXTAS is occasionally seen in female carriers but less frequently than in the male carriers. Rare females have been documented to have the clinical and radiological features of FXTAS. The first five cases of FXTAS in females demonstrated clinical involvement similar to males with FXTAS, including intention tremor, ataxia, and peripheral neuropathy. However, none of these patients exhibited the cognitive decline seen in approximately 20% or more of males with FXTAS.

The diagnostic criteria for FXTAS include major and minor clinical and radiological findings, in addition to a CGG repeat in the range of 55–200. Based on the patient's findings, he or she may be diagnosed with 'definite,' 'probable,' or 'possible' FXTAS. Because FXTAS is a progressive neurodegenerative disease, six stages further describe how the patient's activities of daily living are impacted. Stage 1 is a stage of subtle or questionable tremor or ataxia, whereas the patient later relies on a cane or walker in stage 4, uses a wheelchair on a daily basis in stage 5, and finally becomes bedridden in stage 6. A description of the clinical, radiological, and pathological features of FXTAS follows.

Clinical Features

In the early stages of the disease, a patient may present with one clinical symptom (usually intention tremor in the dominant hand). Then, as the disease progresses, further clinical symptoms typical of FXTAS, plus a radiological sign, can determine a definitive diagnosis. Clinical symptoms, and major clinical diagnostic criteria, include gait ataxia (balance problems when walking), intention tremor (tremor when trying to do something as opposed to the resting tremor associated with Parkinson's disease), parkinsonism (symptoms associated with Parkinson's disease – that is masked facies, resting tremor, etc.), peripheral neuropathy (loss of vibration sense and reflexes particularly in the lower extremities), muscle weakness, and cognitive decline that usually begins with memory and executive function deficits. Patients may also have bowel/bladder incontinence, impotence, hypertension, and orthostatic hypotension. Patients with FXTAS have been misdiagnosed with several different disorders that touch on the clinical involvements (i.e., atypical Parkinson's, peripheral neuropathy, essential tremor, multiple system atrophy, and cerebellar ataxia). If a patient presents with symptoms resembling those of FXTAS, it would be helpful for the examining physician to ask targeted questions about children or grandchildren with mental retardation, autism, or behavioral/learning disorders; daughters or female relatives with infertility or POF; and family members with ataxia, neurological problems, and psychiatric problems.

Patients typically develop a frontal–subcortical dementia in addition to the motor problems of tremor and ataxia. Typically, patients with FXTAS will present with memory loss, executive function deficits, and some anxiety and/or depression. Executive function deficits include disinhibition and working memory difficulties, whereas verbal abilities are relatively well preserved. The most striking deficits are impairment in the initiation of purposeful activity and the disinhibition of inappropriate or irrelevant behavior. Investigation of the cognitive decline in FXTAS is newly described and warrants further study due to the considerable variability in its progression and nature.

Radiological Features

Males with the premutation have been found to have a decrease in total brain volume, including the cerebrum, cerebellum, and cerebral cortex, on magnetic resonance imaging (MRI). The total brain and cerebrum volume is significantly related to CGG repeat size; that is, the higher the CGG repeat number, the lower the brain volume.

There is white matter disease, shown by increased T2 signaling on MRI in males with FXTAS (Figure 2). There is also spongiosis (increased intercellular fluid in the brain) in the middle cerebellar peduncles (MCP) and an increase in ventricular size, resulting from brain atrophy. The MCP sign is composed of white matter tracts coursing from the pons to the cerebellum, and this area of the brain has demonstrated white matter disease in a characteristic way in approximately 60% of individuals with FXTAS. For this reason, the MCP sign is a major radiological diagnostic criterion.

Figure 2 An MRI image of the neurodegeneraton in FXTAS. Note the increased T2 signaling in the MCP (arrows).

Pathological Features

Purkinje cell loss is seen in the cerebellum of patients with FXTAS. Purkinje cells control the output from the cerebellum and are among the largest neurons in the brain.

In addition, the presence of ubiquitin-positive eosinophilic intranuclear inclusions is part of the characteristic neuropathology of FXTAS. The inclusions are found in the astrocytes (a subtype of glial cell) of cerebral white matter, cerebral cortex, cerebellum, and in large numbers in the hippocampus. Inclusions are also found in the autonomic neurons of the spinal chord, which may account for the autonomic dysfunction that often occurs. There is a significant correlation between CGG repeat number, number of inclusions in cortical gray matter, and CA1 pyramidal neurons (the major excitatory neurons of the cortex) in the hippocampus. There is also a correlation between inclusion-bearing astrocytes in cortical white matter and CGG repeat number. *FMR1* mRNA has been identified within the inclusions, supporting the RNA toxic gain-of-function mechanism. This is also supported by the tendency for symptom severity to increase as mRNA level increases. A variety of proteins are sequestered inside the inclusions, including myelin basic protein, lamin A/C, and HnRNPA2. The dysregulation of these proteins is likely the cause of neurodegeneration found in FXTAS.

The mRNA gain-of-function theory in FXTAS is based on the RNA gain-of-function model for myotonic dystrophy. Either expansion of the CUG repeat on the dystrophia myotonica-protein kinase (DMPK) mRNA or the expansion of the CCUG repeat on the *ZNF9* gene lead to inclusions with C(C)UG-binding proteins. Placing an expanded CTG repeat in transgenic mice leads to myotonia. 'Knockin' mice with a CGG repeat of approximately 100 placed in the *FMR1* gene develop ubiquitin-positive intranuclear inclusions in neurons that are similar to what is seen in FXTAS. These mice with the premutation also develop neurological disease with aging.

Conclusions

FXTAS is a newly identified neurodegenerative disorder. Patients present with tremor and ataxia, but neuropathy, autonomic dysfunction, psychiatric problems, and cognitive deficits are common. Because this is a new diagnosis that requires DNA study to document the premutation expansion of the *FMR1* gene, many individuals with FXTAS are misdiagnosed with another disorder. Given the prevalence of FMR1 premutations in the general population, screening of all individuals with tremor and/or ataxia older than 50 years with the FMR1 DNA test is recommended. A positive family history of POF or ovarian dysfunction, mental retardation, or autism will increase the likelihood of a positive test. When the premutation is identified, referral to a genetic counselor or geneticist is recommended for further workup of the family pedigree to identify family members with the premutation or full mutation or family members at risk of having children with FXS. Supportive treatment can also be provided with medications currently available to treat some of the symptoms associated with FXTAS.

FXTAS is one of the most common progressive disorders associated with a single gene defect. It is currently underdiagnosed because it has only recently been recognized. Research toward understanding FXTAS is of far-reaching utility in understanding other inclusion-associated neurodegenerative disorders.

Introduction

Fragile X syndrome (FXS) represents the most common form of inherited mental retardation, and is associated with a highly variable cognitive and behavioral phenotype as well as a characteristic profile of physical features. FXS is an X-linked disorder that affects approximately 1 in 4000 males and females. Previously termed Martin–Bell syndrome, this disorder was named fragile X syndrome because of an apparent fragile site observed at Xq27.3 on the long arm of the X chromosome when cells from affected individuals were cultured in folate-deficient media. It is now known that FXS is caused by a trinucleotide repeat expansion in the *FMR1* gene, which is located at and accounts for the fragile site. This mutation leads to hypermethylation of the promoter region and transcriptional silencing of the gene. Typically, no functional *FMR1* mRNA is produced, and the fragile X mental retardation protein (FMRP) is also absent. In the past decade, significant research advances have been made toward delineating the role of FMRP in normal brain function and the effects of its absence on neuroanatomy and physiology.

Symptoms of FXS

Individuals with FXS exhibit, to variable degree, a characteristic physical profile including a long, narrow face with large, protruding ears and macroorchidism (enlarged testes). Other physical features may include macrocephaly, hyperextensible joints, loose skin over the hands, a high arched palate, a vertical plantar crease, and flat feet.

The predominant and most disabling problem in FXS is mental retardation, with the average IQ in males around 40 and the average IQ in females with the full mutation around 80. IQ varies among individuals, however, ranging from severe functional impairment to normal intelligence, and appears to correlate positively with expression levels of FMRP. Nearly all males with intelligence in the borderline or normal range are genetic mosaics in which methylation of the *FMR1* gene is incomplete and FMRP is expressed, albeit at reduced levels. In females, the distribution is shifted toward higher levels of functioning, compared to males, and intellectual functioning has been correlated with X inactivation ratios (i.e., women and girls with higher percentages of cells with the normal X chromosome active tend to be higher functioning).

When compared with IQ-matched children with other forms of developmental delay (e.g., Down syndrome), children with FXS demonstrate a specific profile of cognitive strengths and weaknesses. Though the available data are not entirely consistent, many of these tests reveal relative strengths in receptive language skills, visual memory, acquisition of factual information, imitation skills, and gestalt processing. Relative weaknesses are often observed in expressive language skills as well as spatial and sequential processing, quantitative and mathematical skills, and executive function. Individuals with FXS often exhibit perseverative speech including imitation of expressions, swearing, or automatic verbalizations; these patterns can be exacerbated by social anxiety. These cognitive profiles are more easily observed in higher-functioning, more testable individuals.

Behavioral and social dysfunction in children with FXS tends to be more severe than would be expected based on cognitive levels. Approximately 90% of boys exhibit hyperactivity, and virtually all have attentional difficulties. Girls frequently have attention problems and may occasionally manifest hyperactivity. Males and females with FXS demonstrate mood lability, compulsive and perseverative behaviors, as well as stereotyped movements such as hand flapping and hand biting. Aggressive outbursts are observed in about 30% of boys with FXS and continue through young adulthood. Many of these behavioral problems appear to be related to an elevated level of anxiety, which also results in social shyness and poor eye contact. Studies of physiologic arousal suggest that sympathetic activity is increased, parasympathetic activity is decreased, and that these systems are poorly coordinated in FXS. Panic attacks are common in individuals with FXS and are often triggered by novelty (e.g., novel social situations), undesired or excessive sensory stimuli, or when the individual is placed 'on the spot' and made the center of attention. A related phenotype in FXS may be an exaggerated hormonal response to behavioral stress. Individuals with FXS also display hyperresponsivity to a variety of sensory stimuli, including auditory stimuli (expressed as an elevated startle response), olfactory stimuli (perceiving neutral scents as noxious), and somatosensory stimuli (expressed as tactile defensiveness).

Autistic symptoms are common in males with FXS (but relatively rare in females with FXS). These

symptoms include poor eye contact, difficulties with peer interactions, unusual nonverbal interactions, and stereotyped behaviors such as hand flapping. Indeed, approximately 30% of these individuals meet the diagnostic criteria for autism spectrum disorders, although they have a pattern of more severe deficit in communication and stereotyped behavioral domains than in reciprocal social interactions. Social anxiety as opposed to social disinterest seems to drive autistic behavioral patterns in FXS individuals. Males with FXS and autism tend to exhibit more severe developmental delays than do those without autism.

Beyond the cognitive and behavioral phenotype, individuals with FXS often exhibit a number of medical problems that may require monitoring and management. Perhaps the most problematic for families of children with FXS is seizures, which has been estimated to occur in 15–20% of male children with FXS and a smaller percentage of females. In most individuals, seizures are limited to childhood, although in up to 25% of cases, seizures can continue into adulthood. Other medical problems seen more often in FXS than in the general population include gastroesophageal reflux and failure to thrive in early infancy, hypotonia with subsequent poor coordination, recurrent otitis media and sinusitis, vision problems including strabismus and farsightedness, cardiac valve prolapse (especially the mitral valve), sleep disorders such as obstructive sleep apnea, orthopedic issues such as joint laxity, and dental malocclusions. Many of these problems have been described in boys with FXS and are thought to be due to mild dysfunction of connective tissue. Girls with FXS may also exhibit these medical problems, although their presence is much more variable.

Current Treatment Strategies for FXS

Currently available treatments for FXS are supportive and are aimed at management of specific symptoms rather than the underlying disorder. Medical problems outlined in the preceding section should be managed aggressively, with placement of myringotomy tubes for chronic ear infections, audiological monitoring, vision monitoring and use of glasses and strabismus surgery as appropriate, tonsilectomy/adenoidectomy for sleep apnea or recurrent infections, and prophylactic antibiotics for dental procedures and surgery if mitral valve prolapse is present. If seizures occur, these should be treated (after appearance of a second seizure episode) with anticonvulsants that do not aggravate behavioral and social dysfunction – carbamazepine, oxcarbazine, and valproic acid can give good control. Phenobarbital should be avoided because of the tendency to aggravate hyperactive and aggressive behavior. Phenytoin also has undesired side effects such as gingival hyperplasia, and should be avoided.

Medications for behavior may be quite helpful for symptomatic management of behavior problems in FXS. Stimulants (methylphenidate and amphetamine salt preparations) have been shown to be useful, both in clinic settings and in a small placebo-controlled trial, for as many as 70% of boys with FXS for management of distractibility and hyperactivity. Clonidine can be helpful for hyperactivity and hypersensitivity, especially in young boys. Selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, citalopram) are effective in managing anxiety and mood problems in FXS, and aggression, outbursts, irritable behavior, and severe oppositionality often respond well to atypical antipsychotics (such as risperidone and aripiprazole). Aripiprazole has a unique pharmacological profile in the central nervous system (CNS) which includes partial dopamine agonist activity and thus seems to be particularly useful in FXS because it targets multiple categories of behavior, including hyperactivity/distractibility as well as irritability/mood, with high clinical response rates. Good clinical success with aripiprazole in FXS has prompted a formal clinical trial, currently in progress.

Treatment of individuals with FXS also includes supportive strategies to assist with development of adaptive skills (early intervention, physical therapy, orthotics for foot positioning and gait training, occupational therapy, and speech therapy). Educational programming should be maximized with a curriculum and environment tailored to the cognitive profile in FXS. Psychological support and social skills training should be available for the individual with FXS. Family therapy can be helpful for coping and comprehensive genetic counseling is crucial for families of individuals with FXS.

Neuropathology in FXS

Although postmortem studies of gross brain morphology have not revealed striking abnormalities in FXS brain, neuroimaging methods have provided researchers excellent tools to investigate brain abnormalities associated with FXS. Structural magnetic resonance imaging (MRI) has revealed a reduction in the size of the posterior cerebellar vermis that may result in the observed enlargement of the fourth ventricle in FXS males. The volume of hippocampus and caudate nucleus appears to be increased in a cohort of males with FXS, and lateral ventricles appear to be slightly enlarged. More recently, diffusion tensor imaging has been used to identify white matter tract alterations in frontostriatal and parietal sensorimotor pathways.

The neuroanatomical phenotype of FXS has also been described on the microscopic level. Early studies of Golgi-stained tissue revealed an abundance of long, thin, tortuous spines (postsynaptic elements of excitatory synapses) along pyramidal cell dendrites in the cerebral cortex of postmortem tissue from adult FXS males. Later quantitative analyses of temporal and occipital cortex revealed that spine length and spine density were elevated in males with FXS compared with controls, and that the adults with FXS exhibited a profile of spine shapes (morphologies) comparable to the young or developing controls. Findings of abnormal spine morphology have been reported in other disorders associated with mental retardation and are not unique to FXS. Yet, the nature of the spine 'dysgenesis' observed in the cerebral cortex of patients with FXS is distinct from other disorders associated with mental retardation, in that adult FXS patients exhibit an elevation in spine density along with longer spines and a morphology profile that resembles an immature state. In the context of changes that typically occur during synaptic development (e.g., synapse overproduction and pruning during development), it has been hypothesized that the spine phenotype in FXS reflects a deficit of synaptic plasticity.

Molecular Genetics of FXS

In 1991, researchers discovered that the genetic basis for FXS is the expansion during early development of an unstable CGG repeat in the 5′ untranslated region of the *FMR1* gene, found at locus q27.3 on the X chromosome. Most repeat lengths of fewer than 45 triplets are stable and considered normal. A repeat length of between 55 and 200 triplets represents the FXS carrier state or 'premutation.' Expansion of this repeat beyond approximately 200 triplets occurs only when the gene is passed on through a female and leads to hypermethylation of the promoter region, and silencing transcription of *FMR1* mRNA, with resultant absence of FMRP and the development of FXS (see **Figure 1**).

Knowledge of the basis of repeat expansion in the transmission of fragile X remains incomplete. Borderline repeat lengths of 45–54 triplets may be stable or unstable, and if unstable, can be passed on to future generations as larger alleles. These alleles have been called 'gray zone' alleles; they are not known to cause disease and do not expand directly to a fragile X full mutation or result in FXS in a single generation. The smallest premutation allele known to expand directly to a full mutation in a single generation contains 59 repeats. Repeat sizes between 150 and 250 are often only partially methylated and result in varying levels of FMRP deficiency and milder FXS phenotypes. Unmethylated alleles in the upper premutation and full mutation length range are transcribed but result in reduced FMRP due to impaired translation in the presence of the long CGG repeat sequences. These mutations typically result in milder FXS phenotypes with symptoms such as attention-deficit/hyperactivity disorder (ADHD), anxiety, social dysfunction, and learning disability rather than overt mental retardation.

Most premutation carriers do not exhibit hypermethylation of the *FMR1* gene and make near normal amounts of FMRP and therefore do not exhibit FXS. The mechanism that underlies hypermethylation and promoter inactivation in alleles with repeats greater than 200 triplets in length remains unknown but is an area of active investigation with therapeutic implications. In males, variability in *FMR1* mRNA and FMRP levels may be due in part to mosaicism of repeat length and methylation (e.g., subsets of cells in the brain or elsewhere in the body with the premutation and other subsets with the full mutation) or to methylation mosaicism alone (as described previously). In females, variability is likely due to differential X chromosome inactivation. These sources of genetic variability reflect the complexity of FXS inheritance and contribute to the remarkably high variability in the phenotype of FXS.

FMRP is a 69 kDa protein found in most adult and fetal tissues (with other splice variants at slightly different molecular masses), but it is present in particularly high levels in the brain and testes. In neurons, FMRP is produced in the soma and also near synapses in response to specific neurotransmitter receptor activation. FMRP expression in oligodendrocytes (glial cells that give rise to myelin) appears to be highest early in development, and FMRP expression in astrocytes (glial cells that serve molecular needs of neurons and synapses) appears to be minimal. FMRP expression in the brain seems to be activity or experience dependent, as protein levels are increased in activated brain regions in response to behavioral demands such as exposure to complex environment or motor skill training, whisker stimulation, and light exposure in dark-reared animals.

Although the specific cellular functions of FMRP are unknown, its role as a putative mRNA-binding protein has been most thoroughly investigated. As shown in **Figure 1**, the protein sequence of FMRP contains several mRNA-binding motifs (two KH domains, an RGG box, and an amino terminus with a strong affinity for RNA), a nuclear localization signal (NLS), and a nuclear export signal (NES). FMRP has been shown to bind to multiple mRNAs and associates with actively translating ribosomes in

Figure 1 The gene *FMR1* is located at Xq27.3 on the long arm of the X chromosome. A CGG repeat sequence in the 5′ untranslated region (UTR) is normally less than 55 repeats in length. Transcribed from this gene is *FMR1* mRNA, which codes for FMRP. Expansion of this sequence to 55–200 repeats represents the unstable 'premutation' and levels of *FMR1* mRNA are elevated. Beyond 200 repeats, the sequence becomes hypermethylated, inactivating the promoter and silencing transcription. The resultant absence of FMRP characterizes the fragile X syndrome. FMRP contains nuclear localization and nuclear export sequences (NLS, NES) as well as several RNA-binding domains (KH1, KH2, RGG box). A missense mutation (I304N) in one of these domains (KH2) is associated with the full fragile X phenotype, indicating the importance of binding RNA in the function of FMRP. Figure created by Georgina Aldridge.

neurons, suggesting not only that FMRP assists in mRNA transport and processing, but also that it is involved in the translation of those mRNAs. Binding of mRNA is critical to FMRP function as evidenced by the identification of a point mutation (I304N) in one of the mRNA-binding motifs (KH2) that leads to loss of mRNA binding and a severe FXS phenotype in an individual with otherwise normal levels of FMRP. Several groups have published lists of the mRNAs bound by FMRP; some of these mRNAs exhibit a secondary structure that has a G-quartet motif shown to bind to the RGG box of FMRP, and others form a 'kissing complex' with FMRP's KH2 domain.

One common theory is that FMRP is involved in nucleocytoplasmic shuttling of a subset of mRNA, and that it helps regulate the synthesis of these messages into proteins that are important for synaptic plasticity and learning and memory (see Figure 2). It is likely that the phenotype of FXS reflects the mRNA cargoes of FMRP and proteins whose synthesis is regulated by FMRP. An aspect of this theory that is under active investigation is whether FMRP functions as an initiator or as a repressor of translation. Several groups have described FMRP as an inhibitor of protein synthesis and have shown that, in the absence of FMRP, baseline levels of protein synthesis are elevated in some brain regions and that the levels of several specific proteins are elevated in the brain. By contrast, FMRP also appears to be required for the initiation of synaptic protein synthesis following metabotropic glutamate receptor activation. Protein translation at synapses in response to neurotransmitter activation is diminished in mice lacking an intact FMR1 gene. These seemingly inconsistent findings may reflect a dual role for FMRP: in a 'resting state,' FMRP may help keep protein translation of its bound mRNAs at low baseline levels, whereas, when activated via cellular signaling pathways,

Figure 2 A putative role for fragile X mental retardation protein (FMRP) in neurons. FMRP binds to its target mRNAs in the nucleus (A) and helps export them to somatic cytoplasm. FMRP and its target mRNA are packaged into transport assemblies (B) and travel, likely via microtubules, down dendrites toward synapses. FMRP–mRNA transport assemblies may repress translation (C) by taking the form of nontranslating granules in the cytoplasm and near synapses, where they await some synaptic signal. Activation of group 1 metabotropic glutamate (Glu) receptors (D) triggers an enzyme cascade that, via many intermediates (broken arrow), signals nontranslating granules to release FMRP-bound target mRNA for translation (E). PKC, protein kinase C; DAG, diacyl glycerol; IP_3, inositol triphosphate; DHPG, (*S*)3,5-dihydroxyphenylglycine. Adapted from Weiler IJ, Spangler CC, Klintsova AY, et al. (2004) Fragile X mental retardation protein is necessary for neurotransmitter-activated protein translation at synapses. *Proceedings of the National Academy of Sciences of the United States of America* 101: 17504–17509, with permission.

FMRP may participate in the initiation of protein synthesis in response to synaptic activity. Very recent reports have suggested that FMRP is transported throughout neurons in granules, and that its dual role in protein synthesis regulation may involve shuttling between these nontranslating granules and actively translating polyribosomes. It therefore is reasonable to hypothesize that many among the broad spectrum of symptoms that stem from this single gene disorder may be associated with the subset of mRNAs whose transport and translation is regulated by FMRP. One putative FMRP cargo mRNA is the glucocorticoid receptor, which provides negative feedback based on the amount of glucocorticoid stress hormones in the circulation. It has been shown that fragile X patients have elevated glucocorticoid levels and protracted glucocorticoid responses to stress. Elevated glucocorticoids are associated with heightened anxiety, a behavioral characteristic of many FXS patients.

Fragile X Knockout Mice

In 1994 the Dutch-Belgian Fragile X Consortium developed a mouse model of FXS that has opened many new doors to investigators studying FXS and the function of FMRP. In this mouse model, the basis for FMRP's absence is not an expanded CGG repeat, but instead a neomycin cassette inserted into exon 5 of the murine *fmr1* gene. This insert disrupts transcription of *fmr1* mRNA and hence translation of functional FMRP. Macroorchidism has been observed consistently in these animals, but compared with the cognitive and behavioral deficits observed in patients with FXS, the behavioral phenotype in *fmr1* knockout mice is quite subtle and, by most accounts, these animals appear relatively normal.

Nevertheless, after over a decade of experimentation in these animals, a profile of behavioral phenotypes, many of which parallel FXS symptoms, is beginning to emerge. The first behavioral phenotype described in *fmr1* knockout mice was impairment on the reversal trial of a spatial memory task, the Morris water maze. This finding has been replicated by others, though animals consistently performed well on other aspects of this task. Impairments in radial maze learning and plus-shaped water maze learning have been reported, and *fmr1* knockout mice also exhibit deficits in object recognition memory, including a failure to habituate to objects. Another behavioral phenotype that has received much attention is behavior suggestive of anxiety, paralleling the social anxiety seen in human patients. In a passive avoidance task, for example, *fmr1* knockout mice demonstrate decreased latency (compared with wild-type mice) to enter the dark area where these animals had received a shock 24 h earlier. With regard to social interaction, *fmr1* knockout mice exhibited increased anxiety-like responses (in the mirrored chamber task), and diminished social dominance.

The behavioral phenotype in *fmr1* knockout mice that is described most consistently involves sensory hyperresponsiveness, particularly to auditory stimuli. Remarkably, a very similar set of symptoms has been reported in FXS patients. The *fmr1* knockout mice bred in various background strains exhibit greater startle responses than do wild-type mice. Similar findings have been reported in a prepulse tone inhibition paradigm: in knockout mice, the first tone elicited a greater inhibition of response to the second tone than in wild-type mice. Loud tones induce audiogenic seizures (leading often to respiratory arrest and death) in *fmr1* knockout mice with much higher frequency than in wild-type mice.

Throughout the investigation for a behavioral phenotype, results on some tasks have varied by laboratory and depending on which strain of mice was used. For example, several groups have measured activity of *fmr1* knockout mice in an open field and results have varied, with some groups reporting a higher proportion of line crosses in the periphery (suggestive of anxiety), and others reporting increased entry to center of the open field. The consistent finding in studies of knockout mouse behavior in the open field, however, has been locomotor hyperactivity. In conditioned fear paradigms, some authors suggest that knockout mice spend significantly less time freezing than do wild-type mice, whereas others have observed no differences. In other tasks, including a complex visual and auditory discrimination task, *fmr1* knockout mice appear to perform better than do wild-type animals. The fact that of some aspects of the *fmr1* knockout phenotype depend on mouse strain or genetic background may model the contribution of genetic background to the variability in expression of symptoms among individuals with FXS. It is particularly interesting in this regard that FMRP regulates the translation of the mRNA products of multiple genes.

Despite their relatively normal behavior, *fmr1* knockout mice exhibit a neuropathologic phenotype that is remarkably similar to that of FXS patients. In the visual and somatosensory cortex, the density of spines along dendrites of pyramidal neurons (an estimate of synapse number) is greater in adult *fmr1* knockout mice than in wild-type mice. Furthermore, knockout mice have, on average, longer dendritic spines in these brain regions than do wild types, as well as spines whose morphology might be considered more characteristic of developing than of mature spines. The manner in which this spine phenotype emerges in *fmr1* knockout mice (and correspondingly in FXS patients) is still an area of active investigation. In the neocortex, *fmr1* knockout mice may fail to undergo normal processes of developmental synapse elimination. Instead, some synapses that might normally mature or undergo 'synaptosis' appear to persist in an immature state into adulthood.

The hypothesis that FMRP is important for developmental pruning has been tested with regard to dendrites in the somatosensory cortex and olfactory bulb of *fmr1* knockout mice. During normal development, excess dendrites in both of these brain regions have been shown to be pruned in an experience-dependent process. Yet in adult *fmr1* knockout mice, many of these excess dendrites remained (compared with wild-type controls), suggesting a deficit in the pruning process. A growing body of evidence indicates that these deficits are part of more global state of brain disorganization which, in human FXS patients, also appears to involve subcortical brain regions, such as the lateral geniculate nucleus.

Further investigation of neural plasticity in *fmr1* knockout mice has revealed important deficits in these animals, particularly in the ability to exhibit long-term potentiation (LTP) and long-term depression (LTD). Although studies in several laboratories have examined LTP in the hippocampus, no consistent differences between wild-type and *fmr1* knockout mice in the extent of short- or long-term potentiation have been reported. By contrast, several groups have reported significant reductions in the magnitude of LTP in the neocortex of *fmr1* knockout mice. Furthermore, one form of LTD appears to be enhanced in *fmr1* knockout mice (metabotropic glutamate receptor- and protein synthesis-dependent LTD). These groups have suggested that FMRP normally limits LTD by suppressing the synthesis of proteins required for this form of synaptic plasticity, and that in the absence of FMRP, translation of these important proteins is increased, such that LTD is enhanced and that *de novo* protein synthesis may no longer be required for induction of LTD in *fmr1* knockout mice. From the finding of enhanced LTD in the absence of FMRP, the metabotropic glutamate receptor, or 'mGluR,' theory of FXS has emerged. This theory hypothesizes that FMRP normally inhibits aspects of postsynaptic signaling that follow stimulation of group 1 metabotropic glutamate receptors. Proponents of the mGluR theory further propose that many of the symptoms of FXS may stem from unbridled transduction of mGluR signals and that antagonism of mGluRs may attenuate some of these symptoms. Early tests using mGluR antagonists have shown some promise, rescuing to near wild-type-levels some behavioral phenotypes of *fmr1* knockout mice. The mRNAs of several proteins in mGluR-driven signaling pathways bind selectively to FMRP, and it is possible that the activity of these pathways is affected in FXS.

Two genes homologous to *FMR1* have been identified in vertebrates, *FXR1* (fragile X related gene 1) and *FXR2*. These genes have relatively high homology to *FMR1* at the protein structural level, bind mRNA, and bind to FMRP. The *FXR1* protein, FXR1P, appears to be expressed in the nucleus of fetal tissue and particularly in developing myocytes, whereas FXR2P is expressed in cell cytoplasm. In the brain, FXR1P and FXR2P are expressed primarily in cell bodies but also in dendrites at synapses. The two FMRP homologs are thought to exhibit different patterns of shuttling between nucleus and cytoplasm. It is thought, therefore, that the mRNA targets of these two proteins are distinct from one another. Both an *fxr1* and an *fxr2* knockout mouse have been produced. The FXR1P homozygous knockout dies within 24 h of birth, and a heterozygous version of this mouse exhibits abnormal limb musculature. The FXR2P knockout has a normal life span and exhibits a behavioral profile of learning deficits similar to that of *fmr1* knockout mice (though some differences exist) as well as circadian rhythm deficits.

A homolog to FMRP has been identified in the fruit fly *Drosophila melanogaster*. Mutant flies that lack the dFMR1 (also called dFXR) protein exhibit overextension of neurites during development of the mushroom bodies (a brain region in *Drosophila* that is linked to memory) and a behavioral phenotype that includes circadian rhythm abnormalities as well as altered courtship behavior. Administration of mGluR antagonists has been shown to restore memory impairments in courtship behavior and structural defects in the mushroom bodies.

Future Treatment Strategies Aimed at the Underlying Mechanism in FXS

Based on information related to synaptic function obtained from the *fmr1* knockout mouse, new treatment strategies have been proposed aimed at correcting synaptic deficits in the underlying disorder in FXS. The finding of reduced LTP and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor number and activity in the *fmr1* knockout prompted a phase II clinical trial of CX516, an AMPA receptor activator, in FXS. The drug proved safe, although low potency precluded definitive results, and use of more potent AMPA activators remains a potential treatment strategy for the future. Lithium has been shown to reduce inositol phosphate turnover, and thus acts on the signaling cascade required for mGluR activation of protein synthesis. It has been proposed that lithium might thus reduce overactive mGluR-mediated protein synthesis in FXS and administration of lithium does rescue the phenotype in *dfxr* fly mutants. There are some anecdotal data suggesting lithium may be quite helpful for behavior in FXS, and a formal clinical trial examining the effects of lithium on cognition and behavior in individuals with FXS is in progress. Negative modulators of mGluR5 receptor activity, similar to those utilized to rescue phenotypes in the mouse and fly models, have been shown to have potent anxiolytic activity in preclinical studies and are in development for use in humans with FXS. In the future, deficits in synaptic plasticity in FXS may treated with one or a combination of these agents or with yet-to-be-discovered pharmaceuticals that act on the CNS mechanism of disability in the absence of FMRP.

Premutation Phenotype and Fragile X-Associated Tremor/Ataxia Syndrome

In the past decade, several phenotypes associated with the FXS premutation have emerged. Some of these phenotypic features represent milder versions of features seen in FXS. Such mild phenotypic features had been difficult to demonstrate because they tend to overlap with the normal population and because there appears to be no evidence of impairment in overall cognitive functioning in premutation carriers. Behavioral features (e.g., anxiety, social phobia, and neurotic tendencies) are increased in premutation carriers relative to control cohorts. In addition, mild executive function deficits and learning disability can be seen in premutation carriers, predominantly those at the higher end of the repeat range (>150 repeats). Physical features of FXS (e.g., prominent ears) are also increased in premutation carriers relative to control groups.

A second set of premutation-associated phenotypes is specific to the premutation and these phenotypes do not occur in individuals with a full mutation. Premature ovarian failure (POF) is one such phenotype, occurring in approximately 20% of premutation carriers. Indeed, roughly 2% of women with sporadic POF and 14% of women with familial POF carry the fragile X premutation, and genetic screening should be offered to these women.

Another phenotype, occurring predominantly in male premutation carriers, is fragile X-associated tremor/ataxia syndrome (FXTAS). These men present with complex tremor, gait disorder, parkinsonian symptoms, and in some cases executive function deficits progressing to a dementia with subcortical features. Autonomic dysfunction and neuropathy may also be seen. The disorder is variably progressive, with many cases progressing over quite prolonged time frames. Traditionally, these individuals have been misdiagnosed with essential tremor, parkinsonism, dementia, stroke, or even multiple sclerosis. The radiological hallmark of FXTAS is increased signal in

the middle cerebellar peduncle (MCP sign) on T2-weighted and fast fluid-attenuated inversion recovery (FLAIR) MR images. Increased signal in subcortical white matter and generalized cerebral and cerebellar atrophy are also often seen. Neuropathological findings associated with FXTAS include eosinophilic intranuclear inclusions in neurons and glia and spongiform change in the white matter with mild axonal and myelin loss. Infrequently, females do seem to develop symptoms of FXTAS, although the symptoms are typically milder, occur later, and are less progressive than in males. This is likely due to the protective effect of the normal *FMR1* gene, and symptom predisposition in females is thought to relate to X-inactivation ratios.

In contrast to patients with the full mutation, premutation carriers have elevated levels of *FMR1* mRNA. Premutation-specific phenotypes are thought to result from cellular toxicity related to elevated levels of the CGG-repeat-containing *FMR1* mRNA. Indeed, the *FMR1* mRNA has been identified within the inclusions in brain samples from FXTAS patients, along with a list of proteins including nuclear regulatory protein lamin A/C. In support of the RNA toxicity mechanism for FXTAS, mouse and *Drosophila* models expressing an expanded CGG repeat have been generated and also develop neurodegenerative signs and neuronal inclusions.

Free Radicals in Autonomic Functions

J Lincoln, University College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Free radicals are molecules that have an unpaired electron. As a consequence, they are highly reactive and they pass freely through membranes. Such properties mean that they do not conform well to standard 'biological rules' where molecular shape and cellular localization govern function. Thus, free radicals have generally been viewed as harmful to cells. However, in 1987, endothelium-derived relaxing factor, known to contribute to normal relaxation of vascular smooth muscle, was identified as the free radical nitric oxide (NO). Subsequent studies established that NO is also synthesized by neurons within the autonomic nervous system and have altered significantly our understanding of the autonomic control of a variety of physiological processes and introduced new approaches for clinical therapy. However, cells still need to handle free radicals with care, and there are a variety of intracellular mechanisms designed to restrict the production and/or reactions of free radicals. When such mechanisms are impaired or the intracellular environment of cells is altered, this can result in toxic effects that contribute to autonomic dysfunction.

Free Radicals, Reactive Oxygen Species, and Reactive Nitrogen Species

Because of their molecular form, free radicals readily undergo oxidation and reduction reactions resulting in a variety of products. In the case of radicals derived from oxygen, these are referred to as reactive oxygen species (ROS), and those derived from nitrogen are referred to as reactive nitrogen species (RNS). Overproduction of ROS or RNS results in the intracellular conditions of oxidative stress and nitrosative stress, respectively. The major free radical derived from oxygen produced by autonomic neurons is the superoxide anion ($O_2^{-\bullet}$) that is readily converted to hydrogen peroxide (H_2O_2) and subsequently to water. In the presence of ferrous or cuprous ions, H_2O_2 can form the hydroxyl radical (OH•) that has the potential to damage all classes of biological molecules. NO can act as an antioxidant preventing lipid peroxidation. However, under conditions in which relatively high levels of both NO and $O_2^{-\bullet}$ are produced, they react together to produce peroxynitrite ($ONOO^-$). Peroxynitrite is a pro-oxidant that has toxic effects. Thus, the intracellular environment can influence what species are produced and whether the result is harmful.

Synthesis of ROS

Neurons have a high level of metabolic activity and contain relatively high numbers of mitochondria. However, there is a price to pay for the production of energy by aerobic metabolism in mammalian cells, and this is the formation of ROS as a by-product. The major site for the production of ROS in cells is mitochondria, and this occurs normally during respiration. Electrons produced by the oxidation of NADH are passed along the electron transport chain in the mitochondrial inner membrane. During this process, oxygen is reduced to water and redox energy is conserved by pumping protons across the inner membrane to build up a proton electrochemical gradient. The proton electrochemical gradient drives the synthesis of adenosine 5′-triphosphate (ATP), during which there is inward flow of protons through ATP synthase. Protons can also re-enter via nonspecific proton leak and by translocation via uncoupling proteins. However, not all of the molecular oxygen is fully reduced to water, and a fraction is incompletely reduced to $O_2^{-\bullet}$. The formation of $O_2^{-\bullet}$ is particularly favored under a condition known as state 4 respiration. This occurs when mitochondria are respiring but there are high levels of ATP. Electrons accumulate on the electron transport chain because the proton electrochemical gradient is not dissipated by ATP synthesis. Reaction of the accumulated electrons with oxygen produces increased levels of ROS.

Synthesis of NO

NO is synthesized by the enzyme nitric oxide synthase (NOS). Three isoforms have been identified. Inducible NOS (iNOS or type 2 NOS) is not present under normal conditions but is induced as part of an immune reaction and subsequently synthesizes large quantities of NO that are toxic to invading organisms. Two isoforms are present constitutively. Endothelial NOS (eNOS or type 3 NOS) was first identified in endothelial cells, and neuronal NOS (nNOS or type 1 NOS) was first identified in neurons. nNOS is a very complex molecule and the synthesis of NO requires the presence of three cosubstrates (L-arginine, molecular oxygen, and NADPH) and five cofactors or prosthetic groups (flavin adenine dinucleotide, flavin mononucleotide, tetrahydrobiopterin, calmodulin, and heme).

Active nNOS consists of two enzymes in one. The C-terminal end of nNOS resembles cytochrome P450

reductase (CPR) and is responsible for the production of electrons from NADPH. The flavin cofactors direct the electrons toward the N-terminal portion. In the N-terminal region, in the presence of electrons, heme, and molecular oxygen, L-arginine is converted to citrulline producing NO in the process. The role of tetrahydrobiopterin has not been fully established, but it is thought to contribute to the conformation of the active nNOS and possibly to the redox reactions required for synthesizing NO. The calcium-binding protein, calmodulin, plays the crucial role of making nNOS activity dependent on the intracellular concentration of Ca^{2+}. Normally, nNOS only synthesizes low concentrations of NO that do not reach a toxic level. However, under certain conditions, nNOS has the capacity for synthesizing alternative products. When L-arginine levels are low, nNOS can actually synthesize $O_2^{-\bullet}$. Furthermore, there is evidence that when tetrahydrobiopterin binding is not optimal, nNOS can synthesize both NO and $O_2^{-\bullet}$. Since NO and $O_2^{-\bullet}$ can react together to produce peroxynitrite, this can be potentially harmful. A spliced variant of nNOS has been identified that is localized in mitochondria (mtNOS). The function of NO synthesized by mtNOS has not been fully established, but NO has the capacity to interact with metal groups present on enzymes within the electron transport chain, particularly cytochrome oxidase. In this way, it has been suggested that it can modify respiration and de-energize mitochondria in a transient and reversible manner.

Intracellular Defense Mechanisms

In view of their toxic nature, autonomic neurons have a variety of mechanisms to defend themselves against ROS and RNS. In the case of NO, the major protective mechanisms act to limit the levels produced. ROS are removed from neurons by a number of different antioxidant processes that act in different cellular localizations. Within mitochondria, the two main protective mechanisms are manganese superoxide dismutase (MnSOD) and glutathione peroxidase (GPx4). MnSOD converts $O_2^{-\bullet}$ to H_2O_2, whereas GPx4 converts H_2O_2 to water, oxidizing glutathione in the process. Glutathione is a major intracellular antioxidant and to maintain its protective effects it has to be continually recycled from its oxidized form by the action of the NADPH-dependent enzyme glutathione reductase. In the cytoplasm, alternative forms of the antioxidant enzymes (Cu/ZnSOD and GPx1) are present and catalyze similar reactions. Additionally, catalase converts H_2O_2 to water. Vitamin C, vitamin E, and taurine also have antioxidant properties. Vitamin C exists in the aqueous environment of the cytoplasm, whereas vitamin E is localized in the hydrophobic environment of membranes. Taurine not only is an antioxidant but also is released from cells under conditions of osmotic stress to maintain the internal osmolarity of the cell.

NO as a Neurotransmitter in the Autonomic Nervous System

Nitrergic Transmission

Despite the fact that NO does not conform to the classical criteria for the definition of a neurotransmitter, it is now accepted that it plays an important role in autonomic neuromuscular transmission. The presence of nNOS in autonomic neurons can readily be demonstrated using specific antibodies raised against nNOS and immunohistochemical techniques. Unlike classical neurotransmitters, in which the arrival of an action potential causes the calcium-dependent release of synaptic vesicles, NO cannot be stored in vesicles within nerves for release. However, the synthesis of NO by nNOS is calcium dependent, and it is this property that enables NO to mediate neurotransmission. A schematic representation of the events of nitrergic neurotransmission is given in **Figure 1**. Under resting conditions, the levels of Ca^{2+} within a nerve are not sufficient to cause the change in conformation of calmodulin required to activate nNOS. During an action potential, the intracellular concentrations of Ca^{2+} rise sufficiently to initiate the activation of nNOS and NO synthesis. NO is only synthesized for as long as the Ca^{2+} levels within the nerve are raised. Thus, only small amounts of NO are synthesized for short periods of time, and they do not reach toxic levels. Both calcium chelators and calmodulin antagonists can inhibit nitrergic transmission. NO is not as reactive as many free radicals and, under normal intracellular conditions, the most likely reaction it will undergo is with transition metals. NO can react with the heme group on nNOS inhibiting activity, providing a mechanism for feedback inhibition that further controls the levels of NO that can be produced.

NO does not produce a response by interacting with extracellular receptors on the target like classical neurotransmitters. Instead, NO reaches and enters the target by diffusion and reacts with the heme group of soluble guanylate cyclase (sGC) within the target. NO binds to heme, forming a five-coordinated nitrosyl–heme complex that results in up to 200-fold activation of sGC. Thus, NO increases synthesis of cGMP, and this causes relaxation of smooth muscle. Evidence that NO can act as an inhibitory neurotransmitter in the autonomic nervous system via the

Figure 1 Schematic representation of nitrergic transmission in the autonomic nervous system. The arrival of an action potential causes a rise in intracellular calcium that binds to calmodulin (Cm) and activates neuronal nitric oxide synthase (nNOS). Nitric oxide (NO) is synthesized by nNOS during the conversion of L-arginine to citrulline. NO is released from autonomic nerves by diffusion and enters the target smooth muscle, where it interacts with the heme group on guanylate cyclase (sGC) activating the synthesis of cGMP and causing relaxation of the smooth muscle. Nitrergic transmission can be modified at the sites indicated: 1, calcium chelators and calmodulin antagonists inhibit the activation of nNOS; 2, L-arginine analogues are specific inhibitors of nNOS and are used to identify whether inhibitory transmission is specifically nitrergic; 3, free radical scavengers and superoxides can react with NO, inhibiting transmission; 4, agents that inhibit sGC can inhibit both the response to exogenous NO and the response to nerve stimulation, whereas drugs that inhibit the breakdown of cGMP by phosphodiesterase have the opposite effect.

production of cGMP has been obtained by demonstrating that a relaxation response following electrical stimulation of autonomic nerves can be prevented by NOS inhibitors and drugs that decrease the stimulation of sGC by NO (Figure 1). L-Arginine analogues are an important group of NOS inhibitors that compete with L-arginine at the active site of NOS, preventing NO synthesis and nitrergic transmission. The effect of these competitive NOS inhibitors can be reversed by high concentrations of L-but not D-arginine. Methylene blue is a nonspecific inhibitor that interacts with heme on both NOS and sGC. ODQ (1H-[1,2,4] oxadiazolo[4,3-α]-quinoxalin-1-one) is a selective inhibitor of sGC that competes with NO for binding and inhibits NO-stimulated cGMP synthesis while leaving basal synthesis unchanged. Some doubt was raised about whether NO was released from autonomic nerves as free NO or a related molecule formed by NO, such as a nitrosothiol, when some free radical scavengers were shown to prevent muscle relaxation in response to application of exogenous NO but had little effect on the response to nerve stimulation. However, it has been proposed that endogenous antioxidant mechanisms within tissue are able to protect the endogenous free NO that is released from the nerve. The susceptibility of NO to reactions with ROS emphasizes the importance of the antioxidant status of an organ in determining the effectiveness of nitrergic transmission.

Physiological Roles of NO in the Autonomic Nervous System

This section focuses on examples of autonomic transmission in which NO has been clearly demonstrated to play the major role and in which a deficit has been implicated in pathological conditions. However, it should be noted that the presence of nNOS-containing autonomic nerves has been demonstrated throughout the gastrointestinal, cardiovascular, and urogenital systems together with nerve-mediated relaxation responses that can be inhibited by NOS inhibitors. As with all autonomic neurotransmitters in which co-localization and cotransmission is a characteristic phenomenon, NO does not occur on its own but, rather, in combination with other transmitters. nNOS is most often present in postganglionic parasympathetic nerves, in which it is commonly co-localized with acetylcholine and/or vasoactive intestinal polypeptide. It is also very well represented in the enteric nervous system. However, there is less evidence for the presence of nNOS in postganglionic sympathetic nerves.

Penile erection Historically, studies of the erectile process have played a pivotal role in establishing NO as an autonomic neurotransmitter. Penile erection is controlled by parasympathetic nerves, in which stimulation results in the relaxation of the

smooth muscle of erectile tissue. However, it has long been known that blockade of the actions of acetylcholine by atropine fails to block the erectile response. The release of an additional neurotransmitter from parasympathetic nerves had been proposed, but its identity was unknown until it was demonstrated that NO could be synthesized by mammalian cells. Autonomic neurons containing nNOS have been demonstrated in pelvic ganglia that supply the penis, and nNOS-containing nerve fibers are present in the erectile tissue of all species including humans. The development of L-arginine analogues to inhibit NOS activity provided the tools to demonstrate that NO is the major neurotransmitter involved in the erectile response.

A decrease in nNOS-containing nerve fibers occurs in erectile tissue from patients with erectile dysfunction. Furthermore, a deficit in neurogenic NO-mediated relaxation occurs in erectile tissue from animal models of diabetes and human diabetic patients and is considered to be a major factor in the increased incidence of impotence associated with diabetes. Understanding of the NO–cGMP pathway in the control of penile erection has led to the development of sildenafil citrate (Viagra) in the clinical treatment of impotence. Viagra is a specific phosphodiesterase inhibitor that acts by decreasing the breakdown of cGMP, thus maintaining the relaxation of erectile smooth muscle induced by NO.

The gastrointestinal tract The enteric nervous system supplies the entire gastrointestinal tract and can act independently of any input from the parasympathetic and sympathetic nervous systems. Enteric neurons are localized in two main plexuses: the myenteric plexus, located between the longitudinal and circular smooth muscle layers, and the submucosal plexus, located between the circular smooth muscle layer and the mucosa. Neurons containing nNOS can readily be demonstrated in both the myenteric (Figure 2) and the submucosal plexuses, sometimes co-localized with vasoactive intestinal polypeptide. Nerve-mediated relaxation of smooth muscle that can be inhibited by NOS inhibitors has also been demonstrated throughout the gastrointestinal tract from the esophagus to the anal sphincter. The first indication of the importance of NO in the autonomic control of the gastrointestinal tract was provided when knockout mice in which the gene for nNOS had been deleted were generated. The major gross change observed in these mice was a markedly distended stomach, indicating that relaxation of the pyloric sphincter had been impaired. Since that time, evidence has accumulated that NO is the major neurotransmitter involved in the relaxation of sphincters throughout the gastrointestinal tract. Similar studies of the urinary tract have suggested that NO is also an inhibitory neurotransmitter in the urethra and bladder neck.

Figure 2 Localization of nNOS in intrinsic neurons of the myenteric plexus. Immunohistochemical labeling of nNOS (green fluorescence) in a whole mount preparation of the myenteric plexus of the rat proximal colon enables the plexus to be observed through the longitudinal muscle layer. The white arrow indicates one of the neurons within the myenteric ganglion positively labeled for nNOS with a negative nucleus. Note that some of the neurons within the same ganglion do not contain nNOS. Scale bar = 55 μm.

Impaired nitrergic transmission has been implicated in a variety of disorders of the gastrointestinal tract. A loss of nNOS-containing nerves has been demonstrated in agangliosis of the gut (Hirschsprung's disease), infantile pyloric stenosis, and achalasia of the gastroesophageal junction and internal anal sphincter, all of which result in impaired motility. In the case of infantile pyloric stenosis, the condition strongly resembles that observed in the stomachs of nNOS knockout mice.

Cerebral blood vessels The cerebral vessels provide an example of cotransmission of NO with the classical neurotransmitter, acetylcholine, in which the NO-mediated response is modulated by its co-transmitter. Co-localization of nNOS and choline acetyltransferase has been demonstrated in the parasympathetic neurons of the sphenopalatine ganglion that supply the cerebral blood vessels. Nerve-mediated relaxation of cerebral blood vessels is blocked by NOS and sGC inhibitors but not by atropine, indicating that NO is the main neurotransmitter mediating cerebral neurogenic vasodilation. Indeed, atropine enhances the relaxation response to nerve stimulation providing evidence that acetylcholine can modulate nitrergic transmission. It has been demonstrated that acetylcholine acts on presynaptic muscarinic

receptors, reducing Ca^{2+} influx via voltage-sensitive N-type Ca^{2+} channels. As a consequence, acetylcholine inhibits the synthesis of NO and nitrergic transmission in parasympathetic nerves supplying cerebral vessels. A loss of nNOS-containing nerves supplying cerebral vessels has been observed in experimental diabetes and implicated in the increased incidence of stroke in diabetic patients.

Parallels between NO and carbon monoxide Once NO had been demonstrated as a neurotransmitter, studies were undertaken to investigate whether other similar molecules could also mediate transmission. These revealed that carbon monoxide (CO) acts in a similar way. Although CO is not a free radical, it has been included here because there are some parallels between the synthesis of CO and NO and their effects. Electrons provided by the activity of CPR are used by the enzyme heme oxygenase (HO) to synthesize CO during the conversion of heme to biliverdin. HO2 is a constitutive enzyme that has been localized in autonomic neurons. CO can also activate sGC by interacting with the heme group causing increased synthesis of cGMP. However, CO forms a different type of heme complex with sGC from that formed by NO, and this is considerably less effective in activating sGC (sixfold compared to 200-fold). One problem in establishing CO as a neurotransmitter within the autonomic nervous system is that it has been difficult to demonstrate that its synthesis is related to nerve stimulation.

HO2 has been co-localized in some nNOS-containing neurons in the myenteric plexus of the gastrointestinal tract, and there appears to be cooperation between the actions of NO and CO in mediating relaxation of gastrointestinal smooth muscle. There is evidence that low concentrations of CO can stimulate the synthesis of NO by nNOS. In studies of nNOS, HO2, and double nNOS/HO2 knockout mice, depolarization of intestinal smooth muscle occurs in both single knockouts and is additive in the double knockout. In HO2 knockout mice, inhibitory responses to electrical stimulation of nerves are nearly abolished despite the fact that nNOS is still expressed. However, exogenous CO can restore normal responses in a manner that is prevented by an NOS inhibitor. Thus, CO is able to regulate nitrergic transmission in the gastrointestinal tract.

Pathological Conditions of the Autonomic Nervous System Involving ROS

Diabetes Mellitus and Oxidative Stress

Diabetes is the single major cause of autonomic dysfunction in humans. All parts of the autonomic nervous system can be affected in diabetes, resulting in a range of symptoms including postural hypotension, impaired control of heart rate, disordered gut motility, impotence, and bladder dysfunction. The presence of autonomic neuropathy in diabetic patients is associated with considerable morbidity and increased mortality and, in view of the dramatic increase in the number of diabetic patients, is a considerable clinical problem. Diabetic neuropathy is often characterized by an initial accumulation of neurotransmitter in the neuronal cell body and loss in the nerve terminal. Ultimately, degeneration of the peripheral nerve fibers occurs as a dying back type of axonopathy. The major factor associated with neuropathy in diabetic patients is poor glucose control, and metabolic changes associated with hyperglycemia have received considerable attention in research on the mechanisms underlying the development of diabetic neuropathy. A common feature of many of the diabetes-induced changes in metabolism in peripheral nerves is oxidative stress. The current major focus for research is now on the role of increased production of ROS in diabetic neuropathy and the potential use of antioxidants in its prevention and treatment. A schematic representation of how oxidative stress may occur in diabetes is shown in Figure 3. The evidence for the pathways described has been derived from a combination of *in vivo* studies of animal models of diabetes and *in vitro* studies of sensory and autonomic neurons exposed to high levels of glucose. It should also be emphasized that the metabolic changes given are not exclusive to neurons. Indeed, there is considerable evidence that similar changes occur in endothelial cells, leading to vascular dysfunction and potentially to decreased nerve blood flow and subsequent nerve deficits.

Nerves do not require insulin for the uptake of glucose; therefore, hyperglycemia in diabetes results in increased intracellular concentrations of glucose. This results in the activation of aldose reductase that converts glucose to sorbitol. Sorbitol dehydrogenase then converts sorbitol to fructose. Aldose reductase is an NADPH-dependent enzyme and it has been proposed that increased aldose reductase activity causes depletion of NADPH. One of the consequences of NADPH depletion is impaired recycling of the antioxidant glutathione by glutathione reductase, which is also an NADPH-dependent enzyme. Increased intracellular glucose also causes osmotic stress that results in depletion of the antioxidant taurine. Glucose can undergo autoxidation, forming reactive species. Under normal conditions, glycation of macromolecules only occurs by an enzymatic process. However, at high concentrations both glucose and fructose can glycate macromolecules via a nonenzymatic process. Following a series of chemical modifications, this results in

Figure 3 Schematic representation of the pathways by which high glucose levels in diabetes may lead to oxidative stress. Hyperglycemia results in high intracellular levels of glucose in nerves that activates aldose reductase, resulting in the formation of fructose and depletion of NADPH. Glucose can undergo autoxidation forming reactive oxygen species (ROS), and high levels of glucose and fructose can also lead to the formation of advanced glycation end products (AGEs) that are highly reactive. Antioxidant defense is decreased as osmotic stress induced by glucose results in the depletion of the antioxidant taurine and the reduction in NADPH levels reduces the recycling of the antioxidant glutathione (GSH) from its oxidized form (GSSG). Glucose also affects mitochondrial function, resulting in increased production of ROS. Glucose results in increased levels of NADH entering the electron transport chain, increasing the production of superoxide ($O_2^{-\bullet}$), hydrogen peroxide (H_2O_2), and also peroxynitrite ($ONOO^-$) by interaction with NO. Depletion of GSH reduces the activity of the mitochondrial form of the antioxidant enzyme, glutathione peroxidase (GPx4).

the formation of advanced glycation end products (AGEs), which are not only highly reactive but also can act on the AGE receptor inducing oxidative stress. Oxidative stress can lead to mitochondrial dysfunction, resulting in a vicious cycle in which increased mitochondrial production of ROS is induced following the production of ROS in the cytoplasm. It has been proposed that high glucose can, via the tricarboxylic acid cycle, produce excessive levels of NADH that enter the electron transport chain and lead directly to increased production of ROS by mitochondria. There is also preliminary evidence that diabetes can result in reduced expression of uncoupling protein-3, thus impairing the ability of mitochondria to dissipate the proton electrochemical gradient and favoring the production of ROS.

The exact sequence of events that occur in diabetic neuropathy has yet to be established unequivocally. One current area of debate is whether diabetes-induced oxidative stress leads to neuronal cell death *in vivo* rather than just leading to axonopathy. There are conflicting reports on the effect of experimental diabetes on sensory dorsal root ganglion neuron number. Studies of the sympathetic superior mesenteric ganglia have demonstrated neuroaxonal dystrophy in diabetes in the absence of any neuronal cell loss. Apoptosis has been observed in nNOS-containing but not tyrosine hydroxylase-containing neurons in the autonomic pelvic ganglia from diabetic rats. The presence of apoptosis was correlated with the diabetes-induced formation of AGEs, and it has been suggested that the interaction of NO with reactive AGEs to produce peroxynitrite may make nNOS-containing neurons particularly vulnerable in diabetes. Whether neuronal cell death occurs in diabetes or not, oxidative stress is regarded as a key

factor in the development of neuropathy. As a consequence, considerable attention is being paid to the use of antioxidants in the prevention and/or treatment of diabetic neuropathy. α-Lipoic acid is an antioxidant that acts in both an aqueous and a lipid environment, and there is evidence from clinical trials that it has beneficial effects in the treatment of cardiac autonomic neuropathy in diabetic patients.

Aging

It is recognized that autonomic dysfunction can occur as a consequence of aging. It has been proposed for some time that oxidative stress contributes to altered function of central neurons in aging and neurodegenerative disease, but there has been less direct investigation of this in autonomic neurons. However, the similarities between the effect of diabetes and the effect of aging on sympathetic neurons suggest that oxidative stress may also be significant in the aging autonomic nervous system. The same features of neuroaxonal dystrophy have been observed in the paravertebral celiac/superior mesenteric sympathetic ganglion in both aging and diabetes in animals and humans. Furthermore, sympathetic neurons of the prevertebral sympathetic superior cervical ganglion are relatively resistant to a degenerative process in both conditions. A loss of intrinsic neurons in the gut in aging has been demonstrated in both rodents and humans. There is preliminary evidence for increased ROS levels and a greater susceptibility to ROS-induced apoptotic cell death in myenteric neurons from aged rats. In addition, caloric restriction of aging animals may exert a protective effect on myenteric neurons against ROS. This is of interest because caloric restriction has been shown to decrease the production of ROS by mitochondria and has been studied extensively in relation to delayed aging and increased longevity in rodents. However, further study is required in order to demonstrate a direct relationship between oxidative stress and autonomic dysfunction in aging.

Conclusions

The transitory nature of free radicals and the complexity of the reactions that they can undergo make it inherently difficult to study their role in autonomic function and in pathological conditions affecting the autonomic nervous system. The discovery of NO as a neurotransmitter in the autonomic nervous system has had a dramatic effect on our understanding of the autonomic control of visceral organs under normal conditions and emphasized that free radicals cannot simply be regarded as dangerous to autonomic neurons. However, studies of the mechanisms underlying the development of neuropathy in diabetes have also highlighted the importance of ROS in pathological conditions and are having a significant impact on current approaches to the treatment of autonomic neuropathy. Research on the autonomic nervous system has lagged behind similar studies on the central nervous system. In particular, there is still a great deal to learn on the role of free radicals in autonomic dysfunction in old age.

Friedreich Ataxia

M Pandolfo, Brussels Free University (ULB), Erasme Hospital, Brussels, Belgium

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Friedreich ataxia (FA), first described in 1863 by Nicholaus Friedreich, professor of medicine in Heidelberg, is the most common of the early-onset hereditary ataxias in Caucasians. It is an autosomal recessive hereditary disease characterized by progressive neurological disability, hypertrophic cardiopathy, and increased risk of diabetes mellitus. Skeletal abnormalities such as kyphoscoliosis and pes cavus are common. On average, after 10–15 years of disease, the progressive loss of coordination and balance results in the use of a wheelchair and in the need of help for all daily living activities. Some patients have a very severe cardiomyopathy that can cause premature death for cardiac insufficiency or arrhythmia. The complications of diabetes may further contribute to disease burden and disability. As it is the case for almost all neurodegenerative diseases, there is currently no treatment to stop the progression of FA. Furthermore, there are no effective symptomatic treatments comparable to levodopa for Parkinson disease, so the patient's condition relentlessly deteriorates as the neurodegenerative process continues its progression. Here, after providing some information on the disease, the most significant advances in our understanding of the molecular and cellular pathogenesis of FA 10 years after the discovery of the causative gene mutation, and how these may lead to the development of effective therapies, are reviewed.

FA: Clinicopathological Features

In Caucasians, FA accounts for half of the overall hereditary ataxia cases and for three-quarters of those with onset before age 25 years, with a prevalence of around 2×10^{-5}. The disease may not exist in non-Caucasian populations. Friedreich's papers reported the essential clinical and pathological features of the disease, a "degenerative atrophy of the posterior columns of the spinal cord" leading to progressive ataxia, sensory loss, and muscle weakness, often associated with scoliosis, foot deformity, and heart disease. However, rigorous diagnostic criteria were established for research purposes only in the late 1970s and early 1980s. The phenotype has been redefined and extended after the discovery in 1996 of the disease gene, FRDA, encoding the mitochondrial protein FXN, and of its most common mutation, an intronic GAA triplet repeat expansion. The typical age of onset is around puberty, but it may vary substantially even within a sibship. Late-onset cases exist, even in the sixth decade and later, a phenomenon now in part explained by the dynamic nature of the underlying mutation. Gait instability or generalized clumsiness are typical presenting symptoms. Scoliosis may already be present when neurological symptoms appear. In rare cases, hypertrophic cardiomyopathy is diagnosed before the onset of ataxia. Ataxia is of mixed cerebellar and sensory type, affecting the trunk, with swaying, imbalance, and falls, and the limbs, with increasing difficulty in activities such as writing, dressing, handling utensils. Ataxia is progressive and unremitting, though periods of stability are frequent at the beginning of the illness. With progression, gait becomes broad-based, with frequent losses of balance requiring intermittent, then constant support. Fine motor skills deteriorate, dysmetria and intention tremor become evident. Mild to moderate limb weakness of central origin is a constant feature of advanced FA. Some amyotrophy, particularly in the hands, is also very common. On average, 10–15 years after onset, patients lose the ability to walk, stand, and sit without support. Evolution is variable, however, with mild cases who are still ambulatory decades after onset and severe cases that are wheelchair bound in a few years. Dysarthria consisting of slow, jerky speech with sudden utterances is a relatively early feature and progresses until speech become almost inintelligible. Dysphagia, particularly for liquids, appears with advancing disease, requiring modified foods and eventually a nasogastric tube or gastrostomy feedings. Cognitive functions are generally well preserved. However, because of substantial physical disability, FA may have a substantial impact on academic, professional, and personal development.

Findings at the neurological examination reflect the underlying pathology. A sensory neuropathy in dorsal root ganglia, accompanied by loss of sensory fibers in peripheral nerves and degeneration of the posterior columns in the spinal cord, is a hallmark of the disease. The larger neurons carrying proprioceptive information are mostly affected, resulting in loss of position and vibration sense and abolished reflexes. Perception of light touch, pain, and temperature only decrease with advancing disease. A progressive degeneration of pyramidal tracts usually determines extensor plantar responses and progressive muscular weakness. Some patients with more limited sensory neuronopathy have retained reflexes.

In these cases, pyramidal involvement may lead to hyperreflexia and spasticity, to the point of mimicking a spastic paraplegia. The relative impact of sensory neuropathy and of pyramidal tract degeneration clearly varies from patient to patient, resulting most often in the typical picture of areflexia associated with extensor plantar responses, but sometimes one component prevails. Such partial pictures are usually observed in milder cases of the disease. Fixation instability with square-wave jerks is the typical oculomotor abnormailty in FA, while gaze-evoked nystagmus is uncommon and ophthalmoparesis does not occur. About 30% of the patients develop optic atrophy, with or without visual impairment, and about 20% develop sensorineural hearing loss.

Neurophysiological studies of the peripheral nervous system (PNS) reveal a severe reduction or complete loss of sensory nerve action potentials (SNAPs), with motor and sensory (when measurable) nerve conduction velocities (NCVs) within or just below the normal range. These neurophysiological abnormalities do not appear to progress with time. In the central nervous system (CNS), degeneration of both peripheral and central sensory fibers also results in dispersion and delay of somatosensory evoked potentials (SEPs) and brain stem auditory evoked potentials (BAEPs). Visual evoked potentials (VEPs) are commonly reduced in amplitude, but not delayed. Central motor conduction velocity, reflecting pyramidal tract function, determined by cortical magnetic stimulation, is slower than normal, and, contrary to the sensory involvement, this slowing becomes more severe with increasing disease duration.

Structural neuroimaging, by computed tomography (CT) or magnetic resonance imaging (MRI), typically shows an atrophic cervical spinal cord; cerebellar atrophy is mild and commonly seen only in advanced cases. Newer MRI approaches, including tractography, may have the potential to reveal degeneration of specific fiber systems, but they have not yet been systematically evaluated in this disease. Preliminary studies with magnetic resonance specroscopy (MRS) are compatible with mitochondrial dysfunction, as were older metabolic imaging studies with fluordeoxyglucose (FDG) positron emission tomography (PET) that showed a diffusely increased FDG uptake in the brain in early FA, suggesting inadequate utilization of energy sources.

Heart disease is most commonly asymptomatic, but it may contribute to disability and cause premature death in a significant minority of patients, particularly those with earlier age of onset. Shortness of breath and palpitations are the usual initial symptoms. The electrocardiogram shows inverted T-waves in essentially all patients, ventricular hypertrophy in most, conduction disturbances in about 10%, occasionally supraventricular ectopic beats and atrial fibrillation. Echocardiography demonstrates concentric hypertrophy of the ventricles or asymmetric septal hypertrophy.

About 10% of FA patients develop diabetes mellitus, 20% have carbohydrate intolerance. The mechanisms are complex, with beta-cell dysfunction as well as peripheral insulin resistance, resembling other mitochondrial disorders.

Kyphoscoliosis may cause pain and cardiorespiratory problems. Pes cavus and pes equinovarus may further affect ambulation. Autonomic disturbances, most commonly cold and cyanotic legs and feet, become increasingly frequent as the disease advances. Sphincteric problems are rare.

The FA Gene (FRDA) and Its Mutations

The FA gene (FRDA) is localized in the proximal long arm of chromosome 9. The main mRNA has a size of 1.3 kb and corresponds to five exons, numbered 1–5a. The encoded protein, predicted to contain 210 amino acids, was called frataxin (FXN) and shown to localize in mitochondria.

The gene is expressed in all cells, but at variable levels in different tissues and during development that can only in part be accounted for by differences in mitochondrial content. In adult humans, FXN mRNA is most abundant in the heart and spinal cord, followed by liver, skeletal muscle, and pancreas. In mouse embryos, expression starts in the neuroepithelium at embryonic day 10.5 (E10.5), it reaches its highest level at E14.5 and into the postnatal period. In developing mice, the highest levels of FXN mRNA are found in the spinal cord, particularly at the thoracolumbar level, and in the dorsal root ganglia. The developing brain is also very rich in FXN mRNA, which is abundant in the proliferating neural cells in the periventricular zone, in the cortical plates, and in the ganglionic eminence. Expression is also high in the heart, liver, and brown fat.

FA is the consequence of FXN deficiency. Most patients are homozygous for the expansion of a GAA triplet repeat sequence (TRS) in the first intron, 5% are heterozygous for a GAA expansion and a point mutation in the FXN gene. Repeats in normal chromosomes contain up to ~40 triplets, 90 to >1000 triplets in FA chromosomes. As in other TRS expansion diseases, pathological alleles show meiotic and mitotic instability.

Two major hypotheses have been proposed to explain the reduced FXN expression in the presence of lengths of the GAA TRS that correspond to pathological FRDA alleles. The first hypothesis is based on

the observation that such repeats can adopt a triple helical structure in physiological conditions. Two triplexes may associate to form a novel DNA structure called 'sticky DNA', a phenomenon that may occur intramolecularly when the TRS is sufficiently long. This structure has been shown to inhibit transcription in *in vitro* and *in vivo* models, providing a mechanism to explain FXN deficiency in FA. The second hypothesis proposes that the GAA repeat, possibly by recruiting specific binding proteins, triggers modifications in DNA packaging proteins that eventually result in chromatin condensation and gene silencing. Chromatin condensation is a well-known mechanism to regulate gene expression. It is largely determined by posttranslational modification of histones, including acetylation, methylation, and ubiquitination. The GAA TRS resembles known heterochromatin-associated DNA sequences like satellite III in *Drosophila*, whose repeating sequence is GAGAA, and it may trigger such modifications by recruiting specific DNA-binding proteins. Experimental evidence supporting this hypothesis mostly comes from studies with transgenic mice. When a reporter gene is associated with GAA TRS in a construct used to create transgenic mice, it will be silenced in a proportion of cells, a phenomenon called position effect variegation that is observed in genes localized close to heterochromatic regions. Recent preliminary data (J Gottesfeld, personal communication) suggest that changes in histone acetylation and methylation indeed occur in the vicinity of the expanded GAA TRS in lymphocyte DNA from FA patients.

As expected by the experimental finding that smaller expansions allow a higher residual gene expression, expansion sizes have an influence on the severity of the phenotype. A direct correlation has been firmly established between the size of GAA repeats and earlier age of onset, earlier age when confined in wheelchair, more rapid rate of disease progression, and presence of nonobligatory disease manifestations indicative of more widespread degeneration. However, differences in GAA expansions account for only about 50% of the variability in age of onset, indicating that other factors influence the phenotype. These may include somatic mosaicism for expansion sizes, possibly variation in the TRS sequence, modifier genes, and environmental factors. In addition, about 2% of the FA chromosomes carry GAA repeat of normal length, but have a missense, nonsense, or splice site mutations ultimately affecting the FXN coding sequence. Most of these individuals have typical FA, but a few missense mutations are associated with atypical, slowly evolving disease, suggesting that the corresponding mutated proteins have some preserved function.

The Function of FXN and Pathogenesis

FXN does not resemble any protein of known function. Its amino acid sequence predicts a small soluble protein with no transmembrane domain. It is highly conserved during evolution, with homologs in mammals, invertebrates, yeast, and plants. FXN is imported into the mitochondria, where an N-terminal peptide of about 40 amino acids is removed generating the mature, functional protein.

Much information on FXN function comes from yeast studies. The yeast frataxin homolog (yfh1) is thought to share function with human FXN, not only because of high sequence similarity and corresponding mitochondrial localization, but also because the latter can fully complement a yfh1 deletion. Most yfh1 knockout (KO) yeast strains, called Δ*yfh1*, lose the ability to carry out oxidative phosphorylation and form petite colonies with defects or loss of mitochondrial DNA that cannot grow on nonfermentable substrates. Most remarkably, iron accumulates in Δyfh1 mitochondria, averaging a more then tenfold excess compared to the corresponding wild-type yeast. Loss of respiratory competence requires the presence of iron in the culture medium, and occurs more rapidly as iron concentration in the medium is increased, suggesting that permanent mitochondrial damage is the consequence of iron toxicity. Ferrous iron reacts with reactive oxygen species (ROS) and can form the highly toxic hydroxyl radical ($OH^{\cdot}$) through the Fenton reaction with H_2O_2 , a process likely to occur in Δ*yfh1* yeast, as suggested by its enhanced sensitivity to H_2O_2. In mitochondria, H_2O_2 is produced by the mitochondrial form of the enzyme superoxide dysmutase (SOD) from superoxide (O_2^-), in turn generated by the reaction of oxygen with electrons prematurely leaking from the respiratory chain. FXN deficiency likely establishes a vicious cycle involving damage to the respiratory chain, increased ROS production, and iron toxicity. Accordingly, a role of oxidative stress in the pathogenesis of FA has been proposed.

Excess iron in Δ*yfh1* yeast has been related to a marked induction (10–50-fold) of the high-affinity iron transport system on the cell membrane, normally not expressed in yeast cells that are iron replete. This induction has been recently identified as a general response to a deficit in the mitochondrial synthesis of iron–sulfur clusters (ISCs). ISCs are complexes of iron and sulfur atoms that act as prosthetic groups in several enzymes of different function and cellular localization. They are synthesized in mitochondria; cytosolic synthesis has been proposed but is somewhat controversial. ISC-containing enzymes as respiratory chain complexes I, II, and III and aconitase (AC) are impaired in

Δ*yfh1* yeast. FXN is thought to be involved in an early step of ISC synthesis, through its interaction with the scaffold protein IscU, where the first ISC assembly takes place, probably facilitating iron incorporation. Iron enters mitochondria through specific trasporters, called Mrs3 and -4 in yeast. In this process, sulfur is provided by the cysteine desulfurase Nsf1, that also appears to interact with FXN. FXN may be a mitochondrial iron chaperone with a more general function to protect this metal from ROS and making it bioavailable. *In vitro*, FXN binds Fe^{2+} with low affinity, as it would be expected for a chaperone, and has the capacity to oxidize it to the much less reactive Fe^{3+} form when its concentration increases. A mitochondrial form of ferritin (m. ferr) may also be involved in this detoxification process. Some data suggest that FXN also acts as an iron chaperone in heme synthesis, providing iron to ferrochelatase (FCH), the enzyme that inserts iron into protoporphyrin IX to form heme (Figure 1). A much higher affinity of FXN for the heme synthesis enzyme FCH than for IscU may explain why heme synthesis is resistant to low FXN level and essentially unaffected in FA patients. FXN has also been implicated in the modulation of AC activity through assembly and disassembly of its ISC.

A mouse model of FA has been difficult to generate because complete loss of FXN, as in FXN KO mice, causes early embryonic lethality. Viable mouse models have been so far obtained only through a conditional gene targeting approach. The first two models utilized Cre transgenes under the control of the muscle creatine kinase (MCK) and the neuron-specific enolase (NSE) promoters to induce striated muscle- and neuron-restricted exon deletion, respectively. NSE mutants have a low birth weight and develop a progressive neurological phenotype with the average onset of ataxia at 12 days, hunched stance, and loss of proprioception. MCK mutants show cardiac hypertrophy with thickening of the walls of the left ventricle, and show myocardial degeneration with cytoplasmic vacuolization in the myocytes, evidence of necrosis, and postnecrotic fibrosis. Loss of activity of ISC-containing enzymes is an early finding in these models. The MCK mutants accumulate iron in heart mitochondria at later stages. Using a similar conditional KO approach, but with a tamoxifen-inducible Cre recombinase under the control of a neuron-specific prion protein promoter, two different lines which exhibit a progressive neurological phenotype with slow evolution that recreates the neurological features of the human disease were developed. An autophagic process was detected in the DRG, leading to removal of mitochondrial debris and apparition of lipofuscin deposits.

Altered iron metabolism, free radical damage, and mitochondrial dysfunction all occur in FA patients, suggesting that the information derived from the investigations on FXN function and from the yeast and animal models is relevant for the pathogenesis of the human disease. Oxidative stress is revealed by increased plasma levels of malondialdheyde, a lipid peroxidation product, increased urinary 8-hydroxy-2′-deoxyguanosine, a marker of oxidative DNA damage, decreased plasma free glutathione, and increased plasma glutathione-S-transferase activity. Increased

Figure 1 Potential functions of frataxin (FXN). General iron chaperone, making Fe^{2+} (●) available to FCH for heme biosynthesis, to IscU2 and Nfs1 for mitochondrial ISC (▣) biosynthesis, to mitochondrial AC. Prevent oxidative stress, protect mitochondrial proteins and mitochondrial DNA (mitDNA) from free Fe^{2+}; by converting Fe^{2+} to Fe^{3+} (●).

free radical production could be directly demonstrated in cultured cells engineered to produce reduced levels of FXN. In addition, patients' fibroblasts are sensitive to low doses of H_2O_2, which induce apoptosis at lower doses than in control fibroblasts, suggesting that even nonaffected cells are in an 'at-risk' status for oxidative stress as a consequence of the primary genetic defect. FA fibroblasts also show abnormal antioxidant responses, in particular a blunted increase in mitochondrial SOD triggered by iron and by oxidants in control cells. Intriguingly, no evidence of oxidative stress was obtained in studies on conditional KO mouse models. However, interfering factors may have affected these results, including the admixture of cells with normal FXN with progressively disappearing cells with no FXN, and the almost complete shutdown of the respiratory chain in the latter.

Mitochondrial dysfunction has been proven to occur *in vivo* in FA patients. Phosphorus-MRS analysis of skeletal muscle and heart shows a reduced rate of ATP synthesis. Finally and most importantly, the same multiple ISC-containing enzyme dysfunctions found in Δ*yfh1* yeast and in mouse models are also found in affected tissues from FA patient.

Activation of stress pathways, triggered by mitochondrial dysfunction causing energy deficit and oxidative stress, occurs in FA and likely plays an important role in cell atrophy and death. Studies on cultured PC12 cells, rat pheochromocytoma cells that can be differentiated into neurons by adding nerve growth factor (NGF), showed in particular an increased expression and activity of the MKK4-JNK kinase pathway, which may be at first a protective response but also eventually trigger apoptosis. Different vulnerable cell types may activate different pathways, as suggested by the observation of the specific occurrence of autophagic vacuoles only in primary sensory neurons in the inducible conditional KO mouse model.

All FA patients carry at least one expanded GAA repeat and therefore make an insufficient amount of otherwise normal FXN. If it were possible to increase their FXN production even to levels that are similar to those of healthy carriers, one could possibly stop the course of the disease and maybe even induce some improvement. An increased FXN production could be obtained: (1) through gene replacement therapy, that is, by introducing a FXN gene without the GAA expansion into the patient cells; (2) by giving FXN directly (the protein should, however, be modified in such a way to be able to reach the nerve cells affected by the disease and the mitochondria inside these cells); or (3) by intervening on the GAA expansion with molecules that can destabilize the triple helical structure and shift the equilibrium toward the physiological double helix that allows FXN expression. Though still in their infancy, all these appoaches are under study. Recently, encouraging results have been obtained for gene replacement therapy, with partial correction of the oxidative stress hypersensitivity of FA fibroblasts by FXN-encoding adeno-associated virus and lentivirus vectors, and for some approaches aimed to reactivate FXN transcription by using histode deacetylase inhibitors (J Gottesfeld, personal communication).

Further possibilities to treat the disease may come from the studies on the function of FXN. Based on these findings, therapeutic approaches aimed to free radical control and respiratory chain activation may be proposed. Concerning antioxidant molecules and respiratory chain stimulants, some coenzyme Q derivatives (idebenone, CoQ-10) have already given promising results, not only in experimental models, but also in clinical trials, at least on the FA cardiomyopathy. An intriguing possibility would be the identification of small molecules capable to effectively replace FXN by binding mitochondrial iron and increasing its bioavailability. A further possibility to treat FA may come from cellular therapies, in particular from the use of stem cells. However, the widespread nature of neurodegeneration in FA is a major obstacle to this approach, because it would require to diffusely deliver cells in the CNS of the patients.

The most positive note is the remarkable progress that was made in understanding the pathogenesis of FA since the responsible gene was discovered in 1996. In addition, investigating the pathogenesis of FA has stimulated research on numerous basic areas of biology, from DNA structure and biochemistry to iron metabolism. But most exciting is the now realistic perspective to develop a treatment for this sofar incurable neurodegenerative disease.

Frontal Cortex Evolution in Primates

Primate-Specific Adaptations

The frontal cortex can be defined as the neocortex anterior to the motor somatosensory–cortex border. This is a large region in primates, containing areas involved directly or indirectly in the control of almost every behavior. It has long been thought that the frontal cortex played an important role in primate evolution. Modern evidence supports this view. Indeed, given the diversity of functions in the region and the variety of unique behaviors exhibited by primates, it would be surprising if the frontal cortex had not evolved unique adaptations.

The common ancestor of eutherian mammals probably had a small body and a small brain. Comparative work in modern mammals suggests it had a basic complement of cortical areas including primary visual, auditory, and somatosensory areas. It also probably had a primary motor area (M1). This means that we could define a frontal cortex in that mammal and that the region of the frontal cortex in modern eutherians (taken as a whole) can be thought of as being homologous.

It is likely however that this broad homology obscures substantial differences in frontal cortex structure between primates and nonprimates. One piece of evidence to this effect is that the frontal cortex scales differently in primates and nonprimates. In primates, the frontal cortex hyperscales with the brain size. This can be seen in the reconstructions in Figure 1 which show the brain of a small primate, the galago, and a larger primate, the macaque. A primate with a larger brain tends to have a disproportionately large frontal cortex. In contrast, in a nonprimate order, carnivores, the frontal cortex size does not vary systematically with brain size. This suggests that the structure and development of the frontal cortex differs substantially in the two orders.

When we focus on specific cortical areas and regions, we again find that the primate frontal cortex differs in important ways from that found in other orders. A variety of evidence suggests that the two main branches of primates, strepsirrhines and anthropoids, share up to ten motor areas in the frontal cortex. Of these, only one or two have clear homologs outside primates. Most eutherians have an agranular M1, with large layer 5 pyramidal cells, somatotopy, and relatively low thresholds of stimulation. Rostral and medial to M1 is a supplementary motor area (SMA, also called M2) in primates. It is also somatotopically organized, and has slightly smaller layer 5 pyramidals than M1. This area may have homologs in other mammals such as rats.

The remaining motor areas which are shared among primates appear not to have one-to-one homologs in other orders. Among these areas are several cingulate motor areas and a number of premotor areas involved in higher-level coordination of movement. Several of these are particularly interesting. The frontal eye field (FEF) is connected with both the sensory visual areas and the prefrontal cortex. Microstimulation here produces saccadic and smooth pursuit eye movements. The FEF may be involved in the voluntary control of eye movements, an attribute of great importance for highly visual primates. Strepsirrhines and haplorhines also share a ventral premotor area (PMV), which appears to have representations of the upper body. One possibility is that PMV is involved in the visually guided grasping of objects, something that would be especially important to a small visual predator. Early primates are thought to have been small arboreal visual predators, and it is tempting to view the evolution of primate motor areas in this light. These areas could be seen as motor adaptations of the earliest primates for a very demanding arboreal niche.

A frontal region of particular interest in primate evolution is the prefrontal cortex. This region has a wide variety of connections with other brain regions, and patients with prefrontal damage show deficits in the ability to plan and organize behavior. This suggests that it is involved in aspects of behavior which have been important in primate evolution.

The question of whether the prefrontal cortex is unique to primates has been controversial. Brodmann originally argued that it was, identifying prefrontal cortex with the well-developed granular layer 4 which is seen in primates. This was later disputed based on connectivity data. Today, there is general agreement that neither of these two types of data alone provides an adequate answer. However, there is less consensus on whether the prefrontal cortex is unique to primates. What is clear, however, is that even if a broadly homologous prefrontal cortex exists in other mammals, it is substantially different from that found in primates. There is no evidence that rats possess anything like the diversity of prefrontal areas found in primates, and many of the details of the primate prefrontal cortex are likely to be unique to the order.

Figure 1 Reconstructions of the brains: (a) *Galago senegalensis*; (b) *Maccaca mulatta*. Frontal cortex is indicated in blue. The position of the motor-somatosensory cortex border was used to delineate frontal cortex. The two brains are shown here in their proper proportions relative to one another.

Specializations within Primates

Anthropoids versus Strepsirrhines

There is also important variation in frontal cortical structure between the two large divisions of primates, anthropoids and strepsirrhines (represented by the macaque and galago, respectively). Among the premotor areas we have discussed, area PMV appears to have developed interesting adaptations in anthropoids. In monkeys, it seems to have an increasing representation of distal forelimb movements. At the same time, it has strong connections to parts of somatosensory cortex which represent information from the cutaneous receptors of the hands. Such information is particularly useful for reaching and grasping motions. These differences have led to the suggestion that anthropoid PMV evolved mechanisms for the improved guidance of reaching and grasping.

In terms of the broader arrangement of areas, however, the premotor cortices in the two groups have many similarities. As already mentioned, electrophysiological data suggest that the motor and premotor regions of anthropoids and strepsirrhines share up to ten areas. Architectonic evidence supports this view. This broad similarity in the arrangement of areas can be found in several other frontal regions. Comparisons in cytoarchitecture and myeloarchitecture suggest that anthropoids and strepsirrhines have a similar arrangement of areas in the orbital and medial regions of the frontal cortex.

In contrast, it seems that there are important differences between the two groups in the prefrontal cortex. Macaques appear to have a much larger number of areas in this region than galagos do. This is suggested by patterns of connectivity between the prefrontal cortex and other regions. Labeling experiments show that the prefrontal cortex in both species has numerous connections with other parts of the cortex. But the pattern of connectivity suggests that galago has fewer prefrontal areas. For example, tracer injections in regions of the parietal cortex produce fewer discrete zones of labeling in the galago prefrontal cortex than in the macaque. A similar result has been found in comparisons of architectonic parcelations in the two species.

Current architectonic and connectional data suggest that most prefrontal areas in galagos can be identified with a homologous area in the macaque. For example, the posterior-most prefrontal areas in galago appear to have homologs in the macaque arcuate cortex region. These conclusions reflect similarities in cell density and size, fiber-staining patterns, and connections to the parietal, superior temporal, and inferotemporal cortices. Similar conclusions have been reached about other areas in the galago prefrontal cortex (e.g., areas in the superior, polar, and ventral parts of the prefrontal cortex).

However, there are a number of areas in the macaque which have no clear homolog in galagos. These areas are concentrated especially around the principal sulcus in macaques, and they may represent anthropoid-specific specializations. This region of the cortex, often referred to as the dorsolateral prefrontal cortex, is thought to be involved in working memory. Classic lesion studies showed that monkeys with lesions in this region have deficits on delayed-response tasks. Such tasks may involve spatial working memory, for example, requiring the monkey to remember a physical position where food was last given. They can also involve nonspatial problems which require the monkey to remember an object's identity over a delay. Working memory of this type is thought to

play an important role in cognition, and in light of this, it is especially interesting that the dorsolateral prefrontal cortex appears to have anthropoid-specific specializations. Also, it is interesting to note that area PMV has developed connections to the dorsolateral prefrontal cortex which are especially prominent in Old World monkeys.

Great Apes and Humans

The fronto-polar cortex (Brodmann's area 10) expands in apes and especially in humans both absolutely and relative to total cortical size. Functional imaging studies indicate that area 10 is activated in the retrieval of episodic memory, in the receipt of monetary rewards, in weighing cost versus benefit, in the formulation of auction bids, in deciding how much to spend to punish cheaters, and in moral decision making. The retrieval of specific past episodes contributes to the complex deliberative socioeconomic decision making that this structure participates in. The slow deliberative nature of this form of cognition stands in contrast to rapid intuition, which another hominoid specialization, the von Economo neurons (VENs) may participate in.

The VENs are large bipolar cells located in anterior cingulate (aCC) and fronto-insular (FI) cortex. They are distinguished from pyramidal cells because they have only a single, large, basal dendrite, whereas pyramidal cells have an array of smaller basal dendrites extending from the cell body. The VENs are present only in humans and great apes and are far more abundant in humans than in apes.

The apical dendrites of VENs are very similar to those of the apical dendrites of neighboring pyramidal cells. The radial orientation and narrow width of the dendritic arborization indicate that the VENs sample a sharply circumscribed cylinder of cortex, possibly corresponding to a minicolumn. They may thus constitute a fast-fire output from minicolumns that provides a rapid relay to other parts of the brain. VEN functions are revealed by immunocytochemical staining with antibodies to neurotransmitter receptors. The VENs are strongly labeled with antibodies to the dopamine D3 receptor, which may signal the expectation of reward under uncertainty. The activation of the FI and aCC increases with the degree of uncertainty. FI and aCC activity is coupled to situations in which the subject sustains a gambling loss (punishment) and then switches to a different behavioral strategy, implying that in normal subjects these areas are involved in adaptive decision making and cognitive flexibility.

The VENs may participate in intuition, a form of cognition in which many variables are rapidly evaluated to yield a fast decision. Typically we are unaware of the logical steps or assumptions underlying the process although intuition is based on experience-based probabilistic models. We experience the intuitive process at a visceral level. Intuitive decision making enables us to react quickly in situations that involve a high degree of uncertainty, which commonly involve social interactions. Frequently we do not have the luxury of sufficient time to perform a deliberative cost-benefit analysis to determine the most appropriate course of action but, instead, must rely on rapid intuitive judgments. The aCC and FI are active when subjects make decisions under a high degree of uncertainty. These areas are also active when subjects experience guilt, experience embarrassment, and engage in deception. The aCC and FI are also active in humor, trust, empathy, and the discrimination of the mental states of others. All these social emotions are influenced by the degree of uncertainty involved. Their large size suggests that the VENs may relay a fast intuitive assessment of complex social situations to allow the rapid adjustment of behavior in quickly changing social situations. For example, humor, which activates the FI and aCC in proportion to subjective ratings of funniness, may serve as a way to recalibrate intuitive judgments in changing social situations, thus resolving uncertainty and relieving tension. The VENs can thus be seen as an adaptation supporting the increased complexity of hominoid and especially human social networks.

Frontal Eye Fields

J D Schall, Vanderbilt University, Nashville, TN, USA

© 2009 Elsevier Ltd. All rights reserved.

Location and Connections

The frontal eye field (FEF) was described first in the late 1800s by David Ferrier, who discovered that electrical stimulation of a portion of the frontal lobe of macaque monkeys elicited movements of the eyes. Today we know that the FEF exists in all primates, including humans. A homolog of the FEF has been described in cats and owls too. Thus, the FEF is present in animals that employ visually guided conjugate movements of the eyes or head to locate objects to approach or avoid.

In humans, the FEF is located in the rostral bank of a portion of the precentral sulcus at the caudal end of the middle frontal gyrus (Figure 1(b)). In macaque monkeys, the animal of choice for investigations of this part of the brain, the FEF occupies the rostral bank of the arcuate sulcus (Figure 1(a)). It occupies the caudal end of the granular prefrontal cortex, with the agranular premotor cortex making up its caudal boundary in the fundus of the arcuate sulcus.

The distinctive cytoarchitecture of the FEF distinguishes it from the surrounding cortex. It contains a high concentration of large pyramidal cells in layer V. This cortex is also characterized by a thinner granular layer 4 compared to the more rostral cortex. The ventrolateral portion of this zone, designated area 45, is distinguished by the presence of large pyramidal cells in layer 3 as well as layer 5. The dorsomedial zone, referred to as area 8A, can be further parcellated based on cytoarchitectonic differences. The cortex within the medial portion of the rostral bank of the arcuate sulcus contains fewer large pyramidal cells in layer 3 and a loosely organized granular layer; it is referred to as area 8Ac. Rostral to area 8Ac medially and area 45 laterally, occupying the convexity of the prearcuate gyrus is a transitional zone, designated area 8Ar, with fewer large pyramidal cells and a thicker, more clearly delineated layer 4. Area 8Ar forms the caudal boundary of area 46 and should probably be considered functionally distinct from the FEF. Curiously, in humans the FEF has been described as being in Brodmann's area 6. However, recent analyses have indicated that this difference between species is more about labels than cortical architecture.

The FEF influences saccade production through four major pathways: (1) a projection to the ipsilateral superior colliculus concentrated in the intermediate layers, (2) a pathway through the basal ganglia via the ipsilateral striatum, (3) a projection to the cerebellum via the pontine nuclei, and (4) a weaker projection to mesencephalic and pontine nuclei that make up the saccade generator circuit (Figure 2). The FEF is innervated by nuclei in the thalamus bordering the internal medullary lamina, mainly the lateral part of the mediodorsal nucleus and the medial part of the ventroanterior nucleus. The thalamic zones most heavily connected with the FEF are themselves innervated by oculomotor afferents from the intermediate layer of the superior colliculus, the substantia nigra pars reticulata, and the dentate nucleus of the cerebellum.

The FEF is connected with diverse cortical areas. Within the frontal lobe, the FEF is interconnected with the supplementary eye field, with prefrontal areas 46 and 12, and weakly with anterior cingulate area 24 and the postarcuate premotor cortical areas.

The FEF also receives abundant inputs from a multitude of extrastriate visual cortical areas in both the dorsal and ventral streams (Figure 3). In fact, the FEF is unique in the extent of its connectivity with extrastriate visual cortex. Moreover, the FEF provides reciprocal connections to the same diverse areas. Thus, the FEF can influence the activation of neurons in the extrastriate visual cortex. Recent evidence and current models identify the FEF as a source of top-down control on visual processing.

The connectivity of the FEF with visual areas caudal to the central sulcus is topographically organized. The more ventrolateral portion of the FEF, which is responsible for generating shorter saccades, is interconnected with the perifoveal representation in retinotopically organized areas, from areas that represent central vision in the inferotemporal cortex and from other areas having no retinotopic order. In contrast, the mediodorsal FEF, which is responsible for generating longer saccades, is interconnected with the peripheral visual field representation of retinotopically organized areas, from areas that emphasize peripheral vision or are multimodal and from other areas that have no retinotopic order.

Role in Producing Movements of the Eyes

The FEF is a key part of the ocular motor system. Most evidence has been obtained through invasive studies with nonhuman primates, but the human FEF has been located through brain imaging, transdural recording and stimulation, and transcranial magnetic stimulation. The FEF contributes to the generation of rapid saccadic gaze shifts as well as

Figure 1 Stylized lateral view of the frontal cortex: (a) of a macaque monkey; (b) of a human. The macaque arcuate sulcus is opened to expose the frontal eye field (brown) on the rostral bank and the frontal pursuit zone (blue) on the fundus. The human precentral sulcus just ventral to the superior frontal sulcus is opened to expose the frontal eye field (red) on the caudal end of the middle frontal gyrus with the pursuit zone (blue) in the fundus. arc, arcuate sulcus; cen, central sulcus; IFG, inferior frontal gyrus; ifs, inferior frontal sulcus; MFG, middle frontal gyrus; pre, precentral sulcus; pri, principal sulcus; SFG, superior frontal gyrus; sfs, superior frontal sulcus.

slow pursuit eye movements and probably also vergence eye movements. In macaques, the zone contributing to the production of smooth pursuit eye movements is located at the fundus of the sulcus, apparently somewhat separate from the area of the FEF that is involved in saccade production (Figure 1(a)).

Electrical Stimulation

Low-intensity electrical stimulation of the FEF in the bank of the arcuate sulcus in monkeys elicits saccadic eye movements directed contralateral to the stimulated hemisphere. Stimulation of the frontal pursuit zone in the fundus elicits pursuit eye movements directed ipsilateral to the stimulated hemisphere. Currents less than 50 μA are sufficient to elicit eye movements, and the movements begin ~30 ms following the stimulation. The saccades elicited by stimulation of a particular site in the FEF have a particular direction and amplitude that does not vary with the orientation of the eyes in the head. The direction and amplitude of evoked saccades varies gradually as stimulating electrodes are moved through the FEF. The amplitude of the evoked saccade increases laterally to medially along the arcuate sulcus (Figure 4(a)). The FEF also contributes to orienting movements of the pinna in macaques. Recent research has also shown that stimulation of the FEF in monkeys with unrestrained heads can evoke coordinated eye and head gaze shifts.

Inactivation and Ablation

Reversible inactivation of parts of the map in the FEF impairs the production of both visually guided and memory-guided saccades. Monkeys initiate fewer saccades to the retinotopic representation of the inactivated FEF site than to others location in the visual field, and the saccades that are produced are initiated with longer latencies, have lower velocities, and have larger targeting errors than normal. These effects are more pronounced for memory-guided saccades. Also, when tested with memory-guided saccades, monkeys produce more premature saccades to targets in the hemifield ipsilateral to the inactivation. The results from inactivation studies show that the FEF contributes to generating contraversive saccades, especially to locations of remembered targets, maintaining fixation and suppressing inappropriate ipsiversive saccades.

These results complement earlier observations that ablation of the FEF causes an initially severe impairment in saccade production that recovers in some but not all respects over time. If the fundus of the arcuate sulcus is ablated, deficits in pursuit occur; the deficits are most evident in producing pursuit that anticipates the movement of predictable stimuli. Clinical signs of FEF damage in humans include deviation of gaze toward the side of the damage and impaired ability to produce saccades that are more voluntary in character, such as a gaze shift opposite a stimulus (antisaccade) or a saccade to a remembered location.

Functional Brain Imaging

In humans as well as macaque monkeys, the FEFs exhibit increased blood flow and oxygen use when saccadic and pursuit eye movements are produced. The functional magnetic resonance imaging (fMRI) studies locate the human FEF in the precentral sulcus. High-resolution scanning indicates that the upper

Figure 2 Schematic of brain structures and some of the anatomical pathways involved in saccade generation. Visual input from the retina in the eye is transmitted to the lateral geniculate nucleus (LGN) and the superficial layers of the superior colliculus (SCs). The LGN transmits visual signals to primary visual cortex, where processing proceeds through areas in the temporal lobe (such as area TEO) and the parietal lobe (such as area LIP). Extrastriate visual areas are reciprocally connected with the frontal eye field. The frontal eye field is also connected with areas in the frontal lobe such as dorsolateral prefrontal cortex (DLPFC) and the supplementary eye field (SEF). The frontal eye field influences saccade production through projections to the intermediate layers of the superior colliculus (SCi), the basal ganglia, the cerebellum, and the mesencephalic and pontine brain stem saccade nuclei. FEF, frontal eye field; LIP, lateral intraparietal area; TEO, area TEO.

portion of the anterior wall of the precentral sulcus contributes to saccade production and that a deeper region along the anterior wall extending in some individuals to the fundus or even the deep posterior bank of the sulcus contributes to pursuit production. This localization shows a high degree of homology in the organization of the FEFs in humans and macaque monkeys.

Neuronal Recordings

The influence of the FEF on saccade production is mediated by neurons that are activated specifically before and during saccades. Two kinds of neurons that control gaze have been distinguished. In general, movement neurons contribute to gaze shifting and fixation neurons contribute to gaze holding (Figure 5(b)). In other words, an increase in the discharge rate of movement neurons increases the probability that a saccade will be produced. In contrast, elevated discharge rates of fixation neurons occur when gaze is fixed on a stimulus of interest and reduced discharge rate increases the probability of saccade initiation. Current models of saccade production conceive of movement and fixation neurons as producing signals that are in a reciprocally inhibitory relationship.

Neurons in the FEF that generate movement-related or fixation-related activity are located in layer 5 and innervate the superior colliculus and parts of the neural circuit in the brain stem that generate saccades. Indirect evidence suggests that fixation neurons are smaller than movement neurons. Physiological recordings indicate that these neurons, in concert with a network that includes the superior colliculus, produce signals necessary to produce saccadic eye movements.

Fixation neurons are modulated during saccades in all directions. Movement neurons, on the other hand, are active before saccades of a particular range of directions and amplitudes, referred to as the movement field. The movement fields of neurons in the lateral aspect of the FEF are less eccentric and smaller,

Figure 3 Selective summary of connections of the frontal eye field with extrastriate visual cortical areas. Red lines indicate connections of the ventrolateral frontal eye field in area 45, and blue lines mark connections of the dorsomedial frontal eye field in area 8Ac. Also indicated schematically are connections with belt and parabelt auditory areas (Aud). LIP, lateral intraparietal area; MT, middle temporal area; TE, area TE; TEO, area TEO, V4, area V4.

and movement field eccentricity and size increase medially in the FEF. In direction relative to current fixation, the movement fields are Gaussian shaped. In amplitude, they exhibit a log-Gaussian shape; this means that the outer border of the receptive field extends further than the inner border from the point of peak activity. The more eccentric the movement field, the further the outer border extends. This arrangement corresponds to the mapping of the visual field in the visual pathways and the mapping of saccade direction and amplitude in the superior colliculus.

Saccades are initiated when the activity of fixation neurons decreases and the activity of movement neurons reaches a threshold (Figure 5(b)). Variability in saccade latency can be accounted for by the time taken to reach this threshold. In general, the form of the activation of these neurons in the FEF corresponds to diffusion processes employed in models of response time. If an interrupting stimulus occurs, saccade preparation is canceled if and only if the activity of these neurons is reduced and prevented from reaching the threshold.

Each movement of the eyes causes a shift of the retinal image. A long-standing problem has been understanding how the brain registers whether a movement in the retinal image is due to a movement in the world or a movement of the eyes. The FEF may contribute to maintaining an up-to-date representation

Figure 5 Target selection and saccade preparation by neurons in the frontal eye field: (a) performance of a visual performance task; (b) location and some neural constituents of the frontal eye field and graphs of modulating discharge rates of the main types of neurons found in the frontal eye field. In the visual search task in (a), the gaze must be shifted directly to the uniquely colored target among distractors. Targets for saccades are selected by the pattern of activity of visually responsive neurons in the frontal eye field as part of a distributed network. In (b), the frontal eye field is shown to be distinguished from the surrounding cortex by the large pyramidal cells in layers 3 and 5. In layer 5, pyramidal cells vary in size from smaller to larger. It is likely that each morphological cell type corresponds to a different functional cell type, as indicated in the graphs. The top neural activity graph illustrates the response to the target in the receptive field (thicker solid line) and the response to a distractor (thinner dotted line), superimposed for comparison. After around 100 ms, a selection process transpires that results in an accurate representation of the location of the target that can be used to guide saccade generation. Saccades are produced when the activity of gaze-holding fixation neurons in the frontal eye field, as part of a network, decreases while the activity of gaze-shifting movement-related neurons in the frontal eye field, as part of a network, increases to reach a fixed threshold. Variability in the time of initiation of the saccade originates in the variable time taken for the activity to increase to the threshold. The relation of activity in the frontal eye field to saccade latency is illustrated by portraying activity on trials with shorter (thin) and longer (thick) saccade latencies.

of eye orientation in the head. This is necessary to direct the gaze correctly when confronted with unexpected perturbations resulting in a mismatch between the retinal locus of a target and the angle of the saccade needed to fixate that target.

Role in Selecting Targets and Allocating Attention

Since the discovery of the FEF, research has focused on the contributions of the FEF to the generation of movements of the eyes. In the last 10 years, a wealth of data has demonstrated that the FEF contributes, as well, to the allocation of covert attention.

Neuronal Recordings

By far, most of the neurons sampled by extracellular recordings in the FEF have visual responses. The neurons are not selective for stimulus features except for some particular exceptions (noted later). The receptive fields of FEF neurons are restricted primarily to the contralateral hemifield and scale in size with

Figure 6 Timing across the visual pathway. Cumulative distributions of visual response latencies are compared for neurons in the magnocellular layers of the dorsal lateral geniculate nucleus (mLGN), neurons in the parvocellular layers of the dorsal lateral geniculate nucleus (pLGN), primary visual cortex (V1), middle temporal visual area (MT), frontal eye field (FEF), visual area 2 (V2), and visual area 4 (V4).

eccentricity. Less eccentric receptive fields are smaller than more peripheral receptive fields. The FEF has a rough map of visual field eccentricity with the central visual field represented laterally and progressively more eccentric visual field represented more medially (Figure 4(b)). This topography arises from the pattern of inputs from the extrastriate visual cortex.

The visual responses occur with latencies comparable to those observed in most extrastriate visual areas, averaging around 70 ms (Figure 6). Furthermore, the neural signals occurring in the FEF coincide with identical signals occurring in a network of interconnected structures, including the superior colliculus and posterior parietal cortex. Recent evidence indicates that FEF neurons may exhibit some selectivity for disparity and direction of motion. Some neurons in the FEF also respond to acoustic stimuli located preferentially in the contralateral hemifield. These responses contribute to orienting to sound sources.

The FEF contributes to selecting the target and shifting attention before gaze shifts, both saccadic and pursuit. In macaque monkeys trained to shift gaze to the odd-ball target in visual search arrays, most visually responsive cells in the FEF responded initially indiscriminately to the target or the distractor of the search array in their receptive field because neurons in the FEF are not intrisinically feature selective (Figure 5(a)). However, before the eyes move, a selection process transpires by which most visually responsive cells in the FEF signal the location of the target stimulus through suppression of the response to nontarget stimuli, leaving only the neurons responding to the target active.

This target selection process occurs if no saccade is made and the target location is signaled by a manual response. The selection process also occurs even if the saccade is directed to a nontarget stimulus. The selection process is influenced by the similarity of the target and nontarget stimuli; if the target is more difficult to distinguish from distractors, then the selection process takes more time and accounts for more of the variability of saccade latency.

The target selection process is influenced by knowledge of target properties acquired over preceding trials or sessions. At one extreme, if monkeys are trained exclusively on one target–distractor pairing, then many neurons in the FEF can appear to acquire immediate selectivity for the overpracticed target. At the other extreme, if monkeys perform a search for one target–distractor pair (e.g., red among green) and then switch to the opposite pair (green among red), they are slower and more error-prone on the first few trials after the switch. Concomitantly, the target selection process in the FEF is later and less certain on the first few trials after the switch.

To investigate more directly the relationship between the allocation of attention and preparation of a saccade, it is advantageous to dissociate at least momentarily the focus of attention from the endpoint of a saccade. This can be accomplished by training macaque monkeys to perform a visual search for an attention-capturing pop-out color target in a search array and then shifting gaze either toward (prosaccade) or opposite (antisaccade) the pop-out target, according to its orientation. Most visually responsive neurons in the FEF initially select the pop-out target while attention is allocated to distinguish its shape, but then these neurons display a strong modulation of the discharge rate whereby they come to select the ultimate endpoint of the saccade. This modulation can be identified with the shift of attention from the pop-out target to the endpoint of the saccade preceding the gaze shift.

These observations motivate the hypothesis that attention is allocated when and to the extent that these neurons in the FEF (and elsewhere in a coordinated network) are active for an object at one (as opposed to any other) location in the visual field. Mechanistically, it can be surmised that these neurons in the FEF (and elsewhere in a coordinated network) make up a salience map guiding covert and overt orienting.

Functional Brain Imaging

Numerous fMRI studies have demonstrated that the FEF and surrounding cortex are involved in the allocation of spatial attention. In fact, current thinking holds that the FEF and areas in posterior parietal cortex make up a network that mediates covert and overt orienting. However, the frontal and parietal areas have distinct roles with the FEF, concerned more with encoding the target of the saccade as such and preparing to execute the saccade, and the parietal cortex, concerned more with representing the visual stimuli.

Several studies have demonstrated the involvement of the FEF in both top-down and bottom-up control of attention. These studies present a cue (such as a small arrow) that instructs observers about some aspect of the forthcoming stimulus (such as the location or visual feature of a target stimulus). While attention is allocated in preparation for the stimulus, activation is observed in the FEF, predominantly in the hemisphere contralateral to the attended location. Studies have also demonstrated fMRI activation in the FEF of participants searching for salient stimuli. Activation is also observed in the FEF when participants maintain a working memory representation. The area of activation overlaps substantially with that activated when saccades are produced.

Inactivation and Ablation

A role for the FEF in the cognitive operations of working memory and allocation of attention is also shown by the effects of ablation or inactivation. Ablation of the FEF in monkeys results in severe deficits in locating a target presented among distractors or maintaining a representation of target location during a delay period. Reversible inactivation of the FEF impaired their detecting a visual target presented among distractors when no eye movements were permitted.

It should be noted that the effects of inactivation of the FEF on search performance are notably different from those seen following inactivation of the lateral intraparietal area in the posterior parietal cortex. Whereas inactivation of the lateral intraparietal area produced deficits that varied in magnitude with task difficulty, inactivation of the FEF produced severe deficits in visual search for single targets that were easy or hard to distinguish from the distractors as well as in search for a target defined by a conjunction of features.

Electrical Stimulation

The contribution of the FEF and surrounding cortex to the allocation of spatial attention has been shown very convincingly using intracortical electrical stimulation in monkeys and transcranial magnetic stimulation in humans. In monkeys trained to locate a single target among conspicuous distractors, stimulation of the FEF increased the probability of locating the target if it was located within the movement field of the site of stimulation. Other work has indicated that this influence may be mediated through a direct influence on the activation of neurons in visual area 4 (V4). In humans, transcranial magnetic stimulation over the FEF can affect attention allocation and awareness of stimuli. Curiously, these effects in humans tend to be specific to the right hemisphere.

These results have been cited in support of the premotor theory of attention, which states that shifting visual spatial attention corresponds to preparing a saccade. The FEF is an ideal region in which to test this theory, being a central node in the network that selects targets and produces saccades. As previously described, the focus of attention can be dissociated momentarily from the endpoint of a saccade when monkeys search for an attention-capturing pop-out color target in a search array and then shift gaze either toward (prosaccade) or opposite (antisaccade) the pop-out target according to its orientation. An experiment used this task and probed the evolution of saccade preparation by measuring the direction of saccades evoked by intracortical microstimulation of the FEF at different times following the search array. The saccades evoked on prosaccade trials deviated progressively toward the target that was the endpoint of the saccade. However, the saccades evoked on antisaccade trials deviated not at all toward the pop-out target but only toward the ultimate endpoint of the saccade opposite the singleton. Recall that, on antisaccade trials, the most visually responsive neurons in the FEF initially select the pop-out target while attention is allocated to distinguish its shape. In contrast, movement neurons are activated but do not produce a directional signal until immediately before the saccade is made. Thus, the FEF can covertly orient attention without preparing a saccade to the locus of attention. These results indicate that the premotor theory of attention must be revised.

In summary, the FEF was discovered over a century ago when it was found that electrical stimulation elicited movements of the eyes. Today, electrical

stimulation of the FEF confirms that it contributes significantly to overt orienting through gaze shift and also to covert orienting through attention shifts.

Introduction

This article describes the functions associated with the frontal lobes, particularly as demonstrated by studies of patients with focal brain lesions. Modern neuroscience is overwhelmingly dominated by functional imaging studies in normal subjects, but functional imaging can only demonstrate, or in some cases only imply, a role for a region in a particular, often very narrowly defined cognitive task. Lesion studies are an essential counterbalance to functional imaging as the only mechanism to identify areas that are necessary for specific functions. Lesion studies have, however, often been hampered by sweeping up an amorphous and varied group of deficits, including cognitive, affective, comportment, and personality changes, under the term 'frontal lobe syndrome' as though there were a single frontal lobe syndrome that only varied in severity. The notion of a unitary frontal lobe syndrome, based solely on the coarsest anatomical distinctions, evolved at a time when lesion location was not easily specified and often in patients who were examined at a later stage of disease. The unitary syndrome notion was not strongly influenced by the observations that it could include diametrically opposite properties: patients could be impulsive or apathetic, distractible or perseverative, restless or bradykinetic, and so on. In recent years, the clinical research focus has changed from a concentration on the anatomical basis of the disordered cognition or behavior to an emphasis on the functional nature of those impairments under the supraordinate label of 'dysexecutive' disorder, but attribution of the dysexecutive syndrome to lesions of the frontal lobes has always been clear, although usually only implied and not demonstrated. This switch to a functional definition has its own problems. It, too, was often seen as a unitary disorder, and many, possibly most, patients with executive impairments did not have lesions restricted to frontal structures. In fact, many had disorders such as depression, sleep apnea, concussions, chronic pain, and other problems not easily tied to a structural injury of the frontal lobes. Although clinical neurology and neuropsychology are still quite tied to the concepts of frontal lobe syndrome and dysexecutive disorder, clinical research has increasingly demonstrated that specific, highly differentiated cognitive, motivational, behavioral, and attentional deficits are associated with discrete regional frontal injuries.

Our analysis suggests that frontal lobe functions fall into four distinct categories, each associated with a different frontal region. Only one of these categories is truly 'executive.' The other three categories cannot be subsumed under the common understanding of executive functions. Executive functions are best understood within a model of higher level attentional abilities. The executive functions are associated with discrete regions within the frontal lobes. We conclude that there is no single frontal system and not even a single frontal executive system and, thus, no undifferentiated frontal lobe or dysexecutive syndrome. There are domain general executive functions, each with a specific regional frontal basis, that are recruited over time in response to contextual demands.

There are four sections to this article. The first summarizes the anatomy and pathophysiology of the frontal lobes to provide a context for understanding research in frontal lobe functions. The second defines the proposed four categories of frontal lobe functions, with an emphasis on the one category most consonant with the term executive. The third section describes the interactive relationship between the executive functions and between executive functions and the other categories of frontal functions, emphasizing the organization of networks of processes and the unfolding of processes in time. We conclude with a brief description of the potential treatment of patients with frontal lobe damage.

Anatomy and Pathophysiology

The frontal lobes are the regions anterior to the Rolandic fissure and superior to the Sylvian fissure. They constitute one-fourth to one-third of the human brain. This article focuses on the prefrontal cortex, the area rostral to primary motor (Brodmann area 4, generation of movement) and premotor (Brodmann area 6, programming of sequential movements) cortex. The prefrontal cortex can be roughly subdivided into regions in which adjacent Brodmann area regions have similar connectivity patterns: lateral (dorsolateral: 9, 46, and perhaps 8; ventrolateral: 44, 45, and lateral 47/12), orbitofrontal (11–14; and orbital 47/12), polar (area 10), inferior medial (ventral anterior cingulate and paracingulate 24, 25, and 32), and superior medial (8, 9, dorsal anterior cingulate 24, 32, and perhaps including supplementary motor

Figure 1 Depiction of the different regions within the frontal lobes.

area 6) (Figure 1). Only the lateral regions show strong functional hemispheric asymmetry.

The prefrontal cortex has strong reciprocal connections with virtually all other cortical regions. The specific patterns of connectivity determine the roles of different prefrontal regions in integrating and influencing all types of mental operations, cognitive and affective. In addition to functionally relevant cortico-cortical connections, there are parallel but independent frontal–subcortical circuits. The circuits are functionally distinct, and damage to any part of a circuit may produce similar discrete functional impairments. These may be more pervasive than suggested by cortical lesion alone and may be significant even in the absence of cortical lesions.

With the possible exception of early frontal–temporal lobe degeneration, there is no natural clinical condition in which pathology only involves the frontal lobes, but almost any neurological disease may preferentially affect the frontal lobes. Each has specific advantages for illuminating frontal functions.

Infarction is most common. Because infarcts are almost always unilateral and lesion boundaries are sharp, infarcts have always been the 'preferred' pathology for clinical–anatomical studies. Anterior cerebral artery (ACA) territory infarction can involve the orbital cortex, the frontal pole, the anterior cingulate, and/or the supplementary motor area. Bilateral lesions may be more frequent with ACA infarction since both ACAs may originate from a common internal carotid artery. Involvement of the anterior corpus callosum aggravates deficits caused by damage to the medial frontal cortex. Rupture of an ACA aneurysm is a common cause of ACA infarction. The perforator branches of that vessel supply the septal nuclei, and infarctions may cause significant limbic dysfunction including memory impairment. The vascular territory of the recurrent artery of Heubner includes the 'limbic caudate' and the inferior anterior limb of the internal capsule, which contains thalamofrontal connections. Middle cerebral artery (MCA) territory infarcts can involve significant regions of the dorsolateral and ventrolateral frontal convexity. Since MCA infarcts are not often restricted to the frontal lobes, care must be taken to demonstrate lesions restricted to frontal regions when studying the effects of MCA infarcts. If the lenticulostriate branches of the MCA are affected, the dorsolateral caudate, dorsolateral anterior limb of the internal capsule, and the putamen may also be damaged. Deep frontal white matter lesions can also affect the interconnection between prefrontal cortex (undamaged) and connected regions (e.g., posterior cortex and fibers of passage from ipsilateral medial frontal lobe and the contralateral frontal lobe).

Intracerebral hemorrhages do not necessarily follow vascular territories, potentially resulting in more anatomical variability than infarctions. Hemorrhages may also complicate behavior–lesion studies because of mass effects, secondary herniation damage, and hydrocephalus. Nevertheless, the potential involvement of combinations of structures not involved in infarctions indicates that hemorrhage cases can be of importance for brain–behavior studies.

Tumors can unilaterally infiltrate the frontal lobe, and as with hemorrhages they may produce a much wider range of combinations of regional injury than infarcts. Not all types of tumors are suitable for brain–behavior correlation study (e.g., rapidly growing intracerebral tumors (gliomas)) because of mass effects and uncertain margins of lesion. Relatively benign primary tumors (ependymomas, oligodendrogliomas, cystic astrocytomas, etc.) that have been excised may provide useful correlations. Extracerebral tumors (meningiomas) may cause considerable cortical impairment by compression and vascular compromise. Both of these tumor types are most informatively studied after resection, and only postoperative neuroimaging can define the areas of damaged brain.

Traumatic brain injury results in two broad categories of brain damage: diffuse axonal injury (DAI) and focal cortical contusions (FCCs). Although much DAI pathology is located in the deep frontal white matter, the widespread nature of DAI hinders demonstration of specific frontal–behavioral relationships. FCCs, on the other hand, may be appropriate for analysis of specific frontal–behavioral relationships provided that there is strong evidence that DAI is relatively modest (e.g., short duration of posttraumatic amnesia). Indeed, inclusion of such patients may be the only way to assess involvement of basal/polar frontal regions. Gunshot or other penetrating head wounds almost routinely produce unusual patterns of brain damage. Diffuse effects may be difficult to measure.

Many other disorders may affect the frontal lobes directly or disrupt the subcortical connections of frontal systems. Herpes simplex encephalitis and frontotemporal dementia commonly involve discrete frontal regions, but usually with extensive temporal injury as well. Large vessel and small vessel vascular diseases, hydrocephalus, and multiple sclerosis produce considerable white matter damage but rarely restricted to the frontal lobes. There are degenerative diseases with a predilection for subcortical structures that are critical components of frontal systems – Parkinson's disease, Huntington's disease, and progressive supranuclear palsy – but pathology is not restricted to these structures and is difficult to specify in life. Since many of these disorders involve multiple brain regions, they are not optimal for analysis of specific functions of the frontal lobes.

For much of the history of neuropsychology, strategies for lesion localization were fairly primitive, often analyzing case material only by frontal/posterior or right–left–bilateral frontal distinctions. In recent years, a variety of different procedures have evolved that sharpen frontal functional/anatomical correlations. Dividing the patients into those with and those without impairment in comparison to the control group and analyzing lesion site differences, either by simple overlaps or by lesion size within site correlations, have been fruitful. The classification and regression tree is a technique that can be used to divide patients based on their performance on a dependent variable into anatomically diverse groups. The performance groups are then analyzed for lesion region differences. 'Hotspotting' requires mapping the lesion of each patient onto an architectonic map. Then, for a defined dependent measurement (e.g., performance on a specific task), all individuals who have damage in a specific architectonic region are compared to all those who do not have damage in that area. This effectively identifies which region (or regions) results in most impairment of that particular process. This procedure requires experimental isolation of the specific process being studied and evaluation of a relatively large number of patients with focal lesions. The end result of fractionation of frontal processes is not phrenology but the identification of specific regions involved in simpler processes as a first step in understanding the unfolding of these abilities in more complex tasks and in real time.

Functional Domains within the Frontal Lobes

The existence of distinct functional domains within the frontal lobes is supported by evidence from developmental, anatomical connectivity, and lesion effects. The human cortex develops from two discrete sources. The lateral prefrontal cortical cortex (LPFC) has developed from hippocampal, archicortical sources. It determines spatial and conceptual reasoning processes. The ventral (medial) prefrontal cortex (VPFC) has evolved from paleocortical sources. It is associated with emotional processing, including the acquisition and reversal of stimulus–reward associations. These two broad developmental divisions form the two major (executive cognitive and behavioral/emotional self-regulatory) functional divisions within the frontal lobes and map onto two of the three proposed frontal–subcortical circuits involved in cognitive and/or emotional processing. Another frontal system is determined by the unique convergence of sensory and

limbic input combined with a distributed frontal output. This characterizes the medial frontal structures that are uniquely placed for regulating energization of all cognitive activities. The final category of frontal functions (metacognitive) is suggested by research on higher order integrative functions of the frontal polar area 10. Some authors use the term 'executive' for all four of these functional domains, but, as described later, we consider this inappropriate.

Regulating Energization

Energization of cognitive functions is important for adequate performance of any function. (This is commonly called activation, but this term has come to have multiple meanings – psychological, vascular, imaging, etc. – and we prefer energization.) Extensive damage to more superior medial (anterior cingulate and superior) frontal pathology results in abulia or severe apathy or, at its worst, akinetic mutism. This lack of energization of activity, defined by a diminished capacity to generate and maintain actions of mental processes, can be demonstrated even in much less clinically obvious cases. Patients with damage in this region are slow in generating lists of words (particularly in the first 15 s); have notably slower reaction time (RT), particularly if tasks are more demanding; are deficient in maintaining over time the benefit of a warning stimulus; and have problems maintaining a selected target such as in the Stroop interference test. RT speed is correlated with functional activation in the same superior medial region. Verbal fluency and the Stroop task are commonly used in the clinical setting to assess energization, but they do not isolate this deficit because they are not specific and require other cognitive (often executive) abilities. Perhaps the best measures to evaluate impaired activation are demanding reaction time tests.

Executive Cognitive Functions

Executive cognitive functions are defined as, and the definition is limited to, those high-level cognitive functions that require control and direction (e.g., planning, monitoring, activating, switching, and inhibiting) of lower level, more automatic functions. Much of the research on executive functions in neuropsychological studies has demonstrated deficits in patients with primarily LPFC damage. Tests commonly used by many clinicians as measures of frontal lobe executive functioning include the Wisconsin Card Sorting Test, Trail Making Test Part B, the Stroop Interference subtest, and specific measures within verbal fluency tasks. These tests are indeed more sensitive in general to focal LPFC (and also not generally to orbitofrontal/ventral medial) pathology and fall within the classification of tests of 'executive cognitive' processes. However, the tests are complex and multifactorial, and individuals can fail for many reasons.

Significant efforts have been made to develop and evaluate tests that more precisely isolate specific executive processes. Structured RT tasks that isolate discrete performance measures have identified specific dissociations of executive cognitive functions. Two major dissociations of executive cognitive functions within the dorsolateral prefrontal regions have been demonstrated. Impaired task setting has been related to left lateral frontal lobe damage, particularly ventrolateral. This has been shown as impaired bias in a feature integration task (errors are primarily false positives) and as significantly increased errors in the first block of 100 trials in a concentrating task requiring rapid stimulus–response matching. This deficient task setting is domain general; that is, deficits can be seen in any task, not just in RT tasks. For example, in a word list learning task, patients with left frontal damage had increased false positive errors in memory recognition.

The right lateral frontal area, on the other hand, is important in monitoring. Damage in this region results in several types of deficits that are attributable to deficient monitoring: as increased errors of all types in a complex feature integration task, indicating a problem in monitoring the difference between targets and nontargets (i.e., impaired sensitivity); as an abnormal foreperiod effect – that is, an increase in RT with longer interstimulus intervals, rather than the normal decrease in RT, suggesting a deficiency in monitoring the occurrence of stimuli over time; and as significantly increased variability of timing performance in a tapping task.

The mechanisms behind this top-down within-subject (intra-individual) variability of performance both within a testing session and across sessions appear to be the same attentional mechanisms evidenced by other RT measures – that is, task setting, monitoring, and energization. As would be expected of impairment in domain general abilities, such intra-individual variability can be seen in other tasks such as memory.

There are efforts to bridge the gap between laboratory tasks of executive cognitive functions and everyday functioning with the investigation of naturalistic actions under controlled conditions. Since 'real-life' measures are more complex and require the involvement of multiple functional systems, these measures overlap with behavioral/emotional self-regulatory measures.

Behavioral/Emotional Self-Regulatory Functions

The VPFC region is involved in emotional processing. An important, and natural, role for the VPFC, because of its involvement in reward processing, is behavioral self-regulation required in situations in which cognitive analysis, habit, or environmental cues are not sufficient to determine the most adaptive response. Patients with damage to the inferior medial frontal cortex have difficulty in understanding the emotional consequences of their behavior, despite intact performance on commonly used neuropsychological tests of executive functioning. Assessments of these abilities tend to be more experimental in nature, and they include gambling tasks and naturalistic multiple subgoal tasks.

Because of the role of the ventral prefrontal cortex in emotional processing (basic drives and rewards that inform and direct high-level decision making), tests assessing the acquisition and reversal of stimulus–reward associations can be used. This reversal learning (interpreted as affective) is dissociable from the impairment in attentional (extradimensional) set shifting found after LPFC lesions, reinforcing the distinction between executive attentional and affective/emotional behavioral measures.

The VPFC is also involved in higher level decision-making tasks involving reward processing in unstructured situations, such as the gambling task that has been suggested as both sensitive and specific to VPFC lesions. However, as with many neuropsychological tests, further evaluation suggests that these tests may also be multifactorial in nature, and the true behavior/anatomy specificity remains to be determined. Decision-making performance on the gambling task has been dissociated from deficits in working memory and inhibition.

A broad term to encompass the type of deficits observed on the gambling task is 'self-regulatory disorder,' defined as the inability to regulate behavior according to internal goals and constraints particularly in less structured situations. Qualitative descriptions with naturalistic multiple subgoal tasks, and paper-and-pencil laboratory versions, have been developed. There are also efforts to develop various scales of behavioral dyscontrol or assessment of frontal lobe personality characteristics.

Metacognitive Processes

The fourth category of frontal function is related to the frontal polar region, Brodmann area 10, although there is still debate as to how much this functional category is associated with damage to a more general area including the anterior medial regions. This frontal region appears to be maximally involved in the metacognitive aspects of human nature: integrative aspects of personality, social cognition, autonoetic consciousness, theory of mind, humor appreciation, and self-awareness. Self-awareness implies a meta cognitive representation of one's own mental states, beliefs, attitudes, and experiences. This self-reflection is key to understand the relationship of one's own thoughts to external events and, from this self-knowledge, to understand the mental states of others. This ability to make inferences about the world, and to empathize with others, allows correct interpretation of events and correct social judgments. Family reports often precisely describe the changes in behavior that have occurred: lack of empathy, unconcern, and inability to appreciate humor that requires self-reflection (appreciation of slapstick humor may be intact).

Because area 10 is among the most recently evolved of human brain regions, it may be uniquely positioned to integrate the higher level executive cognitive functions and emotional or drive-related inputs. This bridging of behavioral self-regulatory and executive cognitive functions may be the neural basis for their role in metacognitive functions. There is evidence, however, that there are potential dissociations within this domain, and that metacognitive processes are not reducible to these other functions.

The neuropsychological assessments in this category of frontal lobe functions are generally experimental. They include reactions to verbal and cartoon humor, visual perspective-taking tasks, and comparison of performance on remember–know memory tasks. For some individuals, however, these tasks can be solved on the basis of factual knowledge, not inference. Moreover, the relationship of process to anatomy is not certain, and it may depend on the differential demand of different tests within the overall 'metacognitive' rubric.

The general localization of the four separable frontal lobe processes is depicted in Figure 2.

Networks and Integration in Time

The evidence for fractionation of the functions of the frontal lobes does not imply that frontal lobes are simply a series of independent processes. Depending on task demands, there is the fluid recruitment of different processes anywhere in the brain into different networks. Lesion research demonstrates the effect of impairment in the networks; functional imaging demonstrates the recruitment of processes. For some task demands, one or more anatomically distinct frontal processes may be recruited. In tasks with simple demands, the more automatic nonfrontal processes function independently; as task demands increase or

Figure 2 Illustration of three of the four major anatomical regions within the prefrontal cortex related to the different functional categories within this brain region. The four categories are energization (superior medial), executive (lateral), behavioral/self-regulatory (inferior medial; not illustrated), and metacognition (polar). Two executive processes are illustrated, one related with the left lateral region (task setting) and the other with the right (monitoring).

alter, there may be increased involvement of different frontal (more 'strategic') regions, even to the point where it appears all frontal regions are involved. In other demands the network may function 'top-down.'

These networks function in real time. Language provides one example. To request an object, answer a simple question, or tell a familiar story require essentially no control or monitoring and these presumably occur with no executive processes required. To give a complicated response to a difficult question will require more control. To tell a complex narrative – deciding what to include, what the listener may already know of the story, what is socially appropriate to include for a particular audience, and to keep track of the goal of the story while adding a critical digression – will require substantial executive control. Setting the task goal, monitoring the content and the listener, and sustaining and maintaining intention are essentially dependent on the several functions described previously. They are recruited at different levels, at different times across the task, and they in turn recruit a variety of posterior cognitive operations, each at a specific point in the narrative. Multiple executive processes, each primarily dependent on a specific frontal region, must be knitted together in real time.

Rehabilitation

There are no class I randomized controlled trials of executive rehabilitation in focal frontal patients, although there are a few studies on patients with traumatic brain injury, primarily DAI. Clinical treatments have been targeted at the disability level of rehabilitation, not at specified frontal lobe impairment. Three types of treatments have been utilized, individually or alone, with some success:

Drugs. Stimulants may help patients with low arousal states or who are easily distracted. Dopaminergic agents may help patients with poor activation (energization).

Cognitive. A few theoretically sound programs addressing 'executive dysfunction' have demonstrated some possible efficacy. These techniques often rely on training patients to stop before they begin a task (inhibit impulsive responses), then explicitly define goals (set task requirements), check off performance as they progress (monitor subgoals), and confirm appropriate completion (compare goal to outcome). Each step in this treatment would appear to be directed at a specific executive or self-regulatory factor of frontal function, but no study has yet assessed the specificity of treatment effectiveness.

Behavioral self-regulation/self-awareness. There have been successful efforts to improve self-awareness. It is uncertain how much of this is dependent on the environmental support provided to the patient.

Compensatory. Commonly, environmental compensation has focused on a limiting disability or handicap, resulting in greater functional independence. These programs make, appropriately, no claims for directly treating executive dysfunction.

Conclusion

Prior to the availability of computed tomography scans, patients with frontal lobe lesions were often not identified until clinical signs were well advanced, and by the time of identification, many patients had lesion extension into brain regions outside the frontal lobes or had extremely large frontal lesions or both. Patients' deficits were often characterized only with behavioral descriptions or with multidimensional tests that have high sensitivity but low specificity for frontal injury. The historical notions of the frontal lobe syndrome come from observations of such patients. In the past 25 years, early diagnosis, precise lesion definition, and a broad range of specific and sensitive tests of regulation of attention, discrete executive functions, self-regulatory behaviors, and empathy and social awareness have combined to provide a much more precise understanding of the many consequences of specific frontal injuries and have made it clear that there is little evidence of a single frontal lobe or dysexecutive syndrome.

Functional Amnesia

M Kritchevsky, San Diego VA Healthcare System, San Diego, CA, USA

Published by Elsevier Ltd.

Introduction

Functional amnesia is an uncommon condition in which patients develop severe retrograde amnesia in the absence of significant anterograde amnesia and without any known brain injury or disorder. This nonneurological syndrome is variously referred to as psychogenic amnesia, hysterical amnesia, dissociative amnesia, and functional retrograde amnesia. Functional amnesia is easily distinguished from the neurological amnesic syndrome that is commonly seen with dysfunction of bilateral medial temporal lobe or bilateral medial diencephalic structures important for memory, in which patients have severe anterograde amnesia with variable retrograde amnesia. In contrast, functional amnesia may be indistinguishable from malingered amnesia. Functional amnesia is the disorder of memory that is most commonly popularized in literature and film, and it appears to be the condition that the majority of lay persons regard as amnesia.

Early descriptions of functional amnesia included large numbers of cases that were characterized primarily by a loss of personal identity. Memory for previously known facts and personal events sometimes was noted to be impaired as well. In 1982 the first case of functional amnesia that had been formally studied with neuropsychological testing was published. Subsequently many additional case studies have been described. In 2004 the first series of patients with functional amnesia who had been studied clinically and neuropsychologically in a systematic fashion was reported. The increasing understanding of functional amnesia has facilitated diagnosis of this condition, but treatment of many patients with functional amnesia has remained difficult.

Clinical Characteristics of the Patient with Functional Amnesia

The Clinical Picture of the Patient

The typical patient with functional amnesia presents with the sudden onset of retrograde amnesia without clinically significant anterograde amnesia. Most commonly, the retrograde amnesia affects all of the memories that occurred prior to the onset of amnesia, including memory for personal identity. Thus, the patient reports that he or she cannot remember their past. They do not know their name, where they were born, or where they were raised. They can not recall where they went to school, when or to whom they were married, where they live, or by whom they are employed. Once their identity is discovered, they do not recognize their name. When they meet their friends and family, they do not recognize them. In general, the loss of past memories affects public as well as personal material. For example, the patient will not recall or recognize previously known public figures such as sports figures, movie stars, and political leaders. They will not recall or recognize previously known public events such as wars or national disasters. Because the person with functional amnesia has no significant anterograde amnesia, they are able to relearn past memories. However, these newly learned memories typically have no sense of familiarity to them.

Uncommonly, the patient with functional amnesia has retrograde amnesia that affects only a period of time before the onset of memory loss. For example, if the period of amnesia is 2 years, then the patient will not recall or recognize memories that occurred during the 2-year period before the onset of amnesia. The patient will know their name and will have normal recollection of memories that occurred more than 2 years ago. However, he or she will give the year as 2 years earlier than the correct year, and will report their marital status, place of residence, and workplace as they were 2 years previously despite any significant changes that may have occurred since. The patient can relearn past memories, but the new memories will not have a sense of familiarity.

The patient with functional amnesia most often will report a complete loss of memories from the period of retrograde amnesia. However, on occasion a patient will be aware of one or more vague and incomplete memories from the period of amnesia.

At about the time of onset of functional amnesia, many patients have one or more abnormalities, in addition to the amnesia, that also appear to be psychogenic. These have included inability to name objects, inability to name numbers, difficulty with calculations, loss of ability to read and write, inability to move the eyes voluntarily during formal testing, bilateral leg weakness with inability to walk independently, weakness on one side of the body, and an inability to carry out previously familiar activities such as using a telephone or driving a car with a manual transmission. One patient has reported that he had to relearn the English language by reading a dictionary during the first 2 days of his amnesia. Another has reported that she could

no longer remember the Spanish language, though she had been bilingual prior to the onset of her amnesia. With regard to anterograde amnesia, patients characteristically have good memory for events that occurred after the onset of amnesia. One patient has reported difficulty with new learning, and on neurological examination was poor at learning new verbal, but not nonverbal, material. However, like other patients with functional amnesia, he did not appear to be forgetful.

Occasionally, a patient with functional amnesia will present immediately after a period of sudden and unexpected travel during which they appear to have exhibited normal behavior. The period of travel is termed a fugue state, and whatever occurred during the fugue state will be included in the period of retrograde amnesia.

Risk and Precipitating Factors

Many patients with functional amnesia have significant premorbid psychiatric histories, including one or more of the following: alcohol abuse, other substance abuse, previous conversion symptoms, anxiety disorder, posttraumatic stress disorder, schizophrenia, depression, history of suicide attempt, and histrionic or borderline personality disorder. Many patients with functional amnesia have one or more of the following possible precipitating factors at the onset of amnesia: intoxication with alcohol, mild closed head injury, active depression, psychological stress, and involvement or alleged involvement in illegal activity.

Clinical Course

The clinical course of patients with functional amnesia is highly variable. Some patients appear to have a full recovery of their retrograde amnesia. In these cases the recovery most often occurs gradually over days to weeks. The recovery most often appears to consist of the gradual return of memories from throughout the period of amnesia. Rarely, the amnesia appears to resolve suddenly. Many patients have only a partial recovery of their lost memories. Sometimes this involves partial but incomplete recovery of memories from throughout the period of memory loss. In contrast, at times the initially extensive retrograde amnesia appears to shrink over a period of months to a shorter period of retrograde amnesia for a period of time (e.g., 6 months) immediately preceding the onset of amnesia. Some patients with functional amnesia report that they experience little or no recovery of their lost memories over an interval as long as 42 months. Patients who experience no significant recovery of memory occasionally appear to have established new personalities. It appears to be very uncommon for functional amnesia to suddenly and completely resolve in association with a mild head injury or a psychological catharsis.

The recovery of lost memories sometimes appears to have been facilitated by reacquainting the patient with their past, or by addressing and initiating treatment for ongoing psychological stressors. Also, sometimes hypnosis or an amobarbital interview appears to facilitate the recovery of lost memories. Memories initially remembered with these therapies sometimes are again inaccessible immediately following the session, but then rapidly return in the following days.

Recovery from retrograde amnesia should be distinguished from relearning lost memories. The patient with functional amnesia usually will report with confidence that a particular memory was relearned. They sometimes will recall the event of relearning and usually will report that the memory feels new and is unassociated with the familiar feel of an old memory.

Additional psychogenic cognitive deficits that are associated with the retrograde amnesia often resolve within hours to days of onset. General neurological deficits, particularly weakness, of psychogenic origin may persist throughout the course of the amnesia.

Laboratory Tests

In patients with functional amnesia, structural neuroimaging tests such as computed tomography (CT) and magnetic resonance imaging (MRI) brain scans are usually normal, though they occasionally show abnormalities unrelated to the functional amnesia. Electroencephalography also is usually normal, but may show abnormalities that are unrelated to the amnesia. Functional neuroimaging tests such as single-photon computed tomography (SPECT), positron emission tomography (PET), or functional MRI brain scans have been reported to show abnormal findings related to the retrograde amnesia in some patients. The findings have not been consistent in the different patients studied. Although the demonstrated functional abnormalities may be related to the patients' retrograde amnesia, the presence of such abnormalities does not imply that functional amnesia is due to or associated with brain injury or disorder.

Differential Diagnosis

Malingered (intentionally feigned) amnesia also can present with the sudden onset of retrograde amnesia without clinically significant anterograde amnesia. In fact, it may be that a patient with malingered amnesia only can be distinguished from a patient with functional amnesia with certainty if the malingerer confesses. One clue that a patient has malingered amnesia may be the absence of a significant past psychiatric history. The precipitating factors for malingered amnesia may be similar to those for

functional amnesia. One malingerer hit himself in the head with a bottle so there would be evidence of an appropriate precipitating factor for his amnesia.

Rare neurological patients have been reported to have significant retrograde amnesia with a lesser degree of anterograde amnesia. This may be associated with bilateral damage to the anterior or inferior temporal lobes. Personal identity probably is preserved, the retrograde amnesia covers a period of several years to several decades, and there is some degree of anterograde amnesia. Neuroimaging typically will reveal the responsible brain injury.

The neurological amnesic syndrome that is commonly seen with dysfunction of bilateral medial temporal lobe or bilateral medial diencephalic structures important for memory is easily distinguished from functional amnesia. Patients with the neurological amnesic syndrome have significant anterograde amnesia with variable retrograde amnesia.

Figure 1 Patients with functional amnesia (FA) and controls were asked to recollect ten autobiographical episodes. Responses were scored (0–3) before (no probe) and after (probe) encouragement by the examiner to elicit as specific a recollection as possible. Each filled circle indicates the score for one subject. The asterisk indicates the score for the patient who later confessed that he had malingered his amnesia. Kritchevsky M, Chang J, and Squire LR (2004) Functional amnesia: Clinical description and neuropsychological profile of 10 cases. *Learning and Memory* 11: 213–226.

Neuropsychological Findings in Patients with Functional Amnesia

In 2004, a series of ten patients who had initially been diagnosed with functional amnesia was published. The patients had been studied clinically and neuropsychologically in a systematic fashion. Nine of the patients presented with loss of past memories that extended into childhood and included loss of personal identity. One had retrograde amnesia that was limited to 2–3 years. Eight of the ten patients were thought to have definite functional amnesia. One of the patients (whose performance is noted by an asterisk in the figures) subsequently confessed that he had malingered his amnesia. The final patient was considered to be a possible malingerer. The patients ranged in age from 28 to 54 years (mean, 37 years). For the eight patients for whom the data were known, education ranged from 9 to 16 years (mean, 13 years). Eight patients were men and two women. Seven were tested neuropsychologically 1–14 days after the onset of amnesia. Three were tested 10 weeks to 9 months after the onset of amnesia. Five patients were tested between 1982 and 1985. The other five were tested between 1992 and 1995. Four men and one woman, matched to the patients with respect to age and education, served as controls. They were tested in 1996. The neuropsychological data presented in this section are from these patients and controls.

Retrograde Amnesia

Figure 1 shows the performance of nine of the ten patients on a test of past autobiographical memory. This test was not administered to the patient who had retrograde amnesia of only 2–3 years. Ten common words (e.g., bird, clock) were presented one at a time with the instruction to recall a specific personal event from any time in the past that involved the stimulus word. Subjects were asked to describe the memory in as much detail as possible and then to date the memory. When recall was not clearly specific to time and place, the examiner probed to elicit the most specific memory possible. Responses were scored on a 0–3 scale, with 3 representing a well-formed episodic memory. The patients performed more poorly than the controls, both without (t [12] = 3.2, $p < 0.01$) and with probing (t [12] = 2.7, $p < 0.05$) by the examiner. The two patients who obtained the best scores were tested 3 and 9 months after the onset of the amnesia. Their good performances resulted from their ability to recall memories from the period after the onset of their amnesia. On neurological examination, both of these patients exhibited significant loss of autobiographical memories for events that had occurred before the onset of amnesia.

Figure 2 shows the percentage of well-formed episodic memories that were recalled from different past time periods (0 days to > 20 years) on the test of past autobiographical memory. One patient, the malingerer, was unable to produce any well-formed recollections and was not included in this analysis. The remaining patients each recalled from three to ten memories. The patients differed markedly from the controls in that they recalled most of their memories from the most recent time period (patients, 78%; controls = 24%; t [11] = 3.1, $p < 0.01$) and very few

Figure 2 Percentage of memories that were recalled from the indicated time periods for patients with functional amnesia (FA) and controls. The data are based only on those recollections given a maximum score of 3 on the ten-item test of past autobiographical memory (**Figure 1**). The patient who later confessed that he had malingered his amnesia had no recollections that were given a three-point score. For the eight patients, all the memories from the 0–9 months time period were taken from the period after the onset of amnesia. Kritchevsky M, Chang J, and Squire LR (2004) Functional amnesia: Clinical description and neuropsychological profile of 10 cases. *Learning and Memory* 11: 213–226.

of their memories from the most remote time period (patients, 3%; controls, 36%; t [11] = 3.2, $p < 0.01$). It was notable that all of the memories recalled by the patients from the most recent time period were drawn from the time after the onset of amnesia. Thus, compared with the controls, the patients had a striking tendency not to recall remote memories, but rather to draw their memories from the period after the onset of the amnesia.

Figures 3(a) and 3(b) show the performance of four of the patients on a test of recall and recognition of public events. These patients were tested between 1992 and 1994. Twenty-four questions about public events that had occurred from 1970 to 1985 were asked. This test first was administered in a recall format (e.g., Who killed John Lennon?) and then, for each item that was not recalled or was incorrectly recalled, in a four-alternative, multiple-choice format (John Hinkley, Sara Jane Moore, David Roth, and Mark Chapman). The recognition score was based on the items that were recalled correctly plus the items that were recognized correctly. The four patients were impaired both at recall (16.7% correct for patients; 39.2% correct for controls; t [7] = 4.2, $p < 0.01$) and at recognition (44.8% correct for patients; 76.6% correct for controls; t[7] = 4.2, $p < 0.01$). One of these patients, who had retrograde amnesia of only 2–3 years, performed better than the other three. However, he still performed at the low end of the control range on recall (29.2%) and poorer than the controls on recognition (62.5%). The six other patients took a similar test consisting of 17–26 questions about the two most recent decades before the onset of their amnesia. They also scored poorly at recall (16.3% correct; one patient did not take the recall test) and at recognition (48.3% correct). One of these patients, the possible malingerer, had a score of 0% on the recall test and 11% on the recognition test (chance = 25%).

Figures 3(c) and 3(d) show the performance of four of the patients on a test of recall and recognition of famous faces. These patients were tested between 1992 and 1994. Nineteen photographs of famous people who came into the news from 1970 to 1989 were shown. The test first was administered in a recall format and then, for each item that was not recalled or was incorrectly recalled, in a recognition format. For recognition, half the items were yes/no questions (e.g., Is this person's name Liza Minelli?) and half were three-alternative, multiple-choice questions (e.g., Liza Minelli, Ann Margaret, Helen Reddy). The recognition score was based on the items that were recalled correctly plus the items that were recognized correctly. As a group, the four patients were impaired both at recall (40.8% correct for patients; 64.2% correct for controls; t [7] = 5.7, $p < 0.01$) and at recognition (80.2% correct for patients; 94.7% for controls; t [7] = 4.2, $p < 0.01$). The six other patients took a similar test consisting of 20–27 faces from the two most recent decades before the onset of their amnesia. They also scored poorly as a group at recall (39.1% correct) and at recognition (77.8% correct; one patient did not take the recognition test). There was marked variability in the individual scores of the ten patients. Thus, both the recall and recognition scores of two patients (one of these was the malingerer) were as good as or better than the control scores. Also, the patient who had retrograde amnesia of only 2–3 years performed just below the controls at recall and obtained a perfect score at recognition. A fourth patient scored well enough on the recognition test to reach the low end of the control range. A fifth patient scored 0% correct at recall but nearly reached the control range at recognition. Finally, a sixth patient (the possible malingerer) scored 0% correct at recall and 18.5% correct at recognition (chance = 41.7%). His overall score on the public events and famous faces recognition tests was 2.75 standard deviations below the score that would have been expected from guessing.

Figure 4 shows the performance of nine of the ten patients on tests of identification of US and southern California cities. First, each subject was read the names of 16 real and 16 plausible US cities and associated

Figure 3 Performance on tests of remote memory for public events and famous faces. Patients with functional amnesia (FA) and controls were asked 24 questions about public events that had occurred during the two decades prior to testing (a) and then took a four-alternative, multiple-choice test about the same events (b). Subjects also were asked to identify 19 photographs of famous people who came into the news during the two decades before testing (c) and then to recognize the names that they could not recall (d). The recognition scores were based on the number of items recalled correctly plus the items that were recognized correctly. Chance = 25% for public events, 41.7% for famous faces. Each filled circle indicates the score for one subject. Kritchevsky M, Chang J, and Squire LR (2004) Functional amnesia: Clinical description and neuropsychological profile of 10 cases. *Learning and Memory* 11: 213–226.

states (e.g., Phoenix, Arizona, or Nelander, Michigan) and asked to identify whether each city name was real or fabricated. Then each subject was read a list of ten real and ten plausible southern California cities (e.g., Oceanside or Palmville) and again asked whether each city name was real or fabricated. The score on each test was the number of cities correctly identified. Overall, the patients performed similarly to the controls (US cities; $t[12] = 1.8$, $p = 0.09$; southern California cities, $p > 0.10$). However, two patients scored more than two standard deviations below the control mean on both tests. One of these, the possible malingerer, scored 47% correct on the US cities test and 30% correct on the southern California cities test (chance = 50% for each test).

In summary, all patients were impaired in their ability to recall autobiographical memories of specific events from their past. In contrast, there was marked variability in their performances on tests of their ability to recall and recognize public events and famous faces from the two decades before the onset of their amnesia. Thus, the possible malingerer scored significantly below chance on the recognition tests, and it is possible that he intentionally chose the wrong answers. Also, three patients (one was the malingerer) performed particularly well on the famous faces tests despite performing poorly on the public events tests. Another patient was unable to recall a single item on the famous faces test, but then did well on recognition of the faces. There was less variability in the patients'

Figure 4 Patients with functional amnesia (FA) and controls were asked to identify the names of cities in the United States (left two bars) and the names of cities in southern California (right two bars) from lists of real and fictitious city names. Chance = 50%. Each filled circle indicates the score for one subject. The asterisk indicates the scores for the patient who later confessed that he had malingered his amnesia. Kritchevsky M, Chang J, and Squire LR (2004) Functional amnesia: Clinical description and neuropsychological profile of 10 cases. *Learning and Memory* 11: 213–226.

ability to distinguish names of real cities from the names of fictitious cities. Two patients, one the possible malingerer, performed abnormally on these tests.

Anterograde Amnesia

Figure 5(a) shows the performance of the ten patients with functional amnesia on a test of story recall. A short prose passage was read to the patient. Recall was tested immediately and again after a 10–20 min delay. The score was the number of story segments correctly recalled. Overall, the patients were marginally impaired at immediate recall (t [13] = 2.1, $p < 0.06$) but similar to controls at delayed recall ($p > 0.10$). Nonetheless, there was considerable variability in the performance of individual patients. Six of the patients (including the malingerer and the possible malingerer) had immediate recall scores that were more than two standard deviations below the control mean. Only the malingerer had a delayed recall score that was more than two standard deviations below the control mean.

Figure 5(b) shows the performance of the ten patients on a test of paired associate learning. A series of ten noun–noun word pairs was presented verbally and visually on each of three study trials. After each study trial, the patient was shown the first word of each pair and asked to recall the second word. The score was the number of words correctly recalled on each trial. Patients and controls performed similarly overall (F [1,13] = 2.7, $p > 0.10$) and improved at a similar rate across the three trials (F [2,26] = 0.5, $p > 0.10$). There was some variability in the scores,

Figure 5 Performance of patients with functional amnesia (FA) and controls on tests of anterograde amnesia. (a) Story recall. Recall was tested immediately (Immed) and again after a delay of 10–20 min (Delay). (b) Paired-associate learning. Ten word pairs were presented on each of three study trials. (c) Copy of a complex diagram and reconstruction of the diagram from memory after 10–20 min (Delay). Maximum score = 36. Each filled circle indicates the score for one subject. The asterisk indicates the scores for the patient who later confessed that he had malingered his amnesia. He did not receive the diagram recall test. Kritchevsky M, Chang J, and Squire LR (2004) Functional amnesia: Clinical description and neuropsychological profile of 10 cases. *Learning and Memory* 11: 213–226.

with four of the patients (including the malingerer) having total number of words recalled across the three trials more than two standard deviations below the overall control mean.

Figure 5(c) shows the performance of nine of the patients on a test of recall of nonverbal material.

This test was not administered to the malingerer. Each patient copied a complex diagram. After a 10–20 min delay and without forewarning, they were asked to reproduce the diagram from memory. The score was the number of parts of the diagram correctly recalled. The patients scored similarly to the controls, both when they copied the diagram and when they reconstructed it from memory ($p > 0.10$). No patient obtained a score on this test that was below the lowest score obtained by the controls.

In summary, the patients as a group performed well on tests of anterograde amnesia for verbal and nonverbal material. However, there was some variability among patients. Some appeared to have abnormal performances on immediate verbal memory for a prose passage or on paired associate learning. Despite these abnormal performances, no patient exhibited any difficulty learning and remembering day-to-day events after the onset of amnesia.

Etiology of Functional Amnesia

Functional amnesia is a nonneurological, conversion symptom-like disorder. The model for the amnesia is the amnesic syndrome that is popularized in literature and film, namely a loss of past memories that usually includes a loss of personal identity. Each patient has their own individual conception of what past memories should be lost, which leads to the striking variability in the clinical and neuropsychological findings of patients with functional amnesia. In functional amnesia, as in a conversion disorder, the patient is not intentionally producing the deficits. It has been proposed that posthypnotic amnesia might serve as a laboratory model of functional amnesia, and self-hypnosis is one possible mechanism of conversion disorder and of functional amnesia.

Evaluation and Treatment of the Patient with Functional Amnesia

The evaluation of the patient should begin with neurological and psychiatric histories. The patient may be able to provide some of this information, but early in the course of evaluation most of the history will come from family members, friends, and healthcare or legal professionals. Neurological and psychiatric examinations should be performed. Laboratory investigations usually are not required, but may be obtained in selected patients.

The patient should be treated in the same manner as a patient with a conversion disorder. They should be reassured that there is no evidence of serious or significant brain problem. Significant psychological stressors should be identified and treated. They should be informed that their memories may begin returning within days of the onset of the amnesia. Contact with friends and family members should be encouraged unless there is a contraindication. If there has been little or no return of past memories within about a week, then treatment with hypnosis or an amobarbital interview should be considered if the treating psychiatrist agrees. If psychologically painful memories are remembered during hypnosis or an amobarbital interview, then the patient will require careful observation to be sure that these memories do not lead to undue distress or even to a suicide attempt. Despite the best possible therapy, some patients have only partial recoveries and some patients do not appear to have any recovery from their functional amnesia.

Functional Connectivity

Introduction

Electrophysiological methods, such as electroencephalography (EEG) and magnetoencephalography (MEG), and functional imaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), are used widely in cognitive neuroscience. A common aim is to understand brain function along two dimensions: functional specialization and functional integration. Functional specialization assumes a local specialization for certain aspects of information processing but allows for the possibility that this specialization is anatomically segregated across different cortical areas. Most current functional neuroimaging experiments have adopted this view and interpret the areas that are activated by a certain task component as the elements of a distributed system. However, this characterization does not address how the locally specialized areas are bound together by context-dependent interactions among these areas – that is, the functional integration within the system. This integration can be quantified in two ways – functional connectivity and effective connectivity. Whereas functional connectivity describes statistical dependencies between remote neuronal data, effective connectivity rests on a mechanistic model of how the data were caused. This article reviews established techniques for characterizing functional integration on the basis of electrophysiological and functional neuroimaging data.

Functional Connectivity

Functional connectivity is operationally defined as the temporal correlation between the time series of different brain regions. (A more general definition of functional connectivity is the presence of statistical dependencies between two sets of neurophysiological data. If one assumes that these data conform to Gaussian assumptions, one only needs to investigate second-order dependencies (i.e., covariances or correlations). For non-Gaussian processes, higher order dependencies need to be taken into account. This can be done, for example, with independent component analysis.) In fMRI and PET, such time series are available for each volume element (voxel) of the brain. For example, given two voxels with time series x and y, the functional connectivity simply corresponds to the Pearson correlation coefficient r of the two time series

$$r_{xy} = \frac{\mathrm{cov}_{xy}}{s_x \cdot s_y} \qquad [1]$$

where s_x, s_y are the standard deviations, and cov_{xy} is the covariance of the two time series. Note that functional connectivity suffers from the general problem of interpreting correlations: are the two time series correlated because (1) x influences y, (2) y influences x, (3) both influence each other, or (4) both are influenced by a third variable? Disambiguating these possibilities requires a model of the causal influences (i.e., effective connectivity).

The previous definition of functional connectivity can be applied practically in different ways. For example, for PET or fMRI data, one can compute functional connectivity maps with reference to a particular seed region or, alternatively, use a variety of multivariate techniques that find sets of voxels whose time series represent distinct (orthogonal or independent) components of the covariance structure of the data. Because of their central role in analyses of functional connectivity, the following section summarizes approaches that are based on eigenimage decomposition of spatiotemporal data.

Eigendecomposition of Spatiotemporal Imaging Data

Given a matrix A, a vector $\mathbf{x}$ is called the eigenvector of A if there is a scalar eigenvalue λ such that

$$A\mathbf{x} = \lambda\mathbf{x} \qquad [2]$$

In other words, eigenvectors are those vectors which are only scaled by A; their direction remains unchanged. Eigenvectors thus represent the principal axes of the linear function encoded by A.

Let us now consider a PET or fMRI data set of m scans obtained for n voxels that is represented by a mean-corrected $m \times n$ matrix Y. The temporal covariance matrix of this data set is given by YY^T and the spatial covariance matrix is given by Y^TY (where T denotes the transpose operator). The challenge is to characterize those patterns in time and space, respectively, that contribute most to the covariance structure of the data. Focusing on temporal covariance, one could perform a principal components analysis (PCA) that reexpresses the data Y in terms of a new orthonormal basis set U comprising the eigenvectors of the temporal covariance matrix YY^T:

$$Y^* = UY \qquad [3]$$

Here, Y^* are the data after projection onto the space defined by U. In this space, the axes account for extreme and orthogonal components of the temporal covariance structure.

A more general and powerful procedure for eigendecomposition of spatiotemporal data is singular decomposition (SVD). SVD decomposes the data matrix Y into three matrices:

$$\mathrm{SVD}(Y) = USV^T \qquad [4]$$

This is a so-called eigendecomposition because the column vectors of U and V represent the eigenvectors of the temporal and spatial covariance matrices, respectively. Each eigenvector in V contains one value per voxel; therefore, it can be displayed as an image and is also called an eigenimage (or spatial mode). The first eigenimage is the spatial pattern that accounts for the greatest amount of the covariance structure of the data. The second eigenimage is orthogonal to the first and explains the greatest amount of the remaining covariance and so on. The amount of covariance explained by each eigenimage is given by S, which is a diagonal matrix of decreasing singular values (the square root of the eigenvalues). (Note that the eigenvalues of the temporal and spatial covariance matrices are identical and, given a data matrix Y with rank r, S has r singular values which occupy the leading diagonal in decreasing order.) The temporal eigenvectors, or eigenvariates, contained by the columns of U, reflect the degree to which an eigenimage is expressed over time and can help to interpret the function of the distributed neural system defined by the associated eigenimage (e.g., by comparing the temporal evolution of the eigenvariate to the temporal sequence of task conditions).

Eigenimage analysis based on SVD has been elaborated in several ways. Notable among these is canonical variate analysis (CVA), which uses a generalized eigenvector solution to maximize the variance that can be explained by some explanatory variables relative to variance that cannot. CVA can be considered as an extension of eigenimage analysis that refers explicitly to some explanatory variables and allows for statistical inference. A technique closely related to SVD is partial least squares, which has been applied in the context of neuroimaging using behavioral data or time series from a reference voxel as explanatory variables.

As explained previously, analyses of functional connectivity only refer to statistical dependencies among measured data and do not incorporate any knowledge or assumptions about the structure and mechanisms of the neural system of interest. This is appropriate if the system of interest is largely unknown and needs to be approached in an exploratory fashion. The results from functional connectivity analyses can then be used to generate hypotheses about the system. However, given a specific mechanistic hypothesis of how system function results from system structure, models of effective connectivity are generally more appropriate and powerful.

Effective Connectivity

Effective connectivity describes the causal influences that the elements of a neural system exert over another. Determining effective connectivity requires a specific model of the neural system of interest that explains how the observed dynamics of the system result from the interactions among its elements. Such a model accounts for the intrinsic structure of the system (i.e., the structural presence or absence of connections) and the external inputs that perturb the system. Before discussing specific models for functional neuroimaging, it is helpful to describe how system models can be formalized in general.

Although systems can be described mathematically in different ways, the underlying concept is quite universal: a system is defined by a set of elements with n time-variant properties that interact with each other. Here, we choose deterministic differential equations with time-invariant parameters as a mathematical framework. Each time-variant property x_i ($1 \leq i \leq n$) is called a state variable, and the n-vector $\mathbf{x}(t)$ of all state variables in the system is called the state vector or simply state) of the system at time t:

$$\mathbf{x}(t) = \begin{bmatrix} \mathbf{x}_1(t) \\ \vdots \\ \mathbf{x}_n(t) \end{bmatrix} \qquad [5]$$

For example, the system elements could correspond to individual neurons, each of which is represented by one or more state variables. These state variables could refer to neurophysiological properties (e.g., postsynaptic potentials and status of ion channels). The crucial point is that the state variables interact with each other; that is, the evolution of each state variable depends on at least one other state variable. For example, the postsynaptic membrane potential depends on which and how many ion channels are open, and the probability of voltage-dependent ion channels opening depends on the membrane potential. Such functional dependencies among the state variables of the system can be expressed quite naturally by a set of ordinary differential equations that operate on the state vector:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \begin{bmatrix} f_1(x_1, \ldots, x_n) \\ \vdots \\ f_n(x_1, \ldots, x_n) \end{bmatrix} = F(x) \qquad [6]$$

However, this description is not yet sufficient. First, the functional dependencies f_i must be specified. This requires a set of parameters θ which represent the form and strength of causal influences between the state variables. In neural systems, these parameters usually correspond to time constants or synaptic connection strengths. Second, we need to consider exogenous inputs into the system (e.g., sensory information entering the brain). Here, we represent the set of all m known inputs by the m-vector function $u(t)$. Extending eqn [6] accordingly leads to a general state equation for nonautonomous deterministic systems:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = F(x, u, \theta) \qquad [7]$$

A model of this form provides a causal description of how system dynamics results from system structure because it describes (1) when and where external inputs enter the system and (2) how the state changes induced by these inputs evolve in time depending on the system structure. Given a particular temporal sequence of inputs $u(t)$, integration of eqn [7] leads to a complete description of how the dynamics of the system (i.e., the trajectory of its state in time) results from its structure and initial state:

$$x(\tau) = x(0) + \int_0^\tau F(x, u, \theta)\mathrm{d}t \qquad [8]$$

Equation [7] therefore provides a general form for models of effective connectivity in neural systems. (We have made two main assumptions to simplify the exposition. First, it is assumed that all processes in the system are deterministic and occur instantaneously. Random components (noise) and delays could be accounted for by using stochastic differential equations and delay differential equations, respectively. Second, we assume that we know the inputs that enter the system. This is a tenable assumption in neuroimaging because the inputs are experimentally controlled variables, such as changes in sensory stimulation or task set.) In the next sections, some specific models of effective connectivity are discussed.

Structural Equation Modeling

Structural equation modeling (SEM) is a multivariate, hypothesis-driven technique that is based on a structural model representing a hypothesis about the causal relations among several variables. In the context of fMRI, for example, these variables are the measured blood oxygen level-dependent (BOLD) time series $y_1, \ldots, y_n$ of n brain regions and the hypothetical causal relations are based on anatomically plausible connections between the regions. The strength of each connection $y_i \rightarrow y_j$ is specified by a so-called path coefficient which, by analogy to a partial regression coefficient, indicates how the variance of y_i depends on the variance of y_j if all other influences on y_j are held constant.

The statistical model of standard SEM can be summarized by the equation

$$y = Ay + u \qquad [9]$$

where y is an $n \times s$ matrix of n area-specific time series with s scans each, A is an $n \times n$ matrix of path coefficients (with zeros for absent connections), and u is an $n \times s$ matrix of zero mean Gaussian error terms, which are driving the modeled system ('innovations'; see eqn [10]). Parameter estimation is achieved by minimization of the difference between the observed and the modeled covariance matrix Σ. For any given set of parameters, Σ can be computed by transforming eqn [9]:

$$\begin{aligned} y &= (I - A)^{-1}u \\ \Sigma &= yy^T \\ &= (I - A)^{-1}uu^T(I - A)^{-1^T} \end{aligned} \qquad [10]$$

where I is the identity matrix. The first line of eqn [10] can be understood as a generative model of how system function results from the system's connectional structure: the measured time series y results by applying a function of the interregional connectivity matrix – that is, $(I-A)^{-1}$ – to the Gaussian innovations u.

In the special case of fMRI, the path coefficients (i.e., the parameters in A) describe the effective connectivity of the system across the entire experimental session. What one would often prefer to know, however, is how the coupling between certain regions changes as a function of experimentally controlled context (e.g., differences in coupling between two different tasks). Notably, SEM does not account for temporal order: if all regional time series were permuted in the same fashion, the estimated parameters would not change. In case of blocked designs, this makes it possible to proceed as if one were dealing with PET data – that is, to partition the time series into condition-specific subseries and fit separate SEMs to them. These SEMs can then be compared statistically to test for condition-specific differences in effective connectivity. An alternative approach is to augment the model with bilinear terms (cf. eqn [9])

which represent the modulation of a given connection by an experimental condition. In this case, only a single SEM is fitted to the entire time series.

A problem with SEM is that one is obliged to use models of relatively low complexity since models with reciprocal connections and loops are often non-identifiable. As a simple example, consider a fully connected model: in this case, the number of free parameters exceeds the number of observed covariances, which means there are no degrees of freedom. Although some heuristics for dealing with complex models have been proposed, this problem, together with the neglect of temporal order, is a critical limitation in the application of SEM to neural systems.

Dynamic Causal Modeling

An important limitation of all approaches discussed so far is that they operate at the level of the measured signals. Taking the example of fMRI, the model parameters are fitted to BOLD series which result from a hemodynamic convolution of the underlying neural activity. Any inference about interregional connectivity obtained by SEM is only an indirect one because these models do not include the forward model linking neuronal activity to the measured hemodynamic response. In the case of EEG, this forward model means there is a major difference between signals measured at each electrode and the underlying neuronal activity: changes in neural activity in different brain regions lead to changes in electric potentials that superimpose linearly. The scalp electrodes therefore record a mixture, with unknown weightings, of potentials generated by a number of different sources.

The causal architecture of the system that we would like to identify is expressed at the level of neuronal dynamics. Therefore, to enable inferences about connectivity between neural units we need models that combine (1) a parsimonious but neurobiologically plausible model of neural population dynamics and (2) a biophysically plausible forward model that describes the transduction of neural activity into measured signals. Such models make it possible to fit jointly the parameters of the neural and the forward model such that the predicted time series are optimally similar to the observed time series. Dynamic causal modeling (DCM) is an approach in which the combination of models of neural dynamics and biophysical forward models is mandatory. DCMs currently exist for both fMRI data and event-related potentials (ERPs) as measured by EEG/MEG. These modality-specific implementations are summarized briefly in the remainder of this section.

DCM for fMRI

DCM for fMRI uses a simple model of neural dynamics in a system of n interacting brain regions. It models the change of a neural state vector $\mathbf{x}$ in time, with each region in the system being represented by a single state variable, using the following bilinear differential equation:

$$\begin{aligned}\frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} &= F\left(\mathbf{x}, u, \theta^{(n)}\right)\\ &= \left(A + \sum_{j=1}^{m} u_j B^{(j)}\right)\mathbf{x} + Cu\end{aligned} \qquad [11]$$

Note that this neural state equation follows the general form for deterministic system models introduced by eqn [7] – that is, the modeled state changes are a function of the system state, the inputs u, and some parameters $\theta^{(n)}$ that define the functional architecture and interactions among brain regions at a neuronal level. The neural state variables represent a summary index of neural population dynamics in the respective regions. The neural dynamics are driven by experimentally controlled external inputs that can enter the model in two different ways (Figure 1): they can elicit responses through direct influences on specific regions (e.g., evoked responses in early sensory cortices; the C matrix) or they can modulate the coupling among regions (e.g., during learning or attention; the B matrices). Given this bilinear state equation, the neural parameters $\theta^{(n)} = \{A, B, C\}$ can be expressed as partial derivatives of F:

$$\begin{aligned}A &= \left.\frac{\partial F}{\partial x}\right|_{u=0}\\ B^{(j)} &= \frac{\partial^2 F}{\partial x \partial u_j}\\ C &= \left.\frac{\partial F}{\partial u}\right|_{x=0}\end{aligned} \qquad [12]$$

The matrix A represents the effective connectivity among the regions in the absence of input, the matrices $B^{(j)}$ encode the change in effective connectivity induced by the jth input u_j, and C embodies the strength of direct influences of inputs on neuronal activity. See Figure 1 for an example.

DCM for fMRI combines this model of neural dynamics with a hemodynamic model that describes the transformation of neuronal activity into a BOLD response. This 'balloon model' consists of a set of differential equations with parameters $\theta^{(b)}$ that describe how changes in neural activity elicit a vasodilatory signal that leads to increases in blood flow and subsequently to changes in blood volume and deoxyhemoglobin content. The predicted BOLD signal is a

Figure 1 Schematic summary of DCM for fMRI. The dynamics in a system of interacting neuronal populations (top left quadrant), which are not directly observable by fMRI, are modeled using a bilinear state equation. The gray box in the bottom right quadrant shows the general state equation of DCM and its specific form for the network shown in this figure. Integrating the state equation gives predicted neural dynamics (x) which are transformed into predicted BOLD responses (y) by means of a hemodynamic forward model. Neural and hemodynamic parameters are adjusted jointly such that the differences between predicted and measured BOLD series are minimized. The neural dynamics are determined by experimental manipulations that enter the model in the form of external inputs. Driving inputs (u_1; e.g., sensory stimuli) elicit local responses which are propagated through the system according to the intrinsic connections. The strengths of these connections can be changed by modulatory inputs (u_2; e.g., changes in task, attention, or due to learning). Note that in this figure the structure of the system and the scaling of the inputs have been chosen arbitrarily.

nonlinear function of blood volume and deoxyhemoglobin content. The combined neural and hemodynamic parameter $\theta = \{\theta^{(n)}, \theta^{(h)}\}$ set is estimated from the measured BOLD data using a fully Bayesian approach with empirical priors for the hemodynamic parameters $\theta^{(h)}$ and conservative shrinkage priors for the coupling parameters $\theta^{(n)}$. The parameter estimation scheme rests on expectation maximization and uses a Laplace (i.e., Gaussian) approximation to the true posterior. The posterior distributions of the parameter estimates can be used to test hypotheses about connection strengths. Usually, these hypotheses concern context-dependent changes in coupling. If there is uncertainty about the connectional structure of the modeled system, or if one would like to compare competing hypotheses (represented by different DCMs), a Bayesian model selection procedure can be used to find the DCM that exhibits an optimal balance between model fit and model complexity.

DCM for ERPs

ERPs as measured with EEG or MEG have been used for decades to study electrophysiological correlates of cognitive operations. DCM for ERPs was developed as a biologically plausible model to understand how event-related responses result from the dynamics in coupled neural ensembles. It rests on a neural mass model which uses established connectivity rules in hierarchical sensory systems to assemble a network of coupled cortical sources. These rules characterize connections with respect to their laminar patterns of origin and termination and distinguish between (1) forward (or bottom-up) connections originating in agranular layers and terminating in layer 4, (2) backward (or top-down) connections originating and terminating in agranular layers, and (3) lateral connections originating in agranular layers and targeting all layers. These interareal cortico-cortical connections are excitatory and arise from pyramidal cells.

Each region or source is modeled as a microcircuit in which three neuronal subpopulations are combined and assigned to granular and supra-/infragranular layers. A population of excitatory pyramidal (output) cells receives inputs from inhibitory and excitatory populations of interneurons via intrinsic (intra-areal) connections. Within this model, excitatory interneurons can be regarded as spiny stellate cells found predominantly in layer 4 and in receipt of forward connections. Excitatory pyramidal cells and inhibitory interneurons are considered to occupy infra- and supragranular layers and receive backward and lateral inputs.

The neural state equations are summarized in Figure 2. To perturb the system and model event-related responses, the network receives inputs via input connections. These connections are exactly the same as forward connections and deliver input u to the spiny stellate cells in layer 4. Input u represents afferent activity relayed by subcortical structures and is modeled as two parameterized components, a gamma density function (representing an event-related burst of input that is delayed and dispersed by subcortical synapses and axonal conduction) and a discrete cosine set (representing fluctuations in input over peristimulus time). The influence of this input on each source is controlled by a parameter vector **C**. Overall, the DCM is specified in terms of the state equations shown in Figure 2 and a linear output equation

$$\frac{dx}{dt} = f(x, u, \theta)$$
$$y = Lx_0 + \varepsilon \qquad [13]$$

where x_0 represents the transmembrane potential of pyramidal cells, and L is a lead field matrix coupling electrical sources to the EEG channels. In comparison to DCM for fMRI, the forward model is a simple linearity as opposed to the nonlinear hemodynamic model in DCM for fMRI. In contrast, the state equations of DCM for ERPs are much more complex and realistic (compare Figures 1 and 2). As an example, the state equation for the inhibitory subpopulation is

$$\dot{x}_7 = x_s$$
$$\dot{x}_8 = \frac{H_e}{\tau_e}((A^B + A^L + \gamma_3 I)S(x_0)) - \frac{2x_8}{\tau_e} - \frac{x_7}{\tau_e^2} \qquad [14]$$

Figure 2 Schematic of the neural model in DCM for ERPs. This schema shows the state equations describing the dynamics of a microcircuit representing an individual region (source). Each region contains three subpopulations (pyramidal, spiny stellate, and inhibitory interneurons) that are linked by intrinsic connections and have been assigned to supragranular, granular, and infragranular cortical layers. Different regions are coupled through extrinsic (long-range) excitatory connections that follow the laminar patterns of forward, backward, and lateral connections, respectively. Reproduced from David O, Kiebel SJ, Harrison LM, Mattout J, Kilner JM, and Friston KJ (2006) Dynamic causal modeling of evoked responses in EEG and MEG. *NeuroImage* 30: 1255–1272, with permission by Elsevier Ltd.

The parameter matrices A^F, A^B, A^L encode forward, backward, and lateral connections, respectively. Within each subpopulation, the dynamics of neural states are determined by two operators. The first transforms the average density of presynaptic inputs into the average postsynaptic membrane potential. This is modeled by a linear transformation with excitatory (e) and inhibitory (i) kernels parameterized by $H_{e,i}$ and $\tau_{e,i}$. $H_{e,i}$ control the maximum postsynaptic potential, and $\tau_{e,i}$ represent lumped rate constants (i.e., lumped across dendritic spines and the dendritic tree). The second operator S transforms the average potential of each subpopulation into an average firing rate. This is assumed to be instantaneous and is a sigmoid function. Intra-areal interactions among the subpopulations depend on constants $\gamma_{1\ldots4}$ which control the strength of intrinsic connections and reflect the total number of synapses expressed by each subpopulation. In eqn [14], the top line expresses the rate of change of voltage as a function of current. The second line specifies how current changes as a function of voltage, current, and presynaptic input from extrinsic and intrinsic sources. For simplification, our description has omitted the fact that in DCM for ERPs all intra- and interareal connections have conduction delays. This is implemented by delay differential equations.

Summary and Outlook

This article has reviewed different approaches to characterizing functional integration in neural systems on the basis of neuroimaging data. Starting with exploratory analyses of functional connectivity, we discussed various models of effective connectivity that allow for increasingly sophisticated modeling of neurobiological mechanisms. DCM is currently the most advanced framework for system models that is applicable to functional neuroimaging data. Various extensions of DCM are in development, such as application to other data modalities than fMRI or ERPs and enhanced state equations for existing models. The hope is that during the next few years, these developments will contribute to a more mechanistic understanding of brain function. Of particular interest will be the use of neural system models such as DCM to understand the mechanisms of drugs and to develop models that can serve as diagnostic tools for diseases linked to abnormalities of connectivity and synaptic plasticity (e.g., schizophrenia).

Functional Electrical Stimulation

R B Stein, University of Alberta, Edmonton, AB, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Many diseases or injuries interrupt the normal conduction of electrical signals such as action potentials. Therefore, people have long tried to replace the natural generation of action potentials by electrical stimulation below the level of the interrupting lesion. Indeed, reports go back over 2000 years to the use of electric eels for stimulation in ancient Greece. Physical therapists and others involved in rehabilitation commonly use electrical stimulation for therapy, to strengthen weakened muscles or increase fatigue resistance; this practice is often referred to as therapeutic electrical stimulation. We and others have shown that 1–2 h of neuromuscular stimulation per day can build muscle strength and restore the fatigue resistance of disused muscles. Rather than a generalized strengthening of muscles, functional electrical stimulation (FES) uses patterned electrical stimulation to assist or replace a particular motor function.

Classes of FES and Related Devices

FES is a general term that can be applied to a variety of functions; some of the devices employed are listed in Table 1 and examples are shown in Figure 1. By far the most successful device has been the heart pacemaker, which is now implanted in more than 400 000 people worldwide every year. Pacemakers replace the normal pattern of heartbeats when the natural cardiac pacemaker is diseased or damaged. The lives of people receiving these implants have been prolonged for years or even decades. Although implanted devices tend to be expensive and have some risk of infection, the life-saving benefits clearly outweigh the costs and risks for most people.

Cochlear stimulators (Figure 1(b)) restore the sense of hearing in completely deaf individuals by patterned stimulation of cochlear neurons in the inner ear. The patterns are determined by an auditory receiver and speech processor (Figure 1(b1)) and are transmitted across the skin to stimulate cochlear neurons using electrodes implanted in the inner ear (Figure 1(b2)). The best stimulators use more than ten channels that are tonotopically organized to match the layout of cochlear neurons and can produce a remarkable degree of recovery in auditory function. Some completely deaf people can understand speech well enough that they can engage in telephone conversations. Deaf children, implanted with a cochlear prosthesis, are often able to attain similar educational achievement as children with some hearing ability. Again, for tens of thousands of individuals (Table 1) the benefits outweigh the costs and risks of implanting a stimulator in the inner ear.

The two cochlear applications differ from the other devices in Table 1 in important ways. Heart pacemakers stimulate heart muscle directly, while cochlear neurons stimulate sensory neurons. Other techniques, such as transcutaneous electric nerve stimulation (TENS), spinal cord stimulators, and acupuncture, also act by stimulating sensory fibers. Their effects, in alleviating pain, for example, could be classified as therapeutic, although the term 'neuromodulation' is often used. This term derives from the fact that many peptide transmitters, such as are released by pain fibers, act on a much longer time scale than classic neurotransmitters do and hence modulate the state of a system rather than providing detailed sensory or motor information. Similarly, deep brain stimulators for Parkinson's disease and other conditions act as neuromodulators in reducing tremor and enabling movements, rather than specifying the pattern of movement to be executed. Therapeutic electrical stimulation and neuromodulation are not considered further here, and the focus will instead be on the replacement of function.

The rest of the FES devices in Table 1 act by stimulating nerve fibers, either in a nerve trunk or at the neuromuscular junction. As a result, the term 'functional neuromuscular stimulation' (FNS) is sometimes used for these devices. Even when the electrodes are placed within a muscle, the lowest threshold is found along the nerve or near the neuromuscular junction. The reason is the tremendous amplification of the neuromuscular junction. The amplification occurs since a small current generated in a nerve can release large numbers of molecules of the transmitter acetylcholine (ACh), each of which can open channels in the much larger muscle membrane and create much larger currents. In addition, a motor nerve fiber often branches profusely to innervate hundreds of muscle fibers, thus providing further amplification.

Finally, the capacitance of the muscle membrane has long been known to be much greater than the capacitance of the nerve membrane, because of the additional membranous systems, such as the transverse tubules in muscle fibers. Thus, the capacity of

Table 1 Estimated number of users of various FES devices

Device	*Number of users*
Heart pacemaker	>400 000 yr^{-1}
Cochlear stimulator	>80 000 total
Bladder stimulator	>2500 total
Phrenic nerve stimulator	1500 total
All FES limb stimulators	<10 000 total

the muscle membrane to store charge is much greater than that of a nerve membrane and much more current must be supplied to depolarize muscle cells directly. Stimulating denervated muscles with large, long-lasting currents has been claimed to prevent or reverse atrophy to some extent. However, the stimulation has not been shown to be functional for particular motor tasks, so further discussion here will be restricted to stimulating nerves for FES.

An example of an FES device for motor tasks that has benefited thousands of people is the bladder stimulator (Figure 1(c); Table 1). With this device, the push of a button produces urination. Previously, people with complete spinal cord injury needed intermittent catheterization or other methods. However, urination has the complication that the bladder muscle must be contracted while the urinary sphincter must be relaxed. In practice, the anterior roots to bladder and sphincter are stimulated at the same time. However, the sphincter is fast skeletal muscle and the bladder is slow smooth muscle, so the bladder continues to contract after the sphincter has relaxed. Clinically, the method requires that sacral dorsal roots be cut, since stimulating these afferents would cause a longer reflex contraction of the sphincter that would block the flow of urine. Various methods are being considered to overcome this problem, but they are outside the scope of this short review.

Similarly, phrenic nerve stimulators (Figure 1(d)) can generate breathing movements in people who have high spinal cord injuries, freeing these people from use of respirators. The late Christopher Reeve benefited from a phrenic nerve stimulator in his final years. Recently, the use of laparoscopy to insert electrodes into the diaphragm has been tested; this procedure could eliminate the need for a thoracotomy and its associated risks. One remaining problem with current devices is that speech must be phrased appropriately with the expiration phase of the stimulator, rather than the pattern of breathing adjusting to the pattern of speech, as occurs in the respiration of able-bodied people.

All of the devices described here are surgically implanted and have been successful clinically to a greater or lesser extent, depending on the relative benefits and costs (both monetary and in terms of risks or drawbacks of the procedures). FES devices to replace limb movements have been less successful, and it is estimated that probably less than 10 000 devices have been fitted worldwide. The vast majority of these have been surface stimulators, so the difference between surface and implanted stimulators must be considered. Actually, limb stimulators for functional movements fall into three categories, based on whether they use implanted, percutaneous, or surface electrodes, and these will be considered in turn.

Electrodes

Implanted Electrodes

Implanted electrodes generally require open surgery. An exception is the BION ('bionic neuron'), developed by Loeb and colleagues, which is small enough that it can be implanted through the barrel of a hypodermic needle near a nerve or neuromuscular junction of interest. An implanted stimulator may contain (1) a battery that will eventually run down and need replacement, such as in a heart pacemaker, (2) a rechargeable battery that is recharged periodically by sending power as a radio wave (telemetry), which is received and processed (e.g., rectified) by implanted circuitry, or (3) no battery, so power must be sent continuously by telemetry whenever operation of the device is desired. Which of the three options is best depends on the total power requirements, the space available for batteries in the device, and the consequences of power loss (e.g., is it life-threatening or not?). In addition to power, the implanted devices must have control circuitry. This can be very simple, such as a pulse generator to generate a pulse about once per second, as in a heart pacemaker, or a series of pulses every few seconds, as in a phrenic nerve stimulator. Where the processing is quite complex, such as for a cochlear stimulator, much of the processing may be external and only a series of commands that encode the stimulation parameters are sent to the internal device periodically. For the bladder stimulator a switch is external, but the circuitry generating the pulses is internal.

Percutaneous Electrodes

Percutaneous electrodes are injected, as for the BION, but the insulated wire from the electrode comes through the skin. This eliminates the need for open surgery, but provides a path for infection to enter through the skin. In addition, stress points occur

Figure 1 (a) A cardiac pacemaker (EnPulse, Medtronic, Inc.). Leads go from the top ports, to stimulate the heart muscle to contract and expel blood from the heart with each heartbeat. (b) A cochlear stimulator (Nucleus Freedom, Cochlear Ltd.). The microphone and speech processor are external (1), but the one shown is small enough to wear behind the ear. Coded signals are then transmitted across the skin to the receiver and stimulating electrodes (2) that are implanted in the canal of the inner ear. Different auditory frequencies stimulate electrodes that activate different cochlear neurons, according to the normal tonotopic organization. (c) A bladder stimulator (Brindley Bladder System, FineTech Medical Ltd.). To urinate, a command from the external controller is transmitted to the receiver, which activates the implanted electrodes on the sacral roots. The bladder and urethral sphincter contract, but the sphincter relaxes first so that urine is expelled. (d) Schematic diagram of a phrenic pacemaker (the Mark IV version developed by Glenn and colleagues). An external pacemaker transmits signals from the antenna across the skin to the implanted electronics. Stimulation of the phrenic nerve contracts the diaphragm and expels air. As the diaphragm relaxes, air enters the lungs. External components are shown on the left side of the picture; internal components are implanted (right side).

where the wires cross the skin and fascial planes between muscles. Frequent bending at these points can eventually cause the wire to break. Percutaneous wires have been used to develop both arm and leg systems, and the properties of metals used in the electrodes have been improved to reduce breakage. However, percutaneous electrodes are now rarely used for long-term systems.

Surface Electrodes

Surface electrodes are applied to the outside of the skin over a nerve or motor endplate and depend on a conductive path through the skin to the underlying target. The conductive path is most commonly a hydrogel, but can be as simple as water, which has a low but usable electrical conductance (thousands of stimulators that used water-filled electrodes were fitted in the former Yugoslavia). Hydrogels are generally sticky enough to adhere to the skin and provide a higher conductance path, particularly if the skin and surface of the electrode are moistened somewhat with water or there is some sweating through the skin under the electrodes. A continuing problem with surface electrodes is that even hypoallergic electrodes can produce allergic reactions or become a site for skin infections (dermatitis) to develop. Passage of electricity for many hours a day can also produce pinhole lesions in the skin, depending on the intensity and shape of the stimulus current (see later). Skin problems are of particular importance in people who have diabetes or other conditions that compromise the health of the skin, and can be more severe in obese individuals, since subcutaneous fat is a poor conductor of electricity. Increasing the voltage to pass more current through the high resistance will increase discomfort by stimulation of pain fibers near the surface of the skin and will increase the chance of lesions. Some disorders produce conditions in which even normal sensations become noxious (allodynia). This may preclude the use of surface and even implanted electrodes. Finally, surface electrodes can only be used to excite nerves reliably that lie close to the surface of the skin. Despite these problems, the vast majority of limb stimulators have used surface electrodes, as will be described later. However, before describing the types of limb stimulators, we need to consider stimulus waveforms briefly.

Stimulus Waveforms

A stimulator can control either the voltage or current applied to the electrodes, irrespective of whether implanted, percutaneous, or surface electrodes are used. A constant voltage is simpler to control (e.g., a battery), although constant-current stimulators are often considered to be superior. The reason is that the current, flowing through a tissue and across the resistance of a nerve membrane, depolarizes the nerve to the threshold for generating an action potential. If the resistance of the skin increases due to the electrode drying out or decreases due to sweating, a constant-current stimulator will adjust automatically. This is typically done by sensing the current flowing through the electrode on each pulse and adjusting the voltage up or down to compensate for any changes, thereby maintaining the current at a desired level. However, constant-current stimulators may be dangerous if an electrode pulls away from the skin and loses contact with all but a small area of skin. Then, a constant-current stimulator will maintain the current, but the current density flowing through the small remaining area of contact can be increased enormously and may lead to skin damage.

For implanted or percutaneous electrodes, the difference between constant-current and constant-voltage stimulators is minimal in the chronic state. The tissue resistance, which links these two variables through Ohm's law, remains constant from day to day, although there is typically a slow increase in resistance of about 30% in the first few weeks after implantation, as connective tissue grows around the electrode and replaces lower resistance body fluids.

Figure 2 (a) Positive and negative charges from the stimulator will bind to the outside of nerve cell membranes and attract negative and positive charges from inside the nerve membrane. If the inside of the membrane near the negative electrode (cathode) becomes sufficiently depolarized, action potentials will be generated. This occurs preferentially in large axons, as explained in the text. (b) The electrodes have a capacitance as well as a resistance, so the input voltage to the electrodes will differ from the output that is actually applied to the tissue (see **Figure 3**).

All stimulators contain at least two electrodes and the current will flow from the positive electrode to the negative electrode. Figure 2 illustrates the path of current flow through the tissue. The region outside the nerve fiber will be more negative near the negative electrode. Since the membrane has a capacity to store charge (capacitance), and unlike charges attract, positive charge will be attracted to the inside of the membrane and can depolarize the membrane to threshold for firing an action potential. Thus, action potentials are generated near the negative electrode (cathode). The flow of current to depolarize the membrane will be much easier in larger fibers, since a fiber twice as large will have 4 times the cross-sectional area and thus one-quarter the resistance to currents flowing along the fiber. The membrane area will be twice as large, but supplied by 4 times the current, so the larger fibers will be more readily depolarized to threshold. This principle is important in enabling large motor nerve fibers to be stimulated without activating small pain fibers. However, other factors, such as proximity, play a role, and fibers nearer to the electrode will be stimulated before more distant ones are. Proximity is particularly important with surface electrodes, since pain fibers will lie in the subcutaneous tissue immediately below the skin and stimulating deep-lying muscles before stimulating pain fibers will be difficult.

Electrodes are complex interfaces that include capacitors as well as resistors. The circuit diagram in Figure 2(b) is a simplification that ignores the spatial properties of the current flow, described in Figure 2(a), as well as the full complexity of the electrode–solution interface, but will illustrate the needed points. Even though the applied voltage (or current) is constant, these variables will not be constant in the tissue, but will change as the electrode's capacitor charges up. The tissue contains a capacitance from the membranes of nerve and other cells, but this has also been ignored in the simplified diagram of Figure 2(b). The voltage in the tissue will actually reverse in sign as the electrode's capacitance discharges (Figure 3(b)), even though the applied voltage does not reverse (Figure 3(a)). Depending on the voltage built up across the capacitor, metal

Figure 3 If a negative-going voltage pulse (solid line in (a)) is applied to electrodes with the circuit diagram of Figure 2(b), the resulting waveform in the tissue will have negative and positive components (solid line in (b)). If the applied pulse is balanced by an equal and opposite waveform (dotted line in (a)), the positive-going voltage in the tissue will be greater in magnitude than the initial negative-going pulse (dotted line in (b)), which can cause excitation at the second electrode. This problem can be alleviated to some extent by delaying the opposite waveform (solid lines in (c) and (d)) and/or changing its time course (dotted lines in (c) and (d)).

particles from the electrode will be lost, including the surface coating. The loss of metal particles will lead to erosion and eventual breakage of the electrode, so this is an important variable in the design of implanted systems. Most stimulators produce biphasic pulses, with partial or complete charge balance. Charge is the integral of current over time, so for complete charge balance the area under the curve of the applied currents as a function of time should be the same for both phases.

Charge balancing is an attempt to recover the material from the electrode that was lost during the stimulation pulse, but many of the metal and other ions will diffuse away. They cannot be recovered, but are replaced by ions from the tissue. For this reason, full charge balance may not be needed. If the second phase is equal and opposite to the first phase, a higher absolute voltage will be reached in the tissue during the second phase (**Figure 3(b)**). The positive electrode (anode) in the first phase will become the cathode in the second phase and may excite nerve fibers. To minimize this secondary excitation, the second phase can be delayed (**Figure 3(c)**) or have a smaller amplitude over a longer period of time, so that the area under the curve is still the same (**Figure 3(d)**). However, the delays allow more opportunity for metal ions to diffuse away. Different implanted FES systems use some of the options illustrated in **Figure 3** for charge balance. Charge balance is also important for surface systems, since injecting materials from the electrode through the skin is thought to lead to some of the unwanted tissue reactions described earlier.

Foot-Drop Stimulators

Liberson and colleagues proposed the first FES system for limb function. They considered the condition of foot drop that occurs commonly after stroke or other central nervous system disorders. In this condition dorsiflexion of the ankle is prominently affected and the foot drops and may drag on the ground during the swing phase of the step cycle. Liberson et al. suggested use of a heel sensor to detect when the heel comes on and off the ground. They stimulated the common peroneal nerve, when the heel came off the ground, to flex the ankle and thereby lift the foot until the heel contacted the ground again. Yet, FES is not the current solution for most patients, but rather use of a plastic brace (ankle–foot orthosis, or AFO) physically prevents the foot from dropping. In fact, hundreds of thousands of AFOs are fitted every year, while probably less than 10 000 FES devices have been fitted for all limb problems since Liberson's suggestion 45 years ago. When given the choice, people overwhelmingly prefer an FES system. Until recently, no US Food and Drug Administration (FDA)-approved FES systems were available for sale in the United States, but three systems have recently come on the market (WalkAide; Odstock Dropped Foot Stimulator; and Ness L300) and the market will determine whether these systems are widely accepted. These systems all use surface stimulation, but implanted stimulators using open surgery or BIONs are being developed. The cost of a sophisticated surface stimulator will inevitably be higher than that of a plastic brace, but the advantages of actively dorsiflexing the ankle, rather than passively fixing it at about 90°, may be sufficient to outweigh the costs. These advantages include (1) flexing the ankle to clear the ground without 'hiking' the hip or circumducting the leg around the body, (2) strengthening the dorsiflexor muscles and any residual descending connections, and (3) being able to wear the same size shoe on both feet or even to go barefoot. This is possible with the WalkAide (see **Figure 4(a)**), which has a tilt sensor built in, rather than using a heel switch.

The second point, the advantage of strengthening muscles and connections, is interesting, since several studies have reported a carryover effect of using the stimulator, both in the short and long term. In other words, after using the stimulator for a period of time, some but not all persons report being able to walk better even without stimulation. This is confirmed by measuring walking speeds and the effort required to walk a given distance. Typically, about half the improvement seen with the stimulator is still present when the stimulator is turned off. This improvement could be due to strengthening leg muscles and spinal circuits by more frequent use. However, recent studies with transcranial magnetic stimulation (TMS) show that the motor evoked potentials (MEPs) recorded in the tibialis anterior muscle, a prime ankle dorsiflexor, are increased by stimulating the common peroneal nerve for 10–30 min. This increase is observed in study controls, as well as in persons requiring a foot-drop stimulator, but the increased MEPs return to control levels within an hour or so. Preliminary evidence from my lab suggests, that by using FES on a daily basis, these transient increases are maintained (**Figure 5**). However, increases in corticospinal connections are not found in all persons, and the reasons for the differences between persons are not known.

Walking Systems after Complete Paraplegia

New training systems that enhance walking abilities in people with incomplete spinal cord injury have been developed, including treadmills, to support

Figure 4 (a) Stimulator for correcting foot drop (WalkAide, Innovative Neurotronics, Inc.). The stimulator contains an inbuilt tilt sensor for control and attaches to a cuff that contains the surface electrodes and fits on the leg below the knee. (b) Stimulator for a walking system for paraplegics with complete spinal cord injury (Parastep, Sigmedics, Inc.). The connectors shown go to surface electrodes on each leg and to a hand switch on a walker for control of the stimulation. (c) System consisting of brace with electrodes built in for stimulating hand grasp and release (H200, Bioness, Inc.) (d) Second-generation implanted hand system developed by Peckham and colleagues, containing ten electrodes for stimulating intrinsic muscles of the hand and muscles above and below the elbow. Also shown is an implanted, Hall-effect, joint angle sensor which can be used to control the external control unit in persons who have some voluntary movement of the wrist.

Figure 5 Effect of 6 months of FES in a head injury patient who began to use WalkAide (see **Figure 4(a)**) 19 years after his injury, showing the motor evoked potentials (MEP) in the tibialis anterior (TA) when the stimulator was applied at various positions anterior, posterior, left, and right from the vertex of the head. (Top) Before using WalkAide. (Bottom) After using WalkAide2 for 6 months. The valley in the center is the normal leg area of the motor cortex. The head injury destroyed this area, although surround areas retained some residual connections. These residual connections were strengthened substantially after using FES, as can be seen by comparing before-use and after-use effects. Adapted from Stein RB, Chong S, Everaret DG, et al. (2006) A multicenter trial of footdrop stimulator controlled by a tilt sensor. *Neurorehabilitation and Neural Repair* 20: 371–379.

part of the body's weight, and robotic manipulators. These devices probably act on the spinal pattern generator for walking and residual descending pathways. Many individuals with incomplete injuries are able to regain functional walking with only crutches or walkers for balance. Others still have problems such as foot drop, which can be treated with the foot-drop stimulators. However, these techniques have proved ineffective in people with complete spinal cord injuries. Systems for restoring walking have been developed for people with a complete paraplegia at the thoracic level. The simplest system involves stimulating the quadriceps muscles, to lock the knees in stance, and the common peroneal nerve, to produce a flexion reflex to enable the leg to swing forward. Others add additional channels of stimulation, such as the gluteal or paraspinal muscles, to enhance upright stance. One such system, Parastep, has received FDA approval and is shown in **Figure 4(b)**. Fatigue remains a problem because of the high level of stimulation required of the quadriceps to maintain the standing posture. The walking is slow and is typically limited to the order of 10 m because of the very high energy consumption.

Popovic and colleagues suggested the concept of a hybrid system which used bracing to maintain the upright posture and FES for propulsion, and a number of these systems have been developed. Some are based on existing braces, such as the reciprocal gait orthosis (RGO). RGOs brace the ankle, knee, and hip. They allow a stiff-legged gait without FES in many paraplegics, and the walking can be enhanced with FES. Speed and endurance are better and the energy cost is less, but the system is cumbersome and difficult to don and doff except from a bed. Sitting and standing up after putting the device on can be difficult. New types of braces (stance control) that allow the knee joint to be locked and unlocked have been developed and control only the joints from the knee down (knee–ankle–foot orthosis; KAFO). A stance-control KAFO can be donned and doffed while sitting in a wheelchair, and my group has added FES to allow easy standing and propulsion for walking. Several groups have developed systems using implanted electrodes to allow stimulation of more muscles and better control of the stepping movements. So far, none of these systems has been commercialized and published data are based on a few intensively trained individuals. No studies directly compare the best implanted systems and the best surface systems, so the relative costs and benefits of surgery are still unknown.

Systems for Hand Grasp

Several FES systems have also been developed for allowing opening of the hand to grasp objects. One system, Ness H200 (**Figure 4(c)**), has received FDA approval and is available for sale in the United States. The H200 is intended for people with stroke or other central nervous system disorders that produce flexor spasticity. In other words, the hand remains in a flexed posture and stimulating the extensors allows the hand to be opened to grasp objects. The stimulation can be used therapeutically to reduce spasticity, as well as in functional tasks. A more ambitious, eight-channel, implanted system was developed by Peckham and colleagues at Case Western University, and successfully tested on about 150 spinal cord-injured individuals. However, the market did not grow fast enough for the company that had commercialized it (Neural Control, Inc.) and the device was withdrawn from the market. Work continues at Case

Western and elsewhere; hopefully, this proven system will again be available, probably in an updated form.

Multijoint Control of the Arm

Clearly, the higher the level of a spinal cord injury and the more joints that must be controlled, the more difficult the problem. In addition, the spinal lesion will denervate some muscles of the arm, so tendon transfers or other surgical procedures may be needed to restore missing functions. Despite the challenges, surface, percutaneous, and implanted FES systems have been developed to control arm movements. To simplify the control problem, synergies involving more than one joint are used, but the movements remain slow and tedious to an external observer. However, for the severely affected individuals, these systems represent progress toward regaining control of their environment. Volunteers are eager to participate in testing these systems, hoping to speed the progress of the product from the laboratory to the community. The higher the level of the injury, the fewer biological control signals are available. Among those that have been used are the contralateral shoulder, electromyogram control from shoulder muscles, and tooth clicks. The ultimate challenge is to record signals from the motor cortex of individuals who have no voluntary arm movements and use these signals about intended movements to control all of the muscles of the arm with FES. Current implants in the motor cortex of humans by Donoghue's group and in nonhuman primates by several groups offer a proof of principle that such a venture is feasible, although many technical problems remain. In conclusion, although the field of FES for limb control has been slow to emerge, several commercial systems are now available. If successful, these systems can form the basis for advancing toward more sophisticated systems that help people with more severe disabilities to participate in a range of activities and to live a fuller and more rewarding life.

Introduction

Neuroimaging is used to generate maps of cortical and subcortical regions involved in the control of movement. Historically, human neuroimaging measured regional brain activity with positron emission tomography imaging that utilized radioactive isotopes to quantify cerebral glucose metabolism or blood flow. These techniques have been largely replaced by functional magnetic resonance imaging (fMRI) of blood oxygen level-dependent (BOLD) signal changes. The BOLD signal correlates with changes of blood flow, local field potentials, and to a lesser degree intrinsic neural activity. Changes of the BOLD signal are not specific to inhibitory or excitatory neurons and reflect a complex combination of inputs, intrinsic neurons, and output neurons within a given brain area. Spatial resolution can be as good as 1 mm, and absolute temporal resolution is limited by the latency of the BOLD response to 3–4 s. However, relative differences in the time of activation between brain areas can be measured with a higher degree of precision.

The most common goal in brain mapping is to localize specific functional attributes within brain regions. This is done with 'subtraction' paradigms and univariate statistics. In subtraction paradigms, experimental conditions are manipulated so that participants are scanned during at least two predefined behavioral states. For example, a participant might perform a visuomotor tracking task versus rest. Differences in brain activity between these two conditions will identify brain areas associated with movement execution (Figure 1). By the use of multiple regression, it is possible to employ more-complex behavioral paradigms, with which multiple trial types can be directly compared or brain activity can be correlated with performance variables such as speed or reaction time. A less common approach is to characterize interactions between sets of brain regions and to determine whether these network interactions are task specific or change as a function of learning or intervention. This approach can be used with multivariate statistics, including partial least squares or independent component analysis. The rich temporal information of neural processing measured with fMRI also provides the opportunity to use dynamic causal modeling or coherence mapping to examine interactions between brain regions. For example, with coherence measurements it is possible to identify cortical areas showing strong task-specific interactions between the supplementary motor area and the motor cortex during voluntary movement (Figure 2). Similarly, it is possible to show that the onset of activity in one brain area with respect to another, that is, their relative phasic relationship, can change as a function of task (Figure 3).

Execution-Related Areas

Imaging studies of voluntary movement compared with rest reveal a large-scale circuit of both cortical and subcortical brain regions (Figure 1). The motor execution circuit involves the sensorimotor cortex as well as premotor areas located on both the mesial and the lateral convexity of the hemisphere. There is typically involvement of the intraparietal sulcus and adjacent superior and inferior parietal lobules and multiple subcortical projection areas, including striatum, internal segment of the globus pallidus (GPi), ventrolateral thalamus, and cerebellar cortex and associated output nuclei. Within the sensory and motor cortex, there is evidence for a crude homunculus with activity related to leg movements in the most superior position, mouth movements in the most inferior aspect, and limb movements in a mid position along the cortical convexity. Within-limb somatotopy of the arm is observed in the motor cortex when measured at a very low spatial resolution. At high resolution there is evidence for a complex, fractured representation, with multiple representations of each joint of the hand and arm distributed throughout the motor cortex. In right-handed people, there is strong evidence for cortical lateralization to the left hemisphere for right-handed movements, particularly in premotor and motor cortex. In contrast, left-handed movements are associated with a more symmetric recruitment of cortical areas. This provides some evidence that the left hemisphere motor areas are normally dominant for right-handed people.

The BOLD signal change in motor areas is very sensitive to the proportion of scanning time consisting of active movement rather than rest. For example, slight increases of movement duration or number of movements per unit of time will lead to large increases in the magnitude of motor cortex activity. Subsets of motor areas demonstrate activity that correlates with kinematic measurements. Increasing movement velocity, force, or amplitude increases activity in

Figure 1 Cortical regions activated during visually guided tracking with the right hand compared with a rest condition are shown in orange. The results are a composite of 15 participants, superimposed on a population-based MRI atlas (PALS atlas, Caret software). Even the simplest of motor tasks engages a broad set of cortical areas to accomplish a motor goal.

contralateral motor cortex and GPi, as well as in ipsilateral cerebellar cortex. From this evidence, it has been proposed that basal ganglia activity may be critical for scaling motor output to a given context and to given task requirements.

Within the network of areas that are recruited during motor execution, there is specialization for the type of action that is being performed. For example, grasping objects relative to pointing recruits the most anterior portion of the intraparietal sulcus in an area considered a homolog of the nonhuman primate anterior intraparietal (AIP) area (Figure 4). Neurons in this area code visual features of an object and are also active during grasping without vision of the hand. In contrast, pointing studies are more likely to recruit the posterior superior parietal lobule and adjacent posterior intraparietal sulcus (IPS) and mesial parietal cortex. This cortex has been proposed as the human homolog of the nonhuman primate area called the parietal reach region. These parietal regions have strong interconnections with the dorsal premotor cortex. Together, they demonstrate that there are multiple specialized pathways between the posterior parietal cortex and premotor cortex for action execution.

Motor Preparation

Motor behavior requires the selection of appropriate motor commands to achieve a particular goal. Using paradigms in which a delay period occurs between task instruction and movement imperative or paradigms in which the instruction is followed by a go or no-go instruction, task planning can be distinguished from motor execution. Tasks requiring selection of a learned response typically recruit the posterior parietal cortex, particularly the superior parietal lobule and adjacent intraparietal sulcus, and the dorsal premotor cortex. This is true for choosing among many types of responses, including movements with different digits, pointing to different locations, or grasping with power or precision grip. These selection areas are particularly important when the relationship between the stimulus and movement is arbitrary,

Figure 2 (a) Neural activation (left) leads to hemodynamic responses (HRF) in the brain (middle) that are delayed and dispersed in time. Coherence mapping is a method to determine whether two areas demonstrate common frequencies of responses irrespective of phasic differences (right). (b) Demonstration of brain areas demonstrating strong coherence with motor cortex at low (left column) and high (right column) frequencies in a movement task. Corr Coef, correlation coefficient; *Z*, distance in millimeters above the anterior commissure. Adapted from Sun FT, Miller LM, and D'Esposito M (2004) Measuring interregional functional connectivity using coherence and partial coherence analyses of fMRI data. *Neuroimage* 21: 647–658.

such as tasks where nonspatial cues are used to indicate where someone should point in space. This dorsal parietal-premotor circuit forms a substrate for learning many types of mappings between stimuli and responses, such as learning that a red light means stop and a green light, go. The left parietal cortex is also involved in implicit action selection. It has long been observed that covert motor attention can be directed to an upcoming movement. Neuroimaging studies show that the left IPL is recruited in experiments when participants covertly prepare movements.

Successful motor behavior requires the ability to switch between mappings as a function of context. Do we continue with the task at hand, such as reading and drinking coffee, or is it time to shift to an alternate behavior such as checking email? The ability to switch or stay with the current task, depending on the context, requires involvement of the medial frontal cortex including the presupplementary motor area (pre-SMA) and adjacent cingulate cortex. These areas are transiently activated at the time that participants switch from one way of responding during a task to another.

Sequential Movement

Complex behavior requires the organization of multiple movements across time. An extensive neuroimaging literature demonstrates that retrieval of already learned sequences is associated with activity in the supplementary motor area (SMA) and pre-SMA regions of the medial bank of the superior frontal gyrus (Figure 5). This is found with human and nonhuman primate lesion studies. Damage to this area of the mesial frontal cortex leads to impairment in organizing sequential movements. Single unit recording studies in nonhuman primate demonstrate individual neurons that represent sequential information in SMA and pre-SMA. There is emerging evidence for involvement of the inferior parietal lobule during sequence learning and retrieval as well. The sequence related activity in IPL overlaps with functional studies localizing brain areas associated with tool use and complex motor behaviors (see below), and is consistent with clinical observations that lesions to the inferior parietal lobule (IPL) in humans can lead to impairments in motor sequencing for complex tasks.

When motor sequences are learned under explicit conditions, such as learning to tap the digits of the right hand in a particular pattern, humans can also draw on working memory and higher-level cognitive circuits to enhance performance. This is reflected in recruitment of dorsal prefrontal cortex when explicit sequences are performed. It has been proposed that the basal ganglia represent sequential information as tasks become overlearned and automated. However, additional evidence is needed to establish a storage role for the basal ganglia or specific cortical regions for motor memories.

Figure 3 The hemodynamic response in the brain limits the time resolution for measuring when an event occurs. However, relative latencies between a set of areas can be distinguished at a subsecond resolution, as shown in (a). The plots show the relative timing of responses in supplementary motor area (1), left premotor cortex (2), left motor cortex (3), left parietal lobe (4), and right ventral premotor cortex (5). Relative differences of the timing when the BOLD response occurs during a motor task are shown in (b). Note the differential timing of response in motor cortex compared to other areas as a function of movement (lower row) or rest (upper row). *Z*, height in millimeters above the anterior commissure. Online Control

A precise movement, such as threading a needle, requires the ability to adjust an ongoing movement in the face of inaccurate preplanning, a changing environment, or an imperfect musculoskeletal apparatus. All these introduce added noise to any planned action. Studies of precision reaching demonstrate robust recruitment of the anterior cerebellar cortex, ipsilateral to the reaching arm during task execution. If external errors are introduced by shifting the target location near the time of movement onset or by introducing a perturbing force to the reaching arm, then increased activity is also seen along the postcentral sulcus, particularly near the anterior intraparietal sulcus contralateral to the reaching arm (Figure 6), suggesting that a common parietal–cerebellar circuit is involved in correcting random errors induced by a number of different causes.

Organization of Complex Behaviors

Humans maintain a broad repertoire of physical skills for solving real-world problems, combined with a seamless ability to work with tools. It has long been known from lesion studies that the explicit retrieval of action knowledge depends critically on the integrity of the left parietal lobule and posterior middle frontal gyrus. Lesions to either of these regions lead to ideomotor apraxia. This localization has been closely replicated in functional neuroimaging studies of participants as they mentally retrieve knowledge about how to use tools. For example, in one study, participants were asked how to use a hammer and other tools. By the use of a go, no-go paradigm, the mental retrieval process was separated from the actual motor execution used to pantomime the action needed for each of the tools (Figure 7). Functional neuroimaging established that during action retrieval, the left supramarginal gyrus was the most consistently recruited sector of the IPL across individual participants, irrespective of whether the action would be pantomimed by the right or left hand.

Figure 7 Cortical areas involved in retrieving (a) and executing (b) pantomimed gestures of common tool use by the right hand. Left and right columns are the left and right hemispheres, respectively. Retrieval of tool-based actions requires the left supramarginal and inferior frontal gyri. Similar retrieval patterns are found irrespective of the hand used to make the gesture. Adapted from Johnson-Frey SH, Newman-Norlund R, and Grafton ST (2005) A distributed left hemisphere network active during planning of everyday tool use skills. *Cerebral Cortex* 15: 681–695.

The neural substrates for action representation can also be identified in studies of action observation. In nonhuman primates there are strong interconnections of AIP, the grasp-related area, with the inferior frontal cortex. These sites contain mirror neurons, individual cells that fire in response to observation of grasping actions by another agent. These neurons are also active during actual grasping. A homologous set of regions, including the ventral premotor cortex and adjacent inferior frontal gyrus (pars opercularis) as well as inferior parietal lobule in the human are activated with action observation as well as execution and imitation, as shown in Figure 8. This network in humans has been labeled the mirror neuron system (MNS) and may be a critical substrate for action organization as well as in understanding actions of others. Activity within some parts of the MNS is experience-dependent. For example, studies have shown that the more physical expertise dancers have in performing a particular movement, the greater the activity in the MNS as they observe others performing the same action.

Complex actions are organized with respect to desired outcomes. From this, intermediate solutions are used to generate actions that lead to those outcomes. For example, on the elevator someone can push the button for the desired floor with the hand, unless it is occupied with another task such as holding an umbrella. In this case one of several alternate solutions is implemented, such as pushing the button with the umbrella, the other hand, or even the foot. There is emerging evidence from studies of action observation that dissociable neural substrates are recruited for these different levels of action organization. When an action is observed, such as someone picking up a cup, the intention of the action will differ if the surrounding dishes are dirty (clearing the table) or filled with food (taking a drink). Activity within the inferior frontal gyrus is modulated when this level of intention is inferred. In contrast, for intermediate levels of action organization, such as the detection of what particular object is being grasped rather than how it is grasped, the anterior IPS demonstrates sensitivity.

Motor Skill Learning

Motor learning is the ability to perform a novel movement to accomplish a behavioral goal, such as playing a musical instrument. In skill acquisition of this type, someone may take years to reach proficiency, and it is difficult to use brain imaging to study the accompanying long-term changes within an individual's nervous system. Instead, neuroimaging studies have focused on other aspects of learning that occur along

Figure 8 Example of the interaction between brain areas that respond to the observation of action and the role of physical experience for those same actions. (a) Participants watched video clips of a teacher performing complex modern dance movements. Note the widespread recruitment of premotor, temporal, and parietal cortex of the lateral left hemisphere (left column), as well as supplementary motor area on the medial surface (right column). (b) A comparison of trials after observers have learned to perform complex dance movements with those in which they have not identifies a more specific set of brain regions in the action observation network. (c) If a measurement of self rated competency is correlated with brain activity acquired while subjects observe of the same movement, there is a strong correlation in inferior parietal and frontal gyri. This demonstrates that some, but not all action observation areas have experience-dependent responses. Adapted from Cross ES, Hamilton AF, and Grafton ST (2006) Building a motor simulation *de novo*: Observation of dance by dancers. *Neuroimage* 31: 1257–1267.

faster timescales. For example, adaptation paradigms can be used to examine learning of task dynamics, analogous to playing a musical instrument with a heavy coat on. In this case the motor skill is already learned, and the performer is adjusting motor output to address a novel environment. In this case, adaptation can occur quickly. Adaptation-related activity is associated with recruitment of parietal and cerebellar cortex, suggesting a close connection between online error correction and adaptive control. Another strategy for examining learning is to examine repeated performance of relatively simple tasks, such as visuomotor tracking. In these cases, activity increases rapidly and dramatically in sensory and motor cortices contralateral to the moving hand. These early increases might be related to temporary changes of cortical excitability that occur with repeated use and reflect reduced cortical inhibition rather than formation of a specific skill. With longer-term practice over hours to days, activity changes have been observed in numerous motor planning areas, including the supplementary motor area, dorsal premotor cortex, and inferior parietal lobule. There is also a close correspondence between activity in the cerebellum and coordination between the eyes and the hand.

Comparisons of expert and novice performers provide an important avenue for defining learning-dependent changes in the brain that emerge over years of practice. Musicians such as professional violinists and pianists demonstrate greater gray matter volume in the motor cortex than their novice counterparts. In contrast, functional imaging experiments of these people performing relevant skills such as keyboard performance show that the experts recruit far less cortex than the novices do in areas including motor cortex, SMA, and dorsal premotor cortex. This is true even when the performance of the two groups is matched in speed and difficulty. This finding supports a model whereby long-term training in

complex skills leads to a strengthening within a subset of neural circuits that can be recruited for a given task, reflected in reduced recruitment of cortical area.

Functional Neuroimaging Studies of Aging

C L Grady, University of Toronto, Toronto, ON, Canada

Introduction

Age differences in cognitive function have been studied for many years, and of all the cognitive domains, memory has probably been studied the most extensively. Compared to young adults, older adults have particular difficulty with episodic memory, defined as the conscious recollection of events that have occurred in a person's experience. In the laboratory, these age differences in episodic memory are seen in a reduced ability to learn and retrieve lists of stimuli, such as words or pictures of common objects. Older adults have particular difficulty in retrieving accompanying information about stimuli learned during the course of an experiment, so-called source memory. For example, when learning a list of words presented verbally by either a male or a female speaker, young adults are readily able to recall both the words and whether they were spoken by a man or woman, whereas older adults will have more difficulty remembering the speaker's gender than the words. Older adults also recall fewer details about real-life, autobiographical memories, and substantial age-related declines are seen on working memory tasks (i.e., tasks that require holding information on line for brief periods of time). In addition to these differences in memory, older adults also show reductions in inhibitory function, reflected in an increased vulnerability to distracting information, as well as lower performance on tests tapping other types of executive function. In contrast, semantic memory, or the accumulation of knowledge about the world, is maintained or even increased in older adults, compared to younger adults. Some aspects of emotional function also are preserved with age, although identifying and remembering negative emotional material are sometimes reduced in older adults. Thus, not all aspects of cognitive function are affected adversely by older age.

In recent years, functional neuroimaging has been used to explore brain activity accompanying cognitive tasks in young and old adults, and to understand the neural mechanisms underlying behavioral differences. Memory has received the most attention in this work, similar to the predominance of memory studies in the behavioral literature. Nevertheless, other cognitive domains have been studied, and some of the fundamental processes contributing to cognitive aging are becoming clear.

Methodological Issues in Studying Aging

Prior to reviewing the results of neuroimaging studies of cognitive aging, it is useful to consider some of the issues that one may encounter when using this methodology to study older adults. The typical techniques used are either positron emission tomography (PET) or, more commonly today, functional magnetic resonance imaging (fMRI). Both of these techniques are based on task-dependent modulation of hemodynamic function, such as blood flow or oxygenation. Therefore, age-related changes in the vasculature might influence the coupling between neural activity and hemodynamic functional measures obtained in the elderly. Although the shape of the hemodynamic response function, as measured with fMRI, is similar in young and old adults, there is reduced signal-to-noise in the elderly. In addition, older adults undergo brain shrinkage, or atrophy, and some loss of white-matter integrity, both of which could impact functional measures independently of any changes in neural activity. Despite these difficulties, several robust and replicable age-related differences in brain activity have been noted, suggesting that these potential artifacts may not pose too severe a problem.

When brain activity in young and older adults is compared on a task, there are at least three possible outcomes in any given brain area: (1) young and old groups could have equivalent brain activity, (2) older adults could show less activity, or (3) old adults could show greater activity. Reduced activity in the elderly can reasonably be assumed to reflect a reduced level of functioning, particularly when accompanied by poorer performance on the task. Equivalent activity is generally considered evidence for spared function in the elderly. The major challenge has been to interpret increased recruitment of task-related brain areas, or activation of unique brain regions in the elderly.

Several analytic approaches have been applied to the study of brain mechanisms underlying cognitive aging. The most common approach has been a straightforward contrast of brain activity between young and old groups of participants and interpretation of the observed differences in activity in the context of behavioral performance on the tasks. Much of this work has focused on the frontal lobes, which are thought to be particularly vulnerable to the effects of aging. However, this type of univariate approach is often plagued by issues related to multiple comparisons and statistical power, which are compounded when more than one group of individuals is studied. Other approaches that utilize multivariate analyses to identify whole-brain patterns of

functional changes, and hence avoid problems with multiple comparisons, have been used with some success in the aging field. Functional connectivity is another type of multivariate approach that focuses on cognitive networks (i.e., groups of regions working in an integrated fashion during cognitive tasks). Connectivity involves assessing how activity in a given region correlates with activity in other areas of the brain during a task. This type of correlation can be done on a pair-wise region basis or across the whole brain. Thus, connectivity approaches emphasize the functional interactions among brain areas and the ways in which these interactions mediate cognitive processing, rather than focusing on the activity in any individual brain region. This 'whole-brain' type of approach has revealed that a number of brain areas, including the frontal lobes, appear to be critical sites of age-related change in function.

Reduced Brain Activity in Older Adults

Reduced brain activity in older adults typically has been noted during encoding, or learning new material. Younger adults have increased activity in left prefrontal cortex when learning new stimuli, and a common finding is that older adults show less activity in this area during encoding compared to younger adults, across a variety of stimulus types (e.g., words, faces, objects; see Figure 1). The age-related reduction of activity in left prefrontal cortex can be ameliorated to some extent by using encoding tasks that promote deep, or semantic, processing of the to-be-remembered information. Both young and old adults show more left prefrontal activity during a semantic encoding task, compared to a task that does not require a focus on the semantic aspects of the stimulus, and this increase in older adults can be

Figure 1 The images depict brain areas with changes in blood flow (measured with positron emission tomography) during encoding (Enc) and recognition (Rec) of faces in a group of young adults (top panel, $n = 12$; mean age 23 years) and a group of older adults (bottom panel, $n = 11$; mean age 70 years). Results are shown on images from a standard structural magnetic resonance image. Yellow/red areas are those with more activity during encoding, compared to recognition, and blue areas indicate more activity during recognition. Young adults show increased activity during encoding in left inferior prefrontal cortex (white arrow), but older adults do not. In contrast, old adults have more activity during recognition, compared to young adults, in widespread areas of left prefrontal cortex (cyan arrow).

large enough to remove any age difference. This pattern of results is consistent with behavioral data suggesting that older adults may not spontaneously engage effective encoding strategies – that is, those involving semantic processing by left inferior frontal cortex – but can use such strategies when required to do so.

In contrast to the left frontal activity seen during encoding, during memory retrieval, when people are attempting to recall or recognize previously learned information, frontal activity often is found predominately in the right hemisphere. Although this right frontal activity is often of the same magnitude regardless of age, older adults do show reduced activity under some conditions. When the retrieval task places a heavy demand on memory search, without providing cues for retrieval, older adults show a reduction in right prefrontal activation. Retrieval of source memory, such as whether a word was spoken by a man or a woman, also places significant demand on memory search and typically activates prefrontal regions in young adults. Consistent with their reduced source memory, older adults have less activation of prefrontal cortex during source retrieval compared to their younger counterparts.

Another area of memory that has been examined fairly extensively in the aging field is that of working memory. A number of working memory tasks have been used, including delayed match-to-sample and *n*-back tasks. Regardless of task, these studies have generally found less prefrontal activity in older adults. When the different phases of the working memory task have been examined separately (memory set presentation, delay, and probe), age differences have been seen primarily during the presentation of the probe – that is, when the memory decision is being made. This suggests that some aspects of working memory, such as rehearsal, might not be affected by age. Some recent work has shown that older adults are able to recruit prefrontal cortex at lower levels of working memory task load, but that this declines at higher task loads, whereas younger adults continue to increase prefrontal recruitment with increasing load. This finding is similar to that noted earlier for episodic retrieval, as both would suggest that tasks with high processing demands are likely to be associated with reduced brain activity in older adults, and potentially poorer performance as well.

In addition to prefrontal regions, less activity during encoding and/or recognition memory in older adults also has been found in other areas important for memory, including the hippocampus and the parahippocampal gyrus, and in visual areas of cortex (Figure 2). Interestingly, when brain activity has been compared across different kinds of tasks, such as working memory and episodic retrieval, similar age reductions in brain activity have been found in visual cortex and hippocampus. Such a result is consistent with the idea that there is a 'common cause' of cognitive aging, and indicates that reductions in both

Figure 2 The images depict brain areas with changes in blood oxygenation (measured with functional magnetic resonance imaging) during recognition of auditorily presented words in a group of young adults ($n = 12$; mean age 26 years) and a group of older adults ($n = 12$; mean age 71 years). Results are shown in red on mean structural magnetic resonance images for the young adults (top) and the older adults (bottom). Young adults had greater activity in a region of left extrastriate cortex (black circle), whereas older adults had more activity in prefrontal regions (one of which is indicated by the blue circle).

sensory processing and memory encoding could be involved in such a common cause. One thing to keep in mind, however, particularly when considering age differences in sensory cortex, is that less activity during a particular cognitive task may mean that older adults have more activity in these areas during the baseline condition. Thus, when activity during the baseline is subtracted from task activity, older adults will have a smaller task-related increase, but this does not mean that the region cannot be activated. Rather, the older adults are starting out from a higher level of activity. Such a phenomenon has been observed in visual cortex.

Functional neuroimaging has also been used to study executive functions, thought to be mediated primarily by frontal cortex, in older adults. One such function, inhibition, has been studied using tasks that require inhibiting a prepotent response or suppressing information irrelevant to the task. Consistent with their poorer performance, older adults have less activity in frontal regions thought to mediate inhibitory processes on such tasks. Activity in frontal regions also is reduced with age during performance of the Wisconsin Card Sorting Task, a standard instrument measuring concept formation and cognitive flexibility. Other brain regions also show age differences during tasks requiring inhibitory processing. Young adults either enhance or suppress activity in regions of occipital cortex that respond selectively to different types of objects depending on whether the objects are attended or ignored. In contrast, older adults show enhanced activity in these areas, but fail to reduce activity in object-specific regions when viewing objects that should be ignored because they are irrelevant to the task at hand. Thus, age reductions in the ability to ignore irrelevant and distracting information may be the result of both top-down (i.e., frontal) and bottom-up (occipital) mechanisms.

Emotional processing and emotional enhancement of memory have been studied for a number of years using animal models, but only recently has investigation of this area of cognition been explored with functional neuroimaging. Consistent with animal work showing critical involvement of the amygdala in emotion, young adults show increased activity in the amygdala when emotional stimuli, particularly negative items, are viewed. This activity also is related to later memory for this material, even when memory is tested months after initial exposure to the stimuli. Older adults show less amygdala activity compared to younger adults during viewing of negative faces and scenes, consistent with their reduced ability to both identify and remember negatively valenced stimuli.

Finally, there has been recent interest in a group of brain areas that have more activity when people are not carrying out a specific task, but are merely monitoring their internal and external milieus, the so-called 'default mode' regions. Young adults show marked reductions of activity in these default areas when carrying out a variety of tasks, whereas older adults have much less change in these areas during tasks. In fact, there appears to be linear reduction in this default region 'suppression' over the adult life span, suggesting a gradual, age-related reduction in the ability to suspend non-task-related, or default, activity and to engage areas for carrying out memory tasks. Thus, it may be just as important to look at age-related differences in activity reductions as it is to explore differences in activity increases.

Increased Brain Activity in Older Adults

It is perhaps surprising that, in addition to reduced brain activity in some areas, older adults often show increased brain activity, compared to young adults. Additional recruitment of brain areas by older adults typically is found in the frontal lobes, either in areas of frontal cortex not active in young adults, or in homologous regions in the opposite hemisphere from regions active in the young. During episodic memory retrieval older adults frequently show more extensive activation of prefrontal regions compared to younger adults, sometimes in those left hemisphere frontal areas that are less active during encoding in older adults. Greater prefrontal activation during memory retrieval has been found in older adults for a variety of stimuli, both verbal and nonverbal (**Figures 1** and **2**). Another way of looking at the brain activity that supports retrieval is to see how activity during encoding of items that are later correctly remembered differs from that for encoding of items that are forgotten, known as the 'subsequent memory effect.' That is, what is the brain activity, during learning, that predicts whether a stimulus will be successfully remembered later? Using the subsequent memory effect, a number of investigators have found that activity in left inferior prefrontal cortex and the left medial temporal region in young adults is greater during encoding of subsequently remembered stimuli. A similar pattern has been found in old adults; however, older adults also have an association between more activity in right prefrontal cortex and subsequent recognition. Thus, older adults can show a more extensive pattern of frontal activity during encoding, as they do during retrieval, but only when that encoding is sufficient to support later retrieval. A similar pattern has been found during some working memory tasks, where frontal activation often is unilateral in young adults, but in both hemispheres in older adults.

There is some evidence for greater brain activity in older adults during memory retrieval tasks in areas outside of the frontal lobes, such as medial temporal cortex. In particular, studies of recognition memory, such as recognition for words presented earlier in the experiment, have shown more activation of parahippocampal regions in older adults, compared to younger adults. Indeed, parahippocampal cortex in young adults often shows less activity when previously seen stimuli are presented during a recognition task, and this reduction in activity is thought to represent a signal of familiarity with the stimulus. Increased activity in older adults in the parahippocampal gyrus may still indicate familiarity, but the nature of the signal may undergo a change with age. Interestingly, although hippocampal activity during memory retrieval is often reduced with aging, bilateral activation of the hippocampus has been reported in older adults during an autobiographical memory retrieval task, whereas young adults had only left hippocampal activation. This bilateral activation is similar to the bilateral prefrontal activity seen in older adults during other memory tasks, and may support those aspects of autobiographical retrieval which are maintained in the elderly.

Increased prefrontal activation in older adults also has been found in other cognitive domains, although less information is available than for memory. For example, there are reports of more prefrontal activity in older adults when carrying out what one might consider relatively simple motor tasks. This may indicate that even sensorimotor tasks require more cognitive control on the part of older adults.

So, what could be the impact of this increased brain activity on behavioral performance in older adults? There have been suggestions that additional recruitment of task-related brain areas, or engagement of unique areas not active in young adults, compensates for age-related changes in brain structure and function. Compensation has been invoked to explain greater prefrontal activity in older adults when they are able to perform a particular task, as well as younger adults. Additional support for this idea has been found in studies showing that older adults who perform better on memory tasks recruit prefrontal cortex to a greater degree than do those performing less well. Older adults also may have more prefrontal activity than do young adults when brain activity is examined just for those task trials where participants respond correctly. Such findings suggest that correct performance may be supported by this overrecruitment of frontal regions. Another approach has been to determine how brain activity is related to task performance by correlating these two measures in groups of young and old adults. Increased prefrontal activity is often correlated with better performance on memory tasks in older adults, but rarely in young adults. In fact, in young adults prefrontal activity is usually correlated with poorer task performance, indicating that with age, the impact of brain activity on memory performance is altered.

On the other hand, some of this increased prefrontal activity in the elderly may reflect greater need or use of frontally mediated executive functions at lower levels of task demand than would be necessary for activation of this area in young adults. In this case the increased activity in prefrontal cortex might not be related to performance on the particular task, but would reflect a type of nonselective recruitment in older adults, perhaps related to task difficulty. Examples of this kind of scenario have been observed, and include increased activity in widely distributed areas of both lateral and medial portions of prefrontal cortex in older adults during tasks on which they perform worse than young adults (Figure 2). These findings suggest that while additional recruitment of prefrontal cortex in older adults may often be compensatory, it is not necessarily so.

Different Cognitive Networks in Older Adults

A relatively new approach to studying brain function is the focus on functional connectivity, or how activity in a given brain area is correlated with activity elsewhere in the brain, to identify networks of interacting regions. Studies using this approach have provided intriguing evidence that young and older adults recruit different networks, even when the measured behavior is the same. For example, when pictures are used as stimuli in memory tasks, they are recognized well by both young and old adults. Encoding of these pictures also is associated with increased activity in medial temporal regions, including the hippocampus, in both young and old groups. However, the areas that are functionally connected to the hippocampus during encoding vary with age. In young adults, during picture encoding, hippocampal activity is correlated with activity in ventral prefrontal and visual regions, whereas older adults show correlations between hippocampal activity and dorsolateral prefrontal and parietal regions (Figure 3). Of particular interest is that these age-specific networks are associated with better memory performance. That is, those individuals in each age group who engage the specific network to a greater degree are the ones who remember the greatest number of pictures.

Different functional connectivity of medial temporal regions in older adults, compared to young adults, also has been found during recognition tasks.

Figure 3 The images depict brain areas where blood flow (measured with positron emission tomography) during picture encoding was significantly correlated with flow in right hippocampus (white arrows). Results are from a group of young adults (top, $n = 12$; mean age 23 years) and a group of older adults (bottom, $n = 12$; mean age 66 years) and are shown on a standard structural magnetic resonance image. Yellow/red areas are those with positive correlations and blue areas are those with negative correlations. In young adults hippocampal activity was positively correlated with activity in ventral prefrontal regions, whereas in old adults hippocampal activity was positively correlated with activity in dorsolateral frontal cortex. The graphs show the scatterplots of activity in these age-specific networks, and recognition accuracy. As activity increased during encoding in the hippocampus, and the areas positively correlated with it, subsequent recognition accuracy increased in both groups.

A recent study found that during recognition, the hippocampus showed stronger functional connections with cortical regions in young adults, whereas the entorhinal cortex showed stronger connections in older adults. This finding was consistent with evidence that these two medial temporal areas mediate recollection and familiarity, respectively, two aspects of memory that tap different qualitative experiences, and with the many studies showing age differences in recollection but not familiarity. Thus, age differences in recollective processes mediated by the hippocampus may be offset by more reliance on familiarity mediated by medial temporal cortex adjacent to the hippocampus. Similar evidence for age differences in cognitive networks involving the hippocampus and its interactions with the cortex has been found in experiments tapping working memory as well. All of these studies that focus on network approaches to image analysis have provided evidence that aging results in the modification of large-scale network operations, in addition to affecting activity in specific brain regions, which in turn has an impact on memory ability.

Genetic Factors in Brain Aging

Recently there has been interest in using functional neuroimaging to study the genetic basis for cognitive behaviors, including memory. Most of this work has been done in young adults, by dividing healthy

samples of people according to different genetic alleles that bear some relation to risk for psychiatric diseases, such as schizophrenia. This work has shown that activity in prefrontal cortex and medial temporal areas differs across genotypes, and that these differences are associated with differences in personality traits, such as risk taking, and in memory function. Little work in this area has been applied to the study of cognitive aging, but a few studies have looked at the effect of *APOE* genotype on brain function and memory in older adults. *APOE* is one of the genes that confers risk for Alzheimer's disease when the *APOE* $\varepsilon 4$ allele is present. Several studies have shown that middle-aged and older individuals who have the $\varepsilon 4$ allele, but are nevertheless asymptomatic, have reduced resting metabolic activity in parieto-temporal cortex compared to those without the $\varepsilon 4$ allele. Follow-up assessments showed that cognitive decline after 2 years was greatest in those *APOE* $\varepsilon 4$ carriers with the lowest metabolism in parietal and temporal regions at baseline. In addition, older *APOE* $\varepsilon 4$ carriers have faster cognitive decline than do noncarriers, and show a relation between subjective memory complaints and decline in temporal lobe metabolism over time. Interestingly, it was found with fMRI that activation of prefrontal and medial temporal areas was increased in *APOE* $\varepsilon 4$ carriers, compared to noncarriers, but only during memory tasks. This finding suggests that the cognitive and neural effort necessary for memory function varies according to one's genetic makeup, and that this effort may also reflect the likelihood of cognitive decline in later years. All of these studies indicate that cognitive changes noted in older adults, even in those individuals who appear to be cognitively normal for their age, may be influenced by genetic factors. In addition, it is possible that genetic differences underlie some of the variability that has been found across neuroimaging studies of older adults.

Conclusions

It is clear that functional neuroimaging has opened a window into cognitive aging, shedding light on the roles of brain areas, such as prefrontal cortex and the hippocampus, in age-related differences in cognitive performance. However, a number of questions remain. For example, the extent to which alterations of brain activity or brain networks seen in older adults are due to changes in the function of the brain regions, or to changes in the white-matter tracts that connect the regions, is unknown. Communication between cortical regions could be reduced or altered because the neurons in the regions have altered function or because the fibers that connect them are damaged or less efficient. Changes with age in white matter, and the impact of these on cognition, have been documented, but how these changes affect functional connectivity of gray-matter regions during cognitive tasks is not well understood. Recent evidence indicates that age differences in white matter are more prominent in frontal than in posterior brain areas, and that white-matter integrity of the frontal lobes is related to activation in prefrontal gray-matter regions in older adults. These structural changes are consistent with age changes in frontal activity that suggest nonselectivity, but not with evidence that frontal cortex is most often recruited for compensatory purposes. Clearly we have much to learn about the complex interplay between brain structure and function, and how this interaction is affected by age.

There are other factors that could influence brain activity in older and younger adults and these are just now beginning to receive attention. An example is education, which has been shown to have a protective effect against decline in cognitive function in older adults. There is some evidence that education, or other indices of intellectual achievement, are related differently to brain activity in young versus older adults, such that education is positively correlated with frontal activity only in older adults. This finding is consistent with the evidence of greater frontal recruitment by older adults and suggests that frontal cortex is engaged particularly by those older adults who are highly educated. Thus, it may be that compensatory brain activity in older adults is most likely to be seen in those with higher education, but more work needs to be done in this area. Other variables, such as personality traits or mood, have yet to be examined, but as age differences have been found on these measures, these factors also could be influencing brain activity in older adults.

Finally, it is important to note that it is possible to identify a difference in functional connectivity, or network interactions, involving a particular brain area even when no change in mean activation is seen in this area. This indicates that a failure to find differences in brain activity between younger and older adults in a given region on a particular task does not mean that the functional communication of that region with other area is the same as well. Thus, one cannot always assume that the function of a brain area is unchanged with age merely by assessing its mean activity level. A more detailed examination of the dynamic interactions among brain regions, in conjunction with underlying structural changes and assessment of the impact of network activity on behavioral performance, will likely be necessary to ultimately understand the impact of aging on cognitive function.

Fusion Pore

J Zimmerberg, L-G Wu, and T S Reese, National Institutes of Health, Bethesda, MD, USA

© 2009 Published by Elsevier Ltd.

When an action potential in an axon depolarizes the membrane at a synapse, voltage-dependent calcium channels open to admit calcium, which then induces vesicles laden with neurotransmitters or neuropeptide to fuse with the presynaptic membrane and secrete their contents. This process of membrane fusion is not restricted to the nervous system but is a general feature of membranes in living cells. Fusion is used for exocytotic secretion at synapses and elsewhere, as well as viral entry, protein trafficking, fertilization, organogenesis, and wound healing. Fusion is not instantaneous but, rather, begins with a set of intermediate states establishing a direct aqueous pathway – a fusion pore – between the interior of the fusing vesicle or interior of a fusing cell and the extracellular space or the interior of the target cell (Figure 1). A minute pore connects the inside of the granule with the extracellular space, and then the pore expands rapidly to expel the contents of the granule.

Techniques

Detailed structural views of exocytosis came from electron microscope examination of ultrathin sections of stimulated secretory cells fixed, stained, and embedded in plastic. The description of omega-shaped fusion openings originated with the work of Douglass on the exocytosis of secretory granules in chromaffin cells. It was expected from the beginning that earlier stages consisting of much smaller vesicle openings or fusion pores must exist.

Early fusion pores were captured by freezing of cells just as they were stimulated to secrete. The idea was to cool the cells so rapidly – within a few milliseconds – that short-lived fusion pore intermediates would be trapped in vitreous ice. Electron microscopy of this material was done after freeze substitution to preserve the original conformations of membranes for ultrathin sectioning. In this way, fusion pores in the 10 nm range were found during granular exocytosis in both mast cells and the amebocyte of the horseshoe crab, *Limulus* (Figure 2). A search for pores in membrane fractures through the pore in both types of secretory cell, as well as at neuromuscular synapses, revealed an actual pore connecting the vesicle with the outside.

Because the early fusion pores were almost 10 times smaller than the thickness of a thin section, detecting them in *Limulus* required viewing stereo electron micrographs. The dimensions of the smallest pore that can be detected by stereo electron microscopy is in the range of 10 nm, but this range could potentially be extended to smaller pores by modern electron microscope tomography. Small fusion pores (10 nm range) were also detected in the fusion of the influenza virus to liposomes that contain the viral receptor ganglioside by freeze-fracture technique. The paucity of fusion pores in many systems is interpreted to reflect the short lifetime of this intermediate, estimated to be less than a few milliseconds at the presynaptic terminal.

One problem in the interpretation of electron microscopic images of fusion pores is that fusion pores associated with exocytosis are not easily differentiated in static images from endocytic fission pores, which are structural intermediates that arise immediately before the final pinching off of an endocytosing vesicle. Time-resolved admittance measurement is a method of detecting fusion that is useful for both differentiating between fusion and fission pores and detecting pores of smaller dimensions. This technique relies on the fact that fusion adds membrane to a cell, and the addition of membrane results in an increase in the capacitance of the whole cell (Figure 3). Although the fusion pore is small, the voltage drop across the vesicle membrane is submaximal because part of the voltage falls across the resistance of the fusion pore. Thus, the fusion pore conductance (permeability to ions) can be calculated at millisecond time resolution from time-resolved measurements of capacitance. More generally, two-phase admittance can be measured, extending the range of fusion pore detection. In addition, the frequency of the inquiring alternating voltage used to measure admittance or capacitance can be altered to probe different ranges of fusion pore conductance. In this way, pores were first detected in the exocytosis of a mast cell from a mutant (beige) mouse, an animal model for Chediak–Higashi syndrome of humans (Figure 3). The pore conductances in exocytosis measured by this technique range from 0.1 to 100 nS. To determine the dimensions of fusion pores that fit this measured conductance, one must make certain assumptions about the geometry of the pore, mainly the relationship between its length and width. Assuming a fusion pore length of 15 nm to account for twice the bilayer thickness and 5 nm of cytoplasm, and assuming a cylindrical geometry, we estimate the internal width of the smallest initial fusion pores measured by admittance to be approximately 1.5 nm. Since an α-helix of a protein is 1 nm in diameter, the measured fusion pores are thus of molecular dimensions.

Figure 1 Stages of pore formation and enlargement based on observation with the electron microscope of thin sections through horseshoe crab blood cells (amebocytes). The amebocytes were stimulated to secrete clotting proteins from their granules. The granule membrane is pulled against the cell membrane and a minute pore forms (b, top). The pore rapidly expands (c, d) to release the clotting proteins. Expansion of the pore progresses from b to c in a fraction of a second, but it proceeds more slowly from c to d. These granules are approximately 1 μm in diameter. Reproduced from Ornberg RL and Reese TS (1981) Beginning of exocytosis captured by rapid-freezing of *Limulus* amebocytes. *Journal of Cell Biology* 90: 40–54.

Almost immediately upon application of the time-resolved admittance measurement technique to cells with large granules, where fusion pore openings could be separated from each other in time, it was appreciated that the fusion pore can close once open. This phenomenon, termed capacitance 'flicker,' is widely found in exocytosis and viral fusion. Even very large pores, up to 8 nm in diameter, can close relatively soon after opening.

Another method for detecting initial fusion pores relies on the discharge of charge stored within vesicles (Figure 4). The resting voltage across the cell membrane can be set to a value different from that of the transmembrane potential. Upon the opening of the fusion pore, the difference in potential is equilibrated, resulting in an exponential flux of charge across the fusion pore. By measuring the exponential decay in this charge dissipation, one can calculate the conductance of the initial fusion pore and confirm its uniformity of size over the time constant of the vesicle capacitance–fusion pore resistance product.

A final method for fusion pore detection, amperometry, relies on detecting directly the discharge of vesicular contents (Figure 5). Certain vesicular contents oxidize or reduce at the surface of an electrochemical electrode (usually a carbon fiber). By placing a carbon fiber near the cell membrane, the momentary burst of released contents can be detected in a time-resolved manner. Occasionally, a slow release can be seen prior to the burst of release, and from this slow flux of contents the fusion pore conductance can be estimated. For vesicles containing insufficient amounts of electrochemically active compounds, often appropriate chemicals can be incubated with the secreting cells to load the vesicles with these exogenous compounds, thus providing a stronger signal for electrochemical measurements than the endogenous contents.

The methods for detecting fusion pores have been refined to allow detection of not only changes to the whole cell membrane but also individual events in both on-cell patches of membrane and excised patches (Figure 6). In addition, hybrid pipettes have been created that allow for simultaneous measurements of capacitance and amperometry.

Fusion Pore Dimensions and Dynamics

Since the smallest fusion pores detected have conductances comparable to those of single ionic channels, the measurement of fusion pores reflects the molecular architecture of the fusion apparatus. Remarkably, both the initial fusion pore and the dynamics of its widening are the same in almost every exocytotic system in which it has been measured, supporting the notion that there is a common molecular mechanism to exocytic fusion.

The initial fusion pore has a very broad distribution of conductance and, hence, size (Figure 7(a)). This fact has been used to reflect a fluid component to the architecture of the fusion pore and thus to the mechanism of fusion (Figure 7(b)). It is not known whether the lumen of the fusion pore is lined with proteins or lipids. There is no way to determine this directly, and the indirect evidence is contradictory. Phenylalanine mutations of the transmembrane domain of syntaxin alter amperometric 'foot' conductance, which suggests an effect of the transmembrane domain on pore conductance. Phospholipid composition alters the fusion pore opening, suggesting that it begins as a lipidic pore within a proteinaceous scaffold. The simplest way to accommodate the data is to imagine that the protein contributing to the initial fusion pore is intimately associated with its structure, either within lipid that arrives later to wet the

Figure 2 Electron micrographs of early fusion pores in horseshoe crab amebocytes (see **Figure 1b**) as seen by freeze substitution (top) and freeze fracture (bottom). The two freeze-substitution images (top) are a stereo pair of a contact between a granule (on the right in both views) and the outside of the amebocyte (on the left in both views). A pore approximately 30 nm in diameter (arrowhead) connects the contents of a granule to the outside of the cell. The freeze-fracture views (below) show the same stage in pore formation. The outer membrane of the amebocyte is pulled up to make a cup containing the granule (granule is fractured away). Another cup (inset) shows a pore approximately 30 nm in diameter that has formed on top of a cup. The small pores are very rare, reflecting their transient, millisecond lifetimes. Scale bars = 0.1 μm (top) and 0.5 μm (bottom). Reproduced from Ornberg RL and Reese TS (1981) Beginning of exocytosis captured by rapid-freezing of *Limulus* amebocytes. *Journal of Cell Biology* 90: 40–54.

connection or from outside as a scaffold. Note that the ionic conductance of the initial pore is in series with its associated access resistance, so the effect of protein or lipid on pore conductance can be due to changes to the outer vestibules of the pore rather than the pore center. In summary, the initial fusion pore has both lipidic and proteinaceous aspects; the structure of the fusion pore is dependent on both proteins and lipids.

There is good evidence for a stage prior to fusion pore opening and widening that depends on the spontaneous curvature of the membrane. Lysolipids

Figure 3 (a) Sketch of the exocytotic pore that has resulted from fusion. Superimposed on the figure is the equivalent circuit. The phase of the lock-in amplifier was set as described by Debus K and Lindau M (2000), thereby compensating the phase shift induced by the series resistance. Rc and Cc, resistance and capacitance of the cell membrane, respectively; Rg and Cg, resistance and capacitance of the granule membrane, respectively; Rp, resistance of the exocytotic pore; Rs, series resistance of the patch electrode. (b) The simplified equivalent circuit. Rc and Rg can be neglected for a sine wave of 806 Hz because Rc,g $<<$ $1/2\pi f$Cc,g. The change in admittance as a result of fusion is given in complex notation by $\Delta Y(\omega) = \mathrm{Rp}(\omega\mathrm{Cg})^2/((\omega\mathrm{CgRp})^2+1) + j(\omega\mathrm{Cg})/((\omega\mathrm{CgRp})^2+1)$. Note that as a result of fusion, Rp varies from infinity before fusion to a small value after fusion. Fusion does not cause any net change in the real part of the admittance. However, during the time that the capacitance increases, Rp decreases, and the real part of the admittance increases and then decreases. The maximum possible change (due to varying Rp) in the real component of the admittance equals ωCg/2, which is one-half the final change of the imaginary component, ωCg. The experimental conductance transients (real component of the admittance) are in quantitative agreement with this theoretical prediction, lending support to this model. For different events, we recorded times $t1/2$ between the initiation of the capacitance growth and the half-maximal capacitance value over the range of 2–59 ms. From the measured capacitance jumps, we calculated that Rp was between 3.1×10^8 and 2.5×10^9 ohms (Gp between 0.4 and 3.2 nS) at times $= t1/2$. Assuming the pore to have the conductivity of bulk solution and a length of 100 A, we estimate that at the time of half-maximal capacitance the pore diameter is between 18 and 52 A. In contrast, in *Limulus* amebocytes the smallest exocytotic pore seen in freeze-substituted sections by electron microscopy was -100 A wide and 150 A long. Adapted from Zimmerberg J, Curran M, Cohen FS, and Brodwick M (1987) Simultaneous electrical and optical measurements show that membrane fusion precedes secretory granule swelling during exocytosis of beige mouse mast cells. *Proceedings of the National Academy of Sciences of the United States of America* 84: 1585–1589.

Figure 4 (a) Membrane capacitance plotted against time in a degranulating mast cell voltage-clamped at 0 mV. Each time a vesicle fuses with the cell membrane, there is a step increase in C_m. (b) Potentials across cell membrane (E_c) and vesicle membrane (E_v) defined as cytosol minus outside and cytosol minus lumen, respectively. (c) Membrane current (thick traces) during a short portion of an experiment as in a except that the sinusoid used to measure C_m was applied only once every 112.5 ms for 12.5 ms at a time. Holding potential, 10 mV. Vertical trace, mean C_m values during the successive 12.5 ms periods; dots, time of measurement. Often, the increase in C_m due to exocytosis of a single vesicle continued over two or three 125 ms episodes; in such cases, the final amplitude of the C_m step was used in the analysis. Reproduced from Breckenridge LJ and Almers W (1987) Currents through the fusion pore that forms during exocytosis of a secretory vesicle. *Nature* 328: 814–817.

that confer positive spontaneous curvature to the monolayer leaflet to which they are added universally inhibit membrane fusion when added to the contacting leaflets before stimulation to fuse. These and other effects of lipids are consistent with the stalk–pore model of membrane fusion. In this hypothesis, the pore develops within a high-energy intermediate, the tension-stressed stalk, whose free energy exceeds that of a small, bent, closed pre-pore. The transmembrane segment of syntaxin, the juxtamembrane segment of SNAREs, and the C2 domains of synaptotagmin have all been implicated in the formation of the fusion pore at this stage.

The Lifetime of the Initial Fusion Pore Varies Widely

After the initial fusion pore widens, a much longer phase of fusion pore fluctuation occurs during which

there is a slow superimposed growth to the fusion pore conductance. Since the widening of the fusion pore requires less motion of bulk material than does the lengthening, we assume that the fast fluctuations detected reflect widening of the pore as the pore slowly lengthens. At some point, there is an abrupt increase in pore conductance and usually recording is terminated at this time. However, there appear to be another phase of fusion pore widening that correlates with a swelling of the vesicular gel components.

Figure 5 Release of serotonin during slow expansion of a fusion pore before completing irreversible fusion. The complex admittance is used to calculate the conductance of the fusion pore (G_p) during these early moments of expansion. The fusion pore conductance is shown to be well correlated with the amperometric current (amp). Reproduced from Alvarez De Toledo G, Fernandez-Chacon R, and Fernandez JM (1993) Release of secretory products during transient vesicle fusion. *Nature* 363: 554–558.

Fusion Pores in Synaptic Transmission

The techniques been used in endocrine cells to measure the fusion pore have encountered two problems when applied to synapses. First, synaptic vesicles are much smaller than the large dense-core vesicles in endocrine cells, making it much more difficult to detect individual vesicle fusion and the fusion pore conductance. Second, for detection of small single vesicle fusion, fusion must occur at the patched membrane. However, the majority of fusion, if not all, at the nerve terminal occurs at release sites apposing the postsynaptic neuron. The postsynaptic neuron may thus prevent the electrode from accessing the release site. These two hurdles have recently been overcome.

In pituitary nerve terminals that do not form synapses, individual vesicle fusion and the fusion pore conductance have been resolved for microvesicles with a size similar to that of synaptic vesicles. Like the much larger granules in secretory cells, the smallest pores appear to be reversible. A pore conductance of approximately 19 pS was found in approximately 5% of fusion events, indicating reversibility. The reversibility led to the hypothesis that some vesicle contents might normally be released through the small fusion pore, which could then close and allow the vesicle to be reloaded, and the hypothesis that has come to be known as kiss-and-run in the context of release of transmitter from synaptic vesicles. Note that no images from the electron microscope show kiss-and-run openings since, as noted previously, static images cannot distinguish between exo- and endocytosis.

Figure 6 (a) Arrangement of a CFE inside a patch pipette. I_A, amperometric current; I_C, sine wave current used to measure capacitance changes. (b) Chromaffin cell with attached patch pipette containing CFE at the beginning of the experiment. Reproduced from Abillos et al.

Figure 7 The first detectable fusion pore is polymorphic in its behavior. It can open to just about any size, without any restricted regions. (b) Biological membrane fusion is likely to proceed through hemifusion to prevent hydration of lipid tails during this transformation of topology. The initial hemifusion intermediate (the stalk) is a structure of overall negative spontaneous monolayer curvature and should be favored in membranes whose composition is negative overall in spontaneous monolayer curvature, such as membranes rich in fatty acids. Likewise, fusion should be inhibited in membranes whose composition is positive overall in spontaneous monolayer curvature, such as membranes rich in lysophospholipids; this prediction is borne out experimentally in all systems tested. (c) Energetically, the major problem in fusion is to convert the stalk to a pore, increasing the radius of the neck of the stalk. For phospholipid membrane fusion, tension is needed to widen the fusion pore. (a) Reproduced from Curran M, Cohen FS, Chandler DE, Munson PJ, and Zimmerberg J (1993) Exocytotic fusion pores exhibit semi-stable states. *Journal of Membrane Biology* 133: 61–75, with permission. (b, c) Reproduced from Zimmerberg J and Gawrisch K (2006) The physical chemistry of biological membranes. *Nature Chemical Biology* 2: 564–567.

The capacitance recording methods developed to resolve small vesicle fusion in this study made it possible to apply the same method to synaptic nerve terminals. To date, the capacitance technique has been applied to only the calyx of Held synapse. To expose the release site of the synaptic nerve terminal, the calyx of Held, a large pipette was used to pull out the post-synaptic neuron (Figure 8(a)). At the exposed release sites, cell-attached recordings revealed individual capacitance up-steps reflecting single synaptic vesicle fusion (Figure 8(b)). For full collapse fusion, the initial fusion pore conductance is usually >375 pS and increased rapidly to ≥299 pS/ms. In a small number of full collapse events, the initial fusion pore conductance of 260 pS was detected (Figure 8(c)). Support for the kiss-and-run type or release is reflected as a brief

Figure 8 Full collapse and kiss-and-run fusion at a calyx-type synapse. (a) The procedure to perform cell-attached recordings at the release face of a calyx. A calyx associated with a postsynaptic neuron was first identified (left). The postsynaptic neuron was sucked and pulled away by a pipette (middle two panels). Another pipette was positioned at the release face of the calyx membrane (right) for cell-attached recordings, from which individual vesicle fusions, such as those shown in b and c were obtained. (b) Im (imaginary component of the admittance, reflecting capacitance) and Re (real component of the admittance, reflecting conductance) traces from a cell-attached recording during application of 25 mM KCl. The inset shows discrete up-steps reflecting single vesicle fusion. (c) Im, Re, and the fusion pore conductance (G_p) during a capacitance flicker. The capacitance flicker with a detectable fusion pore conductance indicates kiss-and-run fusion. A nonflicker up-step (right) occurring 10 s later was not accompanied by detectable Re changes, suggesting a full collapse fusion with the fusion pore that is too fast and/or too large to resolve. Adapted from He L, Wu XS, Mohan R, and Wu LG (2006) Two modes of fusion pore opening revealed by cell-attached recordings at a synapse. *Nature* 444: 102–105.

(<2 s) capacitance flicker with $G_p > 288$ pS for most flickers, but within 15–288 pS for the remaining flickers. As in secretory cells, most fusion events end in full collapse under our conditions.

Comparison of Exocytic and Cell–Cell Fusion Pores

Although all exocytic fusion pores studied to date have very similar initial parameters, the initial fusion pores catalyzed by viral fusion proteins are more varied with regard to conductance, lifetime, and voltage dependence. For example, the initial fusion pore mediated by the baculovirus envelope protein gp64 is approximately 1 nS in conductance and does not show any flickering behavior. Since these proteins are typically expressed in genetically engineered cells, and their fusion pores are measured in cell–cell fusion systems, there are many differences between both the proteins and the membranes in which they are expressed, as well as differences in the local density of the crucial proteins. The relative contribution of these various factors remains to be determined.

GABA Synthesis and Metabolism

Introduction

γ-Aminobutyric acid (GABA) is the major inhibitory neurotransmitter in mammalian brain and is found widely throughout the central and peripheral nervous systems. In the neocortex GABAergic neurons are plentiful, constituting 15–30% of all neurons. GABA serves both metabolic and trophic functions, in addition to its role as a neurotransmitter, influencing the migration of neurons and astroglia to their target locations in the cortex. During early brain development GABA elicits excitatory (depolarizing) rather than inhibitory (hyperpolarizing) postsynaptic responses. Later in development GABA influences the synaptic organization and fine-tuning of local circuits. Because of GABA's many important roles – as neurotransmitter, neuromodulator, trophic factor, and cellular metabolite – GABA metabolism may impact many aspects of brain function.

Brain tissue is highly heterogeneous, and compartmentation of the enzymes of the GABA shunt between neurons and astroglia plays an important role in the function of GABA as a neurotransmitter. The discovery of metabolic compartmentation in the early 1960s to the late 1970s laid the conceptual foundation for our current understanding of brain glutamate and GABA metabolism. Studies using ^{14}C- and ^{15}N-labeled substrates revealed that brain glutamate metabolism was not homogeneous and could be separated kinetically into distinct pools – a large pool labeled from [^{14}C]glucose and a small, rapidly turning over pool labeled from [^{14}C]acetate, [^{14}C]butyrate, and [^{14}C]bicarbonate. The subsequent discoveries that glutamine synthetase (GS; glutamate–ammonia ligase, EC 6.3.1.2) and pyruvate carboxylase (PC; EC 6.4.1.1) were astroglial enzymes provided key information that the large and small pools of glutamate corresponded to metabolism in neurons and astroglia, respectively. Glutamatergic and GABAergic neurons are included within the definition of the 'large pool,' although glutamate levels in the respective neurons differ greatly. Most of the 8–12 μmol g^{-1} of glutamate measured in brain tissue is present in glutamatergic neurons (~80%), with GABA neurons (~2–10%) and astroglia (~10%) containing much less. Astroglia play a critical role in glutamatergic and GABAergic function by maintaining low synaptic and interstitial levels of glutamate and GABA through active uptake and metabolism. Astroglia also provide glutamine, and potentially other precursors, necessary for the resynthesis of these neurotransmitters.

The study of brain glutamate and GABA metabolism has been advanced significantly in recent years through the use of nuclear magnetic resonance (NMR) spectroscopy in conjunction with ^{13}C- and ^{15}N-labeled substrates. The use of isotopically labeled substrates in these studies allows metabolic pathways of GABA and glutamate synthesis and neuron/glial substrate trafficking to be examined noninvasively and in unprecedented detail, revealing new insights into these pathways and their functional interactions.

GABA Synthesis and Degradation in the GABA Shunt

GABA synthesis and degradation occur at the level of the tricarboxylic acid (TCA) cycle. GABA, a product of glucose metabolism, is synthesized almost exclusively from glutamate, a product of the TCA cycle intermediate, α-ketoglutarate, in an α-decarboxylation catalyzed by the pyridoxal-5′-phosphate-dependent enzyme, glutamate decarboxylase (GAD; EC 4.1.1.15). GABA is degraded to succinate by the concerted actions of two enzymes: pyridoxal-5′-phosphate-dependent GABA transaminase (GABA-T; 4-aminobutyrate transaminase, EC 2.6.1.19) and nicotinamide adenine dinucleotide (NAD)-dependent succinate-semialdehyde dehydrogenase (SSADH; EC 1.2.1.24). In the first step of catabolism, GABA nitrogen is transferred to α-ketoglutarate by transamination, forming succinic-semialdehyde and glutamate. In the second step succinic-semialdehyde is oxidized to succinate with reduction of NAD^+ to $NADH_2$; succinic-semialdehyde is a short-lived intermediate and is present at low cellular concentrations. The pathway of GABA metabolism from α-ketoglutarate to succinate forms a metabolic shunt, by passing two enzymes of the TCA cycle, α-ketoglutarate dehydrogenase and succinyl-CoA synthetase (Figure 1). Glucose oxidation through the GABA shunt is slightly (~3%) less energy efficient than through the complete TCA cycle, resulting in one less molecule of guanosine triphosphate (GTP) for each molecule of α-ketoglutarate traversing the shunt.

GABA synthesis occurs only in neurons, whereas GABA catabolism occurs both in neurons and glia. Thus, the resynthesis of glutamate from α-ketoglutarate during transamination with GABA does not occur totally in the same cells in which GABA was formed. Because GABAergic and other neurons are incapable of *de novo* synthesis of glutamate precursors, due to

Figure 1 Metabolic pathway depicting the synthesis and catabolism of γ-aminobutyric acid (GABA) in the GABA shunt and its relationship to glucose metabolism and the tricarboxylic acid (TCA) cycle. The GABA shunt bypasses two enzymatic steps of the TCA cycle, resulting in one less molecule of guanosine triphosphate (GTP) formed for each molecule of α-ketoglutarate metabolized to succinate through the shunt. GABA synthesis occurs in GABAergic neurons but GABA catabolism occurs in neurons and astroglia. Astroglial glutamate precursors (e.g., glutamine) are required to replenish GABA removed and metabolized by astroglia. GAD, glutamic acid decarboxylase; GABA-T, GABA transaminase; SSADH, succinic semialdehyde dehydrogenase; NAD, nicotinamide dinucleotide; CoA, coenzyme A.

the absence of the necessary anaplerotic enzymes, glutamate precursors must be supplied by astroglia to maintain TCA cycle intermediates (and GABA) at constant levels.

The concentration of GABA in brain tissue ranges from ~1 to 5 μmol g^{-1}, with the variation in concentration reflecting the density of GABA neurons and their terminals. GABA levels are very low in the extracellular fluid and in cells which do not express GAD. The GABA concentration within GABAergic terminals may reach 50–100 mM, although much of this is contained in synaptic vesicles and is inaccessible to GABA-T. The concentration of GABA in the cytoplasm and the mitochondrial intermembrane space where GABA-T is located is not well known, but levels are likely to be high and saturating for GABA-T, which has a relatively low K_m (~1 mM). Thus, in neurons GABA levels are likely to be regulated by changes in synthesis and GAD activity rather than catabolism. In contrast to neurons, in astroglia where GABA levels are low and nonsaturating for the glial transaminase, GABA level is likely to regulate the rate of catabolism.

The GABA shunt also generates precursors for synthesis of a limited number of other compounds, the most studied of which are the neuromodulator/neurotransmitters, homocarnosine (γ-aminobutyryl histidine) and γ-hydroxybutyrate (GHB). Homocarnosine is synthesized from GABA and histidine by homocarnosine synthetase, and hydrolysis of this dipeptide by a serum carnosinase regenerates GABA and histidine. GHB is synthesized from succinic-semialdehyde by a specific NADPH-dependent succinic-semialdehyde reductase, and oxidation back to succinic-semialdehyde is catalyzed by GHB dehydrogenase. Tissue levels of GABA, homocarnosine, and GHB can be elevated substantially by pharmacologic inhibitors or gene deficiencies in GABA-T and SSADH.

GABA Transporters Are Expressed in GABAergic Neurons and Astroglia

GABA is transported across the plasma membranes of neurons and astroglia by electrogenic GABA transporters (GATs), which facilitate the reversible symport of GABA with two Na^+ ions and one Cl^- ion. These transporters, like the electrogenic glutamate transporters, require the energy of ATP to maintain the Na^+ ion gradient that provides the driving force and direction of GABA transport. GATs operate at much slower rates than do glutamate transporters, so that efficient clearance of GABA from the synapse requires relatively high transporter densities. The rate of GABA transport is determined by the number of functional GATs residing on the cell surface which are recruited from the cytoplasm. The distribution of GATs between cell surface and cytoplasm is regulated by extracellular GABA levels, protein kinase C, and ligands of G-protein-coupled receptors.

Pathways of GABA Clearance Following Release: Neuronal Reuptake and Glial Uptake

GABA clearance following release into the synaptic cleft occurs both by reuptake into presynaptic terminals and by transport into surrounding astroglia. Isotopic studies which follow the labeling of GABA from different precursors cannot distinguish between the different uptake pathways because GABA metabolism in neurons and glia leads to the same labeling patterns. Thus, the relative quantitative importance of these two pathways to total GABA clearance *in vivo* is unknown and this issue remains a vexing problem. Studies using cell cultures have shown that GABA transport capacity and uptake are greater in neurons than in glia, supporting a predominant role for reuptake in GABA clearance from the synapse. Although reuptake has been suggested to be more energetically efficient because new GABA

synthesis is not required, the activity of GABAergic neurons and vesicular loading of GABA has been shown to involve new GABA synthesis, thus weakening a rationale for reuptake.

GATs are reversible and can function in GABA release as well as uptake. GATs in interneurons operate closer to their equilibrium potentials than do glutamate transporters, providing more favorable conditions for calcium-independent, nonvesicular transport of GABA in either direction. Under depolarizing conditions GABA transport reversal can lead to loss of GABA from the cell, but it has not been shown whether the recovery of GABA levels during repolarization involves reuptake or new synthesis from glial precursors.

GABAergic synapses are closely surrounded by glial end-processes possessing high densities of GATs, and astroglia possess all the enzymes needed to degrade GABA. Studies of isolated glial fractions, astrocyte cultures, and intracellular recordings of glial GABA transporter currents in tissue slices show that glia have a substantial capacity to transport GABA. *In situ* levels of extracellular GABA and the occupancy of postsynaptic GABA receptors are regulated by astroglial transporters. Inhibitors of astroglial transporters show greater antiepileptic efficacy than do neuronal transport inhibitors of GABA, suggesting that glial clearance is quantitatively significant. These observations are consistent with the high rate of GABA synthesis from glutamine (~23% of total glutamate plus GABA cycling) measured in rat cortex *in vivo* using ^{13}C NMR. Whether glial GABA transport is more important in paracrine signaling or synaptic transmission is unclear at present, but such differences may be related to the functions of the two isoforms of GAD, as discussed in a later section.

Precursors of GABA Synthesis

The Glutamate/GABA–Glutamine Cycle

Glutamate precursors for GABA synthesis can be produced directly from the metabolism of glucose in neurons. However, glucose metabolism cannot replace glutamate and GABA carbon lost from neurons during activity due to the absence of the necessary anaplerotic enzymes (e.g., PC), which are expressed only in the astroglia. GABAergic neurons import the needed precursors from astroglia mainly in the form of glutamine. The astroglia which surround GABAergic (and glutamatergic) neuronal processes express high densities of the N-type electroneutral glutamine transporter (SN1), while GABAergic neurons express both of the A-type electrogenic glutamine transporters (SA1 and SA2). Glutamine is hydrolyzed to glutamate and ammonia by phosphate-activated glutaminase (PAG; EC 3.5.1.2), a highly regulated enzyme, present on the outer surface of the inner mitochondrial membrane, which provides glutamate for GABA synthesis to recharge cytoplasmic and vesicular pools. Release of GABA from neurons followed by uptake and metabolism to succinate in the astroglia completes the GABA shunt while regenerating glutamate (by transamination of α-ketoglutarate with GABA). Thus, *de novo* synthesis of α-ketoglutarate by anaplerosis is not required to replenish the GABA catabolized in astroglia. However, GABA catabolism requires an equivalent flow of acetyl-CoA from glucose-derived pyruvate or other substrates (e.g., acetate) to maintain the availability of α-ketoglutarate for transamination with GABA. The glutamate generated by transamination (GABA-T) can be converted to glutamine by GS and is released for uptake and replenishment of glutamate and GABA in neurons. In contrast to GABA, which requires oxidative metabolism in the TCA cycle, much of the glutamate removed by glia (~70–80%) following release from glutamatergic neurons is converted directly to glutamine. A schematic of GABA and glutamate neurotransmitter cycling between GABAergic and glutamatergic neurons and astroglia is shown in Figure 2.

Although glutamine has been shown to be a major glial precursor of GABA *in vivo* and *in vitro*, studies of isolated nerve terminal preparations indicate that glial TCA cycle intermediates (e.g., α-ketoglutarate or malate) might also contribute to GABA synthesis. In addition, the role of phosphate-activated glutaminase in GABA synthesis has been challenged; immunohistochemical findings *in situ* have shown that many neocortical interneurons which co-express certain peptides do not stain positively for PAG, suggesting that a substrate other than glutamine (e.g., α-ketoglutarate) might be utilized for GABA synthesis in these neurons.

GABA Synthesis from Extracellular Glutamate

In addition to glial precursors, extracellular glutamate can enter some GABA neurons through the EAAC1 glutamate transporter, where it can be used in GABA synthesis. This pathway has been observed in the hippocampus and thalamus but not in the cortex. Regional differences in GABA precursors might be related to the apparent heterogeneity seen in PAG immunostaining for different populations of GABAergic neurons. For interneurons using extracellular glutamate in GABA synthesis, glial precursors must ultimately replenish this glutamate in an extended loop, whereby glutamine is redirected first through the glutamatergic neuron and released as glutamate before uptake and conversion to GABA.

Figure 2 Depiction of GABA and glutamate cycling with glutamine between GABAergic and glutamatergic neurons with astroglia via extracellular fluid (ECF). GABA Synthesis from Polyamines

Alternative but quantitatively minor pathways of GABA synthesis from putrescine and other polyamines have been described, but these pathways account for only a small fraction (≤1%) of synthesis in the mature brain. Polyamines may play important but largely unknown roles in GABA metabolism in the developing brain and retina. Putrescine and other polyamines increase in response to stress, but a potential link to GABA synthesis has not been reported.

Nitrogen Homeostasis in Brain Glutamate and GABA Metabolism

The operation of the glutamate/GABA–glutamine cycle requires the efficient transfer of nitrogen as well as

carbon between neurons and astroglia. Nitrogen fixed as glutamine and released from astroglia for the synthesis of glutamate and GABA in neurons must ultimately return to the glia to permit continuous operation of the neurotransmitter cycles. Ammonia is freely diffusible through cell membranes, and the ammonia generated by PAG in the neurons could provide, in principle, the amide-N needed for glutamine synthesis from glutamate, part of which is acquired through uptake of extracellular glutamate or is produced by transamination with GABA. However, astroglia also undergo significant *de novo* synthesis of glutamate (anaplerosis) to replace glutamate and GABA lost by oxidation and diffusion, which may approach ~18–30% of total glutamine synthesis, thus requiring a source of amine-N. Glutamate dehydrogenase (GDH; EC 1.4.1.2) is highly expressed in astroglia but is not believed to be sufficiently active in the direction of glutamate formation under normal physiological conditions. Recent studies suggest instead that amine-N for *de novo* glutamate (and glutamine) synthesis from α-ketoglutarate occurs by transamination with alanine or a branched-chain amino acid (BCAA), such as leucine. Two different nitrogen carrier cycles have been proposed – one involving an exchange of alanine for glutamine in the glia with the product of transamination, pyruvate, returning to the neuron as lactate (alanine/lactate shuttle), and the other involving an exchange of a BCAA (leucine) for glutamine with the product of transamination, branched-chain keto acid (α-ketoisocaproic), returning to the neuron. Alanine and leucine are regenerated in the neurons by transamination with glutamate, the latter formed by GDH and the ammonia from the PAG reaction. Both neurons and astroglia express the necessary transaminases needed to support the operation of these cycles, alanine aminotransaminase (AAT; EC 2.6.1.2) and branched-chain-amino-acid transaminase (BCAT; EC 2.6.1.42). Distinct cytosolic (neuronal) and mitochondrial (astroglial) isoforms of BCAT have been found. Studies of the BCAAs and their transaminases, together with findings of significant ^{15}N labeling of brain glutamate in rodents during intravenous infusion of [^{15}N]leucine *in vivo,* indicate that as much as 25% of brain glutamate nitrogen may be derived from leucine. While studies of nitrogen shuttling between neurons and astroglia have focused mainly on glutamatergic neurons, leucine is likely to be a source of glutamate nitrogen in some GABAergic neurons. GABAergic Purkinje neurons in the cerebellum and basket neurons in the hippocampus express BCATc in their cell bodies. In Purkinje neurons, PAG expression is low, suggesting that GABA synthesis involves substrates other than glutamine. In these neurons and others potentially not expressing PAG, leucine transamination of α-ketoglutarate derived from astroglia during GABA catabolism or *de novo* synthesis could supply glutamate needed for GABA synthesis. Whether the GABA synthetic pathways operating in the many different classes of interneurons (e.g., chandelier, double bouquet, Martinotti neurons) differ from one another is largely unknown, but such differences could play an important role in their function.

Relationship of Cytoplasmic and Vesicular GABA to Different Release Pathways

Studies of cultured neocortical neurons enriched in the GABAergic phenotype demonstrate the presence of cytoplasmic and vesicular GABA pools; one is released by agonists of the glutamate *N*-methyl-D-aspartate (NMDA) receptor and is calcium independent (cytoplasmic GABA), and the other is released by 55 mM potassium and is calcium dependent (vesicular GABA). The vesicular and cytoplasmic GABA produced from glutamine can be distinguished metabolically when neurons are depolarized in a manner related to the pathway of GABA release. Vesicular GABA produced from glutamine involves metabolic processing in the TCA cycle and equilibration of the glutamate carbon skeleton with endogenous mitochondrial glutamate. In contrast, glutamate produced directly from glutamine appears to be a better precursor of GABA released through reversal of membrane transporters (i.e., cytoplasmic GABA). Neuronal firing patterns may also play an important role in the mode of GABA release and thus the functional expression of the GAD isoforms, as discussed in the following section.

Relationship of the GAD Isoforms to Cytoplasmic and Vesicular GABA Synthesis

GAD is expressed as two major isoforms, of 65 and 67 kDa, which are the products of two different genes. The two isoforms of GAD are distributed differently within GABAergic neurons: GAD_{67} is present throughout the cytoplasm, with more in the cell bodies, whereas GAD_{65} is highly enriched in axon terminals and is associated with synaptic vesicles. GAD_{67} appears to play the major role in basal GABA synthesis, and knockout of the gene for this isoform results in a major loss of tissue GABA. GAD_{67} expression is regulated both by transcriptional and by posttranscriptional mechanisms, whereas GAD_{65} expression is regulated at the transcriptional level and by short-term (kinetic) mechanisms. GAD_{65} knockout mice display electrophysiological features consistent with reduced vesicular release of GABA. GAD_{65} binding to synaptic vesicles was shown recently to involve a multiprotein

Figure 3 An idealized depiction of the relationships between cytoplasmic and vesicular γ-aminobutyric acid (GABA) synthesis, GABA release pathways, and glutamic acid decarboxylase (GAD) isoforms. Cytoplasmic GABA ($GABA_{cyto}$) synthesis is provided mainly by GAD_{67}, and this pool/isoform is associated with the majority of neuronal GABA shunt flux. Forward and reverse movements of GABA through GATs lead to uptake or release of GABA to the extracellular fluid ($GABA_{ecf}$). Vesicular GABA synthesis is catalyzed by GAD_{65}, and GABA not returned to the terminals by reuptake is metabolized in the astroglia to succinate (suc) and oxidized in the mitochondrial TCA. Transamination of GABA in the glia by GABA-T generates glutamate from α-ketoglutarate (α-KG), which is used in the synthesis of glutamine by glutamine synthetase (GS). Phosphate-activated glutaminase (PAG) provides glutamate precursors for GABA synthesis. In some GABA neurons not expressing PAG, α-ketoglutarate could serve as a GABA precursor following its uptake and transamination to glutamate in the terminals, possibly by leucine or alanine.

complex of vesicle-associated proteins, the vesicular $GABA/H^+$ antiporter and H^+-ATPase, and Ca^{2+}/calmodulin protein kinase II, which together facilitate vesicular loading of GABA driven by the hydrogen ion gradient. An idealized depiction of the relationship between the two GAD isoforms and the synthesis of the vesicular and cytoplasmic GABA pools is shown in Figure 3.

GAD_{65} is more strongly regulated by the cofactor, pyridoxal phosphate, than is GAD_{67}. The majority of GAD in brain is present as inactive apoenzyme (GAD without bound cofactor), which serves as a reservoir of inactive GAD that can be activated when demand for GABA increases. GAD_{65} binds pyridoxal phosphate less tightly than does GAD_{67} and accounts for the majority of the apoGAD in rat brain. In contrast, pyridoxal phosphate is more tightly bound to GAD_{67}, which explains the importance of this isoform in basal synthesis. The interconversion between pyridoxal phosphate bound (active) and free (inactive) GAD involves a complex cycle of reactions catalyzed by GAD. This cycle is strongly regulated by nucleoside triphosphates (ATP) and inorganic phosphate, which could serve as important regulators to increase GABA synthesis in response to increased demand. The activities of both GAD isoforms also appear to be regulated in opposing directions by protein phosphorylation.

Inherited Disorders of GABA Metabolism

Rare inherited disorders of GABA metabolism have been described involving deficiencies in enzymes in the pathways of GABA catabolism (GABA-T, SSADH, and serum carnosinase) and a cofactor (pyridoxine) required in GABA synthesis. High levels of GABA accumulate in brain and cerebrospinal fluid of individuals deficient in GABA-T and SSADH. In SSADH deficiency, the buildup of the product of GABA-T, succinic semialdehyde, promotes increased synthesis and accumulation of GHB. Homocarnosine levels are elevated in brain and cerebrospinal fluid of individuals with homocarnosinosis, a condition resulting from deficiency of serum carnosinase, a dipeptidase which hydrolyzes homocarnosine and carnosine. Pyridoxine-dependent epilepsy, a rare autosomal recessive inherited

trait characterized by intractable seizures, is treated by administration of pyridoxine (vitamin B6) at pharmacologic doses. Although pyridoxine is a required cofactor of GABA synthesis, and reduced pyridoxine interaction with GAD is suspected in this disorder, a definitive mechanism has not been established.

GABA$_A$ Receptor Synaptic Functions

I Mody, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Introduction

The amino acid neurotransmitter γ-aminobutyric acid (GABA) is responsible for mediating most of chemical inhibition in the central nervous system (CNS). The ionotropic GABA receptors (GABA$_A$Rs) are members of the cysteine-loop ligand-gated ion channel family and form a Cl^-- and HCO_3^--permeable ion pore assembled from five (heteropentameric) subunits selected from the following subunits: α1–6, β1–3, γ1–3, δ, ϵ, θ1–3, π, and ρ1–3. Hundreds of thousands of different combinations are possible, yet no more than a few dozen receptor combinations are likely to exist in the mammalian brain. This is thought to result in part from precise rules of subunit assembly (e.g., two α and two β subunits assemble with either one γ or one δ subunit) and in part from certain rules of specific subunit partnerships that also appear to define their subcellular localization inside and outside of synapses. Loss-of-function mutations in some of these subunits are associated with various rare genetic forms of epilepsy in humans, indicating their importance in subduing neuronal hyperactivity. Over the years GABA$_A$Rs have become synonymous with inhibition, but we now know that depending on a variety of conditions, their activation may excite neurons or may synchronize them, resulting in physiological oscillations or pathological synchrony leading to seizures. In 1963, on behalf of the Nobel Committee upon awarding the Prize to Sir John C Eccles, Ragnar Granit stated: "If the arriving impulse is connected to excitatory synapses the response of the cell is yes, i.e., excitability increases; vice versa the inhibitory synapses make the cell respond with a no, a diminution of excitability." Forty-three years later it is clear that in response to GABAergic 'inhibition' many cells have expanded their vocabulary to 'maybe' and even to 'yes.'

GABA$_A$Rs at Synapses

In the mammalian brain GABA synapses constitute a minority. Only about every sixth synaptic terminal is GABAergic and only every fifth neuron utilizes GABA as a transmitter. Excitation clearly outnumbers inhibition. Yet, in spite of this overpowering excitatory drive, most of the time the GABAergic system manages to keep excitability in check. It does this through a spatially and temporally selective activation of the GABAergic system. The pioneering Golgi impregnation studies of Ramón y Cajal, Lorente de No, and János Szentágothai have distinguished a marked feature of cortical interneurons: they have a highly selective axonal arborization, innervating distinct spatial domains of the principal cells. GABA synapses can be found on cell bodies, dendritic shafts and branch points, spine necks, and axon initial segments, in far more diverse places than excitatory synapses. The strategic positioning of GABA synapses on the target cells can annihilate a specific input or the entire output of the cell. A good example of such selective control of a given input is the hippocampal oriens-lacunosum moleculare (OLM) cell that precisely innervates the most distal dendrites of pyramidal cells. This is precisely the region where the entorhinal cortical excitatory input lands on the principal cells. Since OLM cells are activated by massive intrahippocampal excitatory events, this spatial arrangement of their inhibitory output ensures that the entorhinal input does not have a say during this time. In contrast, the cortical chandelier or axo-axonic cells do not synapse onto a cellular region receiving a specific input. Instead, they control the output of pyramidal cells, by innervating the axon initial segment, where the ultimate action potential output of the target neuron is generated. According to the latest findings however, some of these axo-axonic inhibitory interneurons may elicit firing at the axon initial segment (see later), in stark contradiction to the function implied by their 'inhibitory' name.

The location specificity of inhibitory synapses is complemented by a highly specific assembly of the GABA$_A$Rs that depends on the type of inhibitory interneuron that forms the synapse. There is little known about the mechanisms that sustain this specificity at a given synapse over the lifetime of the neuron. Of the thousands of possible heteropentameric GABA$_A$R combinations that can be formed through assembly from nearly 20 subunits, only a few dozen combinations occur in the brain. These combinations do not appear to be randomly inserted at synapses. The types of subunits present at a given synapse tend to be specified by the GABA neuron that provides the presynaptic bouton of the synapse. The axo-axonic chandelier cells, and the pyramidal cell soma innervating cholecystokinin (CCK)-positive basket cells, are known to form synapses on predominantly α2 subunit-containing receptors. The parvalbumin-containing basket cells synapse onto α1-containing

$GABA_A$Rs, while other combinations are found at synapses made by other interneuron types. The functional significance of this highly specific arrangement is only beginning to emerge. Different GABA receptor subunit assemblies have very different kinetic and desensitization properties when studied in expression systems. Accordingly, one would expect the various synaptic currents generated by diverse $GABA_A$Rs also to be highly variable. However, paired recordings from two interneurons and their target cells usually show similar inhibitory postsynaptic current (IPSC) kinetics, in spite of known differences of $GABA_A$R assemblies at the two synapses. Even if the kinetic differences observed in expression systems do not hold at $GABA_A$Rs assembled at synapses in the brain, the different compositions and locations of $GABA_A$Rs have undoubtedly evolved to participate in widely different control functions of neuronal excitability. Insight into these functions has come from cleverly engineered mice expressing various α subunits insensitive to benzodiazepines (BZs), a class of potent allosteric $GABA_A$R modulators.

Two α, two β, and a single γ subunit assemble to form the most commonly found $GABA_A$Rs in the brain. The function of these receptors is enhanced by BZs as long as the α subunits are either $\alpha1$, $\alpha2$, $\alpha3$, or $\alpha5$, but not $\alpha4$ or $\alpha6$. There is a single amino acid in a critical position (His) that differs between the BZ-sensitive and BZ-insensitive α subunits (Arg in the latter). Mice have been genetically engineered to have BZ-insensitive $\alpha1$, $\alpha2$, $\alpha3$, or $\alpha5$ subunit-containing $GABA_A$Rs. Studies in these mice conclusively demonstrated that the $\alpha1$ subunit-containing $GABA_A$Rs are involved in the sedative–hypnotic actions of BZs, while the receptors containing $\alpha2$ subunits mediate anxiolytic effects of BZs. Does this mean that the function of the synapses predominantly containing $\alpha2$ subunits, such as those found at the axon initial segment or those apposed to the terminals of CCK-containing basket cells, are mainly related to the control of anxiety? At this time it is still too early to say, as there might be specific brain regions rich in $\alpha2$ subunits that could play a significant role in the control of anxiety. Nevertheless, it is clear that specific $GABA_A$R subunit assemblies innervated by specific interneurons play highly specialized roles in the development of neuronal circuitry and in mediating specific higher nervous system functions.

Activation of $GABA_A$Rs at Synapses – Phasic Inhibition

The $GABA_A$Rs usually found at synapses are most likely to contain $\gamma2$ subunits. GABA synapses are 'symmetrical' synapses; called such because on electron micrographs they are devoid of a wide electron-dense postsynaptic density (PSD) which would make the appearance of the synapse 'asymmetric.' Therefore, compared to the PSDs of excitatory glutamatergic synapses containing a stable assembly of over 70 different receptor, scaffold, and signaling proteins, there is a lackluster showing of postsynaptic proteins at the poorly developed PSDs of GABA synapses. Glutamate receptors at synapses associate with the subsynaptic cytoskeleton. $GABA_A$Rs do not. There are, however, some proteins that seem to play a role in the anchoring, insertion, and removal of $GABA_A$Rs at synapses. Gephyrin links up with the subsynaptic microtubule and actin cytoskeleton. It interacts with several microfilament-regulating proteins, including collybistin, profilins, Mena/VASP proteins, and dynein light chain (Dlc)/myosin-Va. However, the role of these protein–protein interactions for the shaping of GABA synapses is largely a mystery. Some GABA synapses express the dystrophin–glycoprotein complex, better known as a connecting element between the extracellular and cytoskeletal matrices of muscle cells. Other proteins are implicated in the trafficking of $GABA_A$Rs: AP2, BIG2, GABARAP, GODZ, Plic-1, and PRIP1/2. To make things more complicated, trafficking of $GABA_A$R subunits seems to depend on the phosphorylation state of the subunit. Various kinases and phosphatases are at hand, as they bind directly to the subunits or are linked to specific $GABA_A$Rs through highly specific adaptor proteins.

As molecular biologists, biochemists, and anatomists continue to pursue the means of $GABA_A$R anchoring and targeting to synapses, physiologists and biophysicist have focused on the means of activation of $GABA_A$Rs at synaptic junctions. The kinetic profile of synaptic $GABA_A$Rs consists of a moderate to low affinity for GABA, some desensitization, and a rapid activation/deactivation. The time course of GABA in the synaptic cleft has been estimated to be less than 500 μs, and the peak concentration reaching the receptors is probably in the low millimolar range. This means that at many synapses where usually no more than tens of $GABA_A$Rs are present, the number of GABA molecules is in excess of the available binding sites, thus providing for a high occupancy of the available receptors. However, this may not be the case at all GABA synapses, as in cerebellar basket/stellate cells, where synapses with hundreds of receptors and synapses with tens of receptors coexist, only the latter appear to be saturated by the released transmitter. In general, the relatively low number of postsynaptic GABA receptors compared to the amount of GABA released into the cleft renders the process regulating the number of receptors an important aspect of $GABA_A$R plasticity. The kinetic properties of the

subunits assembled at the synapses should also affect the properties of inhibition, but thus far there are consistent reports only on the speedy decay of α1 subunit-containing synaptic receptors, while the variety of the biophysical receptor properties seen in expression systems has yet to be demonstrated at synapses. Desensitization is also an important mechanism to consider for regulating the decay of IPSCs, but prolonging the synaptic GABA transient by using uptake blockers does not always prolong the duration of synaptic events as it would be expected from a significant role of desensitization. It appears, however that the duration of the GABA transient in the cleft may itself regulate the decay of synaptic events, which in turn might make it difficult to discern differences that are simply due to underlying channel kinetics. The various brain-state-altering effects of BZs that act to prolong the duration of IPSCs predominantly affecting γ2 subunit-containing synaptic receptors show the importance of regulating the decay phase of IPSCs.

Like at any central synapse, presynaptic mechanisms can also effectively determine how GABA synapses are activated. Again, the most interesting presynaptic aspect of GABA synapses is their specificity with regard to the cell type supplying the presynaptic terminal. For example, there are clear differences in the way GABA is released from parvalbumin- and CCK-containing basket cells, and this may have important functional consequences for the operation of neuronal networks. Other GABA synapses are depressed most of the time by ambient levels of endocannabinoids, and do not become active unless the presynaptic cell fires at high frequencies. Different presynaptic Ca^{2+} channels are responsible for activating GABA release in different interneurons. Moreover, there is also accumulating evidence that the intricate vesicular release machinery may be different between glutamate- and GABA-containing terminals.

Activation of Peri- and Extrasynaptic GABA Receptors: Tonic Inhibition

As is the case for many ligand-gated ion channels, synapses are not the only place $GABA_A$Rs are likely to show up on a cell's surface. But perhaps for more than any other ligand-gated channel, $GABA_A$Rs found outside the synapses are quite special. Although many different combinations of $GABA_A$Rs are scattered outside of synapses, there are only two types of combinations that have been shown to actually respond to the ambient GABA concentrations of less than a few micromoles per liter, as found in the interstitial space of neurons. These two combinations are the δ subunit-containing and the α5 subunit-containing $GABA_A$Rs. The δ subunits combine with α4, α6, and most likely other α subunits to form, together with β2 or β3 subunits, a $GABA_A$R combination that is well suited to be activated by low levels of ambient GABA. These receptors have a high affinity for GABA, they do not desensitize, and are preferentially found extra- or perisynaptically. Their modulation mainly occurs by increasing the efficacy of GABA rather than its potency, as the natural agonist is not very efficacious at these receptors. The other $GABA_A$R combination shown to be activated by ambient GABA is the α5 subunit-containing receptors. The α5 subunits are not exclusively extrasynaptic; they probably combine with other α subunits in synaptic receptors, but in the cells where they are present they readily mediate tonic inhibition. The tonic inhibition, when present, is a significant force in controlling the excitability of the neurons. Charge movement through tonically active GABA channels outweighs 3:1 to 5:1 the charge going through the synaptic receptors, even when the frequency of the synaptic activity is quite high (40–60 Hz). Such a tonically active conductance globally is well suited to regulate the input–output function of the cells.

The δ subunit-containing $GABA_A$Rs mediating tonic inhibition are also an important site of action for various endogenous and exogenous allosteric modulators. Neurosteroids, brain-synthesized metabolites of various sex and stress steroid hormones, specifically act upon these receptors to enhance their activity. Ethanol, at concentrations relevant to impairing sobriety, also appears to target the δ subunit-containing $GABA_A$Rs, which may justify them lately being referred to as the 'ethanol receptor.' The receptors mediating tonic inhibition show a remarkable plasticity, both during physiological (ovarian cycle) and pathological (epilepsy) alterations in neuronal excitability. Selectively eliminating tonic inhibition in hippocampal CA1 pyramidal cells facilitates certain forms of learning, presumably by increasing the sensitivity of pyramidal cells to incoming stimuli. These recent developments in the physiology and pharmacology of extrasynaptic tonically active $GABA_A$Rs will lead to exciting insights into their complex roles in the control of neuronal excitability.

Excitation and Synchrony through 'Inhibitory' Synapses

There is nothing mysterious about 'inhibitory' synapses extending their vocabulary to 'maybe' and 'yes.' The relationship between the time-averaged membrane potential of the neuron and the GABA

equilibrium potential, which is a function of the equilibrium potentials of the two permeant ions, Cl^- and HCO_3, determines whether activation of $GABA_A$Rs will depolarize or hyperpolarize a cell. In fact, 'yes' is the first word uttered by an activated $GABA_A$R. Early on during brain development, when cells are loaded with Cl^-, the activation of $GABA_A$R channels leads to efflux of negatively charged Cl^- ions, thus depolarizing the cell. This makes GABA one of the first depolarizing signaling molecules during development. The depolarization helps bring the membrane potential to the threshold of activation of voltage-gated Ca^{2+} entry, a cation that, once inside the cells, is critical for the activation of a myriad of important developmental signaling cascades. Eventually, later during development, Cl^- is extruded from the cells by various transport mechanisms. Inhibition can thus start to learn to say 'no.' Yet, depolarizing $GABA_A$R-mediated events continue to play an important role in the adult nervous system. The survival of newly generated neurons in the mammalian brain depends largely on the activation of depolarizing, tonically active $GABA_A$Rs. Local peaks in the GABA reversal potential can trigger depolarizing inhibitory postsynaptic potentials (IPSPs) that can passively propagate along the neuron to elevate excitability, or can outright trigger action potentials at the axon initial segment, as we have recently learned from the potentially 'excitatory' function of axo-axonic cells in the neocortex.

Regulated by several exchangers and transporters, the GABA reversal potential can itself become a dynamic force in the control of neuronal excitability. One of the key players is a K^+/Cl^- cotransporter called KCC2. This molecule is critical in extruding Cl^- during development, but reducing its function during spike timing-dependent plasticity of GABA synapses, high-frequency firing of the cells, or neuronal injury leads to an intracellular accumulation of Cl^- and thus the conversion of a hyperpolarizing event into one that will depolarize the affected neuron. An altered KCC2 function is most likely at work to cause the pathological alteration of the GABA reversal potential in subicular pyramidal neurons recorded in tissue samples obtained from temporal lobe epilepsy patients, and causes the conversion to a GABA-induced depolarization of spinal cord neurons during neuropathic pain. Even if depolarizing GABA-mediated events do not push the membrane potential all the way past the threshold of activation of voltage-dependent Na^+ or Ca^{2+} conductances, such events can passively propagate through the cell, thus increasing excitability and promoting neuronal synchrony.

Depolarizing neurons is not the only means by which activation of inhibitory synapses can promote synchrony. If the neurons are equipped with a hyperpolarization-activated excitatory conductance (e.g., I_h) or a low-threshold (T-type) Ca^{2+} current, as most neurons are, then a hyperpolarization induced in several neurons at the same time can lead to a rebound excitation following the cessation of the hyperpolarizing event. Hundreds or thousands of principal cells innervated by a single inhibitory interneuron, or by a few interneurons activated in unison, can thus synchronize their firing without requiring any synchronous excitatory drive. This type of synchronization may specifically spring into action when diffusely acting neurotransmitters, such as acetylcholine (ACh) or glutamate, enhance GABA release by acting at once on the terminals of several inhibitory cells through actions at nicotinic ACh or *N*-methyl-D-aspartate (NMDA) receptors.

In summary, phasic and tonic GABAergic inhibitions exert a substantial control over neuronal excitability. The incredibly diverse GABAergic cells of the brain are the real puppet masters of the principal cells, by controlling their activity both at the level of different single neuronal compartments and at the level of intricately connected neuronal networks. For certain, the diversity and specificity of $GABA_A$Rs, GABAergic neurons, and their functions will keep neuroscientists busy for a while. It may have taken some time, but now we know that it is much easier for the 'inhibitory' GABAergic system to say 'maybe' and 'yes' than it is for excitatory glutamate synapses to learn to say 'no.'

Introduction

γ-Aminobutyric acid (GABA) is the principal inhibitory neurotransmitter in the mature nervous system. It is produced by decarboxylation of glutamate, a reaction for which vitamin B_6 is a necessary cofactor. GABA is released primarily by calcium-dependent fusion of neurotransmitter vesicles with the cytoplasmic membrane of the presynaptic terminal. Binding of GABA to postsynaptic $GABA_A$ receptors opens anion-permeable channels. The main permeant anions are chloride, which flows into the neuron, and bicarbonate, which flows out. Chloride is more plentiful and more permeant, so under most circumstances the net effect of $GABA_A$ receptor activation is hyperpolarization due to intracellular accumulation of negatively charged chloride ions. $GABA_B$ receptors are G-protein-linked receptors that are located both pre- and postsynaptically. $GABA_B$ receptors inhibit calcium channels and activate G-protein-linked inwardly rectifying potassium channels whose activation kinetics are one to two orders of magnitude slower than the $GABA_A$ receptor-operated ion channels. Because GABA inhibits neurons, the principal disorders associated with GABA dysfunction are related to pathological excitation. The prototypical disorder of neuronal overexcitation is epilepsy. Recent research has clearly linked GABA dysfunction to psychiatric, sleep, pain, and movement disorders as well.

Epilepsy

Epilepsy is the propensity for episodes of pathologically synchronous neural network activation called seizures. The most commonly accepted etiology for epilepsy is an imbalance of excitation and inhibition. Although the imbalance idea is an oversimplification, it was conceived on the basis of a large body of experimental data indicating that reductions in inhibition could induce acute epileptiform activity in otherwise normal preparations. The convulsants penicillin and pentylene tetrazol, which are both antagonists of the $GABA_A$ receptor, have been used as experimental convulsants for many decades. More recently, links between dysfunctions of specific aspects of the $GABA_A$ system and epilepsy have been established. These dysfunctions are grouped into presynaptic, postsynaptic, and ion flux problems, and therapies have been developed for each category.

Presynaptic Disorders

Reduced availability of GABA is thought to form the basis for a form of epilepsy manifested in pyridoxine-dependent seizures. In this rare disorder, newborn infants present with recurrent seizures that respond poorly to anticonvulsants but resolve rapidly with the administration of pyridoxine (vitamin B_6) or pyridoxal phosphate, the active form of the vitamin. A similar syndrome occurs in anyone exposed to high concentrations of the antitubercular drug isoniazid, which is also a pyridoxine antagonist. As mentioned above, pyridoxine is a necessary coenzyme for glutamic acid decarboxylase, which catalyzes the conversion of glutamate, the principal excitatory amino acid, into GABA, the principal inhibitory amino acid. This shift between glutamate and GABA is perhaps the clearest embodiment of the concept of an imbalance between excitation and inhibition as the etiology of epilepsy. Glutamate and GABA levels in the cerebrospinal fluid correspond to seizure control, although it may be possible in the future to assay these levels more directly (and less painfully) with magnetic resonance spectroscopy of GABA and glutamate/glutamine levels in the brain.

Therapeutically, several anticonvulsant drugs have been designed as GABA analogs or to increase the availability of GABA. Tiagabine blocks the GABA transporter GAT-1 that is responsible for much of the reuptake of GABA after synaptic release. Tiagabine should therefore increase the concentration of extracellular GABA, an important determinant of the activity of the extrasynaptic $GABA_A$ receptors that mediate tonic inhibition. Two drugs, vigabatrin and pregabalin, were designed as GABA analogs; recent studies have indicated that their anticonvulsant effects are more likely to be mediated via effects on voltage-gated calcium channels.

Postsynaptic Disorders

Subunit mutations A variety of genetically determined epilepsies have been discovered to be due to mutations in genes encoding subunits of the $GABA_A$ receptor. $GABA_A$ receptors are pentameric polypeptides that are typically composed of two α, two β, and either a γ or a δ subunit. Each of these Greek letters represents a family of related subunits, the members of which are designated by numerical subscripts, such as γ_2.

Generalized epilepsy with febrile seizures plus (GEFS+) is a vague name for an epilepsy syndrome, but that vagueness accurately reflects the clinical heterogeneity of the syndrome itself. GEFS+ is an

autosomal dominant disorder in which affected family members may have only febrile seizures. Febrile seizures are triggered in young children when the body temperature rises at the beginning of a fever. Other affected family members may manifest absence seizures, in which brief behavioral arrests are associated with generalized 3 Hz spike-wave discharges of several seconds' duration. However, affected family members may have more-severe seizure disorders, the worst of which is severe myoconic epilepsy of infancy (SMEI). In SMEI seizures also begin as febrile seizures but progress to include afebrile myoclonic and generalized tonic-clonic seizures that are associated with ataxia and developmental delays that are usually profound. These diverse epilepsy syndromes share the same mutations within a family. In keeping with the concept of epilepsy's arising from a change in the balance of excitation and inhibition, the most frequently isolated mutations are in either sodium channel subunits or the γ_2 and δ subunits of the $GABA_A$ receptor. Three laboratories have investigated the γ_2 mutation, R43Q, and uncovered a variety of possible functional implications, including more-rapid desensitization, a reduction in benzodiazepine modulation, and a reduction in the peak current amplitude. The variety of functional defects, while somewhat disconcerting, is common in these types of investigation and arises from a combination of differences in expression systems and the tremendous impact of posttranslational modification on the functional characteristics of ion channels. This issue is also reflected in the heterogeneity of epilepsy phenotypes for a given mutation and demonstrates the strong interaction between mutations in a gene for a GABA receptor subunit, the functional implications of that mutation after posttranslational processing, and the expression of that function in the setting of all the other characteristics of the brain that may either compensate for or exacerbate the underlying functional deficit in GABA signaling. Identification of the factors that modify the functional expression of mutations in GABA signaling proteins may make possible more-accurate predictions of the severity of disease in affected individuals.

Juvenile myoclonic epilepsy (JME) is manifest in adolescence and adulthood by early morning isolated jerks of the limbs and trunk (myoclonus) as well as tonic-clonic convulsions. The electroencephalogram demonstrates bilateral 6 Hz spikes and slow wave discharges. JME was recently demonstrated to be due to a mutation in the $GABA_A$ receptor. Identified mutations include the A322D mutation in the α_1 subunit of the $GABA_A$ receptor, which strongly reduces $GABA_A$ receptor-mediated currents via reduced expression of the receptor on the cytoplasmic membrane in the human embryonic kidney cell 293T expression system.

Subunit expression Extrasynaptic $GABA_A$ receptors mediate the tonic GABA conductance, in which ambient extracellular GABA concentrations activate high-affinity, slowly desensitizing $GABA_A$ receptors that usually contain a delta subunit. These $GABA_A$ receptors are uniquely sensitive to alcohol and neurosteroids. Recently, it has been discovered that changing levels of endogenous neurosteroids occurring during the estrous cycle may contribute to cyclic fluctuations in seizure susceptibility. In humans, the premenstrual reduction in seizure threshold is referred to as catamenial epilepsy. Rather than a direct neurosteroid modulation of $GABA_A$ receptors, the estrous cycle effects were shown to be due at least in part to alterations in the expression of delta subunit-containing $GABA_A$ receptors. The changing level of delta subunit-containing $GABA_A$ receptors alters the level of tonic inhibition, which contributes to the resting conductance of neurons and strongly modulates neuronal excitability and seizure threshold.

Therapeutically, anticonvulsants that increase the postsynaptic actions of GABA include the barbiturates and the benzodiazepines. There is evidence that the oldest of the anticonvulsants, bromide, also works by enhancing the postsynaptic effect of GABA. All these agents prolong the open probability of the GABA receptor. Benzodiazepines do this by increasing the frequency of channel openings, while barbiturates do so by increasing the probability of long channel openings. The net effect of the prolongation of the $GABA_A$ receptor open time is an increase in GABA-gated anionic conductance that hyperpolarizes the neuronal membrane and shunts or short-circuits excitatory conductances. These effects shift the balance of excitation and inhibition back toward inhibition. However, nonspecific prolongation of GABA currents will have a variety of impacts on other brain functions. For example, electroencephalographic rhythms in the gamma frequency band (30–80 Hz) are considered to be important in binding neural activity in different areas of the brain. The precise frequency of the gamma oscillations is determined by the duration of $GABA_A$ receptor-mediated postsynaptic conductances. Prolongation of these conductances by barbiturates and benzodiazepines alters the frequency of the gamma rhythm and is likely to contribute to reduced levels of alertness and cognitive capacity in many patients. Similarly, prolongation and enhancement of $GABA_A$ conductances will limit the voltage-dependent activation of *N*-methyl-D-aspartate (NMDA) receptors and are likely to inhibit NMDA receptor-dependent synaptic alterations thought to be important in learning and memory.

Receptor trafficking As described for the mutation associated with JME, reductions in the surface

expression of $GABA_A$ receptors can be just as problematic as mutations that affect the function of the receptor. This is because shortly after vesicle fusion at GABAergic synapses, GABA receptors are essentially saturated so that receptor number rather than the concentration of extracellular GABA is rate limiting. Under these conditions, a reduction in the density of membrane-bound receptors leads to a reduction in the $GABA_A$ receptor-mediated conductance. Recent studies have demonstrated endocytosis of $GABA_A$ receptors during prolonged seizures, an effect that is thought to be due to prolonged exposure to increased levels of GABA released during the course of the seizure. Similarly, some mutations in $GABA_A$ receptor subunits appear to reduce synaptic $GABA_A$ receptor-mediated conductances by altering receptor trafficking rather than by changing channel function.

Therapeutically, $GABA_A$ receptor trafficking has important implications for the treatment of status epilepticus. Benzodiazepines, because of their limited effect on respiratory drive, are usually the first-line agents in the treatment of prolonged seizures. Reduction in membrane-bound $GABA_A$ receptors correlates with reduced responsiveness to benzodiazepines so that there is a gradual reduction in benzodiazepine anticonvulsant efficacy during prolonged seizures. Barbiturates at high doses remain effective in this circumstance because of the wide variety of channels that interact with higher concentrations of this anticonvulsant. Presumably, anticonvulsants that work separately from the GABA system would also not be affected.

Charge-Carrying Ions

$GABA_A$ receptor-mediated signaling is unique in that it can be modulated not only by manipulation of ligand and receptor interactions but also by the flux of anions through the receptor-operated channel. This is because the driving force for chloride flux through the $GABA_A$ receptor is small and can be reversed by accumulation of a few millimoles of chloride within the cytoplasm. For example, chloride accumulation can be effected by the activity of chloride-accumulating transporters such as Na-K-2Cl cotransporter (NKCC1), as occurs in immature neurons in which GABA receptor activation is excitatory. In adult neurons, the chloride exporter KCC2 is the principal chloride transmembrane transporter and serves to maintain low cytoplasmic chloride concentrations that are conducive to hyperpolarizing influx of chloride during openings of $GABA_A$ receptor-operated channels. However, during prolonged, intense $GABA_A$ receptor activity, chloride accumulation within the cytoplasm eventually abolishes the driving force for further chloride entry. In contrast, bicarbonate efflux can continue indefinitely as a consequence of CO_2 diffusion across the membrane in concert with extracellular hydration and intracellular dehydration of CO_2, as long as the protons that accumulate intracellularly during bicarbonate dehydration can be buffered. The differential duration of the oppositely directed chloride and bicarbonate currents leads to a late depolarizing shift during prolonged $GABA_A$ receptor activation that may contribute to seizures. The importance of chloride homeostasis to $GABA_A$ receptor function was recently demonstrated by the association of generalized epilepsy syndromes with loss-of-function mutations in chloride channel (ClC) 2. ClC-2 is a hyperpolarization-activated, noninactivating ClC that serves as an emergency valve that reduces chloride accumulation within neurons and thereby maintains the $GABA_A$ reversal potential at values negative to action potential threshold.

Therapeutically, depolarizing responses to GABA can be blocked by diuretics. Acetazolamide inhibits carbonic anhydrase, the enzyme that catalyzes the hydration and dehydration of CO_2. This limits the bicarbonate efflux through the $GABA_A$ receptor-operated channel. Acetazolamide is a useful anticonvulsant although, curiously, its efficacy wears off after a few days, perhaps due to increased expression of carbonic anhydrase isoforms that are more resistant to acetazolamide. This limited duration of action is perfect for catamenial epilepsy, and acetazolamide is one of the most frequently used anticonvulsants in this clinical situation. NKCC1, the transporter that accumulates chloride in immature neurons, can be blocked by the diuretic bumetanide, and this has been shown to be an effective anticonvulsant strategy in newborn rats. Human neonatal seizures respond poorly to benzodiazepines and barbiturates, and human neocortical neurons also express NKCC1 in the neonatal period, so it is likely that bumetanide would be an effective anticonvulsant in human neonates as well. Clinical trials to test this hypothesis are currently under way in human neonates.

Alcohol

Extrasynaptic $GABA_A$ receptors that contain delta receptors have a high sensitivity to GABA and a low rate of desensitization, making them well suited for tonic inhibition that contributes to the resting membrane conductance of neurons. As discussed in the section titled 'Epilepsy,' these receptors are sensitive not only to neurosteroids but also to ethanol, and recent research suggests that enhanced tonic inhibition contributes to many of the effects of ethanol intoxication. Chronic ethanol administration is associated with reduced expression of the ethanol-sensitive delta

receptors. Although the delta subunit is an attractive locus for the effect of acute and chronic ethanol exposure on the central nervous system, the characteristics of $GABA_A$ receptors change, as do many other membrane proteins, depending on the cells in which they are expressed, perhaps reflecting the substantial functional impact of cell-specific phosphorylation cascades on receptor function. For example, much less ethanol sensitivity is noted when delta subunit-containing GABA receptors are expressed in oocytes. Ethanol effects on the GABA system may also be mediated by increases in neurosteroids and GABA release. This is an active area of research, driven in part by the hypothesis that familial polymorphisms in GABA receptor subunits may underlie genetic predispositions for ethanol abuse.

Psychiatry

Anxiety and Sleep

There is a long history of use of modulators of GABA receptors for relief of anxiety and sleep, including the use of ethanol, bromides, barbiturates, and benzodiazepines. These agents all have less than optimal side effect profiles, and for all of them, sedation is tightly linked to anxiety relief. Recently, additional insights have been developed using benzodiazepines that are selective for particular subunits and mice in which specific $GABA_A$ receptor subunits have been knocked out. Zolpidem is selective for α1-containing $GABA_A$ receptors and has much more substantial sedative-hypnotic effects than anxiolytic effects. Conversely, α1 knockout mice have anxiolytic but reduced sedative-hypnotic effects in response to benzodiazepine administration. On the other hand, α2 knockout mice show sedative but no anxiolytic effects with benzodiazepine administration. The goal of a pure anxiolytic benzodiazepine is being approached through the development of α2-selective benzodiazepines.

Psychosis

A number of lines of evidence point to altered GABA function in schizophrenia and related disorders, although, with these complex diseases, it is not clear what changes are causal. Schizophrenic patients have reduced cortical levels of an isoform of the enzyme glutamic acid decarboxylase (GAD), GAD67. GAD67 produces GABA from glutamate, and treatment with antipsychotic drugs increases GAD67 levels. Because early cortical injury also alters GAD67 expression, one possible pathophysiology links early injury or dysgenesis to altered cortical circuitry, GAD expression, and psychosis. However, there are many other possible links between GAD67 and psychotic illnesses. For example, single nucleotide polymorphisms in GAD1, the gene encoding GAD67, have been linked to childhood onset schizophrenia.

Movement Disorders and Tremor

Many nuclei of the basal ganglia have GABAergic outputs, as recently described in an excellent group of reviews in *Progress in Brain Research*. Alterations in GABAergic synaptic transmission have long been postulated to be involved in the expression of many movement disorders. Alteration of GABAergic outputs does not mean that these outputs are involved in the pathophysiology. For example, in Parkinson's disease the deficit involves loss of dopaminergic neurons in the substantia nigra. The output of the substantia nigra pars reticulata is predominantly GABAergic, and this output is increased in Parkinson's disease. However, GABA is not directly involved in the pathogenesis of Parkinson's disease, and treatment is directed at replacing the lost dopaminergic drive, rather than antagonizing GABAergic synaptic transmission, because the latter would be nonspecific and would be associated with unacceptable side effects, such as epilepsy.

Some forms of tremor may be related to specific $GABA_A$ receptor polymorphisms. For example, the α1 knockout mice discussed in the section titled 'Anxiety and sleep' also display a prominent tremor that is relieved by alcohol. This is very similar to a tremor in human patients that is often called benign essential tremor or familial tremor. In humans this tremor is inherited in an autosomal dominant fashion. It becomes manifest during skilled movements and is therefore called an intention tremor. It can be disabling and can lead to substance abuse by virtue of tremor suppression by alcohol and other sedative-hypnotic enhancers of $GABA_A$ receptor function. A recent study in humans did not find mutations in the DNA encoding the α1 receptor in a substantial cohort of patients with essential tremor. However, experiences with $GABA_A$ receptor mutations in epilepsy suggest that it is quite possible that receptor trafficking rather than receptor function is altered in essential tremor so that mutations in proteins associated with $GABA_A$ receptor trafficking might represent the next best target for mutational analyses. Alternatively, the knockout mouse may mimic features of human essential tremor; the human disease arises when other subunits are abnormally expressed, and this is mimicked in the α1 knockout mouse.

Spinal Cord Disorders

Spasticity

Spasticity is excessive resting muscle tone that results from inadequate inhibition of lower motor neurons

by descending inputs from the corticospinal tract. Generally, this occurs because of damage to the corticospinal tract, and so spasticity is highly associated with deficits in the skilled use of the affected limb. Because the net effect of activation of these corticospinal inputs is inhibition of lower motor neurons, GABAergic agonists have frequently been used to alleviate spasticity. As mentioned in the introduction, presynaptic $GABA_B$ receptors inhibit transmitter release via activation of potassium channels and inactivation of calcium channels. $GABA_B$ agonists reduce glutamate release that excites lower motor neurons and thereby reduce activation of muscle fibers to decrease spasticity. Systemic administration of $GABA_B$ agonists can produce both unacceptable sedation and, if GABA release is inhibited more than glutamate, seizures. To improve specificity, the restriction of the problem to the spinal cord has been exploited to develop more-specific therapeutic effects via local administration of agonists. Intrathecal delivery of baclofen, a $GABA_B$ receptor agonist, has been demonstrated to be effective in the treatment of both adult and pediatric spasticity, and this method of delivery is associated with minimal central nervous system side effects.

Pain

Phantom or neuropathic pain is a difficult clinical problem in which damage or loss of peripheral nerves is followed by intractable pain experienced in the original somatosensory distribution of the damaged nerve. Many mechanisms have been postulated for this phenomenon, but recent data suggest that an important pathophysiology involves an alteration in the reversal potential for $GABA_A$ receptor-mediated currents in neurons within lamina 1 of the spinal cord. The neurons in lamina 1 are postsynaptic to the neurons in the dorsal root ganglia whose peripheral processes were damaged or severed. There is evidence that this effect on E_{GABA} in the uninjured, postsynaptic neurons in lamina 1 occurs as a consequence of brain-derived neurotrophic factor (BDNF) secreted by microglia. BDNF has been shown to reduce the expression of KCC2, the cation-chloride cotransporter responsible for maintaining low chloride levels in mature neurons. This downregulation reduces the inhibitory effect of GABA by removing the hyperpolarizing component of inhibition. Shunting inhibition remains intact, although modeling studies suggest that at very high intensities of excitatory input, shunting inhibition may fail because the associated reduction in the membrane time constant permits a higher frequency of action potential transmission. Failure of shunting has not been a factor in neocortical studies of epilepsy, but the differences could be due to different rates of synaptic activity in the spinal cord as well as different dendritic geometries that may predispose to activity-dependent shifts in E_{GABA} due to chloride accumulation. Because the shift in E_{GABA} in the spinal cord is due to downregulation of KCC2 instead of upregulation of NKCC1, bumetanide cannot be used to ameliorate neuropathic pain. The involvement of BDNF has provided an important clue for understanding the regulation of transporters, and intervening in the downregulation of KCC2 is an important focus of current research.

GABA-A Receptors: Developmental Roles

Y Ben-Ari, Université de la Méditerranée, Marseille, France

Introduction

In adult neurons, GABAergic synapses provide most of the transmitter-gated inhibitory drive, whereas glutamatergic synapses are responsible for the ongoing excitatory drive that impinges on neurons. $GABA_A$ receptor-mediated signaling also plays a key role in the control of neuronal excitability and the generation of behaviorally relevant patterns and oscillations. Activation of $GABA_A$ receptors synchronizes the activity of principal neurons, leading to the generation of gamma and other network-driven oscillations. Blockade of GABAergic receptors generates seizures and other insults, reflecting the importance of an equilibrated activity of GABAergic and glutamatergic signaling. In cortical structures, GABAergic interneurons represent around 10–15% of the total neuronal population and constitute a very heterogeneous population of neurons with unique features that facilitate the control of all aspects of the activity of principal neurons. One key question in developmental neurobiology is how GABA signaling is installed during maturation and how the balance between excitation and inhibition is preserved throughout. This is an important issue considering the fact that any imbalance would lead to either excitotoxic consequences, if the excitatory glutamatergic drive prevails at any time, or inadequate construction of cortical networks and migration disorders, if inhibitory GABA signaling prevails. An equally important question is the maturation of network-driven patterns that shift from silence to adult networks that generate behaviorally relevant patterns. How does the developmental sequence of intrinsic voltage- and transmitter-gated currents provide a substrate for the development of networks? This is of course central in our understanding of how activity modulates genetic programs to entrain the construction of cortical networks.

Studies initiated primarily in Paris almost 20 years ago have unraveled a developmental program in the establishment of GABAergic signaling that appears to have been conserved throughout evolution. This cascade of events includes several key rules that appear also to provide a progressive shift of developing neurons that will first generate a universal primitive pattern that runs on the engine before the network has a sufficient density of synapses and is capable of generating adult patterns and the integrative functions associated with them. These events and how they shed light on the maturation of neurons and networks are discussed in the following sections.

The Excitatory/Inhibitory Shift of GABA Actions during Development

The activation of GABA receptors leads to the opening of a channel primarily permeable to chloride. In adult neurons, the intracellular concentration of chloride is quite low (a few millimoles per liter) and GABA will induce an influx of chloride and a hyperpolarization associated with a shunt of membrane potential that prevents the generation of action potentials. In developing neurons, studies using a wide range of recording techniques, including single GABA channels and perforated patch recordings that are impermeable to chloride, show that the intracellular chloride concentration ($[Cl^-]_i$) is higher (in the range of tens of millimoles per liter) than in adult neurons (Figure 1). As a consequence, the activation of $GABA_A$ receptors will lead to quite different actions, including a depolarization, the activation of sodium spikes, and voltage-dependent calcium currents leading to an excitation and an increase of $[Ca^{2+}]_i$. Perhaps even more strikingly, the activation of $GABA_A$ receptors leads to a removal of the voltage-dependent Mg^{2+} block of *N*-methyl-D-aspartate (NMDA) channels and thus to an additional increase of $[Ca^{2+}]_i$. This 'synergistic' action of GABA receptors and NMDA receptors that is quite opposite to the actions of GABA in adult neurons has important consequences in terms, notably, of plasticity. Several studies indicate that coactivations of GABA and NMDA receptors or calcium channels lead to alterations of synaptic efficacy of GABAergic synapses, including a long-term depression or potentiation of GABAergic synapses according to the source of calcium influx activated. They also modulate the formation of novel synapses in neurons that are quiescent. Thus, repetitive electrical stimulation of neurons that are silent – with no functional synapses – triggers the expression of GABAergic synapses, as reflected by the presence of spontaneous GABAergic postsynaptic currents (PSCs).

The developmentally regulated reduction of $[Cl^-]_i$ and the excitatory (E) to inhibitory (I) shift of the actions of GABA (E to I) have now been confirmed in all developing brain structures and animal species studied, suggesting that they have been preserved throughout evolution. It is suggested that excitatory actions of GABA provide a source for calcium influx

Figure 1 The developmental shift of γ-aminobutyric acid (GABA) actions. In immature neurons, there is a high intracellular concentration of chloride (Cl^-). This is reduced during maturation, leading to an excitatory-to-inhibitory shift. The mechanisms include an early expression of a chloride importer (NKCC1) and a late expression of a chloride transport extruder (KCC2). From Ben-Ari Y (2002) Excitatory actions of GABA during development: The nature of the nurture. *Nature Reviews Neuroscience* 3(9): 728–739.

needed for growth while avoiding the possible excitotoxic actions of unbalanced glutamatergic drive, because of the small magnitude of GABA excitation and the shunting actions intrinsic to its operation. In this model, the E-to-I shift occurs when the density of glutamatergic synapses reaches a level that requires an efficient compensatory inhibition.

How Does the E-to-I Shift Occur?

The concentration of $[Cl^-]_i$ is regulated by several cotransporters, and two of them appear to play an important role (Figure 1):

1. KCC2 is the principal transporter for Cl^- extrusion from neurons. KCC2 extrudes K^+ and Cl^- using an electrochemical gradient for K^+. Developmental studies suggest that KCC2 is exclusively expressed in mature neurons: the KCC2 that extrudes chloride follows a developmental expression curve that corresponds well with the higher $[Cl^-]_i$ at an early stage. An early expression by gene transfection of the transporter leads to the expected E-to-I shift. Interestingly, in neuronal cultures, an early expression of the transporter at a time when immature neurons have high $[Cl^-]_i$ leads, in addition to the expected shift, to a selective increase of the density of GABAergic – but not glutamatergic – synapses in the transfected neuron. Therefore, the intracellular concentration of chloride plays an important role in synapse formation and by a yet unknown mechanism may regulate the establishment of GABAergic synapses.

2. The NKCC1 is a membrane transport protein that mediates chloride uptake across the plasma membrane, internalizing one Na^+, one K^+, and two Cl^- ions in an electroneutrally coupled fashion. NKCC1 also plays a housekeeping role in cell volume homeostasis. The early expression of this chloride importer plays an important role in maintaining high intracellular $[Cl^-]_i$. Studies using selective antagonists of this transporter suggest that it also plays an important role in early epileptogenesis.

The mechanisms responsible for the reduction of $[Cl^-]_i$ and the excitatory-to-inhibitory shift of GABA actions are not fully understood. Some observations suggest that GABA itself may do the job – that is, it is the activation of immature GABAergic synapses providing the signal that activates KCC2 and the removal of chloride. This is based on neurons in cultures that do not exhibit the shift when $GABA_A$ receptors are blocked. Other studies, however, cannot be reconciled with such a mechanism and suggest that the shift is programmed and occurs even when GABA signaling is blocked.

Therefore, the E-to-I shift adheres clearly to a basic mechanism that includes the expression of mechanisms that remove excess chloride. However, it remains to determine quantitatively the alterations of $[Cl^-]_i$ that occur dynamically during ongoing activity in developing neurons. The issue is to understand how chloride is dynamically regulated when an accumulation occurs and how that process is modified by activity. Other observations suggest that in a variety of pathological conditions, KCC2 is downregulated, leading to a chronic accumulation of chloride occurring on a persistent basis. This suggests that pathological insults in adults recapitulate the developing brain situation, but also that $[Cl^-]_i$ is an important signal in neurological disorders.

When Does the Shift Occur?

The E-to-I shift occurs in a species- and structure-dependent manner. In the rodent hippocampus, the shift occurs during the second postnatal week, although there are important differences between neurons according to their developmental stage: the shift will occur earlier in interneurons or CA3 pyramidal neurons that mature before CA1 pyramidal neurons. In other structures, the E-to-I shift will occur earlier or later according to developmental programs. This is particularly important in humans and subhuman primates, which have an extended developmental period, because recently born cortical neurons will have excitatory GABA whereas adjacent neurons that belong to the same neuronal population but that became postmitotic at an earlier stage will already operate with thousands of inhibitory-operated GABAergic synapses. This heterogeneity must be taken into account in models of network development. In addition, in a clinical perspective, drugs that augment the efficacy of GABA actions (e.g., benzodiazepines) will affect GABA signaling differently in the mother's brain and that of the embryo at a given developmental stage.

GABAergic Synapses Are Formed before Glutamatergic Synapses

In adult neurons, applications of GABA receptor antagonists generate seizures because of the removal of a tonic and phasic inhibitory drive, whereas similar applications of glutamate receptor antagonists produce a full blockade of ongoing excitatory activity. Studies performed in immature slices indicate, in contrast, that similar applications of GABA receptor antagonists block ongoing activity instead of generating seizures, suggesting that the excitatory drive is provided by GABA. However, the effects of antagonists can be misleading, particularly in developing networks, because of their heterogeneous features and expression of different receptor subunits. Direct demonstration that GABA signaling does in fact mature before glutamate signaling matures came from studies performed in primate hippocampal neurons *in utero* and rodent embryos and early postnatal neurons; in these studies neurons were first recorded, their physiological properties were determined, and morphological *post hoc* reconstruction of neurons was performed to determine their developmental stage (**Figure 2**). This showed that silent neurons with no active PSCs have a small axon and little or no dendrites, neurons with a small apical dendrite have only GABAergic PSCs, and neurons with both GABA and glutamate PSCs have longer and more developed apical and basal dendrites. Neurons with glutamate but no GABAergic PSCs were not encountered, suggesting that GABAergic synapses are formed first on apical dendrites and glutamatergic synapses are formed only once the postsynaptic neuron has reached a certain degree of maturity (**Figure 2**). Since afferent glutamatergic axons are already present at an early stage, this sequence is not due to a late arrival of inputs but rather to different requirements for the formation of GABA and glutamatergic synapses: glutamatergic synapses require a more developed postsynaptic target to form synapses than GABAergic axons. Therefore, once neurons have a primitive apical dendrite, they will form GABAergic but not

Figure 2 Early formation of γ-aminobutyric acid (GABA) synapses and the GABA–glutamate (GLU) sequence. CA1 pyramidal neurons from rodent slices at birth (top) and from primate hippocampus at various gestational stages (E85 to E105; bottom) were recorded in slices and reconstructed after identification of their synaptic responses. In both cases, silent neurons with no functional postsynaptic currents are small, with an axon but no developed dendrites; neurons with GABA but no GLU postsynaptic currents have a small apical dendrite, and neurons with both GABA and GLU postsynaptic currents have an elaborated apical and basal dendrite. (Top) Data from Tyzio R, Represa A, Ben-Ari Y, et al. (1999) The establishment of GABAergic and glutamatergic synapses on CA1 pyramidal neurons is sequential and correlates with the development of the apical dendrite. *Journal of Neuroscience* 19(23): 10372–10382. (Bottom) Data from Khazipov R, Esclapez M, Caillard O, et al. (2001) Early development of neuronal activity in the primate hippocampus *in utero*. *Journal of Neuroscience* 21(24): 9770–9781.

glutamatergic synapses, and only once they have well-developed apical and basal dendrites will they also have functional glutamatergic synapses. A similar developmental gradient is observed in other structures. Interestingly, studies in proliferating neurons in the adult fascia dentata show a similar gradient: newly proliferating neurons have initially only excitatory GABAergic synapses and only when they have a more mature dendritic arbor and morphology do they also have functional glutamatergic synapses. Therefore, this sequence is somehow obligatory; neurons must express the E-to-I shift during their maturation. One consequence of this second developmental rule is that at an early stage, GABA provides most if not all ongoing activity.

If GABAergic synapses mature before there is maturation of glutamatergic synapses, then the neurons that synthesize and release GABA must mature before glutamatergic neurons do. This indeed was found to be the case. Patch clamp recordings from immature GABAergic interneurons and reconstruction revealed that they follow the same sequence as the principal neurons do, but earlier: *in utero*, in rodents, interneurons first have GABAergic synapses, and when they are more developed also have glutamatergic synapses, at a stage when most pyramidal neurons are silent. Thus, at E18, in rodents, most pyramidal neurons have no functional synapse at a time when most interneurons already operate with functional GABA and glutamate synapses. In fact, the earliest patterns recorded *in utero* are generated by a network of interneurons, indicating that these neurons, which control the generation of many fundamental adult patterns, also drive early patterns. Therefore, in spite of their long journey along the tangential migration pathway, GABAergic neurons, at least in the hippocampus, become postmitotic first, then establish synapses and extend a dendritic and axonal arbor to organize the first network pattern. The first functional synapses in the developing hippocampus are formed between GABAergic interneurons.

Giant Depolarizing Potentials: A Primitive Network Oscillation, Present in All Developing Systems, That Disappears When the E-to-I Shift Is Completed

Studies performed initially in the developing hippocampus *in vivo* and *in vitro* have unraveled a unique primitive pattern that disappears around the second postnatal week when the E-to-I shift has been completed. This pattern was named 'giant depolarizing potentials' (GDPs; Figure 3), since it was identified in intracellular recordings and was characterized by its long-lasting duration and high amplitude at resting membrane potential. GDPs are characterized by the presence of synchronized synaptic currents mediated by excitatory GABA and glutamatergic PSCs and, particularly, by NMDA receptor-mediated PSCs, suggesting that the GABA and NMDA synergistic actions play a central role in GDP generation. GDPs disappear in the hippocampus by the second week of postnatal life, when more elaborated behaviorally relevant patterns, including gamma oscillations, are first recorded. This pattern is universal in that similar oscillations have been observed in a wide range of developing structures and preparations, including the spinal cord and neocortex. The key signal is the completion of the E-to-I shift that is associated with the loss of GDPs, suggesting that the excitatory actions of GABA are instrumental in the generation of GDPs. GDPs can be generated in small slices in all subregions of the hippocampus, suggesting that a small network of GABAergic interneurons and principal cells can generate them.

To study the propagation of GDPs, an interesting preparation was developed: the intact hippocampi from both hemispheres, along with their dissected connecting commissure, are placed in a triple chamber with three independent compartments, allowing a perfusion of the three components with different liquids. With this preparation, GDPs were found to propagate from one hemisphere to the other, and within the same hippocampus to propagate following developmental gradients: higher-frequency GDPs generated in more developed subregions propagate to less developed regions that generate less frequent GDPs. The entire hippocampus behaves like a syncytium, with all regions generating GDPs but more developed regions having a higher density of glutamatergic synapses generating GDPs with a higher probability of propagating to less developed regions. GDPs have been recorded *in vivo* in rodents, including in their neocortex. These patterns may correspond to the 'delta brush' pattern observed in preterm babies.

GDPs thus provide a signal that entrains large networks together at an early developmental stage by means of the excitatory actions of GABA and the activation of NMDA receptor-driven PSCs that are very long-lasting in immature neurons because of the expression of subunits with longer kinetics. The long-lasting kinetics of GDPs are highly suitable

Figure 3 Giant depolarizing potentials in primate hippocampal neurons *in utero* (E105; P, pyramidal layer; R, stratum radiatum). Two neurons were patch clamp recorded and reconstructed *post hoc*: one was a pyramidal neuron and the other was an interneuron. Both had synchronized giant depolarizing potentials. From Khazipov R, Esclapez M, Caillard O, et al. (2001) Early development of neuronal activity in the primate hippocampus *in utero*. *Journal of Neuroscience* 21(24): 9770–9781.

to activate a very heterogeneous population of neurons, some of which have very few active synapses and others of which already have large numbers of synapses. The long time constant of GABaergic PSCs, in comparison with AMPA receptor-driven PSCs, is useful: with a short kinetic event it would have been quite difficult to activate neurons endowed with a few active synapses. This is an instrumental property that will enable neurons that fire together to 'wire' together, and most likely facilitates the formation of functional units. It remains to determine the mechanisms that eliminate GDPs and the relation between the density of active synapses and this shift. Also, the role of activity in that elimination will have to be better understood.

Developmental Curve of Primate Neurons

Are the principal elements of this cascade present in primate neurons *in utero*? This is quite important, considering the relevance to humans, but also because of the ontogenetic implications of better determining the developmental curves of neuronal maturation in rodents and primates. A pioneer study recorded central primate neurons during fetal development: a cesarean operation was performed in pregnant macaques, the fetal brain was removed, and the entire developmental sequence was determined using a morphofunctional characterization of the properties of neurons in relation to their developmental stage (Figures 2 and 4). At midgestation, pyramidal neurons of CA1 are immature with little or no dendrites and no functional synapses (i.e., no PSCs). Next, neurons have a small apical dendrite and only GABAergic synapses, and only later do they also form glutamatergic synapses. A quantitative analysis revealed that axons develop before dendrites do; also, whereas at midgestation neurons have no spines, a few weeks before full term they have as many as 7000 spines; these data allow quantitation of the speed of formation of synapses in primate central neurons. GABA excites immature neurons, as reflected by the fact that a GABA receptor antagonist has no effect at midgestation but generates seizures a few weeks later. This also reflects the importance of seizures *in utero*, in that neurons are able to generate synchronized patterns *in utero* and are highly excitable (see later).

The curve depicting this maturational sequence in primates, which in fact is more completed than that in rodents, is shown in Figure 4. Note that GDPs are present until a few weeks before delivery; this suggests that the loss of GDP signals is an important maturational stage, when networks can generate behaviorally relevant patterns. Again, the E-to-I

Figure 4 Boltzmann equation used to depict various functions during maturation of primate neurons *in utero*, from neurogenesis in the hippocampus to speed of growth of axons, spine acquisition, and synapse formation. All values are derived from intracellular recordings and reconstruction of primate neurons in slices *in utero* (removed by cesarean surgery), with values calculated. Note the early formation of axons (prior to dendrite formation), the early maturation of GABA signals, and the rapid formation of spines, between midgestation and delivery, shifting from 0 to over 7000 synapses a few weeks before delivery. Note also the domination of giant depolarizing potentials (GDPs) until a few weeks before delivery, indicating that GDPs in primates are an *in utero* pattern, in contrast to that in rodents. From Khazipov R, Esclapez M, Caillard O, et al. (2001) Early development of neuronal activity in the primate hippocampus *in utero*. *Journal of Neuroscience* 21(24): 9770–9781.

shift is an important signal, since the disappearance of GDPs and the completion of the E-to-I shift indicate that at this stage there is a sufficient density of glutamatergic synapses and a network capable of integrative activity. This curve is therefore an important source of information on network development in primates.

Paracrinic Action of GABA Prior to Synapse Formation

In all developing peripheral (i.e., the neuromuscular junction) or central cells, receptors are established before synapses are. Does this contribute to the process that established cortical networks? Do the excitatory actions of GABA also play a role at that earlier stage? Studies performed in immature hippocampal neurons confirm the presence of functional receptors at an early stage and indicate that stimulation of immature neurons that bear no functional synapse generates a long-lasting current present only at an early stage. This early current is mediated primarily by GABAergic receptors, as the current is almost entirely blocked by GABA receptor antagonists. The remaining current is NMDA, but not AMPA, receptor driven. Therefore, these early expressed receptors somehow sense a release of GABA and generate long-lasting currents in neurons with no functional synapses.

How are the transmitters released? Blocking both sodium and calcium currents and vesicular release with toxins fails to block that response. This response persists even in recordings made in a knockout in which vesicular release had been obliterated by inactivating Munc18, a protein required for vesicular release. Therefore, a nonvesicular release of GABA occurs before the conventional vesicular release, and this diffuses to distal neurons to generate long-lasting currents. Again, GABA appears to operate earlier than glutamate does and to exert an important control on early activity.

Are these early actions of GABA – and to a lesser extent, glutamate acting on NMDA receptors – functional? Studies using slice cultures indicate that blocking GABA receptors at a time when neurons have no synapses retards considerably neuronal migration. Therefore, a nonvesicular release of GABA acts on neurons that have receptors, but no functional synapses, to modulate neuronal migration.

The diffusion of GABA to distal sites depends on the efficacy of transporters. Using GABA and glutamate transporter blockers, it was found that glutamate, but not GABA, transporters operate at an early stage. Therefore, GABA will diffuse to distal sites and act in a paracrinic manner whereas the concentration of extracellular glutamate is tightly controlled from the start to prevent toxic actions. In keeping with this finding, *in vivo* and *in vitro* injections of a glutamate transport blocker generate long-lasting oscillations and seizures with a clinical and electrographic pattern reminiscent of encephalopathies.

Trophic Actions of Excitatory GABA

Early studies suggest that GABA exerts a plethora of trophic actions in several systems. GABA stimulates neuronal growth and dendritic arborization, synapse formation, and neuronal differentiation. GABA also exerts an important action on neuronal proliferation by means of action on DNA in neuroblasts. Therefore, at all early stages, GABA can modulate important functions by means of its excitatory action.

I-to-E Shift after Insults: Pathogenesis Recapitulates Ontogenesis

It has long been known that high-frequency electrical activity induces an accumulation of chloride – most likely because the capacity to remove chloride is limited. This is most conspicuously shown in seizures and other insults associated with high-frequency electrical activity. Such activity leads to excitatory actions of GABA in a transient or even quasi-permanent manner; excitatory actions of GABA have been observed in human epileptic tissue months after the last seizure, and various insults, including trauma and lesions, also lead to a long-lasting I-to-E shift.

Recent studies using a convenient novel *in vitro* preparation have enabled determination of the mechanism of induction and expression of this shift and of the electrographic events required for its occurrence. A triple chamber was constructed to accommodate the two intact hippocampi and the commissure connection in three independent chambers that can be perfused with different liquids. One hippocampus was perfused with a convulsive agent (kainate) and the other with an artificial cerebrospinal fluid (ACSF). Seizures generated in one hippocampus propagated to the other hippocampus and led to the formation of a chronic mirror focus, since after a few seizures, the naive hippocampus (the one that did not receive kainate but was subjected to recurrent propagated seizures) became epileptic and generated seizures when disconnected from the other hippocampus. This situation persisted for up to 2–3 days (i.e., as long as the preparation could be kept alive *in vitro*).

This preparation was then used to determine the conditions required for the shift. Applications of an NMDA or GABA receptor antagonist to the naive side – while kainate was applied only to

Figure 5 Seizures beget seizures in the triple chamber *in vitro*. When a seizure is generated in one intact hippocampus, it travels to the other hippocampus and leads to the formation of a secondary epileptogenic mirror focus, capable of spontaneously generating seizures. However, this transformation of a naive network to one that seizes requires high-frequency oscillations in the propagated paroxysmal events. If the electrographic event does not include high-frequency oscillations, it will not lead to long-lasting consequences. Since high-frequency oscillations require functional γ-aminobutyric acid (GABA; and *N*-methyl-D-aspartate) signaling for their generation, blocking GABA receptors does not block the seizures but rather prevents their pathogenic consequences: GABA receptor antagonists are anticonvulsive but not antiepileptogenic. From Khalilov I, Holmes GL, Ben-Ari Y (2003) *In vitro* formation of a secondary epileptogenic mirror focus by interhippocampal propagation of seizures. *Nature Neuroscience* 6(10): 1079–1085.

the stimulated hippocampus – prevented the formation of a mirror focus, although this did not block the propagation of seizures. Therefore, functional GABA and NMDA receptors are required for seizures to beget seizures, although they are not required for the propagation of seizures. What are the elements in the seizure needed for this transformation to take place? When time frequency curves were constructed to evaluate the components of the seizure, it was found that high-frequency oscillations (60–90 Hz) are present in the ictal events that led to the formation of a mirror focus: seizures that included lower frequencies failed to generate a mirror focus, and blocking GABA or NMDA receptors also blocked the high-frequency components of the seizures (Figure 5). Therefore, the GABA–NMDA synergy is needed for seizures to activate a persistent transformation of a network from that of control to an epileptic one. Finally, using this preparation, GABA was found to excite neurons in the chronically epileptic tissue, suggesting that epileptogenesis has induced a shift to an immature state: epileptogenesis recapitulates ontogenesis. This illustrates the dynamic properties of the shift and its contribution to neurological disorders.

Implications of These Basic Rules and a General Model of the Establishment of Activity in Developing Cortical Networks

These observations suggest that the unique features of GABA receptors that are not shared by other transmitters (notably, glutamate) – that is, the capacity to shift from excitation to inhibition in an activity-dependent manner – play an important role in early brain development. The high $[Cl^-]_i$ that appears to be a basic feature of developing neurons, most likely an evolutionarily conserved feature, is used by developing neurons to provide a small excitatory drive and is needed to augment intracellular calcium concentrations with little danger, when compared to the potentially toxic actions of glutamate. The long duration of GABA PSCs – when compared to AMPA receptor-driven PSCs – will also facilitate the generation of synchronized events in neurons that have a few functional synapses. The synergistic actions of GABA and NMDA receptors will further stimulate these effects, in particular when the long-lasting actions of the NMDA receptor subunits, present at an early developmental stage, are considered. The synergistic actions of GABA and NMDA will generate the first network-driven pattern capable of synchronizing a wide range of neurons at very different developmental stages. This primitive pattern, which has little informative content, is present to activate neurons synchronistically; it will disappear when a sufficient density of glutamatergic synapses is present and when the E-to-I shift has taken place in the vast majority of GABA synapses. Only at that stage is the network capable of generating more complex, behaviorally relevant patterns. This suggests that this sequence provides a solution to the issue of how to develop excitatory and inhibitory drives while preventing a

transient imbalance between excitation and inhibition that would have potentially excitotoxic actions.

Introduction

If nervous systems possessed only excitatory neurons, there would be no brake on any signal, excitation would generate further excitation, and a chain of neurons would produce amplifying cascades of excitation, making the system incapable of doing anything useful. By contrast, networks made from both excitatory and inhibitory neurons can self-organize and generate complex properties. Inhibition is essential for every operation performed by any neuronal circuit in any brain region. In vertebrate brains, the inhibitory agent used most often by neurons is γ-aminobutyric acid (GABA), which after release from the presynaptic terminals diffuses across the synaptic cleft to bind to receptor molecules – the so-called GABA$_A$ receptors. As for all other ligand-gated channels, GABA$_A$ receptors convert chemical messages into electrical signals. In less than a millisecond, the binding of two (tiny) molecules of GABA induces a conformational change in the (giant) receptor oligomer that opens the central chloride ion channel. This remarkable process is called 'gating.' Cl^- diffuses through the receptor pore, down the electrochemical gradient, entering the cell and hyperpolarizing it. This results in fast synaptic inhibition (on the millisecond timescale) of a domain of the postsynaptic cell (Figure 1).

Strictly, GABA$_A$ receptors are actually GABA-gated anion-permeable channels, with a HCO_3^-/Cl^- permeability ratio of approximately 0.2–0.4. In adult cells, Cl^- ions usually move into the cell to produce strong inhibitory hyperpolarization, as the reversal potential for Cl^- is 15–20 mV more negative than the resting membrane potential. The Cl^- gradient is maintained by K-Cl cotransporters. HCO_3^- ions move out of the cells through the GABA$_A$ receptor channel (Figure 1); the HCO_3^- efflux is mildly depolarizing (HCO_3^- has a reversal potential of -12 mV), but this is normally offset by the Cl^- hyperpolarization. Depending on the local internal Cl^- concentration, Cl^- ions can also move out after GABA$_A$ receptor activation and depolarize the cell; this happens especially during embryonic and postnatal neuronal development.

Molecular Biology of GABA$_A$ Receptors

In mammals, GABA$_A$ receptors form as heteropentameric assemblies from a family of 19 subunits encoded by distinct genes (α1–α6, β1–β3, γ1–γ3, δ, ε, θ, π, and ρ1–ρ3). Depending on the subunit composition, GABA$_A$ receptors differ in their biophysical properties and affinity for GABA, their pharmacology, and their location on the cell. GABA$_A$ receptors were cloned by the combined efforts of the Eric Barnard and Peter Seeburg groups in 1987 by the classical method: Peptide sequences obtained from purified (bovine brain) receptors were used to construct synthetic DNA probes to screen brain complementary DNA (cDNA) libraries. This was the starting point. By 1990, this now historical technique of screening cDNA libraries had revealed most of the gene family, all the α1–6, β1–3, γ1–3 subunits and one δ subunit; over the remaining decade, a few more subunits, such as ε, θ, and π, were characterized. With the completion of the human genome database, an *in silico* hybridization method was used to screen for further mammalian GABA$_A$ receptor genes, but it found none. Most of the subunit gene family members are in clusters, suggesting gene and then cluster duplication during the evolutionary origin of vertebrates: β2, α6, α1, γ2 form a cluster in that order on human chromosome 5q34; the β3, α5, γ3 genes cluster in that order on human chromosome 15q13; the γ1, α2, α4, β1 genes cluster in that order on chromosome 4p12; the ε, α3, θ genes in that order on X q28; the ρ1 and ρ2 genes, 40 kbp apart on 6 q15; and the π, ρ3, and δ subunit genes are isolated on human chromosomes 5q35.1, 3q12.1, and 1p36.3, respectively.

As determined by both *in situ* hybridization (mRNA localization) with gene-specific probes (Figure 2) and immunocytochemistry (protein localization) with subunit-specific antibodies, the expression of the individual subunit genes is age and region specific. Does the clustering of the GABA$_A$ receptor subunit genes imply they are coregulated? The α1 and β2 genes do indeed share identical transcription patterns; thus, these two genes may share regulatory elements. All the other subunit genes have sometimes common, sometimes divergent expression patterns, with no correlation with which gene is in which gene cluster.

GABA$_A$ Receptor Structure

The GABA$_A$ receptor belongs to a superfamily of ligand-gated ion channels ('Cys-loop receptors') that

Figure 1 The GABAergic synapse in the mammalian brain. GABA is synthesized from glutamate by glutamic acid decarboxylase (GAD) and transported into vesicles by the vesicular GABA transporter (vGAT). When the presynaptic terminal is depolarized sufficiently, GABA vesicles are released into the cleft and diffuse rapidly to activate the postsynaptic GABA$_A$ receptors. GABA is salvaged from the synaptic cleft by, for example, the GAT-1 transporter on presynaptic terminals. The GABA$_A$ receptor is a GABA-gated Cl^- and HCO_3^- channel.

Figure 2 Expression of the GABA$_A$ receptor α subunit genes in adult rat brain (sagittal sections) as detected by *in situ* hybridization. in vertebrates includes the nicotinic acetylcholine receptors, the 5-hydroxytryptamine type 3 (5-HT3) receptors, the zinc-activated ion channel, and the glycine receptors. No direct structural information is available for GABA$_A$ receptors. So in imagining how the GABA$_A$ receptor must look, we can do no better than quote Unwin for his empirical observations on the *Torpedo* nicotinic acetylcholine receptor:

> The receptor (a large 290 kDa glycoprotein) is composed of elongated subunits, which associate with their long axes approximately normal to the membrane, creating a continuous wall around the central ion-conducting path. The whole assembly presents a rounded, nearly 5-fold symmetric assembly when viewed from the synaptic cleft, but is wedge-shaped when viewed parallel with the membrane plane. The subunits of the receptor all have a similar size 30 A × 40 A × 160 A and the same three-dimensional fold. Each subunit is a three-domain protein and so portions the channel naturally into its ligand-binding, membrane-spanning and intracellular parts.

In GABA$_A$ receptors, the arrangement of subunits around the channel is probably $\gamma\beta\alpha\beta\alpha$ or $\delta\beta\alpha\beta\alpha$ counterclockwise when viewed from the extracellular space (Figure 3(a)). For those cells in which they are expressed, ε and π subunits probably replace the γ and δ subunit within the pentamer, whereas the θ subunit might replace a β subunit. As for all members of the nicotinic receptor superfamily, all GABA$_A$ receptor subunits contain a large extracellular N-terminal domain of approximately 200 amino acids shaped by a cysteine disulfide bridge (the so-called Cys-loop, Figure 3(b)). For GABA$_A$ subunits, the amino acid consensus sequence of the Cys-loop is C*****F/YP*D***C*****S (where * is a degenerate residue).

Figure 3 (a) Subunit arrangement in γ2-containing (synaptic) and δ-containing (extrasynaptic) GABA$_A$ receptors; (b) schematic of an individual subunit topology. C, cysteine; N, N-terminus of the protein TM, transmembrane domain. The pore lining domain, TM2, is shown in blue. Pink triangles represent GABA; blue circle represents a BZ ligand.

Each subunit contains four predicted transmembrane spanning domains (TM1–TM4) of about 20 amino acids and a large intracellular loop between TM3 and TM4 (TM3–TM4 loop) (Figure 3(b)). Many GABA$_A$ receptor subunits have the amino acid sequence (TTVLTMTT) in the TM2 domain. Five of these eight amino acids probably line the ion channel. TM1, TM3, and TM4 segregate TM2 from membrane lipid. The selectivity filter and gate lies at the intracellular end of the TM2 domains and includes part of the TM1–TM2 loop. In the 5-HT3 and nicotinic receptors, residues in the TM3–TM4 loop region influence single channel conductance. The TM3–TM4 loop contributes key sites for attaching anchor and regulatory proteins involved in locating the receptor at synapses and in governing the activity of GABA$_A$ receptor.

In the extracellular domain of a typical GABA$_A$ receptor consisting of two α, two β, and one γ2 subunit, the binding pocket for GABA forms at the interface between the α and the β subunit, and the binding pocket for benzodiazepines (BZs) lies at the interface of the α and the γ subunit (Figure 3).

Subunit Assembly Rules for GABA$_A$ Receptors

GABA$_A$ receptor subunit combinations are partly governed by which cell types express which genes and partly by preferential partnering of subunits within a given cell; for example, the α4 and α6 subunits assemble preferentially with the δ subunit (Figure 4(a)). The majority of mammalian brain GABA$_A$ receptors are probably $\alpha\beta\gamma$2 combinations. The subunit ratio is probably $2\alpha/2\beta/1\gamma$. Some receptors also contain different α and β subunits, such as $\alpha1\alpha2\beta2\gamma2$. The $\alpha1\beta\gamma2$ combination is the most abundant GABA$_A$ receptor subtype in the brain (60% of total; Figure 4(b)).

Synaptic GABA$_A$ Receptors: $\alpha\beta\gamma$ Subunit Combinations and Anchoring Role of the γ2 Subunit and Gephyrin

Placing GABA$_A$ receptors at synapses requires specific proteins that interact directly or indirectly with the γ subunits. For example, targeting some GABA$_A$ receptor subtypes to GABAergic terminals involves the widely expressed microtubule-binding protein gephyrin. Gephyrin either helps convey some GABA$_A$ receptor subtypes to the synapse or anchors them there – this requires the γ2 subunit. Without the γ2 subunit, no GABA$_A$ receptors are found in synapses in the developing or adult hippocampus, and without gephyrin, much-reduced numbers of some synaptic GABA$_A$ receptor subtypes, especially those containing α2, are found; some receptor clusters, especially those containing the α1 subunit, persist in hippocampal gephyrin knockout neurons. Other γ subunits can replace synaptic targeting function of γ2; in γ2 knockout mice, GABA$_A$ receptors can be restored to hippocampal synapses by expressing the γ3 subunit by transgenic rescue. Some conserved sequence identity in the large TM3–TM4 intracellular loops of the γ subunits may indicate binding sites for parts of the synapse anchoring mechanism. Distributed cysteine residues are conserved in the γ subunit large intracellular loops but are absent from the β and δ subunits. Palmitoylation of these cysteine residues via a thioester bond plays some role in targeting γ subunit-containing receptors to the synapse. A surprising finding is that the TM4 region of the γ2 subunit is also involved in synaptic targeting, possibly by interacting with lipid rafts occurring in the synapse or by other membrane proteins. The γ2 TM4 is necessary and sufficient for postsynaptic clustering of GABA$_A$ receptors, whereas the cytoplasmic γ2 subunit domains are dispensable. In contrast, both the TM3–TM4 loop and the TM4 domain of the γ2 subunit contribute to efficient recruitment of

Figure 4 Some GABA$_A$ receptor subunit combinations found in adult rat brain: (a) $\alpha4\beta2\delta$; (b) $\alpha1\beta2\gamma2$. The gene expression is visualized by *in situ* hybridization (adult rat brain, horizontal sections). Cb, cerebellum; H, hippocampus; OB, olfactory bulb; T, thalamus. The $\alpha4\beta2\delta$ receptors are particularly prominent in the thalamus; the $\alpha1\beta2\gamma2$ subtype is widespread.

gephyrin to postsynaptic receptor clusters. Thus, the $\gamma2$ subunit TM3–TM4 cytoplasmic loop might be needed for inserting receptors into the plasma membrane but is dispensable for delivery of receptors to subsynaptic dendritic sites. Gephyrin does not bind the $\gamma2$ receptor subunit directly. The identity of the missing link(s) between gephyrin and GABA$_A$ receptor subunits is unknown.

GABA$_A$ Receptor Occupancy at Synapses Is Dynamic

GABA$_A$ receptor expression on the surface of neurons is dynamic; receptors rapidly recycle and leave from or insert into the synapse by lateral diffusion and/or endo/exocytosis. GABA$_A$ receptors diffuse into a synaptic zone and are transiently 'captured' by the anchoring complex. However, for some inhibitory hippocampal synapses, a direct relationship exists between the number of synaptic GABA$_A$ receptors and the strength of the synapse, but it is not clear what mechanisms maintain fixed numbers of GABA$_A$ receptors long-term at specific synapses. As for glutamate receptors at excitatory synapses, neurons probably recycle GABA$_A$ receptors as a strategy for setting their degree of excitability. GABA$_A$ receptors constitutively internalize by clathrin-dependent endocytosis; this requires interactions between the β and $\gamma2$ subunits and the AP2 adaptin complex.

Different Synaptic GABA$_A$ Receptor Subtypes Can Be Enriched on Different Domains of the Same Neuron

As mentioned above, considerable GABA$_A$ receptor complexity arises from differential subunit gene expression and specific subunit assembly rules. In addition, there are undefined determinants specifying that particular $\alpha\beta\gamma2$ subunit combinations are enriched at different postsynaptic locations on the same cell. An example of GABA$_A$ receptor complexity on a single cell type is provided by a hippocampal pyramidal cell (Figure 5). A pyramidal cell is covered with GABAergic terminals; a typical rat CA1 pyramidal cell receives around 1700 GABAergic synapses, with the highest density on the perisomatic region. Inhibition on different domains affects different aspects of pyramidal cell function. GABA$_A$ receptor-mediated inhibitory postsynaptic currents can be generated along the whole somatodendritic domain and on the axon-initial segment (AIS) of CA1 pyramidal cells. The apical dendritic trunk has a high density of GABAergic terminals relative to the rest of the dendrite; strong GABAergic stimulation onto this apical trunk region will isolate the dendritic compartment from the cell body. The inhibition on the more distal dendrites controls Ca^{2+} spike propagation. Inhibiting the AIS will powerfully clamp down the pyramidal cell's activity as this is where action potentials initiate – a typical rat CA1 pyramidal cell has more

Figure 5 Enrichment of α1- and α2-subunit-containing αβγ2 GABA$_A$ receptors opposite different classes of GABAergic terminal (cholecystokinin (CCK)- or parvalbumin (Parv)-containing) on a hippocampal pyramidal cell. Note that for clarity, only a small subset of GABAergic interneurons that project onto any given pyramidal cell are shown.

than 25 GABAergic terminals per 50 μm of the AIS. Thus, GABA$_A$ receptors in the AIS deliver inhibition which controls the overall level of output activity of pyramidal cells (Figure 5).

GABA$_A$ receptors show differential subunit distribution at different synapses of the same pyramidal cell. On hippocampal pyramidal cells, the α2 subunit is enriched in the AIS but is present at only a minority of cell body synapses and synapses on dendrites. The AIS synapse also contains the α1 subunit and possibly the α4 and α5 subunits. GABA$_A$ receptors at the AIS are positioned to exert strong inhibitory influence over action potential generation.

Synapses formed by two types of presynaptic interneuron cells (GABAergic basket cells) on the soma of CA1 pyramidal cells contain distinct GABA$_A$ receptor subtypes: Only those synapses coming from parvalbumin-negative/CCK-positive basket cell interneurons contain the α2 subunit; synapses from parvalbumin-positive basket cells are often α2-immunonegative. This is a preferential targeting or enrichment of the α2 in a particular type of synapse – not an absolute selectivity. Both synapse types contain the same level of immunoreactivity for the β2/3 subunits; both types of synapse made by basket cells onto pyramidal cell somata also contain the α1 and the γ2 subunits. However, the α1 subunit is less abundant in the parvalbumin-negative pyramidal cell synapses than in the parvalbumin-positive ones (Figure 5).

Extrasynaptic GABA$_A$ Receptors: α4βδ and α6βδ Subtypes

Besides mediating precisely timed synaptic point-to-point inhibition (phasic inhibition) via γ2 subunit-containing receptors, GABA$_A$ receptors can convey less-time-locked signals. Low GABA concentrations in the extracellular space, resulting from GABA diffusing from the synapse, can tonically activate extrasynaptic GABA$_A$ receptors. This 'tonic inhibition' is temporally uncoupled from the fast synaptic events, causing a continually present background inhibitory conductance. Such conductances alter the input resistance of the cell and thus influence synaptic efficacy and integration; tonic extrasynaptic conductances, by increasing the electrical leakiness of the dendritic membrane, substantially and indiscriminately diminish the size of excitatory signals in dendrites (Figure 6).

Receptors with the δ subunit, α4βδ in forebrain and α6βδ in cerebellar granule cells, are extrasynaptic; δ subunits are perisynaptic (annular), localized around the edge of synapses in hippocampal dentate granule cells, and totally extrasynaptic on cerebellar granule cells. In all regions so far tested (cerebellar granule cells, hippocampal dentate granule cells, thalamic relay nuclei), δ subunits contribute to GABA$_A$ receptors that provide an extrasynaptic tonic conductance. For GABA$_A$ receptors containing α4βδ and α6βδ subunits, their key properties are high affinity for neurotransmitter and limited desensitization, enabling them to contribute to tonic background conductances (Figure 6).

GABA$_A$ Receptor Agonists, Antagonists, and Allosteric Modulators

GABA$_A$ receptors display a rich pharmacology. Generic GABA$_A$ receptors are selectively activated by the GABA agonist muscimol and blocked competitively by the GABA antagonists bicuculline and SR95531 (receptors assembled with ρ subunits are bicuculline and barbiturate insensitive, having their own unique pharmacology). Picrotoxin blocks GABA$_A$ receptors noncompetitively, probably by binding to a site in the channel. Many drugs bind at sites on the GABA$_A$ receptor distinct from the GABA binding site; these drugs change the shape of the receptor oligomer so that the efficacy of GABA at opening the channel is either increased (positive allosteric agonists, e.g., BZs such as diazepam) or decreased (negative allosteric agonists, e.g., β-carbolines). A few allosteric modulators occur naturally in the brain (e.g., Zn^{2+}, neurosteroids). Generally, positive allosteric agonists are used widely in medicine (e.g., for the induction and maintenance of general anesthesia or to treat anxiety disorders, states of agitation, epilepsy, or

Figure 6 Synaptic and extrasynaptic GABA$_A$ receptors conferring tonic ($\alpha4\beta\delta$ or $\alpha4\beta\delta$) and phasic ($\gamma2$) inhibition, respectively. Synaptic ($\gamma2$-containing) GABA$_A$ receptors can be activated by BZs and BZ-like ligands (e.g., zolpidem). BZs act to increase the peak amplitude and slow the rate of decay of the Cl^- current (red trace). Synaptic transmission is on the millisecond timescale. Extrasynaptic (δ-containing) receptors can be selectively activated by Gaboxadol (red). Note the longer timescale.

sleep disorders), and there is scope to develop these drugs further to produce receptor subtype-selective drugs with fewer side effects; however, negative allosteric agonists also have potential clinical applications; for example, the drug L-655 708 works selectively at $\alpha5\beta\gamma2$ receptors (a subtype mainly expressed in the hippocampus), and by decreasing GABA's action there, it acts as a cognition enhancer. A feature of all allosteric modulators is that they usually work only when GABA is at submaximal activating concentrations (below 1 mmol l^{-1}), and they do not work in the absence of GABA (with the exception of some intravenous anesthetics). Nevertheless, some modulators (e.g., BZs) also strongly influence the deactivation rate of the receptors, even at peak synaptic GABA concentrations, and this may be how some of their *in vivo* effects originate. In the following sections, the drugs that act on particular GABA$_A$ receptor subunit combinations are considered in more detail.

GABA$_A$ Receptors: Allosteric Modulation by BZs and Related Ligands

The main effects of BZs are sedation, anxiolysis, suppression of seizures, and muscle relaxation. These drugs require $\alpha\beta\gamma2$-type receptors ($\alpha1\beta2\gamma2$, $\alpha2\beta2\gamma2$, $\alpha3\beta3\gamma2$, and $\alpha5\beta\gamma2$) with the drug-binding site located between the α and $\gamma2$ subunits (Figure 3(a)). Note that $\alpha4\beta\gamma2$- and $\alpha6\beta\gamma2$-type receptors are insensitive to most BZ drugs, as are any receptors that contain the δ subunit. The substances that act at the BZ binding site include the classical BZs like diazepam or flunitrazepam, as well as chemically different substances, such as the imidazopyridine zolpidem (relatively selective for $\alpha1\beta\gamma2$-type receptors), which is used as a sleeping pill. The BZ site is situated at the interface between the α and the γ subunit. In the $\alpha1$, $\alpha2$, $\alpha3$, and $\alpha5$ subunits, a mutation from histidine to arginine at position 101 abolishes binding of classic agonists like diazepam. The diazepam-insensitive $\alpha4$ (or $\alpha6$) subunits naturally contain an arginine residue at the homologous position, and so $\alpha4\beta\gamma2$ or $\alpha6\beta\gamma2$ receptors are insensitive to most BZ ligands.

In a beautiful series of studies, mice with specific mutations in the key H101 coding position affecting BZ sensitivity were generated in the $\alpha1$, $\alpha2$, $\alpha3$, and $\alpha5$ subunit genes, and the behavioral effects of diazepam were tested. These mice have normal GABA$_A$ receptors, but in α1H101R mice, for example, only the $\alpha2\beta\gamma2$-, $\alpha3\beta\gamma2$-, and $\alpha5\beta\gamma2$-type GABA$_A$ receptors are diazepam sensitive. Thus by a process of subtraction, it can be deduced how different $\alpha1\beta\gamma2$, $\alpha2\beta\gamma2$, $\alpha3\beta\gamma2$, and $\alpha5\beta\gamma2$ subtypes contribute to the diverse *in vivo* pharmacological effects of diazepam and other ligands requiring the H101 site. Thus, α1H101R mice no longer become sleepy when given diazepam, and so the $\alpha1\beta\gamma2$ receptors are required for the sedative effects of diazepam, whereas the $\alpha2$ (and $\alpha3$) mediates diazepam's anxiolytic effects (under the influence of diazepam, α2H101R mice do not venture more into threatening areas, whereas their wild-type littermates do). A different set of studies using $\alpha3$ selective agonists and inverse agonists also showed a significant contribution of the $\alpha3$ subunit in anxiogenesis and anxiolysis. The muscle relaxant activity of diazepam is mediated by the $\alpha2$ and $\alpha3$ subunits, probably because these subunits are expressed in spinal motor neurons.

New Subtype-Selective Drugs for GABA$_A$ Receptors That Work at the BZ Site

GABA$_A$ receptors have always been fertile ground for drug companies. BZs, although for many years the mainstay of clinical treatments for anxiety disorders, fell out of favor to selective serotonin reuptake inhibitors (SSRIs) because of side effects like sedation, cognitive impairment, and abuse liability. But SSRIs are too slow acting for some situations, requiring several weeks to work. Thus there is a medical need for fast-acting anxiolytics with few or no side effects. The knock-in mouse studies mentioned above suggest that $\alpha2$-containing GABA$_A$ receptors would be a prominent target for developing drugs which would be specifically anxiolytic.

$GABA_A$ Receptors: Allosteric Modulation by Intravenous Anesthetics

At clinically relevant concentrations, general anesthetics modulate the activity of various ion channels. Whereas volatile anesthetics (e.g., halothane, enflurane, or isoflurane) are positive modulators of recombinant $GABA_A$ receptors, the intravenous anesthetics (e.g., barbiturates, steroidal anesthetics, propofol, and etomidate) can modulate GABA's action at the receptor but can also activate the receptor directly in the absence of GABA at higher concentrations. Based on the analysis of knock-in mouse lines with propofol- and etomidate-insensitive β subunits (see below), propofol and etomidate exert nearly all their anesthetic actions entirely through $GABA_A$ receptors, whereas volatile anesthetics produce their actions through many diverse ion channel targets.

The action of etomidate and propofol requires residues in TM2 and TM3 in the $\beta2$ or $\beta3$ subunits. A mutation of asparagine to methionine at position 265 (N265M) in the second transmembrane domain of the $\beta3$ subunit abolishes the modulatory and direct effects of etomidate and propofol in recombinant receptors. A mutation of aspargine at the same position in the $\beta2$ subunit also abolishes the action of etomidate on the $GABA_A$ receptor. In $\beta3$(N265M) mice, propofol and etomidate do not suppress noxious-evoked movements and show a strongly decreased duration of the loss of righting reflex, two different endpoints of anesthesia. These results suggest that propofol and etomidate act mainly via the $GABA_A$ receptor and the $\beta3$ subunit in particular to induce deep anesthesia. The remaining effects of propofol and etomidate could be mediated by $\beta2$ subunit-containing receptors. Studies on $\beta2$(N265S) mice have suggested that the $\beta2$ subunit mediates the sedative effects of etomidate, whereas the $\beta3$ subunit is required for etomidate to induce a loss of consciousness. A highly interesting issue is the location in the brain where etomidate and propofol exert their anesthetic effects. Is the modulation of $GABA_A$ receptors in specific nuclei required to induce anesthesia or do these drugs produce global effects at many $GABA_A$ receptors in all brain circuits?

$GABA_A$ Receptors: Allosteric Modulation by Neurosteroids

Neuroactive steroids modulate $GABA_A$ receptor function in many brain regions. Naturally occurring steroid metabolites form locally in the brain: 5α-reductase transforms progesterone to 5α-DPH, which in turn is reduced by 3α-hydroxysteroid oxidoreductase to allopregnanalone. Allopregnanalone potently activates $GABA_A$ receptors. No absolute specificity of neurosteroids for particular $GABA_A$ receptor subunit combinations exists. Many $GABA_A$ receptors are sensitive to the steroid THDOC, but receptors with the δ subunit are particularly sensitive. Thus, endogenous allopregnanolone may act on extrasynaptic $\alpha4\beta\delta$ and $\alpha6\beta\delta$ $GABA_A$ receptors to increase basal levels of inhibition.

New Sleep-Promoting Ligands Acting as GABA Mimetics on Extrasynaptic $\alpha4\beta\delta$ Receptors

Modulating extrasynaptic $GABA_A$ receptors can produce profound effects on the nervous system (Figure 6). Many people suffer from insomnia. This is often treated with ligands, such as zolpidem, with a preferential affinity for the BZ site on synaptic $\alpha1\beta\gamma2$ receptors. By contrast, Gaboxadol is a selective extrasynaptic $GABA_A$ receptor agonist that has its greatest efficacy at $\alpha4\beta\delta$ and $\alpha6\beta\delta$ $GABA_A$ receptors, that is, BZ-insensitive receptors that contribute to tonic inhibitory conductances rather than synaptic inhibitory postsynaptic currents. It is important to emphasize that Gaboxadol, unlike BZs or related ligands, is an agonist at the GABA binding site itself – that is, it is a GABA mimetic, opening the receptor directly. Drugs which promote sleep acting through the BZ biding site of $\alpha1\beta\gamma2$-type receptors can cause various side effects such as disturbances in memory, rebound insomnia on drug withdrawal, and drug dependence. Gaboxadol acts on $\alpha4\beta\delta$ occurring exclusively extrasynaptically and enriched in particular neuronal pathways (e.g., thalamus – Figures 4(a) and 6), and thus has a different side effect profile. Sleep induced by increasing specifically the activity of extrasynaptic $GABA_A$ receptors may be of higher quality.

Conclusions

Many subtypes of $GABA_A$ receptor are used by the nervous system to impart inhibition. These $GABA_A$ receptors differ in their affinity for neurotransmitter and allosteric modulators, activation rate, desensitization rate, channel conductance, and location on the cell. But exactly what selective advantages are conferred by so many receptor subtypes to brain function is unclear and remains a fascinating research issue. In particular, the large number of $\alpha\beta\gamma$ subunit-containing synaptic receptor subtypes, often co-expressed on a single cell type such as a cortical pyramidal cell (Figures 2 and 5), might enhance the computational potential of the cell. Receptors at different synapses might have properties (e.g., deactivation rates) fine-tuned for individual inputs. In principle, evolutionary processes selected these subunit combinations

to be optimal, or at least to provide a reasonable compromise, for the inhibitory function required at each type of location. In some cases, however, multiple genes may exist because of the need to have complex transcriptional regulation that would have been difficult to organize from one gene promoter, rather than from the need to have different receptor properties. If one could engineer it, the hippocampus, or even the entire brain, might work perfectly well with just one type of $GABA_A$ receptor, such as an $\alpha1\beta2\gamma2$ combination. In practice, the $GABA_A$ receptor system remains an important target for new therapeutic approaches.

$GABA_B$ Receptor Function

A J Doherty, G L Collingridge, and S M Fitzjohn, University of Bristol, Bristol, UK

Postsynaptic γ-Aminobutyric Acid B-Mediated Inhibitory Postsynaptic Potential

Activation of postsynaptic γ-aminobutyric acid B ($GABA_B$) receptors produces a hyperpolarization of neuronal membrane potential, accompanied by a decrease in cell input resistance. Synaptic activation of GABA receptors elicits a biphasic inhibitory postsynaptic potential (IPSP), of which the early component is sensitive to $GABA_A$ receptor blockade, and inhibitors of $GABA_B$ receptors block the slower, late component of the IPSP (Figure 1). This late component typically has a time to peak of 50–250 ms and decay time of 100–500 ms. The difference in time course of these two components is due to the different nature of the two GABA receptors. Thus, $GABA_A$ receptors consist of a ligand-gated Cl^- channel with fast kinetics, whereas the $GABA_B$ component is via G-protein activation of a K^+ conductance.

The $GABA_B$ IPSP is mediated by $\beta\gamma$ G-protein subunits activating inwardly rectifying K^+ (Kir) channels, with efflux of K^+ causing membrane hyperpolarization (Figure 1). In the hippocampus, $GABA_B$ receptors couple to activation of the Kir3.2 subunit, and the $GABA_B$ receptor-mediated hyperpolarization of membrane potential is absent in Kir3.2 knockout mice. However, evidence suggests that a small component of the slow IPSP may, in some cases, also be mediated by activation of other K^+ channels, such as small-conductance Ca^{2+}-activated K^+ (SK) channels.

In hippocampal pyramidal neurons, there is a strong co-localization of $GABA_B$ receptors and the Kir3.2 subunit in dendritic spines, with both proteins being enriched around glutamate synapses. In the main dendritic shaft, however, the two proteins show a much more segregated distribution. Kir channels are coupled to G-protein-coupled receptors by membrane diffusion of the $\beta\gamma$ subunit, with effective coupling occurring if the two proteins are located within a 500 nm distance. Thus, it is likely that $GABA_B$-mediated activation of Kir and the associated membrane hyperpolarization are functionally much more important in dendritic spines than in the main dendritic shaft. GABAergic presynaptic fibers generally synapse onto the main dendritic shaft of hippocampal pyramidal neurons, suggesting that the activation of Kir by postsynaptic $GABA_B$ receptors is initiated by GABA spillover from nearby GABA terminals.

The slow time course of the $GABA_B$ IPSP and the localization of $GABA_B$ receptors in close vicinity to glutamate synapses have important implications for $GABA_B$ receptor function. Being closely located near the excitatory input to neurons, the $GABA_B$-mediated response limits postsynaptic excitation. One function of the $GABA_B$ receptor-mediated increase in K^+ conductance and membrane hyperpolarization is to reduce activity of the *N*-methyl-D-aspartate (NMDA) subtype of ionotropic glutamate receptor (NMDAR). The NMDAR has slow kinetics and also displays a voltage-dependent block of the receptor channel by Mg^{2+} ions at membrane potentials more negative than −35 mV. As GABA is released from feed-forward interneurons, which receive their synaptic drive from the same glutamatergic fibers that form excitatory synapses onto hippocampal pyramidal neurons, the dual $GABA_A$/$GABA_B$ IPSP is perfectly timed to prevent NMDAR activation during basal low-frequency activity. Activation of NMDARs is a key initiator of multiple forms of synaptic plasticity, which means that the $GABA_B$ receptor is an important factor in controlling the induction of synaptic plasticity.

Presynaptic Regulation of Neurotransmitter Release

At presynaptic sites, $GABA_B$ receptors inhibit neurotransmitter release at both GABA synapses (acting as autoreceptors) and other neurotransmitter synapses (acting as heteroreceptors, e.g., at glutamate and noradrenaline synapses). This regulation is predominantly caused by inhibition of N- and P/Q-type voltage-gated Ca^{2+} channels. The inhibition is mediated by the $\beta\gamma$ subunits of $GABA_B$ receptor-coupled G-proteins. Inhibition of transmitter release brought about by activation of presynaptic K^+ channels may also occur. Presynaptic $GABA_B$ receptors produce a powerful effect on transmitter release, being capable of inhibiting release by more than 90%.

Autoreceptors

$GABA_B$ receptors located on presynaptic GABA terminals act to decrease GABA release when two or more stimuli are delivered to presynaptic axons, leading to paired-pulse depression (PPD) of postsynaptic $GABA_A$ receptor-mediated responses (Figure 2). PPD occurs when pairs of stimuli are delivered in the frequency range of 0.1–50 Hz, with maximum PPD

Figure 1 Postsynaptic γ-aminobutyric acid B (GABA$_B$) receptors produce a slow postsynaptic membrane hyperpolarization. Schematic diagram showing membrane potential changes produced by synaptic stimulation. Release of glutamate from excitatory synapses activates postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs), producing a fast excitatory postsynaptic potential (EPSP). Activation of GABAergic interneurons releases GABA that activates postsynaptic GABA$_A$ receptors, leading to Cl^- efflux and a fast inhibitory postsynaptic potential (IPSP). Spillover of GABA from the synapse activates GABA$_B$ receptors, where $\beta\gamma$ G-protein subunits activate nearby inwardly reactivating K^+ channels, producing a slow IPSP. This combined IPSP curtails the AMPAR-mediated EPSP and prevents activation of *N*-methyl-D-aspartate receptors (NMDARs). The traces show the change in membrane potential produced by activation of each receptor type. The color of the lines in these traces corresponds to the color of the receptor in the main diagram. The composite EPSP recorded in the postsynaptic cell is also shown.

seen at around 5–10 Hz. Depression of postsynaptic GABA$_A$ responses also occurs during trains of stimuli due to a depression of GABA release, although the effect of presynaptic GABA$_B$ inhibition decreases as the number of stimuli in the train increases or the frequency of the train increases (beyond around 10 Hz for a train of ten stimuli). With sufficient numbers of stimuli, the postsynaptic GABA$_A$ response undergoes activity-dependent facilitation and converts into a depolarizing response.

Role of GABA$_B$ Autoreceptors in the Induction of NMDAR-Dependent Long-Term Potentiation

The effect of decreasing postsynaptic GABA-mediated inhibition during short trains of activity is important for the induction of long-term potentiation (LTP) of excitatory glutamatergic synaptic transmission, which has been particularly well studied in the CA1 region of the hippocampus. LTP is a well-studied form of synaptic plasticity that occurs in many brain regions and is considered a synaptic model of learning. Many, but not all, forms of LTP rely on the activation of NMDARs to act as a trigger for LTP induction. As discussed above, the postsynaptic GABA$_B$ receptor-mediated IPSP acts to inhibit the induction of LTP during basal, low-frequency synaptic activity by preventing activation of the NMDAR. However, during short, high-frequency trains of activity, GABA release from presynaptic terminals is reduced by feedback of GABA onto presynaptic autoreceptors. The result is a decrease in postsynaptic GABA inhibition which, coupled to release from glutamate terminals, leads to a more persistent depolarization of the postsynaptic cell, activation of NMDARs, calcium influx, and the subsequent induction of LTP (Figure 2).

Multiple protocols exist for inducing LTP in experimental systems, and the role of GABA$_B$ receptors in LTP induction varies depending on the protocol used. A typical induction protocol is the delivery of brief high-frequency bursts (e.g., two or more trains of four shocks at 100 Hz) with an interburst frequency of around 5 Hz (i.e., an interburst interval of 200 ms). This is termed a theta burst stimulus train as the 5 Hz pattern of activity mimics the physiological activity that occurs during the theta rhythm, a frequency of activation observed in the EEG when animals are exploring their environment. Such theta burst trains are thus considered potential physiological induction protocols for LTP induction. This frequency corresponds to the near-maximal effect of presynaptic GABA$_B$ autoreceptors, and activity at GABA$_B$ receptors is essential for induction of LTP. Thus,

Figure 2 Activation of presynaptic γ-aminobutyric acid B (GABA$_B$) autoreceptors contributes to the induction of *N*-methyl-D-aspartate (NMDA) receptor-dependent LTP. (a) In response to a single stimulus, activation of postsynaptic GABA receptors produces a membrane hyperpolarization that curtails the excitatory postsynaptic potential (EPSP) and prevents NMDA receptor (NMDAR) activation, which remain blocked by Mg^{2+} ions (.). (b) In response to a train of stimuli, GABA activates presynaptic GABA$_B$ autoreceptors which decrease Ca^{2+} entry into the presynaptic bouton and thus decrease GABA release. This reduces the postsynaptic GABA-mediated inhibitory postsynaptic potential, which prolongs the AMPA receptor (AMPAR)-mediated membrane depolarization leading to expulsion of Mg^{2+} ions from the NMDAR and subsequent Ca^{2+} entry into the postsynaptic neuron. The inset traces show the membrane potential change produced by each constituent receptor and the composite EPSP recorded form the postsynaptic neuron.

$GABA_B$ receptor antagonists block the induction of LTP by theta burst stimuli. Likewise, LTP induced by the delivery of a single priming stimulus followed approximately 200 ms later by a single burst (which could comprise as few as two stimuli, though typically four are used) is blocked by $GABA_B$ receptor antagonists. In this case the priming stimulus allows activation of the presynaptic $GABA_B$ autoreceptors such that during the subsequent burst of stimuli, GABA release is depressed sufficiently to allow NMDA receptor activation.

LTP may also be induced by stronger stimulus trains, typically 100 stimuli delivered at a frequency of 100 Hz. Under these conditions, LTP induction is independent of $GABA_B$ receptor activity due to the conversion of the postsynaptic $GABA_A$ response into a depolarizing response.

Depression of Vesicle Recruitment

At the excitatory calyx of Held synapse in the brain stem, activation of presynaptic $GABA_B$ receptors by GABA spillover from nearby inhibitory synapses elicits heterosynaptic depression of glutamate by depression of Ca^{2+} influx, as seen at other synapses in the brain. However, presynaptic $GABA_B$ receptor activation has an additional effect at this synapse in that it slows vesicle recruitment after strong presynaptic stimulation. This effect is mediated by G-protein inhibition of adenylyl cyclase and thus a reduction in cyclic adenosine monophosphate (cAMP) production. Vesicle priming at this synapse is enhanced by cAMP and Ca^{2+}/calmodulin, and thus a reduction in cAMP levels slows the recruitment of vesicles ready for release.

LTP of Postsynaptic $GABA_B$ Responses

In addition to being involved in the induction of LTP of excitatory synaptic transmission, postsynaptic $GABA_B$ receptors may also undergo LTP. Thus in the hippocampus, NMDAR activation can lead to an enhancement of the slow, $GABA_B$ receptor-mediated IPSC in CA1 hippocampal pyramidal neurons. This form of LTP requires influx of Ca^{2+} through the NMDA receptor and the subsequent activation of Ca^{2+}/calmodulin dependent protein kinase II, although the precise mechanism of the enhancement of $GABA_B$ receptor function is unclear. It remains to be seen whether other forms of plasticity exist to modulate $GABA_B$ receptor function.

Coupling of $GABA_B$ and Metabotropic Glutamate Receptors

In the cerebellar cortex, $GABA_B$ receptors are expressed in Purkinje cells (PCs) at the extrasynaptic site of excitatory input from parallel fibers. This extrasynaptic localization is also seen for the metabotropic glutamate receptor subtype 1 (mGluR1), stimulation of which produces a slow excitatory postsynaptic current and mobilization of Ca^{2+} from intracellular stores. Activation of postsynaptic $GABA_B$ receptors by agonists or synaptic GABA release produces an enhancement of mGluR1-mediated synaptic currents and Ca^{2+} mobilization, an effect that is dependent on $G_{i/o}$ G-protein signaling, activation of phospholipase C, and release of Ca^{2+} from intracellular stores.

It is interesting that facilitation of mGluR1 in PCs by $GABA_B$ receptors can also occur independently of classical receptor activation. In the absence of $GABA_B$ receptor agonists, increases in extracellular Ca^{2+} elicit a constitutive increase in the sensitivity of mGluR1 to glutamate, facilitating mGluR1 effects. This effect of extracellular Ca^{2+} is independent of $G_{i/o}$ activity and thus differs from the enhancement described above. $GABA_B$ and mGluR1 receptors appear to exist in a protein complex in PCs, and thus this enhancement may be due to changes in protein complex structure rather than to G-protein signaling.

Therapeutic Potential of $GABA_B$ Receptor Ligands

Genetic deletion of either of the two $GABA_B$ receptor subunits or pharmacological blockade of native $GABA_B$ receptors produces spontaneous epileptic seizures, demonstrating the important role that $GABA_B$ receptors have in preventing overexcitation of neuronal networks and maintaining normal brain function. As such, it is possible that dysfunction of $GABA_B$ receptor activity may be implicated in human epilepsies, and polymorphisms of the $GABA_{B1}$ receptor subunit are linked to increased susceptibility to temporal lobe epilepsy. In contrast, antagonists of $GABA_B$ receptors suppress absence seizures seen in animal models, whereas agonists promote seizures in these animals, suggesting that antagonists may be of potential therapeutic use in human absence seizures. However, in these models, high doses of $GABA_B$ receptor antagonists are prone to induce convulsions, highlighting the difficulty in targeting the $GABA_B$ receptor to treat this disease, in particular because of the widespread distribution of these receptors and the lack of receptor subtypes.

The $GABA_B$ receptor agonist baclofen is currently used to treat spasticity and muscle rigidity in patients with multiple sclerosis and spinal cord injury. The effect of baclofen is thought to be due to activation of presynaptic heteroreceptors in the spinal cord, reducing the release of excitatory transmitters. Reduction of transmitter release in the spinal cord (particularly glutamate and substance P) probably also contributes to the antinociceptive effect of baclofen administration, although additional actions in the

brain, such as in the rostral agranular insular cortex, likely also contribute to it. $GABA_B$ receptor subunit knockout animals display heightened sensitivity to painful stimuli such as heat, confirming the role of $GABA_B$ receptors in modulating pain pathways.

A potential use of $GABA_B$ receptor agonists is in the treatment of drug addiction. Thus, agonists such as baclofen can reduce craving seen with drugs such as alcohol, cocaine, morphine, and nicotine. In addition, genetic studies suggest that there is a link between $GABA_B$ receptor variants and potential for addiction. This action of $GABA_B$ receptor activation in reducing addiction probably relates to activity in the mesolimbic dopamine system, which is part of the reward and reinforcing pathways of the brain. A further postulated use of activating $GABA_B$ receptors is to treat anxiety as $GABA_B$ receptor subunit knockout mice show increased anxiety in behavioral tests and baclofen has anxiolytic effects.

Introduction

γ-Aminobutyric acid (GABA) is the single most important inhibitory neurotransmitter within the mammalian brain, in which it is estimated that 40% of all inhibitory synaptic activity is mediated through this neutral amino acid. GABA can activate both ionotropic ($GABA_A$) and metabotropic ($GABA_B$) receptors, and these are present inside and outside the brain of mammals and also evident in lower species. This article focuses on the metabotropic receptor, $GABA_B$.

The receptor was originally defined in the 1980s by pharmacological characterization in isolated tissue preparations. The structure of the receptor was identified approximately 18 years later.

Unlike $GABA_A$ receptors, $GABA_B$ sites do not affect Cl^- membrane conductance in neurons but instead their activation increases K^+ conductance and decreases Ca^{2+} conductance. These effects tend, although not exclusively, to be site directed such that the decrease in Ca^{2+} is more associated with presynaptic receptors, whereas K^+ effects are predominantly postsynaptic. As a consequence of these effects, receptor activation can produce neuronal hyperpolarization (K^+ effect) or a decrease in evoked neurotransmitter release (Ca^{2+} effect). It is this latter effect that was the basis of the first observed characteristic of $GABA_B$ receptors. GABA dose dependently reduced the electrically evoked release of tritiated noradrenaline from rat isolated atria. This effect was neither blocked by recognized GABA antagonists nor mimicked by established GABA agonists. Conversely, baclofen (β-chlorophenyl GABA), which is inactive at chloride-dependent GABA receptors, was able to mimic the action of GABA in the atrial preparation and in other $GABA_B$ receptor systems. The subsequent development of a membrane receptor binding assay firmly established the existence of the metabotropic GABA receptor in mammalian brain tissue.

Receptor Structure

$GABA_B$ receptors exist naturally as heterodimers and comprise subunits designated $GABA_{B1}$ and $GABA_{B2}$ (Figure 1). Although the subunits exhibit 35% homology, they have quite distinct characteristics. Whereas $GABA_{B1}$ contains the binding domain for GABA in its extracellular N-terminal, the $GABA_{B2}$ subunit appears to be responsible for engaging and activating the G-protein-coupled signaling system. $GABA_{B1}$ and $GABA_{B2}$ must remain linked as a dimer after insertion into the cell membrane to fully maintain receptor function. $GABA_{B1}$ subunits remain associated with the endoplasmic reticulum, and only when they link with $GABA_{B2}$ is the dimer transported to the cell membrane. Each subunit has a seven transmembrane spanning domain and they are linked via their C-termini through coiled-coil structures. A number of splice variants of the $GABA_{B1}$ subunit have been identified, namely $GABA_{B1a–1g}$ (Figure 1, inset), but not all have been shown to have a physiological function. Only $GABA_{B1a}$ and $GABA_{B1b}$ have been implicated in the functional receptor, and although $GABA_{B1c}$ has been reported to be functional *in vitro*, evidence for an *in vivo* role is equivocal. The 1a and 1b proteins differ significantly in their amino acid sequences within the N-terminal; 1a has a unique sequence of 162 amino acids, whereas 1b has a shorter unique sequence of 47 amino acids. The distribution patterns of these two subunits within the rat brain indicate that they have different roles, although these have yet to be established. For example, within the spinal cord, the level of $GABA_{B1a}$ is reported to be tenfold higher than that of $GABA_{B1b}$ within the primary afferent terminals, and the $GABA_{B1b}$ subunit appears to predominate at postsynaptic sites in the cerebellum. However, elsewhere in the brain, $GABA_{B1b}$ appears to predominate in presynaptic terminals, whereas $GABA_{B1a}$ is associated with postsynaptic sites, for example, within the thalamocortical system.

There is no unequivocal evidence to support the existence of variants of the $GABA_{B2}$ subunit, although two variants of the human $GABA_{B2}$ subunit have been proposed. However, these were probably artifacts of the isolation process.

The expression of $GABA_{B1}$ and that of $GABA_{B2}$ appear to be independent of each, even though there is a 1:1 stoichiometric relation between the two proteins. Invariably, $GABA_{B2}$ is expressed more abundantly than $GABA_{B1}$ under experimental pathological conditions.

Protein–Protein Interactions

The possibility of a mismatch between $GABA_{B1}$ and $GABA_{B2}$ levels raises the possibility that other proteins might form a dimer with the $GABA_B$ subunit to form a functional receptor. Numerous proteins have been described which interact with either $GABA_{B1}$ or $GABA_{B2}$, and some of these have such high affinity that they are able to compete with one $GABA_B$

Figure 1 Diagram of the heterodimer that forms the GABA$_B$ receptor. The receptor comprises two subunits, GABA$_{B1}$ and GABA$_{B2}$, which are inserted into the plasma membrane after having been coupled intracellularly. GABA$_{B1}$ contains the GABA binding domain in its extracellular N-terminal chain, whereas GABA$_{B2}$ does not bind GABA but has a modulatory site within the transmembrane region which appears to be specific to this subunit. This subunit also seems to be responsible for coupling to the second messenger G-protein system. Receptor activation manifests as an increase in K^+ conductance, a decrease in Ca^{2+} conductance, and/or an inhibition of adenylate cyclase (AC). The inset indicates the primary isoforms of GABA$_{B1}$. Courtesy of Stefano Tacconi and Rachel Ginham.

subunit for binding to the other subunit. However, no evidence of the formation of a functional receptor from any protein–protein interaction has been reported. Thus, if the interaction is not producing a receptor, what purpose(s) does this protein coupling serve? It might be to provide a directional mechanism to enable the correct site insertion of the dimer into the plasma membrane or merely to act as a scaffold or anchoring device to support the dimer when inserted. Alternatively, because of the high affinity of these proteins, they might regulate the formation of the dimer, limiting the level of functional receptor, or by interacting intracellularly with the formed dimer, they may reduce its cell surface expression. The exact role of these interacting proteins, including CREB2/ATF4, 14-3-3, fibulin-2, CHOP, and Marlin-1, has yet to be established.

Receptor Subtypes

Despite the presence of structural variants of the GABA$_{B1}$ subunits and the possibility of functional modifications of the receptor heterodimer by interacting proteins, there is still no unequivocal evidence for the existence of functional GABA$_B$ receptor subtypes. Pharmacological differences between autoreceptors and heteroreceptors as well as between the dual actions of GABA$_B$ agonists on adenylyl cyclase activity have been suggested by individual research groups. However, both a lack of reproducibility and sufficient distinction between the effects and the failure to emulate observations made by other groups have cast doubt on the existence of functional receptor subtypes. In general, the available receptor agonists and antagonists do not distinguish between potential subtypes of the GABA$_B$ receptor. Nevertheless, it has been suggested that gabapentin is a GABA$_B$ agonist which selectively activates the form of the receptor comprising a combination of GABA$_{B1a}$ and GABA$_{B2}$ and expressed in isolated *Xenopus* oocytes. However, this could not be confirmed by others, especially in *in vivo* systems. Thus, although this was an exciting and potentially important observation, the failure of others to reproduce the original findings has tempered enthusiasm not only for understanding the mechanism of action of this anticonvulsant/analgesic agent but also for the possibility of relating receptor structure to functional diversity. A further lack of support for receptor subtyping derives from studies performed on developmental knockout mice in which either GABA$_{B1}$ or GABA$_{B2}$ subunits have been deleted. No supporting evidence for any receptor subtyping was observed in these animals.

Receptor Distribution

GABA$_B$ receptors are distributed throughout the mammalian system and are not confined to nervous tissue.

Although their function is probably of greatest physiological importance within the central nervous system, their presence in peripheral organs is well established. In fact, it was their presence in the heart atrium of the rat that led to their discovery. They are present on autonomic nerve terminals, and when activated by GABA, this decreases the evoked release of transmitter from the terminal. Of course, this is only of physiological importance when the receptor agonist is present, and in the periphery this is unlikely to occur at most sites. However, in the enteric nervous system, in which GABA-releasing neurons are present and impinge on autonomic cholinergic nerve fibers, $GABA_B$ receptors probably contribute to the control of intestinal movement and sphincters. Individual $GABA_{B1}$ and $GABA_{B2}$ subunits have been detected in peripheral tissue, but their distribution does not always appear to be coincident, for example, in the uterus and spleen. In general, there appears to be a paucity of $GABA_{B2}$, suggesting that another protein may form a dimer with $GABA_{B1}$ if the receptor is to function as described elsewhere. There is also a differential distribution of the $GABA_{B1}$ isoforms such that $GABA_{B1a}$ is in, for example, the adrenals and prostate of the rat, whereas $GABA_{B1b}$ is the form present in the kidney.

The distribution of $GABA_B$ sites in the mammalian brain is quite wide, although there are regional variations. Receptor autoradiography has shown that the highest densities of the receptor are in the thalamic nuclei, cerebellum (molecular layer), cerebral cortex, interpeduncular nucleus, and dorsal horn of the spinal cord. Moderate to low levels are present elsewhere, but this does not necessarily reflect the physiological importance of the receptor in those regions. For example, in the hippocampus the significance of $GABA_B$ receptors in neural transmission may not be matched by the overall density of receptors. The distribution patterns of the individual receptor subunits, as determined by immunocytochemistry, generally match each other, supporting the concept of heterodimer receptors. However, in the caudate putamen $GABA_{B2}$ is not detectable even though $GABA_{B1}$ and the native receptor are present, which could support the notion of another, as yet undefined, protein subunit.

Physiological Significance

The physiological relevance of the $GABA_B$ receptor was first established within the hippocampus, where it was shown to be responsible for generating the late hyperpolarization associated with orthodromic synaptic transmission in Ammon's horn. Subsequent studies provided evidence for the same pattern of activity within other brain regions, such as the lateral geniculate nucleus.

The mechanism underlying this neuronal hyperpolarization is an increase in membrane K^+ conductance mediated by activation of postsynaptic $GABA_B$ receptors. However, this is not the only mechanism through which $GABA_B$ activation occurs. The predominant location of the receptors appears to be presynaptic, where they function as autoreceptors and heteroreceptors to limit the release of a variety of neurotransmitters. A reduction in membrane Ca^{2+} conductance is produced by activation of $GABA_B$ sites, which reduces the cytosolic concentration of Ca^{2+} to inhibit transmitter release. Whereas the physiological significance of autoreceptors seems straightforward because of the local availability of neurotransmitter, the role of heteroreceptors on non-GABAergic terminals is not so obvious because evidence for axo-axonic contacts at nerve terminals is lacking. The only substantiated evidence is at primary afferent terminals in the spinal cord, where GABA interneurons innervate the terminal regions of the primary afferent fibers. However, despite the apparent lack of innervation, there is strong evidence for GABA acting in a 'paracrine' manner to activate $GABA_B$ heteroreceptors. GABA released from GABAergic terminals 'washes over' onto adjacent terminals where $GABA_B$ sites are present. The estimated concentration of GABA in the cleft, following synaptic release, is approximately 0.01 M, and because the affinity of GABA for heteroreceptors is approximately 0.000 000 01 M, sufficient GABA should be available to interact with sites in close proximity. Heteroreceptors are therefore of physiological as well as pharmacological importance.

Effector Mechanisms

As indicated previously, more than one signaling system mediates the response to $GABA_B$ receptor activation. Either an increase in K^+ or a reduction in Ca^{2+} membrane conductance provides the neuronal response, and both of these events are mediated by G-proteins that are members of the pertussis toxin-sensitive family $G_{i\alpha}/G_{o\alpha}$. However, presynaptically mediated events, which are generally associated with reduced Ca^{2+} conductance, appear to be less sensitive to pertussis toxin. The predominant calcium channel linked to $GABA_B$ sites appears to be the 'N' type, although 'P' and 'Q' type channels are also implicated. Multiple K^+ channel types seem to be associated with postsynaptic $GABA_B$ receptors.

The third signaling system associated with $GABA_B$ sites is adenylyl cyclase, which is normally inhibited by receptor activation but if the enzyme has been activated by G_s-coupled receptor agonists such as isoprenaline, the β-adrenoceptor ligand, $GABA_B$

receptor activation enhances the formation of cAMP above the level achieved with isoprenaline alone. This observation prompted a search for receptor subtypes by comparing the abilities of different GABA$_B$ receptor agonists to inhibit or enhance cAMP production. However, no clear separation has been established.

GABA$_B$ Receptor Ligands

Agonists

One of the original criteria for establishing the presence of GABA$_B$ receptors was to show that β-[4-chlorophenyl] GABA (baclofen) was a stereospecific agonist. Subsequently, other agonists, such as 3-aminopropyl-phosphinic acid (3-APPA) and 3-aminopropyl-methyl-phosphinic acid (3-APMPA), emerged which were approximately tenfold more potent than R-(−)-baclofen, the active isomer, at GABA$_B$ receptor binding sites (Figure 2). *In vivo* studies have also indicated that 3-APMPA has greater brain penetration than either baclofen or 3-APPA. The agonist CGP44532, which has an affinity comparable to that of (−) baclofen for GABA$_B$ receptors (Figure 2), is reported to be selective for GABA$_B$ autoreceptors.

Antagonists

The first selective GABA$_B$ antagonists to be described were phaclofen, saclofen, and 2-hydroxy saclofen (Figure 2). These have only low affinity for the receptor, with p*K*i values of 4–5. However, phaclofen was used to great effect in obtaining the first evidence in 1988 for the physiological role of GABA$_B$ receptors in synaptic transmission within the rat hippocampus. Subsequent studies led to the introduction of a compound that was able to cross the blood–brain barrier (CGP 35348) and the first orally active agent (CGP 36742). However, both of these compounds have low affinities, as does the chemically distinct antagonist SCH50911 (Figure 2). A major breakthrough was obtained when 3,4-dichlorobenzyl or 3-carboxybenzyl substituents were attached to the existing molecules to produce a variety of compounds with affinities in the low nanomolar range, such as CGP 55845 and many others, which in all cases contain a phosphinic acid moiety. Ultimately, such antagonists, when radiolabeled with ^{125}I, provided photoaffinity ligands suitable for the successful elucidation of the structure of the GABA$_B$ receptor.

Effects of GABA$_B$ Receptor Activation

Receptor activation within the mammalian brain can produce a variety of effects as a consequence of

Figure 2 Selection of GABA$_B$ receptor ligands and their comparative potencies at the native receptor in rat brain cerebral cortex membranes. Note the radical increase in potency of the examples of the dichlorobenzyl-substituted antagonists, CGP52432 and CGP55845.

Table 1 $GABA_B$ receptor activation

Effect	*Site of action*
Antinociception	Spinal cord, thalamus
Antitussive action	Cough center in medulla
Drug addiction suppression	CNS–mesolimbic system
Enhanced feeding	Higher centers
Fat intake reduction	Higher centers
Gastrin/gastric acid secretion altered	Vagal center
Generation/exacerbation of absence epilepsy	Thalamus/somatosensory cortex
Inhibition of neurotransmitter release	CNS and peripheral nerve terminals
Inhibition of cognitive function	Higher centers
Insulin/glucagon release	Pancreas
Modulation of long-term potentiation	CNS, hippocampus
Muscle relaxation	Spinal cord
Smooth muscle relaxation	Lung, bladder, intestine
Smooth muscle contraction	Uterus, oviduct, gall bladder
Neuronal hyperpolarization	CNS (numerous locations)
Neutrophil chemotaxis enhanced	Leukocytes
Respiratory depression	Brain stem
Suppression of CRH/MSH release	Pituitary
Suppression of panic behavior	Dorsal periaqueductal gray
Vasopressor action	Nucleus tractus solitarius

inhibition of transmitter release and/or postsynaptic neuronal hyperpolarization. Information derived from knockout mice, which exhibit hyperalgesia, seizures, hyperlocomotion, impaired learning, loss of responses to baclofen, and lack of $GABA_B$ binding sites throughout the brain, together with the actions of $GABA_B$ agonists and antagonists have provided the basis for defining the physiological role of the receptor as well as indicating the potential therapeutic benefits of receptor ligands. Some of the actions of baclofen (*in vitro* and *in vivo*) are shown in Table 1, and predominant among the *in vivo* effects are the muscle relaxant, antinociceptive, anti-drug-craving effects and reduction in cognitive behavior.

Potential Therapeutic Uses of $GABA_B$ Receptor Ligands

Skeletal Muscle Relaxation

The centrally mediated muscle relaxant properties of baclofen make it the drug of choice for spasticity associated with cerebral palsy, multiple sclerosis, stiff-man syndrome, and tetanus. However, the side effects produced by this drug, which include seizures, nausea, drowsiness, dizziness, hypotension, muscle weakness, hallucinations, and mental confusion, are often poorly tolerated by patients. These are, in part, due to the need for high doses to be administered to allow for poor brain penetration. This problem has been addressed by the introduction of intrathecal administration using an indwelling pump inserted into the peritoneal cavity. Administration in this way, directly to the site of action within the spinal cord, requires only local concentrations that are too low to appear in the systemic circulation, thus avoiding the production of adverse effects. The reduced extracellular level of the agonist also decreases the possibility of receptor desensitization. The response to systemic administration of baclofen is reduced after chronic treatment, but this does not seem to be the case after chronic intrathecal infusion.

Nociception

Baclofen and other $GABA_B$ receptor agonists have antinociceptive activity in acute pain models, such as the tail flick and hot plate tests in rodents. This occurs at doses below the threshold for muscle relaxation, enabling impairment of locomotor activity to be excluded as a confounding reason for the effect. This antinociceptive action stems, in part, from a reduction in the release of nociceptive transmitter from primary afferent fibers within the dorsal horn of the spinal cord. In addition, action within higher centers, particularly the thalamus, also contributes. In spinal cord slices from control rats, the application of $GABA_B$ receptor antagonists produces little or no increase in the evoked release of transmitter, but if the antagonist is applied to a cord slice from a monoarthritic rat, an evoked release of primary afferent transmitter occurs. If the antagonist is administered *in vivo* to rats with the same lesion, significant hyperalgesia occurs. This contrasts markedly with a lack of effect in control rats. These results suggest that an increase in $GABA_B$ innervation to primary afferent terminals occurs during chronic inflammation, and this acts as a pathological antinociceptive process to decrease the enhanced sensory input. The use of baclofen as an analgesic in humans has been very limited, presumably due, in part, to rapid tolerance and adverse effects following systemic administration.

As mentioned previously, the spinal cord is not the only site where $GABA_B$ agonists exert their antinociceptive effect. Focal injections into the ventrobasal complex within the thalamus can suppress nociceptive processing in chronic inflammation. It has also been observed that the antinociceptive effect of the GABA uptake inhibitor tiagabine in rodents, which can be attributed to $GABA_B$ receptor activation, is associated with an increase in the extracellular concentration of GABA within the thalamus.

In contrast to models of inflammatory pain, the induction of neuropathic pain in rodents does not

produce an increase in GABA levels within the spinal cord. However, baclofen can produce an antinociceptive effect in models of chronic neuropathy. Support for a role for GABA$_B$ receptors in pain mechanisms also derives from developmental knockout studies in mice. In these mice, functional GABA$_B$ receptors are not formed because the mice are deficient in either of the individual GABA$_{B1}$ or GABA$_{B2}$ subunits. In both forms of null mutant mice, hyperalgesia was exhibited in acute nociceptive tests, suggesting that functional heteromeric GABA$_B$ receptors are required to maintain pain thresholds.

Cognitive Function

GABA$_B$ receptor agonists suppress cognitive behavior in animals, and this action is reversed by GABA$_B$ antagonists. Moreover, basal cognitive activity can even be enhanced by GABA$_B$ antagonists without prior suppression by an agonist. This raises the possibility that GABA$_B$ antagonists might provide a novel opportunity to treat cognitive impairment in humans, and this hypothesis is being tested in clinical trials. Evidence suggests that the site of action of GABA$_B$ antagonists in relation to cognition may be the hippocampus, where an increase in long-term potentiation (LTP) has been implicated but the nature of this modification appears to depend on the frequency of stimulation employed to produce LTP.

Depression and Anxiety

A role for GABA$_B$ receptors in functional depression was first proposed more than 20 years ago. An upregulation in GABA$_B$ binding sites occurs in rat frontal cortex after chronic administration of a variety of antidepressant drugs, and although these findings were disputed, there is little doubt that GABA$_B$ mechanisms can be associated with depression. Antagonism of GABA$_B$ receptors produces a reversal of depressant-like behavior in animal models such as the rodent forced swim test and learned helplessness models. It has been observed that mice lacking GABA$_{B1}$ or GABA$_{B2}$ receptor subunits exhibit antidepressant-like behavior but they appear to be more anxious. Therefore, GABA$_B$ receptor activation appears to produce anxiolytic activity, whereas a loss or blockade of GABA$_B$ receptor function produces antidepressant-like effects. In support of this distinction, GABA$_B$ receptor activation in the dorsal periaqueductal gray of rats impairs one-way escape in the elevated T-maze test, which is consistent with an anxiolytic effect.

Drug Addiction

Therapeutic treatment of dependence on drugs of abuse is still inadequate and is therefore a major clinical goal. A number of receptor systems appear to provide potential targets, including dopamine and glutamate receptors, but GABA$_B$ receptor activation may provide an additional approach. Baclofen was initially shown to reduce the reinforcing effects of cocaine in rats, but it soon became clear that other drugs of addiction, including nicotine, morphine-related agents, and ethanol, were also sensitive to GABA$_B$ agonists, whereas food reinforcement was unaffected.

The finding that baclofen reduces craving for a variety of unrelated addictive substances, including heroin, alcohol, and nicotine, suggests that there may be an underlying common mechanism for the GABA$_B$ agonist in all cases. The reward center within the mesolimbic system, possibly the ventral tegmental area, would provide the focus for this action where control of the release/action of dopamine is implicated. Raising endogenous GABA levels within the mesolimbic system should have the same effect as administering a GABA$_B$ agonist. Thus, if vigabatrin, an inhibitor of GABA metabolism, or the GABA uptake inhibitor NO-711 are administered centrally in rats, they both attenuate heroin and cocaine self-administration and prevent cocaine-induced increases in dopamine in this brain region.

Clinical data indicate that baclofen is also effective against cocaine and alcohol craving in humans. However, the administration of baclofen can produce adverse effects as well as muscle relaxation, and these effects may detract from any potential benefits.

Therefore, what might provide an alternative approach? The presence of a positive allosteric modulatory site on the GABA$_{B2}$ subunit could provide the answer.

Allosteric Modulation of GABA$_B$ Receptors

The location of the modulator allosteric site appears to be the heptahelical domain of the GABA$_{B2}$ subunit. Although the GABA$_{B1}$ subunit has the agonist binding domain, it does not have an allosteric site, whereas the converse appears to be true for GABA$_{B2}$. Two compounds, CGP7930 and GS39783 (Figure 2), were originally reported to be positive modulators. Neither has any direct agonist activity, but both accentuate the effects of GABA and baclofen. These compounds have been examined in rat models of addiction and both modulators reduced the self-administration of cocaine.

Seizure Generation in Absence Epilepsy

Absence seizures have a characteristic EEG waveform of a 3-Hz spike and wave which stem from discharges

in the thalamic nuclei. It is believed that the thalamus is the site from which these discharges originate, and although an intact thalamocortical network is necessary for generating spike and wave discharges, the origin of these discharges appears to lie outside the thalamus. The site of origin appears to be within the perioral region of the somatosensory cortex. This discharge spreads rapidly across the cortex and initiates a corticothalamic cascade. Injection of a $GABA_B$ agonist into the ventrobasal thalamus or reticular nucleus of a rat exacerbates this activity. By contrast, injection of a $GABA_B$ antagonist into the same regions suppresses the spike and wave discharges. If the $GABA_B$ antagonist is administered systemically, the same effect occurs. This might indicate that interference with the GABAergic innervation from the reticular nucleus disrupts the thalamocortical loop which generates the spike and wave activity. However, microinjection of the same selective antagonist into the somatosensory cortex can also suppress the seizure activity, indicating the involvement of $GABA_B$ergic mechanisms also at this level.

In patients with existing absence seizures, $GABA_B$ receptor agonists would likely enhance seizure activity, and any increase in GABA concentration in the vicinity of the thalamus would be expected to enhance seizure activity. Thus, for example, vigabatrin and tiagabine would be, and are, contraindicated in such individuals. The mechanism(s) underlying seizure exacerbation by $GABA_B$ agonists is unclear, but involvement of transient Ca^{2+} T currents seems possible.

It has been suggested that γ-hydroxybutyrate (GHB), which can produce absence-like seizures, is a weak $GABA_B$ receptor agonist. If GHB mimics the effect of the endogenous agonist, GABA, at $GABA_B$ receptors, then $GABA_B$ receptor antagonists would be expected to block the spike and wave discharges produced by GHB, which they do.

Conclusions

The $GABA_B$ receptor system is of predominant, but not exclusive, importance within the central nervous system, and it may provide an important drug target in a variety of central nervous system disorders. It is a member of group 3 G-protein-coupled receptors and exists as a heterodimer with various isoforms comprising the $GABA_{B1}$ subunit. However, lack of demonstrable functional subtyping of the receptor has limited exploitation of any pharmacological specificity. The only receptor agonist in current clinical use is baclofen, which has many limitations, including poor brain penetration. To date, little has emerged which is an improvement over baclofen. However, the discovery of allosteric modulators of the $GABA_B$ system may provide the possibility of producing compounds that will readily gain access to the central nervous system while facilitating receptor function.

Gain Modulation

Origin and Key Issues

The term 'gain field' was coined to describe an interaction between visually evoked responses and eye position first documented by Andersen and Mountcastle in 1983. In their experiment, as well as in those that followed, neurons from parietal cortex were recorded in awake monkeys and the responses were systematically mapped by varying both eye position and the location of a spot of light. Surprisingly, although the shape of the response curves as functions of stimulus location did not change with eye position, their amplitude, or gain, did. Figure 1(e) shows an idealized example. In analogy with the receptive field, the gain field corresponded to the full map showing how the response changed as a function of eye position. Initial work described gain fields that depended on eye position, but an additional dependence on head position was demonstrated later, such that the combination of head and eye angles – the gaze angle – seems to be the relevant quantity. These interactions are well approximated by a multiplication of two factors, such that the firing rate r of a visual parietal neuron can be expressed as $r = f(x)g(y)$, where x is the location of a visual stimulus and y the gaze angle. The functions f and g may have a variety of forms, but what is important computationally is that there are two separate terms that are combined nonlinearly (multiplicatively in this case).

In the last 25 years or so, abundant experimental evidence has accumulated showing that, in the central nervous system, gain modulation is a widespread mechanism for combining information from multiple sources, not just vision and gaze angle. At the same time, complementary modeling studies have addressed two issues: (1) the kinds of computational problems that can be solved or substantially simplified by using gain modulation and (2), the biophysical mechanisms that may give rise to nonlinear interactions between two types of inputs converging on a neuron, as observed in experiments reporting changes in gain. Some of the highlights of this work are described here.

Gain Modulation and Coordinate Transformations

Zipser and Andersen were the first to demonstrate the power of gain modulation in a specific biological computation. They trained an artificial neural network to transform the location of a stimulus from an initial eye-centered representation to one in head-centered coordinates. Their network essentially learned to produce multiple neural responses like that in Figure 1(f) given an input that encoded gaze angle and a set of standard eye-centered (or retino-centered) responses like the one in Figure 1(d). What they found, after their network learned to perform the transformation, were intermediate model units that had developed gaze-dependent gain fields much like those in parietal cortex (see Figure 1(e)). This result suggested that gain fields were in some sense optimal for performing a coordinate transformation, which was an extraordinary breakthrough. However, it was not entirely clear why gain modulation was optimal. Subsequent theoretical studies showed that a network of neurons that respond to stumulus location x and are gain-modulated by gaze angle y is useful because it acts as a flexible set of building blocks from which any other, arbitrary functions of x and y can be constructed downstream. Mathematically, the gain-modulated neurons are said to serve as a basis set, meaning that by adding their responses in various proportions one can construct any desired function of x and y. Furthermore, with gain-modulated cells many important downstream functions can be generated using simple synaptic modification rules (Hebbian, or correlation-based, learning rules).

The implication is that if area A has neurons that respond to stimulus x and are gain modulated by a quantity y, neurons in a downstream area B that are driven by A will probably respond in more complicated ways as functions of x and y; perhaps they will respond to $x+y$ or $x-y$, in which case their tuning curves as functions of x will shift with different values of y (as in Figure 1(f)), or perhaps the dependencies will be nonlinear. Tuning curve shifts associated with a variety of coordinate transformations have been documented in several cortical and subcortical areas, including the lateral parietal area (LIP), the ventral parietal area (VIP), premotor cortex, and the superior colliculus.

Other Reference Frames

Although the variables x and y introduced here initially represented target location and eye position, the mechanism for generating transformed representations is extremely general, so the results are valid for any other encoded variables. Indeed, neurophysiological experiments have documented modulation by a variety of internal or proprioceptive signals. Examples include gaze direction, eye or head velocity, arm position, and attentional location. Typically, these signals seem to be directly combined with spatially tuned

Figure 1 Transforming stimulus location from retino-centered to head-centered coordinates. The top panels schematize experiments in which visual receptive fields are mapped at three eye positions. The cross corresponds to the fixation point; small dots above it indicate locations tested with flashed stimuli. Blue and red circles indicate receptive fields of neurons in (d) and (f) respectively. Gaze angle is *y*. (a) Gaze is directed to the left. (b) Gaze is directed straight ahead. (c) Gaze is directed to the right. (d) Responses of a hypothetical early visual neuron in the three conditions schematized above. Firing rate is plotted as a function of stimulus location *x*, which is measured relative to the fixation point (i.e., in retinal coordinates). The tuning curve is independent of gaze angle. (e) Responses of a hypothetical parietal neuron that is gain modulated by gaze. Its receptive field location stays invariant relative to the fixation point, but its amplitude or gain depends on gaze direction. (f) Responses of a hypothetical neuron that encodes stimulus location in head-centered coordinates. Its receptive field stays in the same location relative to the head, so its tuning curve shifts as a function of *x*.

sensory responses to produce a change in reference frame, as in the case of eye position.

The generality of this framework – the idea that arrays of gain-modulated neurons constitute basis sets for constructing more elaborate representations downstream – also extends the concept of coordinate transformation to perceptual processes, such as object recognition. For instance, directing attention to different locations in space modifies the gain of many visual neurons that react selectively to specific features of an image. According to work by Salinas and Abbott, such attentional modulation may give rise to visual responses that are, to a good degree, independent of where they appear in the visual field. Some neurons in inferior-temporal cortex (IT) seem to have this property, also known as translation invariance: they respond depending only on the type of image presented, regardless of its location. According to the theory, they encode visual information in attention-centered coordinates. These cells are considered the neural correlate of our ability to recognize objects independently of where they appear in the visual field.

Partial Shifts in Recurrent Networks

Recurrent connections are ubiquitous in cortical networks, so it is important to understand how computations mediated by gain modulation change in networks with feedback interactions. Studies by Xing and Andersen and by Pouget and collaborators have investigated this in networks trained to perform coordinate transformations to and from diverse reference frames, but where feedback between neurons is allowed. With such feedback, the sensory responses that are optimal for implementing the transformations – the basis functions – still show nonlinear dependencies on the relevant proprioceptive parameters (eye position, head position, etc.). But in addition to changes in gain, their tuning curves show partial shifts as functions of stimulus location, particularly when more than two reference frames are involved. In other words, with feedback and multiple coordinate systems, the most efficient neuronal responses turn out to be intermediate between those shown in Figures 1(e) and 1(f), so individual neurons should display changes

in gain together with tuning curve shifts that are smaller than those expected for a full transformation. Indeed, this mixture is typical of data from various experimental preparations, suggesting that models with feedback capture more of the complexity of real neuronal circuits.

Arbitrary Visuomotor Remapping

Most theoretical studies on gain modulation have focused on the idea that proprioceptive signals combined with spatial sensory information lead to changes in reference frame. However, gain interactions may serve to integrate sensory information with other types of events, not necessarily proprioceptive, and in that case the mechanism works for establishing arbitrary associations between sensory stimuli and motor actions. This refers to tasks or behaviors in which a given stimulus is arbitrarily associated with two or more motor responses depending on separate cues, which provide a context. A simple example is illustrated in Figure 2, where the color of the fixation point indicates whether the correct movement should be a saccade (eye movement) toward a spot of light or an antisaccade away from it. Importantly, the stimulus may appear at many different locations. Gain modulation can be used to construct network models for tasks like this, in which multiple maps between sensory stimuli and motor actions are possible, but only one map, depending on the context, is implemented at any given time. This is illustrated in Figures 3 and 4.

Switching Sensory–Motor Maps

Figure 3 depicts four hypothetical tuning curves from neurons that respond in the task of Figure 2. Each unit has a preferred stimulus location and a preferred context, with red and green corresponding to saccade and antisaccade conditions, respectively. Modulation strength varies across cells and is strongest for the unit in Figure 3(a), which is fully suppressed in the nonpreferred context. Such a 'switching' neuron is entirely turned on and off by context. It is straightforward to see that an array of switching neurons can be easily configured to generate saccades in one context and antisaccades in the other: the neurons that are turned on in context 1 can establish their own set of synaptic connections regardless of the connections established by the other neurons, which are active only in context 2, and vice versa. However, to switch sensory–motor maps it is not necessary that individual neurons turn on and off with context. Figure 4 illustrates this point.

The results in Figure 4 were obtained with a simple network without feedback in which 60 gain-modulated sensory neurons drive a set of 25 output or motor neurons through synaptic connections, and the output firing rates (black dots) are determined by weighted sums of the sensory firing rates (colored dots), such that

$$R_i(x,y) = \sum_j w_{ij} r_j(x,y) \qquad [1]$$

Figure 2 An arbitrary sensory–motor mapping task. In each trial, a stimulus (black dot) is presented at a distance x from the fixation point (colored dot); the stimulus disappears; two targets appear (gray dots) and the subject responds by making an eye movement (arrow) to one of them. The color of the fixation spot acts as a contextual cue indicating whether the movement should be a saccade or an antisaccade. (a) In context 1 the fixation spot is red and the movement is to the target at x. (b) In context 2 the fixation spot is green and the movement is to the opposite target, at $-x$. Adapted from Salinas E (2004) Context-dependent selection of visuomotor maps. *BioMed Central Neuroscience* 5: 47.

Figure 3 Responses of four hypothetical gain-modulated neurons in the remapping task of Figure 2. Each graph plots the mean firing rate of a model neuron as a function of stimulus location. Red and green traces correspond to sensory responses evoked during contexts 1 and 2, respectively. (a) A unit that prefers context 1 and is 100% suppressed in the nonpreferred condition. (b) A unit that prefers context 2 and is 62% suppressed in the nonpreferred condition. (c) A unit that prefers context 1 and is 39% suppressed in context 2. (d) A unit that prefers context 2 and is 13% suppressed in context 1. Adapted from Salinas E (2004) Context-dependent selection of visuomotor maps. *BioMed Central Neuroscience* 5: 47.

Figure 4 A model network that switches between saccades and antisaccades. The model consists of 60 sensory neurons driving 25 motor or output neurons through synaptic connections. The box marks a single trial. Colored traces are the firing rates of the 60 gain-modulated neurons in the network; 30 of them (red) prefer the direct saccade condition and 30 (green) prefer the antisaccade condition. Black dots are the 25 motor responses driven by the gain-modulated neurons. The *x*-axis is preferred stimulus location for the sensory cells and preferred movement location for the motor cells. In context 1 (direct saccades), the peak of motor activity should be aligned with the peak of sensory activity; in context 2 (antisaccades), the motor activity should peak at the mirror-symmetric point from the sensory activity. (a) Firing rates of all model cells when the sensory units are fully modulated by context (switching neurons). The context in each of four trials is indicated on the left. Trials with $x = -15$ and $x = 10$ alternate. The profile of output activity always peaks at the location of the correct saccade. (b) As in (a), but when all gain-modulated neurons are partially modulated by the same amount. (c) As in (a), but when all the gain factors are chosen randomly. Sets of neurons with diverse gain modulation factors can, with appropriate synaptic weights, perform the same input-output transformations as neurons that are fully modulated. Adapted from Salinas E (2004) Context-dependent selection of visuomotor maps. *BioMed Central Neuroscience* 5: 47.

Here, $R_i(x, y)$ is the firing rate of output unit i, w_{ij} is the synaptic connection from sensory neuron j to output unit i, and $r_j(x, y)$ is the firing rate of sensory neuron j when the context is y (1 or 2) and the stimulus is located at x. In Figure 4(a) the model neurons are fully modulated by context, so only one subnetwork is active in context 1 (red dots) and only the other in context 2 (green dots). The two subnetworks are never active simultaneously, so they can establish independent connection matrices and generate separate sensory–motor maps for contexts 1 and 2. In Figure 4(b) the model works similarly, except that the sensory neurons are only partially suppressed in their nonpreferred context. Although the synaptic connections that allow the model to perform the two versions of the task (saccades and antisaccades) are different than in Figure 4(a), with the appropriate connections w_{ij}, performance is again accurate. This is true even when each sensory cell is modulated by a different, random amount, as in Figure 4(c).

More generally, the key result is that, if certain mild conditions on the modulation strengths are satisfied, then any downstream function $R_i(x, y)$ that can be constructed with switching neurons can also be constructed with neurons that are only partially suppressed. In practice, this means that anything that can be done with subpopulations of switching neurons can also be done with neurons that modulate their responses only moderately. This result offers a useful intuition as to why gain modulation is so powerful: modulating the activity of a neuronal population is equivalent to flipping a switch that turns on or off various sets of neurons.

Evidence of Context-Dependent Modulation

Although relatively little is known about how sensory-triggered activity is modified by arbitrary contextual cues, there are several experimental reports revealing (1) neuronal responses that are sensitive to more than one variable or stimulus feature and (2) that the interactions between those variables are generally nonlinear, and thus consistent with changes in gain. For example, the activity evoked in prefrontal neurons by moving dots varies substantially depending on

whether their color or their direction of motion is relevant to the task at hand. Similarly, visual responses may change depending on the probability of obtaining a reward in the current trial, or on the rule that is used to link them to a motor behavior. Such effects could be used for generating abstract transformations in which the contextual or modulatory signal itself lacks any spatial information.

Mechanisms Underlying Changes in Gain

What biophysical mechanisms might allow a neuron to combine two input signals in a multiplicative way? The problem is this. Suppose there are two nearby synapses, a and b, that generate depolarizations ΔV_a and ΔV_b, respectively, when activated individually. To a first approximation, the depolarization observed when activated together should be $\Delta V_a + \Delta V_b$, and indeed this assumption is valid under various conditions. The question is how to make the combined response of synapses a and b nonlinear, and in particular, how to make it so that the neuron's firing rate behaves approximately as a product of a- and b-dependent terms, as observed in extracellular recordings.

Proposed Solutions

In recent years this issue has attracted considerable attention, so several candidate mechanisms with quite different properties have been proposed. One of the earliest suggestions was that of Mel, who showed using biophysically detailed computer simulations, that dendritic conductances with nonlinear voltage dependencies could boost the responses of nearby synapses that are activated simultaneously. That is, due to depolarizing currents in the dendrites, nearby synapses a and b that are active together can generate a depolarization that is much larger than $\Delta V_a + \Delta V_b$. There is experimental support for this effect: on some pyramidal neurons, nearby synapses on the same dendritic branch appear to sum sigmoidally, whereas synapses that are either far apart or on different branches sum linearly.

A second possibility is based on the observation that circuits with positive feedback tend to amplify their inputs. In this scheme, strong recurrent activity between neurons with similar gain fields is the basis for generating a multiplicative effect without the need for synapses to interact. Another mechanism that does not place any restrictions on the synapses themselves has been proposed by Chance and collaborators. They showed that the gain of a neuronal response to excitatory drive can be modulated by varying the overall level of synaptic input. Simultaneously increasing both excitatory and inhibitory background firing rates in a balanced manner results in a divisive effect that modulates the responsiveness to excitatory drive. This, however, requires coordinated changes in the background activity; that is, although each input neuron needs to modify its firing rate by only a small amount, similar changes must occur across a large number of input neurons for the mechanism to work. In addition to these proposals, shunting inhibition, inhibitory synchrony, and input–output functions described by a power law have also been discussed in theoretical studies as being possibly implicated in regulating the gain of neurons.

Two more mechanisms have been suggested recently on the basis of experimental observations. The first one is based on results by Larkum and colleagues showing that, in layer 5 pyramidal cells, there is a nonlinear interaction between inputs that arrive at the soma and at the apical dendrites. The key is that back-propagating action potentials help activate high-threshold dendritic calcium conductances, such that bursts of spikes are produced only when somatic and dendritic inputs coincide. Thus, a weak, asynchronous current at the distal dendrites can generate extra spikes, because of the evoked bursts, and this increases the gain of the response to somatic input. Finally, Mehaffey and colleagues suggested that a neuron's gain may be controlled through inhibition that is applied at the dendrites, and specifically not at the soma. Due to the back-propagation of action potentials and to voltage-dependent currents at the dendrites, after a neuron fires a spike, a depolarizing afterpotential is typically generated. The crucial observation is that the size of this afterpotential regulates the gain of the cell, and that dendritic inhibition – but not somatic inhibition – reduces it. Therefore, dendritic inhibition decreases the gain.

This last idea is interesting because the biophysical requirements for this form of divisive gain control are relatively simple. However, it is likely that neurons use a variety of mechanisms to regulate their gain over different timescales, so the possibilities mentioned earlier (and future ones) should not be considered mutually exclusive.

Galanin and Receptors

K R Bailey and J N Crawley, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Discovery and Distribution of Galanin

Kazuhiko Tatemoto and Viktor Mutt at the Karolinska Institutet in Stockholm discovered galanin in extracts from porcine intestine. It was first reported in 1983; the name galanin was taken from the first and last amino acids of the porcine sequence, glycine and alanine. The amino acid sequence of galanin is highly conserved across species, consisting of 29 amino acids with an amidated N-terminal. The exception is human galanin, composed of the non-amidated 30 amino acid sequence Gly-Trp-Thr-Leu-Asn-Ser-Ala-Gly-Tyr-Leu-Leu-Gly-Pro-His-Ala-Val-Gly-Asn-His-Arg-Ser-Phe-Ser-Asp-Lys-Asn-Gly-Leu-Thr-Ser. Synthesis is by enzymatic cleavage from a larger preprogalanin protein. Preprogalanin contains a second biologically active sequence, galanin-like peptide, composed of 60 amino acids. Galanin and galanin-like peptide share 13 homologous amino acids but appear to mediate different biological functions. The chromosomal location of the human preprogalanin gene is 11q13.3–q13.5.

In the mammalian central nervous system, galanin is discretely distributed and coexists with several other neurotransmitters. High concentrations of galanin-like immunoreactivity are seen in the rat hypothalamus, locus coeruleus, and dorsal horn of the spinal cord. Galanin and galanin mRNA are present in the amygdala, basal forebrain, cerebral cortex, dorsal raphe, hippocampus, medulla, striatum, and many other brain regions. Coexistences vary by species. In the rat, galanin-like immunoreactivity is found within approximately 90% of tyrosine hydroxylase-immunoreactive neurons of the locus coeruleus, 30% of the serotonergic dorsal raphe neurons, and 30% of the cholinergic neurons of the diagonal band and medial septum. Smaller percentages are seen in the coexistences of galanin with dopamine in the median eminence, with gonadotropin-releasing hormone in the preoptic area and with vasopressin in the bed nucleus of the stria terminalis. In the peripheral nervous system, galanin is prominent in the dorsal root ganglia, sympathetic nerves, heart, lung, pancreas, liver, gastrointestinal tract, and pituitary gland. Galanin expression in the pituitary is strongly upregulated by estrogen.

Discovery and Distribution of Galanin Receptors

Galanin binds selectively with high affinity to three receptors, presently termed GalR1, GalR2, and GalR3 (Figure 1). Cloned sequences in rodents and humans were published in 1994–98 by several prominent galanin research teams. The three known galanin receptor subtypes are typical members of the G-protein-coupled superfamily of receptors. Chromosomal locations in the human genome are 18q23 for GalR1, 17q25.3 for GalR2, and 22q12–q13.3 for GalR3. The three subtypes share only approximately 50% sequence homology with one another, but their gene sequences are highly conserved across species. The three subtypes activate somewhat different postsynaptic signaling events. GalR1 and GalR3 activate $G_{i/o}$ and inhibit cyclic adenosine monophosphate (cAMP) synthesis, whereas GalR2 couples to $G_{q/11}$, activates phosphatidyl inositol hydrolysis, stimulates Ca^{2+} release, opens Ca^{2+}-dependent channels and, subsequently, activates $G_{i/o}$.

In the mammalian central and peripheral nervous systems, high-affinity galanin binding is widely distributed. The anatomical distribution of mRNAs for the three galanin receptor subtypes is discretely localized. GalR1 and GalR2 are expressed at moderate to high levels in the hypothalamus, hippocampus, amygdala, cortex, basal forebrain, dorsal root ganglia, spinal cord, pituitary, pancreas, stomach, and large intestines. Some differences between GalR1 and GalR2 localizations are notable; for example, only GalR1 mRNA is seen in the substantia nigra. GalR3 is primarily expressed in the hypothalamus, locus coeruleus, dorsal raphe, central gray, dorsal root ganglia, heart, lung, adrenal gland, pancreas, spleen, kidney, colon, and testis.

Peptidergic ligands with moderate selectivity for each galanin receptor subtype have been synthesized (Figure 1). Historically, the lack of nonpeptide ligands with high subtype selectivity and bioavailability slowed the galanin research field.

Central Nervous Systems Actions of Galanin

Corroborating results from biochemical assays, tissue-slice preparations, and *in vivo* microdialysis indicate an overall dampening action of galanin on neural circuitry. Presynaptic actions of galanin include the inhibition of the release of glutamate, acetylcholine, serotonin, and norepinephrine. Postsynaptic actions

Figure 1 Three known galanin receptor subtypes, their signaling mechanisms, and their selective receptor ligands. Both peptidergic and nonpeptide small-molecule ligands are included. cAMP, cyclic adenosine monophosphate; GALP, galanin-like peptide; GalR, galanin receptor; GIRK, G-protein-activated inwardly rectifying potassium; MAPK, mitogen-activated protein kinase; SNAP, synaptosomal-associated protein. From Robinson JK, Bartfai T, and Langel Ü (2006) Galanin/GALP receptors and CNS homeostatic processes. *CNS & Neurological Disorders – Drug Targets* 5: 327–334.

of galanin include inhibition of phosphatidyl inositol hydrolysis, adenylate cyclase production of cAMP, and cAMP responsive element-binding protein (CREB) signaling.

Galanin Stimulates Feeding

Central microinjection of galanin into the lateral ventricles, third ventricle, paraventricular nucleus of the hypothalamus, and nucleus tractus solitarius evokes feeding in satiated rats (Table 1). Galanin-induced stimulation of consumption was highest at the beginning of the dark phase of the circadian cycle and greatest for foods with high-fat and -carbohydrate contents. Peptidergic galanin antagonists decreased feeding in some model systems (e.g., in rats selected for high levels of fat consumption) but not consistently across model systems and laboratories. Expression levels of galanin mRNA in hypothalamic nuclei varied with level of fasting and refeeding. However, mice with a conventional lifetime targeted mutation in the gene for galanin, the GalR1 receptor, or the GalR2 receptor maintained normal body weights. The actions of galanin at multiple receptors and the interactions of galanin with other neurotransmitters and hormones, including norepinephrine, serotonin, neuropeptide Y, leptin, and insulin, may be responsible for the modulatory actions of galanin on food consumption.

Ethanol and Drugs of Abuse

A single-nucleotide polymorphism haplotype for the galanin gene was found to be associated with alcoholism in Finnish and Plains Indians populations. This genetic finding in the clinical literature is supported by reports that paraventricular hypothalamic administration of galanin increases ethanol consumption in rats (Table 1).

Galanin treatment reduced morphine-withdrawal behaviors and blocked place preference to morphine in normal mice. Expression of galanin mRNA was highly elevated in the locus coeruleus of mice and rats after morphine withdrawal. Galanin-overexpressing transgenic mice displayed fewer morphine withdrawal signs, whereas galanin knockout mice displayed exacerbated morphine-withdrawal signs. Attenuation of cAMP production and CREB phosphorylation by galanin appears to be the mechanism underlying the reduction in morphine-withdrawal responses (Table 1).

Table 1 Behavioral and physiological functions of galanin on central and peripheral nervous systems[a]

Nervous system actions	*Test*	*Species*	*Treatment/transgenic mutation*	*Biological effect*
Central nervous system				
Feeding		Rat	Exogenous galanin	↑ Feeding
		Rat	Galanin receptor agonists	↑ Feeding
		Mouse	GalR1 −/−	Normal body weight
		Mouse	GalR2 −/−	Normal body weight
Reinforcement/withdrawal		Rat	Exogenous galanin	↑ EtOH intake
		Rat	Galanin antagonist M40	Attenuated galanin ↓ EtOH intake
		Mouse	Exogenous galanin	↓ Morphine withdrawal symptoms
		Mouse	Galanin −/−	↑ Withdrawal symptoms
		Mouse	Galanin transgenic (Dβ H promoter)	↓ Withdrawal symptoms
Learning and memory				
Spatial memory	Acquisition	Rat	Exogenous galanin	Impaired
		Mouse	Galanin transgenic (Dβ H promoter)	Normal
		Mouse	Galanin transgenic (PDGF promoter)	Impaired at older ages
		Mouse	GalR1 −/−	Normal
		Mouse	GalR2 −/−	Normal
	Retention	Rat	Exogenous galanin	Impaired
		Mouse	Galanin transgenic (Dβ H promoter)	Impaired
		Mouse	GalR1 −/−	Normal
		Mouse	GalR2 −/−	Normal
		Mouse	Galanin transgenic (PDFG promoter)	Normal
	Working memory	Rat	Exogenous galanin	Impaired
Emotional memory	Trace fear conditioning to context	Rat	Exogenous galanin	Normal
		Mouse	Galanin transgenic (Dβ H promoter)	Normal
		Mouse	GalR1 −/−	Normal
		Mouse	GalR2 −/−	Normal
	Trace auditory cue fear conditioning	Rat	Exogenous galanin	Impaired
		Mouse	Galanin transgenic (Dβ H promoter)	Impaired
		Mouse	GalR1 −/−	Impaired
		Mouse	GalR2 −/−	Normal
	Passive avoidance	Mouse	Exogenous galanin	Impaired
Olfactory memory	Social transmission of food preference	Mouse	Galanin transgenic (Dβ H promoter)	Impaired
		Mouse	GalR1 −/−	Impaired
Seizure susceptibility	Seizure activity	Rat	Exogenous galanin	Suppressed
		Rat	Galanin receptor agonist	Suppressed
		Rat	Galanin receptor antagonist	Increased
		Mouse	Galanin −/−	Increased
		Mouse	GalR1 −/−	Increased
		Mouse	Galanin transgenic (Dβ H promoter)	Suppressed
		Mouse	Galanin transgenic (PDGF promoter)	Suppressed
	Hippocampal excitability	Mouse	Gal −/−	Increased
		Mouse	GalR1 −/−	Increased
Anxiety-related/depression-related	Approach–avoidance conflict tests			
	Elevated-plus maze	Rat	Exogenous galanin	No effect

[a]Exogenous administration by an intraventricular or site-specific microinjection route into brain regions, or of the galanin gene by adeno-associated viral vector delivery; administration by intrathecal routes for nociception studies and intravenous routes for peripheral studies. Phenotypes of mice with a targeted mutation in the gene for galanin or a galanin receptor subtype are included. ↑, increased; ↓, decreased, DβH, dopamine β-hydroxylase; EtOH, ethanol; Gal, galanin; Gal-OE, galanin overexpressing; GalR, galanin receptor; LHRH, luteinizing hormone releasing hormone; MPA, medial preoptic area; PDGF, platelet-derived growth factor.
[b]Galanin-null mutant mice were hyporesponsive in the formalin test. Possible loss of small unmyelinated sensory fibers, throughout development, may explain this apparent contradiction with the actions of exogenous galanin.

Overexpression in Alzheimer's Disease and in Learning and Memory Impairments

Galanin is overexpressed in the basal forebrain in Alzheimer's disease (Figures 2(g) and 2(h)). Dense galanin-immunoreactive fibers course through the region of the nucleus basalis of Meynert, and galanin-immunoreactive terminals appear to decorate and synapse on the remaining cholinergic nucleus basalis of Meynert cell bodies. Postmortem concentrations of galanin in basal-forebrain samples from Alzheimer's patients are approximately twice as high as in age-matched controls. In the same samples, cholinergic markers are lower in Alzheimer's versus age-matched controls, and levels of other neuropeptides localized in the basal forebrain do not differ between groups. Increased galanin in the basal forebrain is apparent at middle to late stages of the disease progression.

Administered centrally to rats, galanin impairs performance on a wide variety of learning and memory tasks (Table 1). Transgenic mice overexpressing galanin selectively in adrenergic neurons displayed deficits on more difficult memory tasks. The release of glutamate and acetylcholine was reduced in the hippocampus of galanin-overexpressing transgenic mice, indicating a mechanism through which galanin impairs performance on challenging learning and memory tasks. In hippocampal slices, galanin reduced long-term potentiation when administered exogenously and when overexpressed in galanin transgenic mice. Peptidergic galanin receptor antagonists have been reported to improve cognitive performance in some rat models. Galanin receptor antagonists have been proposed as a treatment for Alzheimer's disease to remove the putative inhibitory actions of excess galanin within the neuropharmacological circuitry required for learning and memory. Targeting the most relevant galanin receptor(s) could improve memory in Alzheimer's patients directly or could increase the efficacy of existing therapeutics by removing inhibitory modulation.

Anticonvulsant

Central microinjection of galanin inhibits picrotoxin-kindled seizures in rats (Table 1). Resistance to seizures induced by electrical stimulation of the perforant path was seen in galanin-overexpressing transgenic mice. Galanin-null mutant mice displayed higher seizure susceptibility. Adeno-associated viral vector delivery of the galanin gene into the inferior colliculus of rats increased the threshold for focal seizures after electrical stimulation of the collicular cortex and protected hippocampal hilar neurons from death after kainic acid administration. Inhibition of glutamate release by galanin, demonstrated in potassium-stimulated hippocampal slices taken from galanin-overexpressing transgenic mice, appears to be one mechanism underlying the antiseizure actions of galanin. GalR1 and GalR2 peptidergic agonists mimicked the actions of galanin (1–29), indicating the potential clinical efficacy of ligands at both receptor subtypes as novel treatments for epilepsy.

Anxiety and Depression

Centrally administered galanin produces anxiolytic-like responses in some, but not all, model systems (Table 1). In rats, galanin decreased punished responding when administered intraventricularly before the Vogel conflict test. Following immobilization stress or treatment with the noradrenergic autoreceptor antagonist yohimbine, anxiety-related behaviors on the elevated-plus maze and social interaction tests were attenuated by galanin treatment. However, in normal C57BL/6J mice, the intraventricular administration

Figure 2 Similarities between galanin overexpression in the basal forebrain in Alzheimer's disease and galanin overexpression in transgenic mice with the galanin transgene generated on a dopamine β-hydroxylase (DβH) promoter: (a) schematic of the insertion of hDβH promoter into the mouse preprogalanin gene; (b) dot blot showing the increased expression of galanin in the forebrain of this mutant mouse; (c) photograph of a wild-type mouse (left) and its brain (right); (d) photograph of a transgenic mouse showing similar body phenotype (left) and its brain (right); (e) minor galanin-immunoreactive fiber staining in the wild-type mouse septal area; (f) overexpression of galanin-immunoreactive fiber staining in the transgenic mouse septal area; (g) cholinergic neuron (brown) with minor galanin innervation (black) in a human age-matched control case; (h) galanin hyperinnervation surrounding a cholinergic neuron and fiber in Alzheimer's disease; (i) galanin-positive fiber in the hippocampus of an APP/PS1Detla E9 wt mouse; (j) galanin-positive plaques and neuritis in the hippocampus of an APP/PS1Delta E9 transgenic mouse; (k) hippocampal plaque immunoreactive for amyloid (yellow) and galanin-immunoreactive neurites (black) in an APP/PS1Detla E9 transgenic mouse. In (c) and (d), the apparent difference in size of the mice is a photographic artifact, and the photographs of the brains show the lack of gross morphological difference between the genotypes. Galanin plasticity in the cholinergic basal forebrain in Alzheimer's disease and transgenic mice. *Neuropeptides* 39: 233–237, with permission from Elsevier.

of galanin did not affect baseline performance on the elevated-plus maze or light↔dark exploration. Galanin-overexpressing transgenic mice displayed normal baseline performance on anxiety-related tasks but displayed less anxiety-like behavior in response to the anxiogenic-like actions of yohimbine. GalR1 and GalR2 knockout mice displayed a significant anxiolytic-like phenotype on the elevated-plus maze task but not on other anxiety-related tasks.

Centrally administered galanin increases immobility on the forced-swim test in rats, a finding replicated by several laboratories. Galanin-overexpressing

transgenics generated with a platelet-derived growth factor B promoter displayed increased immobility on the forced-swim test, particularly at older ages. However, galanin transgenics generated on a dopamine β-hydroxylase promoter and GalR1 knockout mice were not significantly different than wild-type littermate controls on the tail suspension test. The inhibitory actions of galanin on the release of serotonin, norepinephrine, and dopamine, as well as the effects of galanin on serotonin receptors, may mediate its depression-like effects. Antidepressant-like and anxiolytic-like actions of a GalR3 antagonist in rats, mice, and guinea pigs have led to clinical trials, presently in progress.

Analgesia

Intrathecally administered galanin produces analgesic actions on the C-fiber flexor reflex in rats. Systemically administered galanin increased latencies on the hot-plate and tail flick tests in rats and mice, and potentiated morphine-induced antinociception. Galanin mRNA was upregulated in neurons of the rat dorsal root ganglia after sciatic nerve transaction and constriction, and after persistent inflammation. Galanin-overexpressing transgenic mice displayed longer latencies to respond to noxious heat stimulation and showed attenuated responses to repetitive C-fiber stimulation. GalR1-knockout mice showed a somewhat longer duration of mechanical hypersensitivity after sciatic nerve injury in a neuropathic pain model (Table 1). Agonists of galanin receptors are under consideration for the clinical treatment of chronic pain.

Neuroprotection

Upregulation of galanin mRNA is highly significant in dorsal root ganglion and some brain nuclei after nerve damage, including sciatic nerve ligation, colchicine treatment, and site-specific excitotoxin lesions of brain structures. Knockout mice deficient in galanin showed slower rates of nerve regeneration and reduced neurite outgrowth of cultured dorsal root ganglia neurons after sciatic nerve crush. In GalR1 knockout mice, neurite outgrowth was normal in cultured dorsal root ganglia neurons after sciatic nerve damage. However, GalR2 knockout mice had fewer surviving dorsal root ganglion neurons than controls after sciatic nerve transaction, suggesting a role for the GalR2 receptor subtype in neuroprotection. Higher levels of galanin promoted the survival of hippocampal neurons after kainic acid lesions, possibly through the inhibition of glutamate release. Long-term neuroprotective actions of endogenously administered galanin in the adult central nervous system remain controversial.

Peripheral Nervous Systems Actions of Galanin

Galanin and its receptors are localized in neurons of the sympathetic nervous system and peripheral sensory nerves. Galanin immunoreactivity is found in the epithelial cells of the colon, myenteric plexus of the gastrointestinal tract, stomach, liver, pancreatic islet cells, vas deferens, heart, carotid artery, dorsal root ganglia, trigeminal ganglia, skin, and pituitary gland. As in the central nervous system, the biological actions of galanin are generally inhibitory. Release of insulin from pancreatic islet cells was inhibited by galanin in some species, implicating galanin in metabolism, liver function, diabetes, and obesity. Actions of galanin on gastrointestinal motility included inhibiting contraction of circular smooth muscle in the ileum, increasing basal tone in the lower esophageal sphincter, and causing smooth muscle relaxation in the internal anal sphincter. Experimentally induced inflammation was found to upregulate galanin GalR1 expression in intestinal smooth muscle cells. Colonic fluid secretion in response to inflammation was reduced in GalR1 knockout mice, implicating galanin in colitis. In some species, galanin inhibited cholinergic innervation of the heart, thereby attenuating parasympathetic slowing of heart rate (Table 1).

Progenitor Cells

Galanin was identified by serial analysis of gene expression (SAGE) as being highly expressed in undifferentiated mouse pluripotent stem cells, compared to differentiated embryonic tissues. Galanin was the third most abundant transcript in these embryonic stem cells compared to other SAGE catalogs. Galanin expression was transiently induced in oligodendrocyte progenitor cells in the rat cortex. Several classes of tumors and cancer cell lines expressed galanin-like immunoreactivity and galanin mRNA, including neuroblastomas, gliomas, pheochromocytomas, melanomas, and testicular germ cell tumors. Galanin expression in the anterior pituitary was dramatically upregulated by estrogen treatment. Galanin was secreted from pituitary tumor cultures, and galanin levels were high in estrogen-induced prolactinomas, pituitary adenomas, and adrenocorticotropin-secreting tumors that cause Cushing's syndrome. A cocktail of galanin, serotonin, and octreotide was reported to be efficacious in treating colorectal cancer.

Although the neurotransmitter actions of galanin in the central and peripheral nervous systems have received the greatest attention, the actions of galanin on endocrine, proliferative, and neurodegenerative processes are increasingly intriguing.

Game Theory and the Economics of Animal Communication

R A Johnstone, University of Cambridge, Cambridge, UK

© 2009 Published by Elsevier Ltd.

Introduction

One may contrast signals with cues – traits that influence the behavior of others but have not been favored by selection for this reason. The rustling of a mouse running through long grass may, for instance, draw the attention of a predatory owl; the sound here serves as a cue to the location of the mouse, but it does not represent a signal (nor is this an instance of communication), because it is not adapted for this purpose. Selection has not favored mice who attract the notice of predators in this way; if anything, quieter individuals who minimize the noise they make are more likely to survive. By contrast, a display trait such as the song of a nightingale, the roar of a red deer, or the train of a peacock has been favored by selection precisely because of the responses it evokes, and thus it constitutes a true signal.

Selection of Signals – Efficacy versus Strategy

The first requirement for an effective signal, in any context, is that it should be readily detectable and identifiable by the appropriate recipient. Yet communication may often take place over long distances or in a noisy environment, so by the time they reach the receiver, signals are attenuated, degraded, and overlaid by irrelevant stimuli. Selection will therefore tend to favor conspicuous and distinctive signals that are easier to detect and identify, even in the presence of noise. At the same time, such displays may be energetically costly or time consuming to produce and may draw the unwanted attention of 'eavesdroppers' such as predators and parasites. The displays we see in nature should be those that strike the best balance between the opposing selective pressures for greater efficacy and lower cost.

Many studies have looked at the design of animal signals from this perspective, focusing on the features that enhance signal efficacy. There is evidence, for instance, that the details of visual and vocal signal design are often adapted to the particular physical environment in which communication occurs, and to the sensory capacities and 'psychology' of receivers, so as to facilitate efficient detection. But the emphasis in this article is on a different aspect of signal design. It is not enough that a display should be readily detectable. If it is to be favored by natural selection, it must also, once detected, tend to elicit responses that are beneficial for the signaler. This 'strategic' perspective on signal evolution emphasizes those properties of a display that render it effective in eliciting a beneficial response rather than those that facilitate detection.

To understand the strategic aspect of signal design, we must consider selection from the perspective of both the signaler and the receiver. Selection favors signalers that elicit favorable responses from receivers; it also favors receivers that respond appropriately to signalers. Game theory, with its emphasis on strategic interaction, is thus a powerful tool for modeling this aspect of signal evolution.

Conflicts of Interest and the Problem of Honesty

In some 'cooperative' contexts, the recipient of a signal also gains by responding in a manner that is beneficial for the signaler. Under these circumstances, the evolutionary interests of the two parties are aligned. Consider, for example, the 'dance language' of honeybees, by means of which a worker returning to the hive can convey to her sisters the location of a food source. The worker benefits by recruiting others to the food, just as they stand to gain by responding to the information she provides. Selection on both parties thus favors efficient communication.

In most cases, however, there is an evolutionary conflict of interest between signaler and receiver because the latter suffers by responding in a manner beneficial to the former. Bolas spiders, for instance, attract male insect prey by means of a pheromonal lure that mimics the sex pheromones of females of the prey species. Responding to such a chemical 'lure,' while it may benefit the spider, is clearly detrimental to the prey.

The conflict in the above case is extreme, but even in situations where there is a degree of common interest between signaler and receiver, there will usually be an element of conflict too. For instance, both males and females share a common interest in finding and identifying potential mates of their own species. However, males are typically under stronger selection to acquire many mates, and females to acquire better mates. This gives rise to a conflict of interest. Females stand to gain by accurately assessing the mating benefits (material or genetic) that a potential partner has to offer, in order to reject suitors of low value. Conversely, males stand to gain by misleading females as to their own value, in order to gain additional matings. In a similar way, conflict arises between

parents and offspring, even though both have a genetic stake in each other's survival. Offspring are selected to demand more food than parents are selected to provide. As a result, parents stand to gain by accurately assessing offspring need, but offspring stand to gain by misleading parents as to their own condition in order to extract additional resources from them.

The first theoretical game models of animal communication suggested that because of the underlying conflict of interest between signaler and receiver, informative or honest signaling cannot persist. Consider, for instance, a population in which signalers reliably advertise their aggressive intentions by means of a threat display. Maynard Smith, using game theory to model conflict behavior, argued that threat displays that provided receivers with accurate information about an animal's intentions would not be evolutionarily stable. If a display provides honest information about an opponent's propensity to fight, receivers should attend to it and should be more likely to back down when they confront an opponent who signals strongly. Consequently, it seems that a 'deceitful' mutant that always announced a high level of aggression would prosper because its opponents would more often retreat. The spread of such mutants would, however, devalue the signal. Ultimately, it would no longer pay to attend to the display, because it would no longer provide reliable information.

The same argument seems to apply to any signaling system in which there is a conflict of interest between signaler and receiver. Any correlation between the production or intensity of a display and the underlying state of the signaler can be disrupted by the spread of a 'deceitful' mutant that gains by adopting a misrepresentative signal. Consequently, the models seemed to suggest that communication should be viewed, not as a cooperative exchange of information, but as the focus of an arms race between signalers as 'manipulators' and receivers as 'mind-readers,' the former standing to gain by effective exploitation, the latter by effective extraction of information. Honesty, from this perspective, merely represented a temporary phase of the arms race in which receivers have 'drawn ahead' of signalers.

Constraints and Costs – The Handicap Principle

Despite the potential benefits that signalers stand to gain by misleading receivers, the majority of signals seem to convey at least some reliable information. In other words, stable honesty is the usual outcome of the arms race between signaler and receiver. How can such honesty persist in the face of the evolutionary conflict between the two?

Honesty may endure if it is physically impossible for a signaler to produce a misleading signal. In some cases there is a material link between the signal and some underlying aspect of the signaler's state, such that the former is constrained to provide information about the latter. For instance, many animals display bright coloration attributable (in part at least) to carotenoid pigments. Since most cannot synthesize carotenoids themselves but must acquire them as part of their diet, the intensity of carotenoid coloration is inescapably linked to (past) foraging success. An individual that fails to acquire sufficient carotenoids through foraging simply cannot manufacture the pigments needed for vivid color. Studies of the house finch (*Carpodacus mexicanus*), for instance, a species in which males display patches of carotenoid pigment on the crown, breast, and rump, have shown that females prefer redder males and that vivid coloration reflects nutritional state at the time of molt. Since molting precedes mate choice by some time, redder males may not necessarily be in better condition when they are actually chosen as partners, but plumage coloration was correlated with nest attentiveness and overwinter survival, suggesting that brighter males do make, on average, better fathers.

While a few signals may be 'unfakable' because of such physical constraints, most are not. An individual's choice of one threat display or another, for instance, is not physically constrained by its fighting ability or motivation, nor is the length of a bird's tail inescapably tied to its value as a mate. To account for widespread honesty, therefore, an explanation is required that is applicable to situations in which the relationship between the signal and the underlying state of the signaler is open to behavioral or evolutionary change.

Amotz Zahavi was the first biologist to propose such a general explanation for honesty. He suggested that a signal could provide reliable or 'honest' information about the quality of the signaler if it were costly to produce. Consider, for instance, a population in which males reliably advertise their value as mates by means of some sexual display. The correlation between signal and mate value would seem vulnerable to disruption by the spread of a deceitful mutant that adopts the display typical of the most desirable males, regardless of its own quality. Suppose, however, that the signal is costly to produce but that superior males can more easily bear these costs than can inferior males. Under these circumstances, it might pay an inferior male to refrain from signaling, even though it would be physically able to do so, because the costs involved would outweigh the benefits to be gained. At the same time, for superior males who can more easily bear the costs of display,

production of the signal would yield a net benefit. Under these circumstances, honesty can persist.

While Zahavi initially focused chiefly on sexual displays, he has subsequently argued that the handicap principle is applicable to many and perhaps all forms of communication. Costly signals could serve to advertise fighting ability, for instance, and thereby to deter rivals, or could deter predators by advertising ability to escape or fend off attack. Costly contributions to group activities could, in a similar way, advertise social status, provided that only dominant, high-quality individuals can afford to invest time and energy in such pursuits. In short, receivers in most contexts can obtain reliable information about signaler quality by attending to displays that are costly to produce.

A Simple Model

Zahavi's handicap principle suggests a possible solution to the problem of honesty. At first, however, it was widely dismissed as unworkable. In part, this rejection of the idea was due to Zahavi's verbal formulation, which was open to different interpretations, leaving some doubt as to precisely what was meant. Acceptance had to wait until the development of formal models, in many cases based on game theoretical techniques. Indeed, the problem of honesty has been, and remains, the chief focus of game theoretical models of animal communication, and such models have played a key role in establishing the plausibility of honest, costly advertisement (it must also be noted that economic game theory had reached similar conclusions rather earlier).

To illustrate this approach, this article presents a very simple (perhaps the simplest possible) game theoretical model of honest signaling. Suppose that one individual, the signaler, is informed of the value of an uncertain parameter q (possibly representing some aspect of the external environment, but more likely some aspect of its own type or state). The signaler than chooses an action s, referred to as a signal. Another individual, the receiver, who is unaware of the value of the parameter q, observes the signal s and decides, on this basis, to adopt some response r. In our simple case, q, s, and r all take values of either 0 or 1. Each player then receives a payoff that may depend on q, s, and r.

The problem of honesty arises when receivers gain by responding differently to signalers of different type, but at least some signalers stands to gain by eliciting a response that is, from the perspective of the receiver, inappropriate for their type. Suppose, for instance, that the receiver obtains a payoff of 1 if its response matches the signaler's type (i.e., if $r = q = 0$ or $r = q = 1$), but a payoff of 0 otherwise (if $r \neq q$). All signalers, by contrast, obtain a payoff equal to r and therefore prefer a response of 1 to a response of 0. How is a separating equilibrium, at which signalers of different types adopt different signals, possible under these conditions? Any such equilibrium appears vulnerable to invasion by a rare class of mutant signaler that, regardless of its true type, adopts the signal typical of individuals of type $q = 1$, thereby eliciting the favorable response $r = 1$.

Suppose, however, that the signal adopted by individuals of type 1 is costly to produce. The handicap principle suggest that this can serve to maintain honesty. For simplicity, let us restrict our attention to the potential separating equilibrium at which individuals of type $q = 1$ adopt the signal $s = 1$ (eliciting the response $r = 1$), while individuals of type $q = 0$ adopt the signal $s = 0$ (eliciting the response $r = 0$). Now suppose that production of the signal $s = 1$ entails an additive cost of magnitude c_i (≥ 0) for signalers of type i, whereas the signal $s = 0$ is cost-free. Provided that $c_0 > 1 > c_1$, the separating equilibrium is stable against invasion by the cheating mutant suggested above because the cost of adopting signal $s = 1$ outweighs the benefits to be gained thereby for individuals of type 0 but not for those of type 1. Cheating in this case may be possible, in the sense that a mutant individual can arise that adopts signal $s = 1$ when of type $q = 0$, but it proves unprofitable.

In the above case, signalers differ in the cost they pay to produce the 'favored' signal $s = 1$, but all stand to gain the same benefits by eliciting the 'favorable' response $r = 1$. Suppose, by contrast, that all signalers pay the same cost, of magnitude 1, to produce the favored signal, but that the benefit they stand to gain by eliciting the favorable response $r = 1$, denoted b_i for signalers of type i, differs according to their type. Provided that $b_1 > 0 > b_0$, the separating equilibrium is once again stable against invasion by the cheating mutant because the signal $s = 1$ is unprofitable for individuals of type $q = 0$. In this case, however, honesty is maintained not by the differential cost of the signal but by differential benefit. The former case is often described as a signal of quality, the latter as a signal of need.

In reality, of course, signalers may vary both in the cost of signaling and in the benefits they stand to gain, and some more-realistic models have incorporated both factors (though surprisingly many analyses continue to focus exclusively on one or the other).

Evidence for Honesty

Even the very simple model presented above suffices to demonstrate that signal cost can, in principle at least, serve to maintain honesty. But is there any evidence that the handicap principle plays such a role in nature? This article offers two illustrative

examples of the kind of studies that have been undertaken to confirm its importance.

Perhaps the best evidence for honest, costly advertisement of quality comes from work by Mappes and colleagues on sexual display in the wolf spider *Hygrolycosa rubrofasciata*. Males of this ground-dwelling species attract mates by drumming on dry leaves on the substrate with their abdomen. Experiments have shown that drumming entails energetic costs – males kept under standardized conditions lose weight faster and experience greater mortality when induced to drum more often by exposure to females. At the same time, those males who were observed to drum more frequently and vigorously under natural conditions suffer less when subsequently induced to drum in the lab, indicating that the costs of the display are indeed lower for those males that signal more strongly, as the handicap principle predicts.

Turning to advertisement of need, some of the best evidence for honest, costly signaling comes from work by Kilner on the begging displays of captive canary (*Serinus canaria*) nestlings. When an adult canary returns to the nest with food, the offspring stretch and posture, gape and call as the adult empties its crop and distributes the regurgitated food among the brood. Chicks that attain positions closer to the parent are likely to receive more food, but when offspring proximity to the parent was experimentally controlled and hunger manipulated, parents were observed to preferentially feed hungrier chicks, suggesting that they respond to cues indicative of offspring need. What form might these cues take? The mouths of canary nestlings exhibit a rapid change in color intensity, the 'flush,' following the onset of begging, and subsequent experiments revealed that this change in color accurately reflects a nestling's state of need and that parents preferentially feed chicks with artificially reddened mouths. Gape color thus appears to provide parents with an honest signal of chick hunger (although parents may also respond to chick posturing and calling as well). Finally, when pairs of canary siblings were induced to beg for markedly different durations, greater begging was found to retard growth, both immediately and in the long term. This growth cost is likely to entail a reduction in fitness, because daily mass gain was strongly correlated with survival of chicks to independence. It thus appears that chick begging in this species constitutes a costly, as well as an honest, signal of hunger.

Occasional Deceit

The handicap principle seems to offer a simple and widely applicable solution to the problem of honesty. But if receivers can obtain reliable information about signaler quality or condition merely by attending to costly displays, how can one account for instances of deceit?

Selection will favor receivers who respond to a signal if, on average, they obtain a net benefit by doing so. But a benefit 'on average' is compatible with occasional exploitation. Suppose, for instance, that a rare class of signaler finds display cheaper than other individuals do, for the same level of quality, or stands to gain more by eliciting a favorable response, for the same level of condition. Such individuals do best to produce a 'misleading' signal, typical (in most cases) of signalers of higher quality or in greater need than themselves. This will lead receivers to respond more favorably to them than to other signalers. We might expect receivers to adjust their behavior to take account of the presence of these deceptive individuals – the risk of encountering one will favor lower responsiveness to intense displays. Nevertheless, provided that the frequency of such individuals is low enough, and the cost of responding to them inappropriately is not too great, they need not disrupt the signaling system altogether. Evidence of occasional deceit can thus support the handicap principle if it can be established that deceitful signalers do differ from others in the net benefit they stand to gain from display (and if there are constraints on the frequency of deceit).

A good example is the use of deceptive begging signals by avian brood parasites such as cuckoos. As discussed above, there is evidence that chick begging constitutes (in at least some cases) an honest signal of hunger. Models of begging predict that chicks who are less closely related to their nestmates and to the adults raising them should beg more intensely because they have less to lose by depriving their competitors of food and/or forcing the adults to work harder. A brood parasite chick is an extreme instance of this: Since it is entirely unrelated to the other chicks in the nest or to its host parents, it has no genetic interest in their survival. Accordingly, Kilner and colleagues have shown that chicks of the common cuckoo exploit the signaling system of reed warbler hosts by begging at a greater rate than do host chicks. Intriguingly, parents appear to respond to both the vocal and the visual signals of their offspring. Cuckoo chicks, which eject all host young from the nest, display a reduced gape area compared with a host brood yet apparently compensate by more rapid calling.

Exploitation of host parents by specialized brood parasites may appear an extreme and unusual instance of deceit. However, more subtle forms of intraspecific deception may be widespread. A nice illustration is the occurrence of bluffing in the marine stomatopod crustacean *Gonodactylus bredini*, studied by Adams and

Caldwell. Males of this species defend cavities in coral rubble and ward off intruders with a meral spread threat display. Following molt, an individual's soft condition means that it is unable to fight effectively, yet newly molted owners threaten more often than those that are capable of fighting, thus reducing the chances that intruders will attack and discover their opponents' vulnerability. That this deceit does not destabilize the signaling system entirely presumably reflects the relativey low probability of encountering a newly molted opponent.

Cost-Free Honesty?

The evidence discussed earlier shows that signal cost can indeed, as the handicap principle suggests, favor quality-dependent or condition-dependent expression of display traits. Cost, in other words, is sufficient to maintain honesty. But is it necessary? The more-enthusiastic proponents of the handicap principle have argued that honest signals must be costly, otherwise what is to prevent cheating? But more-recent analyses suggest that cost-free honesty is possible. Two rather different mechanisms have been proposed that might maintain signal reliability even in the absence of cost.

The first mechanism was suggested in the context of signaling of need by offspring to their parents. As pointed out above, offspring are selected to demand more resources than parents are selected to supply. Consequently, an honest signal of need is potentially subject to devaluation by deceitful mutants that misrepresent their need, thereby attaining additional resources. However, since offspring have a genetic stake in the well-being of their parents, selection will not favor unlimited selfishness on the part of young. Offspring stand to gain by simulating a level of need that is slightly greater than their true need, but not so great that they might elicit excessive investment that would be overly costly to the parent. Selection, in other words, will act against offspring that are too deceptive.

As a result of selection against excessive deception, a cost-free signaling equilibrium is possible at which offspring divide into two or more discrete categories, according to their need, in each of which all individuals adopt the same begging behavior (sometimes referred to as a 'pooling' equilibrium). In the simplest case, for instance, those whose need falls below some threshold refrain from begging while the remainder beg. Under these circumstances, the parent cannot distinguish among nonbegging young and must attribute to them all the same 'average nonbegging' level of need; similarly, the parent cannot distinguish among begging young and must attribute to them all the same 'average begging' level of need (greater than the average for nonbegging young). A nonbegging offspring may thus stand to gain by exaggerating its need slightly, but it cannot do so – by choosing to beg, it will cause the parent to greatly overestimate its level of need, to an extent that can prove disadvantageous, even if begging entails no direct costs.

Formal game-theoretical models have confirmed that a cost-free equilibrium of the above kind is possible in principle. Whether actual chick begging represents a cost-free or a costly signal remains, however, controversial. As described earlier, there is evidence that begging entails fitness costs in at least some cases. But in other instances, the costs are less obvious – most attempts to measure the energetic cost of begging, for instance, suggest that this is very small. Similarly, while experiments have shown that playback of begging calls can increase the risk of nestling predation, this result holds true only for offspring in open nests and perhaps overlooks the fact that parents may normally be able to warn their offspring to remain silent when predators are nearby, so reducing the effective cost of begging. Despite the paucity of evidence for substantial costs, however, offspring typically do not exhibit 'pooling' but instead show continuous variation in begging intensity, which better fits the predictions of costly signaling models. Perhaps, in reality, begging may involve both costly and cost-free components – it is certainly a composite signal, often combining posturing, calling, and gaping.

In any case, 'pooling' models of cost-free begging are based on the fact that signalers (offspring) have a genetic stake in the well-being of receivers (their parents). Because this is not the case in many other signaling systems, such models are of restricted applicability. A second mechanism for the maintenance of cost-free honesty, however, is of much broader scope. Looking back at the very simple model we introduced earlier, we showed that in the case of a signal of quality, stable honesty is possible provided that $c_1 > 1 > c_2$, that is, provided that the cost of signaling exceeds the benefit to be gained for individuals of class 1, but not for individuals of class 2. This condition allows for the possibility that $c_2 = 0$, that is, that the signal is entirely cost-free for individuals of class 2. Because it is only these individuals that employ the signal at equilibrium, the outcome is then one in which no cost is paid. What maintains honesty (in the face of a conflict of interest between signaler and receiver) is the fact that low-quality individuals 'would' incur a cost 'if they were to adopt' the display behavior typical of a high-quality signaler. This does not mean, however, that such display behavior must entail a cost for the high-quality individuals that actually employ it.

The above argument suggests that cost-free honesty is possible in any context, provided that cost is incurred only by those signalers that misrepresent their state. It is difficult to envisage a physical mechanism that could give rise to such conditional costs. When costs are socially imposed, however, it does seem plausible that receivers might punish only those signalers that are subsequently discovered to have employed misrepresentative or deceptive signals. For example, rhesus monkeys living on the island of Cayo Santiago, Puerto Rico, often (though not always) produce distinctive vocalizations when they discover or eat food, particularly high-quality food such as coconut. Following the discovery of food by one individual, other group members were in some cases observed to detect and approach the food source and its original discoverer. Some discoverers were then attacked and injured, whereas others were allowed to keep the food they had collected. It appears that individuals who call when they discover food are more likely to be approached by other group members, and as a result suffer from increased feeding competition. However, discoverers who call incur less aggression when subsequently detected than do those discoverers who remain silent. In this case, then, the threat of aggression directed at 'deceptive' individuals who refrain from calling may serve to maintain honest advertisement of food discoveries.

Further Questions

This brief review makes clear, the important role that game-theoretical models have played, and continue to play, in the study of animal communication. Because most forms of communication involve an evolutionary conflict of interest between signaler and receiver, they are potentially vulnerable to disruption by 'dishonest' signalers. Game-theoretical models have served to verify the logic of Zahavi's handicap principle and to confirm that signal cost may indeed support honest signaling in the face of a conflict of interest, a suggestion for which there is now some empirical support. At the same time, such models have also suggested that honesty need not always entail signal cost. This last issue remains the subject of much controversy, and the study of putative cases of cost-free honesty continues to attract much interest. There are also many further questions that fall within the scope of game theory, but which have not been touched on here. Three topics that are of particular interest, for instance, are the evolution and use of multiple signals, the dynamics of extended communicatory interchanges, and the evolution of signaling within a communication network in which multiple receivers may eavesdrop on a signal (and multiple signalers may compete for the attention of a receiver). Given the many questions that remain to be answered, it seems likely that game theory still has much to contribute to the study of animal communication.

Games in Monkeys: Neurophysiology and Motor Decision-Making

Stages of Decision Making

Decision making can be defined as choosing a particular option from multiple alternatives, and it is often carried out in order to maximize certain desirable quantity, such as reward or utility. Animals rely heavily on the sensory stimuli they receive from their environment to choose appropriate behavioral responses (Figure 1). A precise pattern of sensory stimuli impinging on the animal's nervous system is determined by the positions and orientations of the animal's sensory organs as well as the current state of the animal's environment. These sensory inputs are inevitably corrupted to a variable degree by the noise in the animal's nervous system. Based on this noisy representation, individual objects in the environment are recognized and additional properties of these objects that the animals have learned from their previous experience can be retrieved from their memory storage. This is the process of perceptual decision making. Based on the outcome of perceptual decision making, the animal chooses what to do, and this is referred to as cognitive decision making. For example, should the animal eat the apple it just discovered from a tree, or save it for a rainy day? Even when all the objects in the animal's environment are correctly identified, the animal's behavioral response may change depending on the animal's metabolic needs, and the animal's cognitive limitations may prevent the animal from selecting a behavioral response that produces the most desirable outcome. Finally, the number of various movement trajectories that can be chosen to accomplish a particular behavioral objective is often infinitely large, and the selection of a particular motor trajectory can be referred to as motor decision making. For example, a light switch can be turned on by the right or left hand or even by one's head if both hands are occupied or injured. This article focuses on the neural mechanisms of cognitive and motor decision making in monkeys with a particular emphasis on cognitive decision making in the context of social interaction.

Utility Maximization and Reinforcement Learning

Standard economic analysis of choice behavior, such as the expected utility theory, begins with the assumption that decision makers assign a numerical score to each available option according to the subjective desirability of its outcome, commonly referred to as utility function. It is also assumed that decision makers make their choices so as to maximize the expected value of utility function. Numerous studies of human choice behavior have shown that these assumptions are often violated. Many of these violations are accounted for by alternative theoretical proposals, such as the prospective theory of Kahneman and Tversky and the regret theory of Bell, Loomes, and Sugden. Nevertheless, the expected utility theory still remains as a core theory in microeconomics, and accounts for a wide range of choice behavior in both humans and animals.

To understand the neural basis of decision making within the framework of the expected utility theory, it is important to distinguish two different types of utility which Kahneman referred to as decision utility and experienced utility. Decision utility corresponds to the amount of subjective pleasure expected by the decision maker during the process of decision making. In contrast, experienced utility is the amount of actual pleasure or satisfaction derived from chosen actions or from the consumption of chosen objects. If the decision maker makes correct predictions regarding the outcomes of chosen actions during the time of decision making, experienced utility would be equal to decision utility. In reality, however, the decision maker's knowledge of his or her environment is seldom complete, and there is often a discrepancy between these two types of utilities. It is, therefore, possible that decision utility and experienced utility might be represented and processed in separate brain areas. The results from previous neuroimaging studies in human subjects, however, show that decision utility and experienced utility influence the level of metabolic activity in similar brain areas, including the dorsolateral prefrontal cortex, the orbitofrontal cortex, the anterior and posterior cingulate cortex, the posterior parietal cortex, and the basal ganglia. Activity of individual neurons in many of these brain areas has been examined in nonhuman primates, and the results are largely consistent with the findings from the human neuroimaging studies. Thus, signals related to decision and experienced utilities are encoded in a broadly distributed network of cortical and subcortical areas.

If the animal's environment is stationary, the probability that a given action would produce a particular outcome would be fixed, and, therefore, optimal decision-making strategies can be hardwired in the form of stimulus–response mapping. In reality, the environment is almost always dynamic, and the actual outcomes frequently differ from the outcomes

Figure 1 Different stages of decision making.

anticipated during the process of decision making, so decision utilities may deviate from the experienced utilities. To make choices optimally, therefore, decision makers need to adjust decision utilities according to their experience. In reinforcement learning theory, decision utilities are referred to as value functions and the difference between decision and experienced utilities is referred to as reward prediction error. The work of Schultz and his colleagues showed that reward prediction error is encoded by the activity of dopamine neurons in the primate ventral tegmental area and substantia nigra pars compacta. These dopamine neurons project densely to the striatum, and neuroimaging studies in human subjects found that the activity in the striatum also reflects reward prediction error. Therefore, dopamine neurons and their target neurons in the striatum might play a key role in updating and encoding the value functions during dynamic decision making.

Game Theory and Adaptive Social Decision Making

To make choices optimally, decision makers must be able to predict the outcomes of their actions correctly. For animals in a social context, the outcomes of their choices often depend on the behaviors of other animals, so they must be able to predict the choices of other animals. The mathematical problem of finding an optimal decision-making strategy in a socially interactive setting is addressed by the game theory introduced by von Neumann and Morgenstern.

In game theory, a game is characterized by a set of players, a set of available actions for each player, and a payoff function that assigns utility to each player according to the choices of all players. As in the expected utility theory, game theory assumes that players in a game seek to maximize their utility functions individually, and then provides normative predictions as to the choices that rational players should make. One such prediction is provided by Nash equilibrium, which is defined as a set of strategies for all players from which no players can deviate individually to increase their payoffs. Although game theory provides such solutions to many different types of games, many studies in behavioral economics have found that people often display systematic deviations from such theoretical predictions.

Matching Pennies Game

Barraclough and his colleagues investigated whether the choice behavior of monkeys during a simple zero-sum game, known as matching pennies (Figure 2(a)), follows the prediction of Nash equilibrium. In each trial, a monkey and a computer opponent each chose either the left-hand or the right-hand target, and the monkey was rewarded only when it chose the same target as the computer. The computer was programmed to simulate a utility-maximizing player capable of analyzing and exploiting the animal's behavior. In the matching pennies game illustrated in Figure 2(a), choosing one of the options exclusively is not a part of the Nash equilibrium. For example, if the monkey and the computer always choose the left-hand and right-hand target, respectively, their payoffs would be both zero. This is not a Nash equilibrium, since the monkey can increase its payoff by increasing the probability of choosing the right-hand target. The Nash equilibrium for this matching pennies game is for each player to choose the two targets with equal probabilities. Barraclough and his colleagues found that the overall probability that the animal would choose each of the two targets was quite close to this equilibrium prediction. However, there was still a bias for the animal to choose the same target chosen by the computer opponent in the previous trial, which was exploited by the computer to reduce the probability of reward for the animal.

		Computer: Inspect	Computer: Not inspect
Monkey	Work	(0.5, 2–*I*)	(0.5, 2)
	Shirk	(0, 1–*I*)	(1, 0)

Figure 2 Payoff matrix for matching pennies game (a), rock–paper–scissors game (b), and inspection game (c). Each game is played by a monkey and a computer opponent. For each payoff matrix, rows correspond to the alternative choices for the monkey, and columns correspond to the choices of the computer opponent. Two numbers inside the parentheses correspond to the payoffs or utilities for the monkey and the computer opponent, respectively. In the matching pennies game, the optimal strategy, known as Nash equilibrium, is for each player to choose the left-hand and right-hand targets randomly with equal probabilities. The equilibrium strategy in the rock–paper–scissors game is to choose each option with a 1/3 probability. In the inspection game, I indicates the cost of inspection ($0 < I < 1$), and the optimal strategy is for the computer opponent to inspect with the probability of 0.5 and for the monkey to shirk with the probability of I.

The fact that monkeys displayed small but systematic biases in their choice behavior during the matching pennies game might reflect a specific learning algorithm used by the animal to approximate the optimal decision-making strategy. Therefore, the choice behavior of monkeys during the matching pennies game was analyzed further with a reinforcement learning model. Such a model formalizes Thorndike's law of effect and generalizes the so-called win–stay–lose–switch strategy. In this model, the probability of choosing each target is determined by the logistic function of the difference between the value functions for the two targets. In addition, value functions are adjusted according to the outcome of the animal's choice in each trial, and the effect of the animal's choice in a given trial decays exponentially during the following trials. Accordingly, the value function of a target increases gradually if its choice is rewarded frequently. The animal's choice behavior during the matching pennies game was indeed consistent with the predictions from this simple reinforcement learning model.

During the matching pennies game, neurons in the dorsolateral prefrontal cortex display several different types of signals that might reflect the process of reinforcement learning. First, many neurons modulate their activity according to the animal's choice in the previous trial. In many decision-making problems, the outcome of a particular choice is often revealed after some delay. In such cases, it is necessary to maintain information about the action taken by the animal until its outcome is revealed, so that its value function can be adjusted appropriately. In reinforcement learning, such memory of a previous action is referred to as eligibility trace. Therefore, activity in the dorsolateral prefrontal cortex related to the animal's choice in the previous trial might provide the neural substrate of eligibility trace. Second, activity of neurons in the dorsolateral prefrontal cortex often reflects whether the animal was rewarded in the previous trial or not. This suggests that the dorsolateral prefrontal cortex may be involved in adjusting the value functions for the recently chosen actions, since the outcome of a given choice determines how its value function would be updated in reinforcement learning. Finally, some neurons in the dorsolateral prefrontal cortex displayed modulations in their activity according to the combination of the animal's choice in the previous trial and its outcome (Figure 3). Such signals can provide information about the choice of the computer opponent, and therefore can also contribute to the process of updating value functions, since during the matching pennies game, the choice of the opponent determines the animal's choice that would be rewarded.

Rock–Paper–Scissors Game: Reinforcement Learning versus Belief Learning

Although the choice behavior of monkeys during the matching pennies game was relatively well described by a simple reinforcement learning model, the simplicity of this game makes it difficult to test whether the animal might rely on an alternative learning algorithm. For example, in belief learning, the decision makers update their beliefs about the choices of other players, and choose the best action that maximizes the expected payoffs based on such beliefs. For the matching pennies game, reinforcement learning and belief learning models cannot be distinguished. To understand this, imagine that the animal selects the left-hand and right-hand target in two successive trials while the computer selects the right-hand targets in both trials. The animal would then be rewarded only in the second trial. In a reinforcement learning model, the value function for the left-hand target would decrease after the first trial and the value

Figure 3 Temporal changes in the spike rate of a single neuron in the dorsolateral prefrontal cortex of a monkey during a matching pennies game. The activity of this neuron was modulated by the animal's choice in the previous trial (a), its outcome (b), and the animal's choice in the current trial (c). In addition, this neuron increased its activity significantly when the animal chose the right-hand target after the same choice was not rewarded in the previous trial (d). Adapted from Barraclough DJ, Conroy ML, and Lee D (2004) Prefrontal cortex and decision making in a mixed-strategy game. *Nature Neuroscience* 7: 404–410.

function for the right-hand target would increase after the second trial. Accordingly, after two such trials, the animal would be more likely to choose the right-hand target. In a belief learning model, the animal would strengthen its belief that the computer opponent would choose the right-hand target, and therefore the value function for the right target would increase after each trial. As in reinforcement learning, this would also increase the probability that the animal would choose the right-hand target. These two scenarios would become indistinguishable if the value functions are related to the probability of choosing each action through a logistic function that determines the animal's choice as a function of the difference between the two value functions.

The difference between reinforcement learning and belief learning can be revealed if a player has to choose from more than two alternatives. In such cases, belief learning might be a more efficient way to improve the strategy of a decision maker compared to reinforcement learning. This can be illustrated using the example of a rock–paper–scissors game (**Figure 2(b)**). In reinforcement learning, if a player chooses rock and is defeated by the opponent who chooses paper, the value function for rock and the probability of choosing it would decrease, but the value functions for paper and scissors would not be affected. In belief learning, the player would strengthen his or her belief that the opponent would choose paper again, so the value function for scissors and the probability of choosing scissors would increase more than for paper. It should be noted that if the opponent plays according to the Nash equilibrium strategy, the average payoff to the other player would be fixed regardless of his or her strategy and regardless of the learning algorithm used to update the strategy. However, if the opponent has a bias toward a particular choice, then belief learning may lead more efficiently to the strategy that can exploit such a bias.

The experienced-weighted attraction (EWA) model proposed by Camerer and Ho incorporates the features of both reinforcement learning and belief learning model according to a weight parameter that specifies the relative contribution of each learning algorithm. They found that the EWA model was more consistent with the results obtained from experimental games in human subjects compared to either reinforcement learning or belief learning models. Consistent with these findings, the choice behavior of monkeys during a computerized version of a rock–paper–scissors was also better accounted for by a model that incorporated the features of both reinforcement learning and belief learning.

Inspection Game

When multiple decision makers interact in a dynamic environment, their payoff matrix and therefore the optimal decision-making strategies might change unpredictably. Dorris and Glimcher investigated the abilities of monkeys to adapt to such unpredictable changes in the payoff matrix during an inspection game. Similar to matching pennies game, each of the two players in this game has two alternatives. For the monkey, these two targets correspond to work and shirk, respectively (**Figure 2(c)**). If the animal chooses the 'work' target, it receives a fixed amount of reward. Otherwise, it receives a larger or smaller amount of reward, depending on whether the computer decides to inspect or not. The Nash equilibrium for the computer is to inspect with the probability of 0.5, whereas the optimal strategy for the monkey is to shirk with the probability equal to the inspection cost (I). Although the probability that the animal would choose each of the two targets roughly followed the

predictions of the Nash equilibrium, there was still a systematic discrepancy between the theoretical prediction and the animal's choice behavior. Specifically, the animal chose to shirk more often than the equilibrium prediction when the inspection cost for the computer opponent was small. It should be noted that during this inspection game, the animal was always rewarded by the same amount of reward for choosing to work, and therefore did not receive any information as to whether the computer opponent chose to inspect or not. Therefore, choosing to shirk might have additional advantage in that it provides some information about the behavior of the opponent, and this may explain why the animal chose to shirk more frequently than the Nash equilibrium solution, especially after an unpredictable change in the payoff matrix.

The lateral intraparietal area (LIP) is a region in the primate posterior parietal cortex closely connected with other oculomotor centers, such as the superior colliculus and the frontal eye field. Neurons in the LIP often modulate their activity according to the direction of eye movement during its preparation and execution, and might be actively involved in the process of decision making. For example, activity of LIP neurons is systematically related to the probability and magnitude of reward expected from certain eye movements. The possibility that the activity of LIP neurons reflects the subjective value of the expected outcome from an eye movement toward its receptive field was tested using the inspection game paradigm. Although the decision to shirk leads to a variable outcome depending on the choice of the opponent, the expected utilities for shirking and working must be equal at the Nash equilibrium. This prediction was tested by requiring an animal to indicate its choice to shirk by making an eye movement toward a visual target in the receptive field of an LIP neuron. Although the probability of making such eye movements varied according to the inspection cost and the corresponding Nash equilibrium, the activity of LIP neurons remained relatively constant. In addition, LIP activity was significantly correlated with the trial-by-trial variation in the utility of choosing the target in the neuron's receptive field. These results are consistent with the hypothesis that LIP neurons encode subjective utilities of eye movements.

Utility and Cost Functions in Motor Control

In combination with appropriately chosen utility functions, the principle of utility maximization can account for a wide range of choice behaviors in both humans and animals. Similarly, changes in the choice behavior during social interactions and other behavioral changes in a dynamic environment can be modeled with reinforcement learning algorithms. In order to produce the physical movement in the animal's body, however, the brain has to translate its chosen behavioral goal into a specific pattern of muscle activations.

Due to a large degree of redundancy in the motor system, there are practically an infinite number of muscle activation patterns that can accomplish more or less the same desired final configuration of the animal's body. For example, when a person or a monkey reaches for an object, either of the two hands can be used, and often a variety of grasp postures can be chosen. When monkeys are allowed to choose freely their hands to acquire a food item, they often display hand preferences. However, such hand preference is not complete, and the animals tend to switch their hands in successive trials. This indicates that utilities for reaching and grasping movements incorporate the relationship between successive movements. Similar to the cortical circuitry involved in the selection of a behavioral goal, the neural system responsible for motor decision making is also distributed. For example, neurons encoding information about the movement target and the hand chosen to acquire it are found in multiple cortical areas, including the dorsal premotor cortex, the dorsolateral prefrontal cortex, and the supplementary motor area.

Even the trajectories of simple movements, such as reaching or saccadic eye movement, have a large degree of freedom. Nevertheless, the trajectories of such movements tend to be highly stereotyped and typically bell shaped. This led to the assumption that specific movement trajectories are chosen as a result of optimization. For example, it has been proposed that the motor system chooses a particular trajectory to minimize the rate of change in acceleration (jerk) or torque. The function to be minimized during optimization, such as the total jerk, is referred to as the cost or loss function, and therefore can be considered as negative utility function. In general, the cost function computed from the error at the end of the movement does not make specific predictions about the movement trajectory, unless the effect of neural noise is considered. Trains of action potentials recorded from the neurons throughout the motor system, including the motor neurons in the spinal cord, display highly irregular patterns, and the amount of such neuronal noise tends to increase with the average activity. This is referred to as signal-dependent noise. The variability at the end point of a given movement, such as reaching, would increase if the hand is suddenly accelerated, requiring rapid muscle contraction and higher activity of motor neurons. In fact, the optimal trajectory that minimizes the variability in the end point in the presence of signal-dependent noise resembles

those with minimum jerk. Motor errors are encoded by climbing fibers in the cerebellum, and such signals can be used to reduce the positional error by modifying the corresponding movement trajectory.

GABA – The Inhibitory Neurotransmitter

γ-Aminobutyric acid (GABA) is the most abundant inhibitory neurotransmitter in the central nervous system (CNS). It was discovered in the CNS around 1950 by Eugene Roberts, but it was not until the 1960s that GABA was suggested to be an inhibitory neurotransmitter. GABA is also present in organs other than the brain. For example, it also is present in pancreatic β cells, where it appears to act as a signaling molecule between cells within the pancreatic islets. Moreover, the entities of the GABAergic neurotransmission (biosynthetic/metabolic enzymes, receptors, and transporters) are expressed in the reproductive organs (testes and ovaries), the adrenal gland, and the gastrointestinal tract. With regard to the reproductive system, GABA has an effect on release of estradiol and progesterone in the ovary and it also appears that GABA may modulate sperm function, perhaps *via* a stimulatory effect on testosterone production. In the adrenal gland, steroidogenesis is influenced by GABA in a paracrine or autocrine manner. This could modulate release of catecholamines from the adrenal glands. In the gastrointestinal tract, there is ample evidence to suggest a neurotransmitter or neuromodulatory role for GABA. Hence, GABAergic activity seems to modulate contractile responses *via* an action on acetylcholine release.

GABA Metabolism

GABA is synthesized from glutamate, catalyzed by the enzyme L-glutamate decarboxylase (EC 4.1.1.15; GAD). It has been suggested that during early postnatal development, GABA might be synthesized through an alternative pathway involving ornithine. Classically, GAD has been considered to be a marker for GABAergic neurons in the CNS. However, recent studies have indicated that GAD might be present in at least a subpopulation of excitatory neurons as well. This localization in excitatory neurons might reflect the possible role of GABA as a neurodifferentiative agent during early postnatal development in the CNS.

GABA is metabolized by GABA transaminase (EC 2.6.1.19; GABA-T) in the GABA shunt (Figure 1). In contrast to GAD, GABA-T, which is localized in the mitochondrial matrix, is an enzyme that is ubiquitously expressed in not only the brain but also other organs. GABA-T converts GABA to succinic semialdehyde, using α-ketoglutarate as the amino group acceptor forming glutamate. The enzyme requires pyridoxal phosphate (PLP) as a coenzyme, and hence, carboxyl trapping agents inhibit GABA-T. Succinic semialdehyde is subsequently oxidized to succinate, which enters the tricarboxylic acid (TCA) cycle (Figure 1). Large differences exist in the reported fluxes through the GABA shunt compared with TCA cycle activity. They range from 2% to 17%, with the highest value obtained from analysis of mouse brain metabolism.

GAD_{65} and GAD_{67}

GAD exists in two isoforms, known as GAD_{65} and GAD_{67}, according to their molecular masses (i.e., approximately 65 and 67 kDa), and they are encoded by two independent genes. GAD_{67} seems to be a cytosolic enzyme distributed throughout the GABAergic neurons in the cell body as well as in their processes. In contrast, GAD_{65} is predominantly found to be located in nerve terminals and it might be anchored in the membrane of the vesicles containing the neurotransmitter. The regulation of GAD is complex and has not been fully elucidated. PLP is the cofactor for GAD, and the association and dissociation of this cofactor play a major role in the short-term regulation of GAD. Fifty percent of GAD is present in the brain as the apoenzyme, thereby providing a large 'dormant' catalytic capacity, which may be readily recruited whenever necessary. GAD_{65} is the predominant contributor to this large pool of apoenzyme, whereas GAD_{67} primarily exists as a holoenzyme. The interconversion between apo- and holoGAD is regulated by physiological concentrations of adenosine triphosphate (ATP) and inorganic phosphate. It has been shown that soluble GAD (presumably GAD_{67}) is inhibited by protein kinase A-mediated protein phosphorylation, whereas membrane-associated GAD (presumably GAD_{65}) recently has been shown to be activated by ATP-mediated phosphorylation. These findings illustrate the pronounced complexity in the regulation of GABA synthesis.

The rationale for the existence of two enzymes, GAD_{65} and GAD_{67}, that are expressed by independently regulated genes and that are distinct with regard to regulation and localization is at present not understood. It has been speculated how this might be connected to the fact that GABA exists in at least two separate compartments, named the

cytoplasmic and the vesicular pools, which might have distinct functions. The neurotransmitter function from the vesicular pool seems obvious. However, the function of the metabolic pool is more uncertain. However, in addition to a possible modulatory role during neurotransmission, it may be of importance for the action of GABA as a neurodifferentiative agent during development. As further evidence in support for multiple pools of GABA and their functional significance, antiepileptic drugs acting through an interference with GABA metabolism have been found both *in vitro* and *in vivo* to affect distinct pools of GABA. Because GAD is dependent on PLP, carbonyl trapping agents inhibit GAD and act as anticonvulsants.

Glutamine as GABA Precursor

In GABAergic neurotransmission, a net flow of GABA from the neuronal to the astrocytic compartment occurs. This net flow needs to be compensated by a flow of a GABA precursor in the opposite direction due to the lack of a neuronal anaplerotic pathway. It has been convincingly demonstrated in different brain tissue preparations that glutamine, which is exclusively synthesized in astrocytes, can function as the precursor for the synthesis of GABA. Glutamine is to a large extent metabolized through the TCA cycle before conversion to glutamate and subsequently to GABA (Figure 2). This mitochondrial involvement in GABA biosynthesis might be an important regulatory point. The extent of TCA cycle metabolism before GABA synthesis from glutamine appears to be dependent on the pool – that is, the vesicular or metabolic pool from which GABA is released.

GABA Release

GABAergic neurons contain specialized vesicles equipped with a GABA transporter that is capable of concentrating GABA approximately 10- to 20- fold over that present in the cytoplasm. After depolarization of the neuronal plasma membrane, these vesicles may fuse with the membrane in a process involving a number of specific proteins (synaptin, neurexins, synaptotagmin, syntaxin, and synaptophysin) that are activated and reorganized on an elevation of the intracellular Ca^{2+} concentration brought about by opening a number of pharmacologically distinct voltage-gated Ca^{2+} channels. Ultimately, this leads to the release of the vesicular GABA, which spreads in the narrow synaptic cleft, allowing activation of a set of postsynaptic and presynaptic GABA receptors.

In addition to the vesicular or quantal release mechanism that leads to a spatially highly localized release, GABA may also be released by reversal of the plasma membrane GABA transporters, which are electrogenic and therefore sensitive to depolarization. When this mechanism is operating, GABA release will be spatially different from the vesicular release, which may have important functional consequences. Another important difference is that the transporter-mediated release of cytoplasmic GABA is not Ca^{2+} dependent.

GABA Receptors

Following its release from GABAergic nerve endings, GABA is bound to a variety of receptors (Table 1). These are separated in two major classes – that is, the ionotropic ($GABA_A$ and $GABA_C$) and the metabotropic ($GABA_B$) – in accordance with either formation of an ion channel (A and C) or association with G-proteins, which link receptor activation to either K^+ or Ca^{2+} channels or to adenylate cyclase.

Ionotropic Receptors

The $GABA_A$ and $GABA_C$ receptors form chloride channels, which, upon activation by GABA, open

[a]$GABA_A$ and $GABA_C$ receptors form Cl^- channels in pentameric homo (C) or heteromeric subunit complexes. The Greek letters denote subunit families, each of which shows about 70% homology in the amino acid sequence. The corresponding homology across the families is about 30–40%. $GABA_B$ receptors are G-protein-coupled 7-TM receptors and consist of heterodimeric complexes of B1a/B2 or B1b/B2.

and allow Cl^- to be fluxed into the cell, resulting in a hyperpolarization. In this context, it may be mentioned that owing to differences in the Cl^- distribution intracellularly versus extracellularly, in neurons during early developmental stages compared with mature neurons, opposite Cl^- fluxes occur in immature neurons. Therefore, depolarizing effects of GABA are often observed in the embryonic nervous system, a property of GABAergic neurotransmission that very likely is important for the neurotropic action of GABA during early development.

The distinction between $GABA_A$ and $GABA_C$ receptors rests essentially only on pharmacological grounds (Table 2). $GABA_C$ receptors are characterized by an activation by *cis*-4-aminobut-2-enoate (CACA), whereas classic $GABA_A$ receptor agonists such as isoguvacine have no effect. Because the $GABA_C$ receptor is a homomeric complex of ρ-subunits sharing a considerable amino acid sequence homology with the remaining $GABA_A$ receptor subunits, it may be concluded that this receptor subclass should be termed a pharmacologically distinct $GABA_A$ receptor.

In addition to the GABA-binding site normally thought to be located at the interphase between the α and β subunits, which are found in essentially all $GABA_A$ receptors, the receptor complex is endowed with a multitude of pharmacologically highly important recognition sites for drugs such as benzodiazepines (γ subunit), barbiturates, ethanol, steroids, and picrotoxinin. This is the basis for $GABA_A$ receptors being a highly important target for drugs acting as tranquilizers, anesthetics, anticonvulsants, and convulsants.

The ionotropic GABA receptors are regulated in terms of activity in numerous ways. Essentially all subunits contain phosphorylation sites for protein kinases A, C, and G, as well as calmodulin kinase and tyrosine kinase, leading to regulation of activity of the ion channel. Another important regulation is associated with desensitization, the characteristics of which exhibit subunit specificity. Also, channel opening kinetics are characterized by subunit diversity. Recently, a GABA receptor anchoring protein has been identified and cloned. This protein plays an important role in regulating trafficking, targeting, and assembling $GABA_A$ receptors in the plasma membrane. Attention has also been focused on the subset of $GABA_A$ receptors containing $\alpha4$, $\alpha6$, and δ subunits and which are mainly located extrasynaptically. It appears that this subclass of receptors has interesting pharmacological properties. The classical $GABA_A$ specific agonist 4,5,6,7-tetrahydroisoxazole[5,4-*c*] pyridin-3-ol (THIP) has been shown to act particularly effectively on these receptors, and the mechanism of action of some anticonvulsants acting via inhibition of GABA transporters (see later) also appears to involve extrasynaptic GABA receptors.

Metabotropic Receptors

The metabotropic GABA receptors, originally termed $GABA_B$ because they are pharmacologically distinct from $GABA_A$ (being activated by baclofen and insensitive to the $GABA_A$ receptor antagonist bicuculline), belong to the G-protein-coupled seven-transmembrane (7TM) receptor family (Table 1). Recent cloning strategies have resulted in the identification of two subtypes, $GABA_{B1}$, and $GABA_{B2}$, which have to form a heterodimeric complex in order to be functionally active. As mentioned earlier, baclofen is the prototype agonist, whereas 2-OH-saclofen is the most commonly used antagonist (Table 2). $GABA_B$ receptors expressed at postsynaptic sites normally lead to hyperpolarization if activated due to coupling to K^+ channels that increase the membrane K^+ conductance. Presynaptically, $GABA_B$ receptors are coupled to Ca^{2+} channels, and activation leads to a decrease in Ca^{2+} conductance, resulting in inhibition of transmitter release. These basic properties of $GABA_B$ receptors lie behind their therapeutic relevance because agonists produce muscle relaxation and antagonists act as antiepileptics, particularly in absence seizures.

GABA Inactivation

GABA is inactivated by uptake either into the presynaptic GABAergic nerve ending, allowing recycling of the neurotransmitter, or into surrounding astrocytes, leading to degradation via transamination (GABA-T) and oxidation to succinate. So far, three GABA transporters and a betaine transporter also

capable of GABA transport have been cloned. In the mouse, these transporters are termed GAT1–GAT4, where GAT2 is synonymous with the betaine transporter. Although GAT1 is preferentially located on neurons but also to some extent on astroglia, the other transporters and particularly GAT4 are mainly nonneuronal. These differences in expression among neurons and astroglial cells are of interest in relation to pharmacological differences among the cloned transporters and in regard to the possibility to use this as a basis to explain some of the pharmacological differences noted between neuronal and astroglial GABA uptake. Close inspection of the pharmacological properties of these GABA transport entities reveals, however, that it is not possible to explain the distinct differences between neuronal and astroglial GABA uptake on the basis of known pharmacological properties of the cloned transporters (Table 3). This has led to the proposal that GABA transporters may exhibit cooperativity when expressed heterologously.

GABA transporters may be regulated by phosphorylation – for example, through protein kinases A and C – and, moreover, membrane trafficking and anchoring appear to be activity dependent. Furthermore, neuronally produced proteins have been shown to be of importance for the regulation of expression of GABA transporters in astrocytes. Hence, the synaptic machinery for GABA recognition and inactivation appears to be highly plastic and regulated in an activity-dependent manner. The development of tiagabine, which specifically inhibits the GAT1 transporter (Table 3), as an antiepileptic drug has provided proof of principle that GABA transporters constitute important drug targets. This notion has been extended to include other than GAT1 transporters by the demonstration that GAT2 (the betaine transporter) inhibitors may have novel anticonvulsant properties involving a mechanism implicating activation of extrasynaptic $GABA_A$ receptors (see earlier).

Functional Implications of Inhibition

Immunohistochemical visualization of GABAergic neurotransmission through the GABA-synthesizing enzyme GAD, the neurotransmitter (GABA) itself, and its receptors has clearly and indisputably shown GABAergic transmission to be highly ubiquitous in

the CNS. This confirms the original notion by Eugene Roberts that inhibition is the governing principle of function in the brain. This means that disinhibition leading to excitation may be as important as, if not more important than, excitation itself. Therefore, it is not surprising that aberrations in GABAergic function at the level of enzyme defects, receptor dysfunction, or transporter failure are involved in a vast number of neurologic and psychiatric disorders, including epilepsy, anxiety, insomnia, Alzheimer's disease, and schizophrenia, just mentioning a few examples. Therefore, the different entities of the GABA system have been among the major targets for development of drugs that are therapeutically active against these diseases. Among these drugs, the benzodiazepines may constitute one of the most important drug discoveries of modern pharmacology.

Gap Junctions, Connexins, and Intercellular Communication in the Nervous System

Gap junctions are intercellular channels which directly connect the cytoplasm between neighboring cells. As such, they form an extensive pathway of intercellular communication in the nervous system. The structural unit of the gap junction is the 'connexon,' a proteinaceous cylinder with a hydrophilic channel, which spans the plasma membranes of closely apposed cells to align end-to-end, forming intercellular channels which provide for the exchange of small molecules (less than 1200 Da). This channel underlies the phenomenon of gap junctional intercellular communication (GJC). The gap junction proteins, called connexins (Cx), are encoded by a multigene family consisting of at least 20 members in rodents (21 in humans), many of which are found in the nervous system, where they are involved in coupling various kinds of cells. In addition, other gap junctional candidates which should also be considered are the pannexins and the mammalian counterpart of the invertebrate gap junction proteins called innexins. The subset and the expression of connexins vary depending on the type of cell and the stage of development. Neuronal gap junctions are involved in electrical coupling, and may play a critical role in neural development. Astrocytes are generally highly coupled by gap junctions, leading to an extensive cellular network which is critical to maintaining ionic and metabolic homeostasis. The myelinating cells of the nervous system, that is, the oligodendrocytes (in the central nervous system (CNS)) and Schwann cells (in the peripheral nervous system (PNS)), also express a number of connexins. In Schwann cells, these are present between the layers of myelin in order to allow for efficient intracellular metabolic coupling. Of increasing importance is the unraveling of the function of gap junctions and connexins in the neural cell network, involving neurons, astrocytes, oligodendrocytes, and microglia.

The role of connexins, gap junctions, and hemichannels in the pathology of diseases in the nervous system is coming to light through a combination of cellular and animal models and the ongoing discovery of human genetic disorders associated with connexin mutations. Since connexins associate in both homomeric or heteromeric forms, and can form homotypic or heterotypic cellular associations, mutations in individual connexin genes can impact the entire intercellular communication network within a tissue, organ, or organism. In addition, modulation of connexin gene expression by growth factors or cytokines, and alterations in phosphorylation can profoundly affect gap junction channel gating, and thus function. In this review, we address the possible roles of gap junctions and connexins in neural development, as well as in neurological disorders such as stroke and epilepsy in light of insights gained from genetically engineered mice and characterized human genetic mutations.

Connexins and Neural Development – Building the Gap

During development, there is extensive regulation of the spatial and temporal expression of gap junctions. This regulation is being implicated in the control of differentiation and growth. In general, there is high intercellular coupling during development, with a loss or attenuation of coupling during terminal differentiation. GJC and cellular expression of connexins have been partially characterized in the developing nervous system. The functional significance of connexin expression in astrocytes, oligodendrocytes, and neurons is only beginning to be resolved. The changes in the expression of gap junction genes during postnatal brain development coincides with various major differentiative events, including cellular proliferation and migration, neurite outgrowth and synaptogenesis, myelination, neurotransmitter differentiation, and neuronal death. For the most part, it remains to be determined if gap junctions play any direct role in such developmental events.

Electrotonic coupling between mammalian neurons has been shown in many areas of the CNS, and has been implicated in neuronal synchronization. For example, during neocortical development, there is a high degree of intercellular coupling between neurons. Studies in the rat indicate that neuroblasts are coupled with approximately 30–60 others in columns within the ventricular zone of the developing cerebral cortex. The zone is comprised of mitotically active epithelial cells lining the ventricles. These cells have been shown to express Cx43 and Cx26, and the

coupling appears to involve both neural precursors and radial glia. This extensive coupling is maintained throughout all neocortical layers during the first 2 weeks after birth, decreasing significantly thereafter. The specific connexins responsible for this transient neuronal coupling have not been definitively determined. Although Cx43 has been reported in neurons of the cortical plate, with some Cx32 appearing as neurons mature, the pattern of expression of Cx26 and Cx36 in the developing brain is consistent with the transient GJC observed in the neocortex.

It has been suggested that this early electrotonic coupling via gap junctions may function in determining the phenotype and positional fate of neurons in the cortex, providing a mechanism for laminar organization. Thus, GJC may establish cortical domains in the developing neocortex that underlie the adult pattern of functional cytoarchitecture. In addition, the establishment of an early system of electrotonic synapses may be the precursor of the more differentiated chemical synapses which follow. When embryonal carcinoma cells differentiate into neurons in response to retinoic acid, the expression of Cx43, and the level of GJC, progressively disappear, similar to what is seen *in vivo*. Interestingly, blocking of GJC disrupts retinoic acid-induced neuronal differentiation in this same system. It therefore appears that the temporal pattern of connexin expression and GJC during neuronal differentiation *in vitro* is critical.

Gap junctions have also been implicated in the migration of neurons during development. A null mutation of Cx43 perturbs the migration of neurons during neocortical development. This suggests that GJC or connexin expression defects may underlie some of the migrational disorders in nervous system development, and thus may also contribute to epilepsy (see below).

Connexin Mutations – Breaking the Gap

Following the identification and cloning of the connexin genes, functional studies were rapidly pursued utilizing knockout and transgenic technologies. Coincidental with the characterization of these genetically engineered mice, mutations of some of the human connexin genes were identified. This allowed for a phenotypic comparison between mice and men. These are summarized in Tables 1 and 2.

Connexin Knockouts and Transgenics

While targeted gene knockout through homologous recombination to eliminate expression of connexin genes in transgenic mice has been pursued since 1995, this strategy has provided little insight into the role of GJC in neural development. The homozygous Cx43 null mutation in mice is lethal at birth. Thus, any neural phenotype of these knockout mice is confounded by cardiac malformation and neonatal death. Knockout of another neuronal candidate, Cx26, is embryo lethal, and thus additional strategies must be followed to investigate its function in neuronal development. Most recently, Cx36 knockout mice have been shown to be viable, and although visual deficits are apparent, no major CNS phenotype has been reported. These results highlight several problems inherent in this genetic approach.

1. In the brain, except for Cx36 which is neuronal, most connexins are expressed in several cell types.
2. All CNS cell types express multiple connexins, so possible compensation for loss of function of one connexin by another may occur.
3. Many connexins are expressed during development, so embryonic lethal phenotypes are not uncommon in knockout studies.
4. If the knockout is not lethal, we need to interpret the phenotype in light of possible disruption of developmental processes which rely on specific connexins. To circumvent many of these problems, more recent approaches have employed conditional knockout strategies.

Table 1 Some observed nervous system abnormalities in connexin knockout mice

Knockout mouse	*Abnormalities*
Cx26	Embryonal lethal
($Cx26^{fl/fl}$, Otog-cre)	Hearing impairment
Cx29	Hearing impairment
	Demyelination
Cx30	Severe hearing impairment
	Reduced exploratory activity
Cx32	Demyelination in PNS
	Hyperexcitability in CNS
	Enhanced neuronal injury in ischemia
Cx36	Visual deficit
	Synchronization defect in hippocampus
	Disturbed synchronous inhibitory activity
	Disrupted gamma frequency oscillations in cortex
Cx43	Neonatal lethal
	Subtle neural changes in embryo
	Neural crest migration defect
	Disturbance of neural migration in embryonic neocortex
(Cx43+/−)	Enhanced neuronal injury in ischemia
($Cx43^{fl/fl}$,GFAP-cre)	Increased spreading depression in hippocampus
	Enhanced neuronal injury in ischemia
Cx47	Vacuolation in nerve fibers
(Cx47/32 double)	Severe demyelination in CNS

Table 2 Human connexin mutations

Gene/protein	*Abnormalities*
GJB2/Cx26	Dominant deafness; skin disorders
GJB6/Cx30	Dominant deafness; skin disorders
GJB4/Cx30.3	Dominant deafness; skin disorders
GJB3/Cx31	Dominant deafness; skin disorder
GJB1/Cx32	CMTX demyelinating disorder; deafness
GJA9/Cx36	Juvenile myoclonic epilepsy
GJA1/Cx43	Oculodentodigital dysplasia; deafness
GJA3/Cx46	Cataracts
GJA8/Cx50	Cataracts

Connexin Mutations and Genetic Disorders

With the identification of connexin genes, several genetic disorders have been linked to specific mutations. While some of these result in a nervous system phenotype, others manifest in diverse systems. Several of these are briefly summarized here.

Cx32 mutation and CMTX The first human genetic disorder attributed to a connexin mutation was X-linked Charcot-Marie-Tooth disease (CMTX), a dominant demyelinating peripheral neuropathy. Cx32 is expressed in the Schwann cells that myelinate peripheral nerves. To date, over 270 mutations have been identified in Cx32, with most of these being point mutations that alter connexin protein trafficking and gating properties. Interestingly, when Cx32 knockout mice were generated, they also exhibited a demyelinating peripheral nerve phenotype, and in addition display neuronal hyperexcitability in the CNS. Furthermore, mice with a double knockout of Cx32 and Cx47 die by postnatal week 6 from profound abnormalities in CNS myelin indicating that these two connexins are critical for normal central myelination.

Cx43 mutation and ODDD Oculodentodigital dysplasia (ODDD) is a congenital autosomal dominant disorder with face, eye, limb, and tooth abnormalities associated with mutation of Cx43. There are approximately 30 Cx43 mutations that have been identified in ODDD. On the one hand, the broad spectrum of systems involved is not surprising given the extensive expression of Cx43 in the body. On the other hand, this being the case, it is surprising that the phenotypes are not more severe.

Connexins mutated in deafness Four different connexin genes have been found with mutations associated with deafness (i.e., nonsyndromic sensorineural hearing loss) – Cx26, Cx30, Cx30.3, and Cx31. For Cx26 alone, over 100 mutations have been identified which lead to deafness, with some of these also linked to skin disorders (see below). These connexins are expressed in the cochlea and appear to be critical for potassium buffering and recycling. In mice, targeted ablation or dominant negative mutation of Cx26 in the Organ of Corti causes degeneration of the sensory hairs cells resulting in deafness.

Connexins mutated in skin disorders Interestingly, the same connexin genes mutated in deafness are also associated with hyperproliferative skin disorders (i.e., erythrokeratodermia). At least nine different connexin genes are co-expressed in the epidermis and there is evidence indicating that they play a critical role in regulating keratinocyte growth and differentiation. The loss of connexins and GJC has long been correlated with disruption in cell growth control and cancer (see below).

Connexins mutated in cataracts In the lens three connexins are expressed: Cx43, Cx46, and Cx50. Point mutations in these genes have been identified in patients with inherited zonular pulverulent cataracts. In the mouse, Cx46 knockout is characterized by severe cataracts without effects on lens development and growth. In contrast, Cx43/Cx50 double knockout exhibited normal lens demonstrating that these two connexins are not required for lens development.

Connexins and Neuroprotection – Minding the Gap

Given the extent of GJC among astrocytes in the CNS and the proposed role of these glial cells in spatial buffering of potassium and glutamate, a protective role of gap junctions has been proposed. In contrast, this extensive network of intercellular communication has been implicated in the propagation of cellular injury at least between astrocytes. These contrasting opinions are likely based, in part, on experimental brain ischemia models (see Table 3). The use of these models is based on the clinical impact of such injuries. Cerebrovascular diseases rank as the third leading cause of death in the United States and the fourth in Canada, most commonly manifesting as ischemic brain stroke.

Several lines of evidence support a neuroprotective role of gap junctions. (1) Blocking astrocytic gap junctions enhances neuronal vulnerability either to glutamate cytotoxicity or metabolic stress in neuron/glial co-cultures and under experimental ischemia using oxygen and glucose depletion in hippocampal slice cultures. (2) *In vivo*, heterozygote Cx43 knockout mice showed a significantly increased stroke volume compared to wild-type mice following middle cerebral artery occlusion (MCAO), accompanied by

Table 3 Connexins, gap junctions, and neuroprotection

Injury	*Cx*	*Main observation*
Focal ischemia		Octanol reduces infarct volume
Metabolic stress in glial cultures	Cx43	GJC amplifies cell injury
Focal brain ischemia		Halothane reduces injury
Global cerebral ischemia		Octanol decreases neuronal death
Hypoxia-hypoglycemia to organotypic slices	Cx32, Cx26, Cx43	Reduction of GJC decreases neuronal vulnerability
Traumatic impact injury to organotypic slices	Cx32, Cx26, Cx43	Reduction (enhancement) of GJC decreases (increases) neuronal vulnerability
Oxygen glucose deprivation		Increased GJC and apoptosis which was reduced by blockers
Excitotoxic injury to organotypic and dissociated cultures		Blocking GJC exacerbates injury
Focal brain ischemia	Cx43	Cx43 heterozygotes present larger infarct volume
Excitotoxicity to dissociated cultures		Blockade of GJC increased cell death
Global brain ischemia	Cx32	Cx32 knockouts show enhanced neuronal vulnerability
Focal brain ischemia	GFAP-Cre/Cx43$^{fl/fl}$	Cx43 deletion resulted in increased infarct volume
	GFAP-Cre/Cx43$^{fl/fl}$	Increased hippocampal spreading depression

enhanced apoptosis. (3) More recent use of targeted deletion of connexins, specifically in astrocytes, provides further evidence that astrocytic gap junctions play a neuroprotective role in ischemic insults. (4) Cx32 knockout mice have been reported to exhibit an enhanced vulnerability of hippocampal neurons against global brain ischemia compared to wild-type mice, suggesting that gap junctions of hippocampal interneurons play a neuroprotective role in ischemic insults.

On the other hand, there is evidence that gap junctions enhance neuronal injury. (1) Neuronal death caused by oxygen and glucose depletion was decreased when Cx43 was blocked by specific antisense oligodeoxynucleotides in hippocampal slice cultures. (2) Similarly, the stroke volume following MCAO in the rat model was reduced by blocking gap junctions using octanol. (3) It has been suggested that the spreading depression caused by ischemic insult propagates via astrocytic gap junctions which remain open during the ischemic condition, resulting in the expansion of the stroke volume.

The role of astrocytic connexins could also be mediated by hemichannel opening. Recently, it has been reported that astrocytic hemichannels which are closed under normal conditions remained open under experimental ischemia induced by glucose and oxygen depletion. It is possible that open hemichannels allow for the release of glutamate causing loss of membrane potential, or hemichannels may contribute to the distribution of antiapoptotic factors in the lesion area.

A number of factors may contribute to the above apparent contradictions. (1) Studies vary considerably with regard to the system employed, including the ischemia model and the gap junction blockers used. (2) In ischemic injury, there are critical stages with specific time parameters. Thus, GJC may be beneficial at one point in the injury cascade but deleterious at another point. (3) The regulation of connexin expression can be mediated by various types of cells other than neurons and astrocytes following ischemic stress. For example, expression of connexins can be affected by macrophages and microglia.

Connexins and Epilepsy – Wiring the Gap

Epilepsy affects about 1% of the world's population and presents a greater burden of disease than stroke, in part because it can be a lifetime disease. About 25% of epileptics have seizures that do not respond to available pharmacotherapy. Recently, gap junctions have become an attractive target for the development of novel therapeutics, although at present there are no available clinically used drugs which knowingly affect GJC. Gap junctions are logical targets for anticonvulsants since they facilitate neuronal synchronization, a hallmark of epilepsy.

Blocking GJC potently depresses seizure activity in many diverse *in vitro* and *in vivo* animal models. *In vitro* studies include the use of low magnesium, 4-aminopyridine, bicuculline, kainate, and repeated tetanizations. *In vivo* studies showed efficacy of gap junctional blockade in animals made epileptic by focal cortical application of 4-aminopyridine, atypical absence seizures induced by the cholesterol synthesis inhibitor AY9944, and in a genetic model of absence epilepsy (GAERS rats). The problem with these studies is that all gap junction blocking agents used to date are nonspecific and have other

effects not related to gap junctions, including effects on neuronal excitability. Hence, epileptogenesis in genetically modified preparations is the obvious strategy, but very little work in this regard is published. The next question is whether connexin expression and function are altered in seizure models. There are reports of increased GJC in seizure models, using fluorescent recovery after photobleaching, which does not differentiate between glial and neuronal GJC. The gold standard for measuring GJC between cells is dual electrophysiological recordings wherein one measures the passage of electrical current from one cell to the other, an approach not yet published in seizure models. As for gap junctional protein expression, there are several conflicting reports showing both up- and downregulation of connexins (usually mRNA measures) in seizure models. The cellular locations and functionality of these epilepsy-related gap junctional proteins are unclear. Furthermore, there are no published reports concerning epilepsy, involving the recently discovered gap junctional proteins in the mammalian CNS, called pannexins, which localize primarily to neurons. Finally, connexon hemichannels control neuronal excitability and can release metabolites (e.g., ATP) and glutamate, but their role in epileptogenesis is not yet studied.

We tend to assume that neuronal gap junctions are the most important for epileptogenesis and anticonvulsant action. However, gap junctions are far more prevalent in glia, which are more abundant than neurons and are now being recognized as playing a key role in neuronal function and in epileptogenesis. Furthermore, when the various gap junctional blockers are administered, one does not know whether it is a neuronal and/or a glial action that is the basis of their very powerful anticonvulsant effects. Glia form a cellular network coupled by gap junctions through which ions such as calcium and potassium flow. They are considered to play a major role in spatial buffering of these ions, both of which have profound effects on neuronal excitability and synaptic transmission. For example, blocked glial gap junctions could focally raise extracellular potassium which could enhance epileptogenesis at lower concentrations and diminish seizures at higher concentrations. The role of glial gap junctions in epilepsy is surely critical, but as yet remains poorly understood.

Studies of brain gap junctions in humans and their role in seizures are sparse indeed. There are conflicting reports of increases and decreases of connexins (mainly mRNA and from glia) in tissue removed from epileptic or brain tumor patients. Furthermore, the expression of proteins does not tell us about their function. A recent report demonstrated an association of the connexin36 gene with juvenile myoclonic epilepsy, suggesting that mutation of this gene is related to the pathogenesis of this common type of human epilepsy. Further work integrating animal studies, genetic studies, and the development of novel pharmacotherapeutics is required so that we can better understand clearly the powerful role that GJC plays in epilepsy, and thereby develop better treatments.

Connexins and Brain Tumors – Enhancing the Gap

Glioma is the most common brain tumor. The severity of gliomas is divided into four categories, from most malignant tumor to benign tumor. In general, glioma is a space occupying mass in the brain and causes high intracranial pressure, vessel occlusion, and brain edema. In some preclinical and clinical studies, higher-grade gliomas express lower levels of Cx43.

Gap junctions have long been implicated in the control of cell proliferation and suppression of tumor progression. Downregulation of connexins, gap junctions, and GJC has been observed in a variety of tumor cell lines and cancer tissues. The expression of connexins and the presence of gap junction channels can be readily altered by exogenous factors. In the context of carcinogenesis, many tumor-promoting agents have the ability to downregulate connexin expression and GJC, while many antineoplastic agents are capable of reducing tumor cell growth in association with enhanced connexin expression and GJC.

The most direct mechanism to increase connexin protein resides at the level of gene expression, which has been shown to be increased by numerous endogenous factors, including growth factors. The effect of gap junction proteins on proliferation has been more directly studied by analyzing both the inhibition and the forced expression of connexins. The decrease in connexin expression and loss of gap junctions in many cases correlates with an increase in growth rate *in vitro* and tumor formation *in vivo*. In glioma studies, both Cx43 and Cx30, the main astrocytic connexins, act as tumor suppressors. Many transformed cells transfected with connexin cDNAs exhibit suppression of growth and/or tumorigenicity. However, some other connexins fail to exhibit this growth suppressive phenotype. Reasons for selectivity remain elusive, but may depend on connexin-interacting proteins and associated signaling pathways.

Upregulated GJC reduces the *in vitro* proliferation and *in vivo* tumor formation of a number of cancer cells, including glioma cells. On the other hand, gap

junctions appear to facilitate glioma cell aggregation and invasion. Astrocytes co-cultured with C6 glioma cells overexpressing Cx43 underwent phenotypic transformation, suggesting that tumor cells may affect phenotypical alteration of surrounding tissue through gap junctions.

Gene transduction is a potential strategy for glioma treatment. Gap junctions between glioma cells may play a critical role in the mechanism of this therapy. Glioma cells infected with the herpes simplex virus thymidine kinase gene can be killed upon exposure to ganciclovir. Neighboring glioma cells that are coupled by gap junctions to the targeted cell subsequently die due to a 'bystander effect.' The lethal bystander effect can be enhanced when the glioma cells are forced to express Cx43.

Recently, several reports have shown that Cx43 plays a role in suppressing tumor growth independent of gap junction formation. Many intracellular proteins have been identified to interact with the connexins, including Cx43, providing a context for signaling events which may influence cell growth without the formation of GJC.

Conclusions

In a simple sense, gap junctions can be viewed as forming an intercellular communication pathway that links cells together, allowing them to share a pool of small molecules and ions. However, it is clear that there are several levels of complexity associated with the regulation of the connexin genes and proteins (i.e., transcription, translation, posttranslational modifications, oligomerization, intracellular trafficking, and turnover), the gating of gap junction channels, the selectivity of GJC, and the specificity of cell types in which they are expressed. This is particularly evident in the nervous system, where these channels play an integral role in the functions of neurons and glial cells. The impact of gap junctions in normal brain function is realized when one considers the consequences of perturbed connexin expression and gap junction formation.

Gap Junction Communication

For a long time, it has been well established that gap junctions provide a direct pathway for cell-to-cell communication. This mode of intercellular communication is widely present in all vertebrate species and also in most tissues and organs including the central nervous system (CNS). Compared to other types of cell interaction, gap junctional communication (GJC) mediates direct cytoplasmic exchanges from one cell to one or several neighbors. These exchanges are characterized by a weak ionic selectivity (electrical coupling) and a permeability for small molecules up to 1.8 kDa (metabolic or biochemical coupling). Such properties indicate that intercellular communication through gap junctions is likely relevant for excitable cells as neurons where they constitute the morphological substrate of electrical synapses. However, GJC also plays an important role in nonexcitable cells such as glial cells since they are permeable to signaling molecules.

Connexins (Cxs) are the molecular constituents of gap junction plaques consisting of closely packed hemichannels formed by a hexameric ring of Cxs which align head-to-head between neighboring cells to form functional and regulated intercellular channels. Invertebrates have a different, but functionally equivalent, family of proteins making up gap junctions, the innexins. Moreover, another gene family with functional characteristics similar to the Cxs and innexins has been discovered and named the pannexins, at least two of which are expressed in the mammalian CNS, whereas their function is not well defined. Interestingly, evidence is accumulating that Cxs interact by their cytoplasmic domains with other proteins that may be important for different aspects of their biology. These Cx-interacting partners, which are signaling and/or scaffolding proteins, have been proposed to be components of a dynamic multiprotein complex involved in the intracellular transport of Cxs, hemichannel assembly, full channel formation, junctional plaque assembly and stability, and regulation of channel permeability.

In addition to the well-known intercellular function of full gap junction channels, it has been reported that Cx channels can also operate as hemichannels, allowing exchanges of ions and small molecules between the cytoplasm and the extracellular space. Thus, in addition to providing a direct cell-to-cell pathway, Cxs are also involved in extracellular pathways mediating autocrine and paracrine processes.

Brain Connexins: Where and When

Between Neurons

Although coupling persists in many brain regions in the adult, during development there is a progressive decrease in Cx expression and GJC in CNS neurons. The correlation between changes in Cx expression and neuronal differentiation suggests that early GJC permits signaling molecules to diffuse between neurons and contributes to their differentiation. Eight different Cxs have been detected in defined neuronal cell populations (Cx26, Cx32, Cx36, Cx37, Cx40, Cx43, Cx45, and Cx47), mainly in the hypothalamus, striatum, inferior olive, hippocampus, olfactory bulb, retina, cerebral cortex, and cerebellum. Interestingly, in the CNS Cx36 represents the first Cx isoform expressed exclusively in neurons and exhibits typical functional properties compared to other Cxs. In the hippocampus of the adult rat, this Cx predominates and is mainly expressed in interneurons.

Between Glial Cells

In the CNS, glia represents the major population of cells coupled through gap junctions, and their connections establish compartments of communicating cells. This expression persists throughout adulthood, with qualitative and quantitative differences between glial classes: (1) each glial cell type expresses a set of specific Cxs, none being specific for glia; (2) the strength of coupling and the level of connexin expression depend on the glial cell type; and (3) not all classes of glial cells are coupled together, which contradicts the initial concept of a glial syncitium. Indeed, astrocytes are organized as a network composed of only subpopulations of glia that are under the control of biological signals, including neurotransmitters.

This network organization can be studied in acute brain slices after injecting low-molecular-weight tracers into a single astrocyte that results in the staining of large groups of 10–100 coupled cells. Such large coupling areas have also been described *in vivo* in the cortex, the hippocampus, and the cerebellum (Bergmann glial cells). Besides minor detection of Cx26, Cx40, and Cx45, two main junctional proteins are expressed in astrocytes: Cx43, which is widely present at both adult and embryonic stages, and Cx30, which is detected in mature gray matter astrocytes. In addition, the relative levels of Cx43 and

Cx30 expression vary according to the developmental stage and region studied.

Oligodendrocytes, the myelin-forming cells of the CNS, are endowed with gap junctions found in almost all areas of their plasma membranes; however, they are not detected between successive layers of myelin. Expression of Cx32 and Cx47 has been shown in oligodendrocytes studied *in vitro* as well as *in situ*, and indirect evidence suggests that Cx29 is also expressed in oligodendrocytes.

Finally, the presence of Cx43 has been described in microglial cells. In normal tissues, <5% of microglial cells in adult rat cerebral cortex are Cx43 immunoreactive, and in culture only low levels of Cx43 have been detected. However, *in vivo* after a stab wound or in culture after treatment with cytokines, Cx43 is observed at the interfaces between activated microglia cells that become dye coupled.

The Language of Connexins

The molecular complexity of Cx channels bears important consequences on their function. Cxs speak an articulate language and have evolved diverse forms of intercellular communication among cells. First, channels composed of different Cxs are endowed with distinct biophysical and regulatory properties. Although Cxs do not form ion-selective channels in the classical sense, they exhibit a certain degree of selectivity with a preference for cations versus anions. Because gap junctions are permeable to cyclic nucleotides and inositol 1,4,5-trisphosphate (IP3), which are negatively charged at normal intracellular pH, ionic selectivity may allow the discrimination and modulation of the kinetics of intercellular propagation of known second messengers. Size selectivity is also a Cx-specific feature. It had long been thought that connexins were permeable to molecules up to 1800 Da. The use of different fluorescent tracers demonstrated that some connexins can discriminate between molecules of 400 and 600 Da, thus favoring the passage of a distinct set of signals. A second form of intercellular language is based on compatibility – that is, the ability of Cxs to functionally interact with different family members. On the basis of Cx topology relative to the plasma membrane, the docking of two facing hemichannels implicates the recognition between their two extracellular domains. Experimental data have shown that the ability to establish direct communication between adjacent cells is dependent, at least in part, on the ability of Cxs to discriminate between different partners. A consequence of the restricted ability of Cxs for heterotypic interactions is that expression of different Cxs in a group of cells may provide a powerful means to limit or segregate intercellular communication. Finally, the functional status of intercellular channels can be regulated by both covalent and noncovalent modifications of Cxs which affect the channel structure, a third form of intercellular language called 'gating.' Despite the overall degree of homology, Cxs exhibit in their two major cytoplasmic domains stretches of unique sequences that probably adapt channel properties to the specific tissue requirements. The behavior of Cx channels has been studied extensively in various *in vitro* expression systems, and these biophysical studies have established that individual Cxs are endowed with unique gating properties, including voltage dependency, pH sensitivity, subconductance states, and residual conductance.

What Goes through Connexin Full and Hemichannels?

Intercellular Communication through Gap Junctions in Neurons and Glia

The initial evidence of gap junction-mediated exchanges of ions was obtained by electrophysiological recordings of electrical coupling between neurons or between glial cells. These pioneering works were then confirmed by a number of studies that established the contribution of gap junctions to electrical coupling between CNS cells and their regulation by several factors, including neurotransmitters, voltage, and certain brain pathologies or lesions. This was further investigated by expressing neuronal or glial Cxs in cell lines lacking endogenous Cxs and by using the double patch clamp technique to establish selectivity profiles for cations versus anions and the number of charges. The development of dual patch clamp recordings from neurons in brain slices permitted functional studies of electrical synapses.

Of great interest is the permeability of Cx channels for small molecules since this intercellular exchange supports a biochemical and metabolic coupling that is likely important for signaling between nonexcitable cells. Thus, an important issue concerning the role of gap junctions between glia is the identification of signaling molecules exchanged through this intercellular pathway. Since the permeability profile of Cx channels depends on their molecular constituents, it is expected that the amount and the nature of permeating ions or signals is directly related to their identity. The diversity of Cx expression in CNS cells suggests that intercellular exchanges are likely dependent on several types of gap junction channels made by these Cxs. Although essential, this issue has been very difficult to address *in situ* due to technical limitations and the expression of several Cxs per cell. For this reason, the situation is much more favorable *in vitro* for

cultured astrocytes since most gap junction channels are made up of Cx43, as demonstrated by quantitative analysis showing that 95% of the electrical coupling is lacking in astrocytes cultured from Cx43 knockout mouse brain.

Although Cx43 channels are poorly selective for ions, double patch clamp recordings have established that they favor the passage of cations versus anions. In addition, there is converging evidence indicating that intercellular exchange of signaling molecules occurs in cultured astrocytes and in glioma cell lines transfected with Cx43. The permeability of astrocyte gap junctions for glucose and its metabolites, including lactate, was initially characterized by using radiolabeled compounds and by investigating their intercellular diffusion by adapting the scrape-loading dye-transfer technique. Moreover, the use of several unrelated gap junction inhibitors has shown that this diffusion occurs through gap junction channels. This has been confirmed by use of a fluorescent glucose molecule, 2-(*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-Y1) amino)-2-deoxyglucose. Interestingly, gap junctions were shown to participate in the propagation of intercellular calcium waves. In this context, the demonstration that astrocyte gap junctions are permeable to IP3 has contributed to establish the key role of this second messenger in the propagation process. In addition, transfection of C6 cells with Cx43 allowed the demonstration that several nucleotides, particularly ATP and ADP, can be transferred through Cx43 channels. Finally, radiolabeled glutamate and glutamine have also been shown to permeate Cx43 channels in astrocytes.

Whereas in some systems electrical coupling between neurons is strong enough to allow transmission of action potentials, such as in early development, in many cases coupling is weak. In addition, gap junction channels act as a low-pass filter, and gap junctions are generally located primarily on dendrites so that fast action potentials are attenuated. Taking these considerations into account, it is unlikely that coordination of spike propagation through gap junctions is the primary function of coupling between neurons. Although this statement argues for a role of biochemical coupling between coupled neurons, there is very little information about what can cross neuronal gap junctions. Indeed, besides the demonstration that glycine can be exchanged through gap junctions between neurons in the retina, the other evidence for the passage of signaling molecule concerns IP3. In this case, the permeation of IP3 was reported to contribute to the propagation of calcium waves in neuronal domains, whereas an increase in Ca^{2+} alone was not sufficient.

Connexin Hemichannels: An Alternative Release Pathway

Classical pathways for neurotransmitter release that have been extensively described in neurons and in astrocytes include calcium-dependent vesicular release and the purinergic ionotropic receptor (P2X7). In addition, Cx hemichannels have also been proposed to operate in certain retinal neurons and in astrocytes. The unitary conductance of Cx hemichannels has been recorded in cultured astrocytes and is twofold higher than that recorded for the Cx43 full channel. The activity of these Cx hemichannels is very low in resting conditions but can be increased either after ischemic treatment or metabolic inhibition or in low divalent solution. There is evidence that ATP and glutamate can be released from astrocyte Cx hemichannels under these nonphysiological conditions.

Functional Consequences of Cx-Mediated Communication

In addition to its contribution to synaptic transmission, the permeability of gap junction channels for ions may serve to maintain ionic homeostasis between cells, particularly between glial cells, which have for a long time been proposed to play a role in ionic buffering. This is particularly relevant for K^+ since astrocytes mainly exhibit voltage-dependent and passive conductance for this ion. Indeed, several studies have also demonstrated that in cultured astrocytes, GJC is also involved in the intercellular homeostasis of Na^+ and Ca^{2+}. This is particularly relevant when the pharmacological heterogeneity of astrocytes is considered, since not all astrocytes will respond primarily to the stimulation of a membrane receptor agonist. However, the permeability of gap junction channels for calcium ions and IP3 will enable neighboring coupled cells to develop a secondary calcium response. Accordingly, the regulation of GJC may contribute to unmask a pharmacological heterogeneity of astrocytes. In addition, the permeability of Cx43 channels for IP3 is proposed to contribute to the propagation process of intercellular calcium waves, establishing an important functional role for gap junctions in astrocyte physiology and neuroglial interactions.

The possibility for astrocytes to exchange energetic compounds provides an intercellular pathway that may participate in metabolic trafficking between the source of energetic substrates and the main site of energy consumption – respectively, the blood circulation and neurons. In this way, gap junctions may contribute to the distribution of cellular metabolites and the maintenance of the energy status over a glial

cell population. This role for gap junctions is further strengthened by the enriched expression of Cx43 and Cx30 antibodies at contacts between astrocytic endfeet enwrapping blood vessels. This may create local zones of intercellular communication that favor glucose uptake and its spreading into several astrocytes through a metabolic network.

The observation that astrocyte gap junctions are permeable to glutamate and glutamine is of particular interest since after release from glutamatergic neurons, the neurotransmitters are rapidly inactivated by cellular uptake, predominantly into astrocytes. Glutamate is then amidated to glutamine by the ATP-consuming reaction catalyzed by glutamine synthetase, an enzyme present in astrocytes but not in neurons. Glutamine is then released by astrocytes and taken up by neurons, where its hydrolysis provides glutamate. Consequently, the regeneration of this neurotransmitter should not solely be considered as the result of the contribution of isolated and independent astrocytes but, rather, as a result of groups of communicating astrocytes that can exchange glutamate and glutamine. Thus, the permeability for this excitatory amino acid may play an important role in the interaction between astrocytes and neurons that are in part mediated by glial release of glutamate. In certain conditions, this release could also be mediated by Cx hemichannels. A similar situation may occur for the release of ATP that was also shown to operate through Cx43 hemichannels in astrocytes. In these situations, Cx hemichannel-mediated communication has been proposed to contribute to the propagation of calcium waves between astrocytes as well as to the modification in neuronal activity. Finally, Cx hemichannels in horizontal cells of the retina exert a feedback-mediated response that affects the activity of calcium channels and subsequently glutamate release controlling the output of the cones.

Conclusions and Perspectives

It is clear that the analysis of the functional state of gap junctions in the brain is still limited for at least several reasons. First, it is still difficult to study intercellular coupling in brain slices, especially at adult stages, and only a few studies have been performed in the mature brain. Second, dye-coupling experiments may not be sufficiently informative to identify the role of gap junctions in nonexcitable cells. Indeed, this approach only allows one to follow the intercellular diffusion of small molecules (Lucifer yellow, biocytin, 6-carboxyfluorosceine, sulforhodamine B, etc.) that have no biological relevance and solely diffuse along their concentration gradient. Also, not all Cxs have the same permeability for these intercellular tracers. Moreover, the morphology, the location of coupling sites, and the electrical properties of astrocytes studied *in situ* and in cultures are not suitable for optimizing the information obtained by dual patch clamp recordings. Consequently, in the future it will be beneficial to develop and use new molecules or probes that will allow the tracking of biological signals which are relevant to astrocytic gap junctions. Also, many of the experiments performed to demonstrate that gap junctions in the CNS are permeable to signaling molecules used cultured cells. This limits the relevance of these observations, and in future this should be assessed in more integrated systems to weigh the physiological significance of this mode of intercellular communication. Finally, the role and the real contribution of Cx hemichannels is still unclear and needs further investigation to evaluate the conditions under which they are functional and which physiologically relevant molecules cross them.

Gap Junctions and Electrical Synapses

M V L Bennett, Albert Einstein College of Medicine, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Synapses are specialized areas of contact between neurons, between sensory cells and neurons, or between neurons and effector cells. Synapses mediate communication between cells; synaptic transmission from pre- to postsynaptic cell can be mediated by electrical current flowing from the presynaptic cell or by a neurotransmitter molecule secreted by the presynaptic cell. (Neurons are not known to communicate by mechanical means, but some muscles are mechanosensitive, and junctions between them can mediate mechanical transmission.) A key word in the first sentence is 'specialized'; there may be disagreement about what it means. Electrical and chemical interactions can occur over greater separations than at the canonical synapses. 'Ephapse' and 'ephaptic transmission' have been used to describe electrical interaction at a fortuitous close apposition of two cells; 'field effects' denotes interactions across greater distances and may involve many cells. Analogs for chemical transmission include transmitter 'spillover,' in which a high frequency of presynaptic secretory activity causes transmitter to diffuse beyond where its usual receptors are located, and paracrine action, in which transmitter is released and acts at some distance without an obviously specialized relation between secreting and responding cells. Endocrine actions by hormones involve widely separated secretors and targets. The same molecule can be a transmitter at synapses, have paracrine actions, or be a hormone, such as epinephrine.

The most common and best characterized electrical synapses are gap junctions between neurons. A gap junction is a cluster of small channels connecting the interiors of adjoining cells (Figure 1(b)). There are also electrical inhibitory synapses, originally described at the Mauthner cell of teleosts and subsequently in the mammalian cerebellum. This type of synapse is uncommon but will be described briefly in the section titled 'Electrical Inhibitory Synapses'.

Some appositions between neuronal cell bodies are specialized in that intervening glia are absent (e.g., hippocampal pyramidal cells, some hypothalamic neurons), but there do not appear to be gap junctions. Electrical interactions are more likely to be found between these cells than between neurons separated by glial ensheathment. If there are interactions, these relatively unspecialized appositions might well be considered electrical synapses.

Since gap junctions provide ultramicroscopic cytoplasmic continuity between cells, their presence could be viewed as contradicting Cajal's neuron doctrine that each neuron is a distinct cell (although he wrote in his wonderful autobiography, "Neuronal discontinuity . . . could sustain some exceptions"). As will be seen, the properties of gap junctions are reasonably subtle in spite of their relative simplicity; a functional syncytium, as coupled cells have been described, does not necessarily mean that all cells do the same thing.

Properties of Gap Junctions

Molecular Composition of Gap Junctions: Connexins and Pannexins

Known gap junctions in vertebrates are composed of connexins, encoded by a gene family in mammals of ~20 members. Connexins are commonly named by their predicted molecular mass to the nearest kilodalton with a prefix for species or an additional significant figure where necessary to avoid ambiguity, as in human Cx30, Cx30.2, and Cx30.3, encoded by three distinct genes. Molecular weights range from 25 to 57 kDa. Most connexin genes have the entire coding region in a single exon; the Cx36 gene and several others have the coding region in two exons. In some connexins, alternative splicing in the 5′ noncoding region permits use of different tissue-specific promoters.

The connexins are tetraspan integral membrane proteins, that is, they cross the membrane four times. The N- and C-termini (NT, CT) are cytoplasmic, and there are four transmembrane domains (TM1–TM4) connected by two highly conserved extracellular loops (E1 and E2) and a cytoplasmic loop (CL). This topology was confirmed for several connexins by antibody labeling and identification of peptides following protease treatment that cleaved at exposed sites.

The degree of conservation of sequence differs along the molecule. The N-terminus, membrane-spanning regions and extracellular loops are well conserved; the cytoplasmic loop and C-terminal domain are much more variable, in length as well as sequence, and length of the CT domain accounts for most of the differences in molecular weight. Conservation of the extracellular loops may reflect the shared function of docking with another hemichannel. Several regions in the CT contain binding sites for protein–protein interaction, including with the cytoskeletal protein ZO-1.

Figure 1 Gap junction morphology. (a) A gap junction in thin section, an electrical synapse on a Mauthner cell dendrite. A long gap junction is seen between the axon (upper) and dendrite (lower). The axon also contains presynaptic vesicles. In an enlarged view (inset) the gap junction exhibits the typical seven-layer structure. (b) From Makowski L, Caspar DL, Phillips WC, and Goodenaugh DA (1977) Gap junction structures. II. Analysis of the x-ray diffraction data. *Journal of Cell Biology* 74: 629–645.

Given that the human and mouse genomes have been sequenced, few additional mammalian connexins are likely to be found. Different connexins assemble to form junctions that differ in single-channel conductance, gating, permeability (depending on both size and charge), and temporal and spatial patterns of expression. At a gap junction, each cell membrane provides hemichannels, or connexons, that dock one to one with hemichannels in the other membrane. Hemichannels are hexamers, homomeric if they are comprised of one kind of connexin and heteromeric if they are comprised of more than one kind.

Many connexins are expressed in more than one kind of cell, and co-expression of multiple connexins is common in a given cell type. Heteromeric hemichannels do occur, although their prevalence and stoichiometry are poorly known. (Factors controlling oligomerization are not well understood, but assembly does not appear to be random.) Hemichannels of the same kind form homotypic junctions; hemichannels of different kinds form heterotypic junctions. It is also useful to distinguish homo- and heterocellular junctions, that is, junctions between the same or between different types of cells, and these junctions may be homo- or heterotypic. (The terms 'homologous' and 'heterologous' are sometimes used for junctions between the same and between different kinds of cells, respectively.) 'Compatibility' between connexins, the property that allows the formation of heterotypic junctions, has been determined for only a small fraction of the 190 possible pairwise combinations of homomeric hemichannels (for 20 different connexins), but it is not universal and may be uncommon. For example, Cx32, Cx36, and Cx43 do not form junctions in any of the three pairwise heterotypic combinations. Compatibility in this sense is only one of the factors determining where gap junctions form; cell adhesion molecules and almost certainly other as yet undetermined mechanisms are also operative.

The connexins found in the nervous system include the following: the most common neuronal connexin is Cx36 (which is also expressed in pancreatic islets). An additional neuronal connexin is Cx45. Retinal horizontal cells are coupled by Cx57 junctions. Other connexins may be expressed by neurons transiently during development. Astrocytes express predominantly Cx43, but also Cx26 and Cx30. Oligodendrocytes express Cx29, Cx32, and Cx47. Distributions may vary. Astrocyte Cx26 and Cx30 can mediate coupling to oligodendrocyte Cx32.

Identification of the connexin genes permits gene knockout, antisense or small interfering RNA(siRNA) knockdown, replacement of the coding sequence with a reporter gene, and exogenous expression in cell lines or other tissues. Knowledge of sequence also permits *in situ* hybridization, polymerase chain reaction, and the raising of antibodies against specific (or common) sequences to be applied to identification and localization of connexin expression. Site-directed mutagenesis can be used to identify residues critical for particular junctional properties. These approaches have led to an explosion of knowledge of function and distribution.

Although most mammalian connexins have orthologs in other vertebrates and known vertebrate gap junctions are connexin based, gap junctions in nematodes, mollusks, and arthropods (the protostome line) are formed of a family of proteins known variously as innexins (which they were named when they were thought to be expressed only in invertebrates) or pannexins (when it was demonstrated that the same gene family is found in both major branches of the animal kingdom, protostomes and deuterostomes, which include vertebrates). Cnideria have pannexins, and connexins may have evolved in the deuterostome lineage. *C. elegans* has 25 innexins/pannexins; *Drosophila* has eight. Mouse and human each have three pannexins. Two of the mammalian pannexins are expressed in neocortex, hippocampus, and cerebellum, apparently in association with the postsynaptic density. The mammalian pannexins can form gap junctions when exogenously expressed in *Xenopus* oocytes but may only form hemichannels in mammals. The many convergences and few differences between connexin gap junctions in deuterostomes and pannexin gap junctions in protostomes will be noted in the section titled 'Evolution.' Otherwise, gap junction will refer to connexin-based junctions.

Structure

In an early electron microscopic thin section study of gap junctions, the extracellular space between the adjoining cells appeared reduced to a narrow gap (Figure 1(a)), and the channels crossing the gap were not well resolved. Thus, the term 'gap junction' derives from a structural characteristic not obviously related to function. The gap distinguishes these junctions from 'tight junctions' or 'zonulae occludentes' (singular: zonula occludens), in which the intercellular space between adjoining cells appears completely occluded. The gap could be penetrated by small extracellular markers, such as colloidal $La(OH)_3$. Freeze-fracture replicas in the plane of the junction show junctional particles on the protoplasmic face and corresponding pits on the external face (Figures 2 and 3). These structures are often hexagonally packed. With good resolution, the particles show a central depression that presumably is the site of the aqueous channel (Figure 2, inset). Gap junctions can be isolated by several techniques that

Figure 2 Gap junction between blastomeres of a fish shown by freeze fracture electron microscopy. The protoplasmic leaflet of the plasma membrane (P face, or PF) lies to the upper left; the external leaflet (E face, or EF) lies to the lower left. The gap junction is characterized by an aggregate of P-face particles and complementary E-face pits where the particles were pulled out in the fracture process. The inset shows the particles at higher magnification. Many of them show a small central pit that corresponds to the channel. Reprinted from Ne'eman Z, Spira ME, and Bennett MV (1980) Formation of gap and tight junctions between reaggregated blastomeres of the killfish, Fundulus. *American Journal of Anatomy* 158: 251–262, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. Copyright (1980).

Figure 3 Freeze fracture replica immunolabeling (FRIL) of gap junctions between cells of the nervous system. Gap junctions, characterized by aggregates of external leaflet face (E-face) pits or plasma membrane face (P-face) particles, are clearly labeled by specific antibodies followed by secondary antibodies with attached gold beads of predetermined diameter. The technique labels only a small fraction of the replicated channels, and the length of the antibodies permits the gold beads to be some distance from the edge of the junctions. (a) A dendrite in the inferior olive of the rat shows two gap junctions as arrays of E-face pits. 1 and 2 are endings on the dendrite; DS is a cross-fractured dendritic spine. The gap junctions are shown enlarged in (b, c), and each is immunolabeled with six 20 nm gold beads. The primary antibody is against Cx36, a neuron-specific connexin. (d) Gap junctions on an inferior olive oligodendrocyte show both P-face particles (Ol P) and E-face pits; the junctions are labeled with an anti-Cx32 primary antibody and 20 nm gold beads; the rightmost junction is enlarged. A gap junction on an astrocytic process in the same replica (lower left, identified by aquaporin square arrays of particles not included in the micrograph) is negative for Cx32, but these junctions can be labeled using Cx43 antibodies. Scale bar = 100 nm (a–c). Reproduced from Rash JE, Staines WA, Yasumura T, et al. (2000) Immunogold evidence that neuronal gap junctions in adult rat brain and spinal cord contain connexin-36 but not connexin-32 or connexin-43. *Proceedings of the National Academy of Sciences of the United States of America* 97: 7573–7578, with permission from National Academy of Sciences, USA. Copyright (2000).

dissolve away surrounding membrane. Isolated junctions, when negatively stained, usually show domains of hexagonal symmetry (Figure 4). There is a central dot at the presumed site of the channel lumen and a hexagonal lattice surrounding the dots that results from stain in the intercellular gap, which is interrupted by the bridging structures (cf. Figure 1(b)). Atomic force microscopy of separated junctional membranes confirms the general features of the junctions and suggests structural changes associated with gating (Figure 5). Low-dose electron microscopy of isolated junctions reveals four alpha helical regions crossing the membrane, but matching to the amino acid sequences is not yet possible (Figure 6). Scanning cysteine accessibility mutagenesis is revealing channel lining residues, although the data are still somewhat controversial.

When hemichannels come together to form a cell–cell channel, one hemichannel is rotated by 30° relative to the other (Figure 7). Antibodies against the junctional protein or connexin can be used to label gap junctions at the light and electron microscopic levels; the intercalated discs of cardiac ventricle are illustrated in Figures 1(c) and 1(d)). Freeze fracture followed by immunolabeling of residual protein on the replica allows precise localization of particular connexins in identifiable gap junctions (Figure 3).

Figure 4 Isolated liver gap junction from rat, negatively stained with uranyl formate. The junctional channels are hexagonally arrayed. The hexagonal lattice represents stain in the extracellular gap; the central dots mark the location of the channel. From Hertzberg EL and Gilula NB (1979) Isolation and characterization of gap junctions from rat liver. *Journal of Biological Chemistry* 254: 2138–2147.

Figure 5 Atomic force microscopy of external face of an isolated gap junction that has been split open mechanically. The same junction in zero Ca^{2+} (left) shows larger openings than after addition of 0.5 mmol l^{-1} Ca (right). The insets are averages. The (hemi)channel has six subunits. The circles indicate channels that presumably have been damaged. The apparent openings in the channels are wider in zero Ca^{2+} (left) than in 0.5 mmol l^{-1} Ca^{2+}, a concentration that closes gap junction channels when in the cytoplasm. From Muller DJ, Hand GM, Engel A, and Sosinsky GE (2002) *EMBO Journal* 21: 3598–3607.

Figure 6 Molecular organization of a gap junction channel. (a) Side view. (b) Side view showing the channel interior. The approximate boundaries for the membrane bilayers (M), extracellular gap (E), and the cytoplasmic space (C) are indicated to the left. (c) Cross-sections parallel to the membrane at the levels indicated by the arrows in (b). The red contours in (c) define the boundary of the channel. The yellow contours are at increased density and are consistent with four transmembrane alpha helices for each of the six connexins, as predicted from the amino acid sequence. The red asterisk in (b) marks the narrowest part of the channel, where the channel lumen is ~1.5 nm in diameter, excluding the contribution of amino acid side chains that were not resolved. Comparison of upper and lower cross sections in (c) shows the 30° rotation in docking the two hemichannels. Note that both are viewed from the same side of the channel and are therefore mirror images. From **Figure 2** in Unger VM, Kumar NM, Gilula NB, and Yeager M (1999) Three-dimensional structure of a recombinant gap junction membrane channel. *Science* 283: 1176–1180.

Distribution

Gap junctions connect many kinds of nonneuronal excitable cells where they mediate propagation of action potentials, such as in heart, smooth muscle, and pancreatic islets. Gap junctions are also found widely in inexcitable tissues, such as liver, epidermis, exocrine pancreas, salivary glands, neuroglia, and lining of the gut from mouth to anus. Although gap junctions are very common in these tissues, they are absent in many contacts between specific kinds of cells. They are not found between adult vertebrate skeletal muscle fibers or erythrocytes and are rare or absent between neurons and glia and between many kinds of neurons that come into close contact.

Figure 7 Fitting of the extracellular surfaces of two hemichannels to form a cell–cell channel. (a) Surface representation of a single hemichannel (connexon) viewed from the cytoplasm, from the membrane side, and from the extracellular side. The structure of the external and cytoplasmic surfaces are quite different. (b) Two hemichannels fit together at their external surfaces by rotating one 30°. From Perkins GA, Goodenough DA, and Sosinsky GE (1998) Formation of the gap junction intercellular channel requires a 30 degree rotation for interdigitating two apposing connexons. *Journal of Molecular Biology* 277: 171–177.

Electrical Coupling and Circuit Parameters

When a current is passed in one cell to change its potential, a smaller potential change is recorded in cells joined to it by gap junctions (Figure 8). Current flows from cell to cell through the junctional channels just as in electrotonic spread along a core conductor (hence the terms 'electrotonic junction' and 'electrotonic synapse'); the gap junctions act as a conductor, and both hyperpolarizing and depolarizing potentials are recorded in the follower cell. This current is carried largely by K^+ ions, the primary mobile ion in the cytoplasm. Before concluding that the cells are coupled by gap junctions, cytoplasmic continuity must be excluded, which is commonly done with gap junction blockers (see the section titled 'Pharmacological block of gap junctions') or by injecting a visualizable molecule that is too large to permeate gap junctions, such as fluorescently labeled dextran (see the section titled 'Dye coupling and permeability'). Also, recording outside the cells may be necessary to demonstrate that the intracellular potential in the coupled cell is not a result of a voltage drop in the extracellular space. Both electrical and dye (see the section titled 'Voltage gating of gap junctions') measurements indicate that there is little leakage from the channels as they cross the gap and that they constitute a private pathway between the cell interiors that is not accessible from the extracellular space.

For steady state potentials, the ratio of pre- to postjunctional potential is termed the coupling coefficient or coupling ratio. In the equivalent circuit of two isopotential cells connected by a gap junction, each cell is represented by its conductance and capacitance in parallel, and the cells are connected by the junctional conductance, g_j (Figure 9). (Isopotential means that the cytoplasmic resistance is small compared with the membrane resistance and that all points within the cell are at virtually the same potential. In neuronal processes, i.e., the axon and dendrites, cytoplasmic resistance is no longer negligible, and the potentials in these processes can differ from that in the soma.) For small potentials, junctional and nonjunctional conductances can be treated as constant. The junctional membrane has little capacitance compared with nonjunctional membrane because of its small area and the presence of the gap, which is likely to be at a potential close to that of the surrounding extracellular space. The parameters of steady state transmission (which excludes the effect of cell capacitances) are easily described using the circuit. The

Figure 8 Electrical coupling mediated by gap junctions between bipolar (inhibitory) interneurons in the visual cortex of the rat. Four superimposed records with current applied in cell 1 in the upper set in (a) and in cell 2 in the upper set in (b); recordings from the follower cell at higher gain in the middle sets of traces. Both hyperpolarization and subthreshold depolarization spread between cells. Larger polarizations in the polarized cell result in larger polarizations in the follower cell, and the relation is essentially linear under these conditions. Impulses, which are evoked by the strongest current, are more attenuated than steady polarizations, and the peak of the 'spikelet' in the postsynaptic, nonstimulated cell is delayed compared to the presynaptic spike; superimposed presynaptic spikes and postsynaptic responses are shown in the bottom records at greater time resolution. Pre- and postsynaptic are defined here as the stimulated and follower cells; the synapse is symmetric, and transmission is bidirectional. Reproduced from Venance L, Rozov A, Blatow M, et al. (2000) Connexin expression in electrically coupled postnatal rat brain neurons. *Proceedings of the National Academy of Sciences of the United States of America* 97: 10260–10265, with permission from National Academy of Sciences, USA. Copyright (2000).

Figure 9 Equivalent circuit of a coupled pair of cells. (a) Isopotential cells: Each of the cell has a nonjunctional conductance (g_1, g_2) and a membrane capacitance (C_1, C_2). The cells are joined by a junctional conductance, g_j. Current is applied and voltage measured in each of the cells (I_1, I_2, V_1, V_2). Capacitance of the junctional membrane is negligible. (b) An axosomatic synapse. The postsynaptic response (electrical excitatory postsynaptic potential, EPSP, V_{pre}) is attenuated and delayed with respect to the presynaptic impulse, V_{pre}. The delay introduces a synaptic delay that can be comparable to delays at chemical synapses. g_j and g_{post}, junctional and postsynaptic conductances; *c*, postsynaptic capacitance. (b) From Bennett MVL (2000) Seeing is relieving: Electrical synapses between visualized neurons. *Nature Neuroscience* 3: 7–9.

coupling coefficient for a current applied in cell 1 is the ratio of the potential generated in cell 2 to that in cell 1: $k_{12} = V_2/V_1$. If the nonjunctional conductances of the cells are g_1 and g_2 and the junctional conductance is g_j, $k_{12} = g_j/(g_2 + g_j)$, and for currents applied in cell 2, $k_{21} = g_j/(g_1 + g_j)$. Note that k_{12} is independent of g_1, and k_{21} is independent of g_2. If k_{12} is small and $g_j < g_2$, $g_2 \approx I_2/V_2$ and $g_j \approx g_2 k_{12}$, and similarly for k_{21}.

Where the circuit of Figure 9(a) is valid, one can apply current first in one cell and then in the other and from the resulting voltages calculate the cell and junctional conductances precisely, but the equations are somewhat messy. A simpler method to determine g_j is

to voltage clamp the two cells to a common holding potential by means of a voltage clamp and then step the voltage in one cell to a new value. The current applied in the other cell to keep its voltage constant is equal and opposite to the current flowing through the junction at the given transjunctional voltage, $V_j = V_1 - V_2$ and $g_j = -I_2/V_j$ the minus sign is because the current into cell 2 is opposite in sign from the current flowing through g_j); g_1 is given by $(I_1 - I_2)/V_1$. Stepping cell 2 while holding V_1 constant measures g_j and g_2. (If both cells are stepped to the same potential, $V_j = 0$, $g_1 = I_1/V_1$, and $g_2 = I_2/V_2$.) Equality of g_j for V_j of either sign is an important validation of the equivalent circuit.

If the cells are not isopotential and even if they are part of a large coupled network, one can still calculate effective values for g_1, g_j, and g_2 for any two recording sites. However, the values will not correspond in any simple way to the conductances of the gap junctions coupling the cells, and coupling conductance, or g_c, is a more accurate term than g_j.

Voltage Gating of Gap Junctions

Gap junctions formed of most connexins exhibit varying degrees of sensitivity to V_j. In dual voltage clamp, a large step in cell 1 causes a current in cell 2 that decreases to a new steady state more or less exponentially, and this new value is smaller for larger V_j (Figure 10). (A virtue of dual voltage clamp is that the change in g_j is immediately apparent in the I_2 record.) In homotypic junctions, the decrease is in most cases symmetric for transjunctional voltages of either sign generated by hyperpolarization or depolarization in either cell. This finding indicates that the junctions are insensitive to the potential between the interior of the cells and the external medium. A few connexin-based junctions show a minor degree of dependence on the voltage between the cell interior and the extracellular medium ($V_{i\text{-}o}$ or V_m). The eponymous gap at the junction is accessible to the extracellular medium, so there should be little or no potential change along the gap, and the voltage across the channel walls should be the voltage between the channel lumen and the extracellular space at some distance from the junction. If the voltage differs in the two cells, the voltage is not uniform along the channels.

The steady state macroscopic currents for each polarity of V_j can be reasonably described by a Boltzmann relation:

$$g_j = [g_{jmax} - g_{jmin}]/(1 + \exp[A(V_j - V_0)]) + g_{jmin}$$

where g_{jmax} is the maximum value of g_j, which is approached at large values of V_j; A is a constant expressing voltage sensitivity; and V_0 is the voltage at which the conductance is halfway between g_{max} and g_{min}. The Boltzmann relation describes the equilibrium between two states, in this case high and low conductance, where the energy difference between them is a linear function of $V_j - V_0$ and $A = nz/(kT)$, where n is the equivalent number of electron charges, z, moving through the full voltage V_j, and kT has its usual meaning. The time course of changes in macroscopic currents in response to voltage steps

Figure 10 Voltage-dependent gating of gap junctions formed by human Cx32 wild-type and a mutant, Cx32-220 stop, one of many mutations that cause Charcot–Marie–Tooth disease, a peripheral neuropathy. The cRNAs were expressed in *Xenopus laevis* oocytes that were then paired and allowed to form junctions. The upper sets of traces show voltages applied in one cell (V_j) while the other cell was clamped at the holding potential. The lower sets of traces are the currents in the cell clamped at the holding potential and are equal and apposite to the transjunctional currents (I_j) associated with the voltage steps. The graph shows the steady state junctional conductance (g_j) as a function of transjunctional voltage (V_j). g_j decreases quite symmetrically for increasing V_j of either sign. The decrease approaches a plateau value accounted for by the residual conductance seen in voltage gating at the single-channel level (see Figure 11). The decline is steeper for the mutant (filled circles) than for wild-type (triangles). From Revilla A, Castro C, Barrio LC (1999) Molecular dissection of transjuctional voltage dependence in the connexins-32 and connexins-43 junction. *Biophysical Journal* 77: 1374–1383.

is approximately exponential, consistent with a Boltzmann process.

Single Channels and Gating

The conductances of single gap junction channels of known composition can be measured in connexin-deficient, high-resistance cells after transfection with specific connexins. In well-coupled cells, the number of open channels can be reduced with various blocking agents (see the section titled 'Pharmacological block of gap junctions') until single-channel activity is observable (Figure 11). Alternatively, separated cells can be apposed and the formation of junctions observed at the level of the first channels to open. The clear transitions between closed and quite stable open states, and often substates, allow identification of single-channel conductances. These conductances range between ~15 pS for Cx36 and ~200 pS for Cx37. Two modes of voltage gating, fast and slow, can be identified from single-channel recordings. Fast gating occurs on a millisecond timescale between the fully open state and a residual state with a conductance in the range of 10–30% of the maximal value. Slow gating requires 5 ms or more and occurs between the fully open state and the substate or the fully closed state. It appears to result from poorly resolved transitions between multiple unstable substates. For most connexins studied, both kinds of gate have a high open probability at $V_j = 0$, and open probability is decreased by increasing V_j. The more rapid rate constants of the fast gating process and its greater voltage sensitivity cause it to dominate the current–voltage relation. In this case g_j for either sign of V_j can be reasonably described by a Boltzmann relation for each of the oppositely oriented series hemichannels; one sign of V_j closes the gate in one hemichannel and has little effect on the gate in the other hemichannel. In this description, probability of being in the fully open state is the dependent variable; macroscopic g_j is given by the open probability P_o multiplied by the number of channels, N, and single-channel conductance, γ.

$$g_j = P_o N \gamma$$

The oppositely oriented gates in the two halves of a cell–cell channel are closed by opposite signs of V_j, which accounts for the symmetry of the I/V relation. Symmetry, however, precludes inference of the sign voltage sensitivity of the individual hemichannels from these data. Comparison of heterotypic and homotypic junctions or experimental induction of asymmetry by, for example, unilateral acidification, does allow determination of gating polarity, and it has been shown that different connexins can form hemichannels with opposite signs of gating polarity. Moreover, charged amino acids that constitute part of the voltage sensor have been identified, and charge substitutions in the N-terminal residues can reverse the gating polarity.

While only an approximation, and definitely not mechanistically justified for slow gating, Boltzmann relations are a convenient descriptor of the degree of voltage sensitivity of fast gating, as well as of slow gating when fast gating is absent. Voltage sensitivity in terms of charge can approach that of the channels

Figure 11 Single-channel currents showing fast gating between the fully open state and a substate and slow gating between the closed and fully open states. A well-coupled pair of fibroblasts expressing Cx43 were exposed to CO_2 equilibrated saline, which blocked the junctional conductance. (a) The upper record shows the last two channels closing in response to cytoplasmic acidification (arrows). The solid lines indicate the conductance level of the two open channels (10, 20). The dotted lines (s) indicate the substate conductance level, and c indicates the closed state. The boxed record below shows at higher gain and faster timescale two sojourns to the substate via fast transitions before the last slow transition to the closed state. The small circles on the records occur at 1 ms intervals. (b) The upper record shows the first two channels to open again after ~10 min washing in normal saline (arrows). The second channel opens fully while the first channel is in the substate (right arrow); subsequent fast transitions between open state and substate cannot be unambiguously assigned to one or the other channel. The boxed record below shows the initial slow transition from closed to open state, followed by a fast transition to the substate and a fast transition from substate to open state. From Bukauskas FF and Peracchia C (1997) Two distinct gating mechanisms in gap junction channels: CO_2-sensitive and voltage-sensitive. *Biophysical Journal* 72: 2137–2142.

of impulse-generating membrane, but the transition rate constants are long, in many cases hundreds of milliseconds to seconds. For a given connexin, the slow gating mechanism may have voltage sensitivity opposite that of the fast gating mechanism.

Heterotypic Channels, Gating Asymmetry, and Rectification

Hemichannels formed of different connexins can form heterotypic gap junctions that are quite symmetric or very asymmetric. Asymmetry of voltage gating results in junctional conductance that depends on polarity of transjunctional voltage, but the characteristic rates of change in conductance are slow, as described in the preceding section. At one extreme, the hemichannels have opposite polarity of voltage sensitivity referred to the voltage at their cytoplasmic ends, and both hemichannels are closed by the same sign of V_j. The macroscopic current–voltage relation of these junctions is very asymmetric.

Another factor in gating asymmetry is single hemichannel conductance. If a low-conductance hemichannel is in series with a high-conductance hemichannel, most of an applied voltage will be developed across the low-conductance (high-resistance) hemichannel. Its sensitivity to an applied V_j will be increased relative to its sensitivity in a homotypic junction. Similarly, the sensitivity of the high-conductance hemichannel will be reduced compared to that in its homotypic junction. In heterotypic junctions, small shifts in resting potential difference between two cells can cause large changes in junctional conductance and may be important in controlling chemical communication.

Asymmetric junctions can also show fast rectification (important in some rectifying synapses) in which the open channel rectifies, presumably on a microsecond timescale, and passes more or less current for a given transjunctional voltage, dependent on its sign. Rectifying electrical synapses are morphologically asymmetrical in that they occur between cells of different types and have a preferred direction of transmission. The polarity of rectification determines direction of impulse propagation and which elements are the pre- and postsynaptic ones. The constituent connexins have not yet been identified and may be encoded by different genes, or the same connexin on both sides may be differentially modified posttranslationally. The rectification is ascribed to differences in fixed charge in the constituent hemichannels. Fast rectification in inwardly rectifying K channels is due to channel block by internal polyamines. Similarly, differences in the composition of cytoplasm on the two sides of a gap junction could lead to rectification.

For most gap junctions, V_j dependence of g_j appears too weak and slow to have much physiological significance and appears unsuitable for processing of neuronal impulse activity. For some tissues, such as heart, with its long-duration action potentials, voltage insensitivity could be an advantage.

Dye Coupling and Permeability

A cell may be injected with (or induced to take up) a probe molecule such as a dye or a radioactive tracer, and contacting cells can then be assayed for appearance of the probe (**Figure 12**). Measurements of this kind indicate that the channel diameter is ~1.4 nm, and molecules of molecular weight of ~1 kDa can permeate (as can extended molecules of somewhat larger molecular weight, such as short interfering RNAs). The channel can be traversed by small ions, polypeptides, and nucleotides, including for some connexins cyclic adenosine monophosphate (cAMP), adenosine triphosphate (ATP), and other molecules of intermediary metabolism. This chemical communication may mediate metabolic cooperation in which one cell provides a molecule that another cannot synthesize or where random metabolic differences between cells are compensated for. Some but not all connexins form junctions with significant charge selectivity, and maximum size for permeation varies with connexin (**Figure 12**). Gap junctions are impermeable to large polypeptides, long nucleic acids, and, of course, subcellular organelles.

Dye coupling can be quantified in terms of junctional permeability, which is conveniently normalized to junctional conductance. For probes to which the surface membrane is impermeable, the dye coupling coefficient, defined as steady state ratio of concentration in a recipient cell to that in the source cell, is unity. However, in large networks of cells, the time to reach equilibrium may be longer than the usual measurement time, and postjunctional concentration may not reach its theoretical final value. Gap junctions do not rectify in respect to dye flux; in the absence of an asymmetric driving force, permeation is not polarized. However, dye coupling between a large cell and a small cell can be asymmetric at short times; the same dye flux in one or the other direction would produce a higher concentration in the smaller cell. Differences in nonjunctional membrane permeability could also lead to apparent asymmetry in dye coupling. A further issue in asymmetric systems is degree of binding, which can alter fluorescence of the bound molecules and concentration of the free dye in the cytoplasm.

A crude but convenient technique to measure dye coupling is scrape loading. As commonly used,

Figure 12 Cells joined by gap junctions show spread of dyes from one to another, that is, dye coupling. Dye coupling depends on the connexin, some of which are permeable to larger molecules than others are and some of which are charge selective. The figure shows Neuro-2a cells transfected with Cx46 (upper row), Cx32 (middle row), or Cx43 (lower row), phase micrographs on the left and fluorescence on the right in each pair of images. In each case, cell 1 was injected with the fluorescent dye Lucifer yellow (ion molecular mass 443 Da, two negative charges, left column) and DAPI (4′,6-diamidino-2-phenylindole, ion molecular mass 279, two positive charges, right column). Cx46 junctions are cation selective and are impermeant to Lucifer yellow but show some permeation by DAPI, which fluoresces when bound to nuclei. Cx32 junctions are anion selective and are permeable to Lucifer yellow but not to DAPI. Cx43 junctions readily transfer both Lucifer yellow and DAPI. Junctional conductance, g_j, is shown for each cell pair, and low level of coupling did not account for selectivity. From Trexler EB, Bukauskas FF, Kronengold J, Bargiello TA, Verselis VK (2000) The first extracellular 100p domain is a major determinant of charge selectivity in connexin 46 channels. *Biophysical Journal* 79: 3036–3051.

a confluent monolayer is cut with a razor blade in the presence of dye. Many of the cells can heal over, trapping dye in their cytoplasm. The dye bathing solution is then washed away, permitting observation of dye coupling to cells at some distance from the cut. Simultaneous application of a larger, junction-impermeant molecule with a different fluorescence allows identification of cells that were cut open, which have both markers, and the recipient cells, which have only the smaller, permeant species.

Formation and turnover In addition to the rapid gating mechanisms, specific treatments can induce cells to form gap junctions or to remove them. Most types of connexin hemichannel are assembled in membrane of the endoplasmic reticulum (ER) or post-ER compartments. Cx26 may be an exception and can insert into membranes posttranslationally. Vesicles with hemichannels are transported to the cell surface and inserted into the external membrane (Figure 13). Hemichannels then diffuse in the plane of the membrane until finding a hemichannel in an apposed membrane. Unapposed hemichannels in the surface in general are not open. The final steps are apposition or docking of intact hemichannels in the two membranes (Figure 7) and interaction with the extracellular loops to form the complete channel in a kind of ligand–receptor interaction in which each is a molecule of the same kind. When the first channel opens, the current through the nonjunctional membrane is unchanged (Figure 14). Thus, the hemichannels forming the first channel are not open to the extracellular space before they open to connect the two cells. (In some conditions, physiological or pathological, hemichannels open without interacting with a hemichannel in an apposed membrane (see the section titled 'Hemichannels that open').

Gap junctions can grow by accretion of new channels at their periphery because membranes are closely apposed in this region rather than exhibiting the wider gap of nonjunctional appositions. Targeted

Figure 13 Connexins are synthesized in the endoplasmic reticulum (ER) and assembled into hemichannels in the ER or later compartment. They are then transported to the surface as integral membrane proteins in vesicles, which are inserted. The hemichannels diffuse in the surface to find a hemichannel in an apposed membrane and then join to form a cell–cell channel; each cell contributes a hemichannel to a cell–cell channel. Unpublished diagram by Jorge E. Contreras.

delivery of vesicles with hemichannels to junctional regions has been reported, but membrane insertion can also occur without directional transport. The mechanism by which the separated membranes are pushed close enough together for initial junction formation is unknown.

There is evidence that a large number of hemichannels must be clustered before the first cell–cell channel opens. Quantitation of junctional area and number of open channels determined from conductance indicates that only a small fraction of cell–cell channels are open, ~10%, a fraction that is likely to be connexin dependent. It is not clear whether a subpopulation of channels opens with a larger probability or whether probability is uniform and small. The atomic force data in Figure 5 suggest that all the channels are changing conformation during gating.

Normal connexin turnover time is a few hours in several cell types in culture and in rodent liver and heart. In marked contrast, gap junctions in the lens do not turn over in the lifetime of the organism after maturation of the lens fibers, in which their messenger RNA (mRNA) is lost. In turnover, junction removal apparently proceeds through internalization of the full thickness of the junction by one or the other cell (Figure 15) and may involve an entire junction or just a small region from the center. The hole in each cell that this mechanism requires presumably seals over with negligible leak. Internalization leads to the production of 'annular' gap junctions that can be seen in the subsurface cytoplasm; these structures are the internalized junctions with a little perijunctional membrane, and they contain a small amount of cytoplasm from the 'loser' cell. The transfer of cytoplasm from one to the other cell could be important in antigen transfer and presentation.

Eventually the internalized junctions are transported to lysosomes for degradation; there is no indication of recycling of hemichannels or connexins that have formed cell–cell channels. However, unapposed hemichannels in the surface membrane can enter the constitutive membrane recycling pathway and be internalized and reinserted.

Activation of kinases may accelerate junction formation or removal, depending on the tissue. In some systems, precursor connexin appear to be present, and junction formation can occur spontaneously even when ATP levels are reduced; in other systems, protein must be synthesized. Formation requires cell adhesion, and block of adhesion can block junction formation. Also, specific antibodies to the extracellular loops or peptides corresponding to the extracellular loops can prevent junction formation. If junction turnover is sufficiently rapid, these agents potentially provide a highly specific method of blocking junctional communication.

Degree of coupling can be regulated by controls of transcription and mRNA degradation as well as by those of formation and internalization. The cell biology of regulation of coupling is a field of active exploration.

Figure 14 Hemichannels in cell–cell channels are closed before opening to connect the interiors of the apposed cells. (a) Opening of the first channels after washout of a agent that blocked gap junctions connecting two cardiac myocytes. (b) Equivalent circuit of the cells, where cell 1 and cell 2 each has a voltage, V_1 and V_2, a current, I_1 and I_2, and a conductance g_1 and g_2, and I_j is the current through g_j, the junctional conductance. The first cell–cell channel to open caused equal and opposite currents in the two cells. Thus, the nonjunctional currents in the two cells were unchanged, indicating that the hemichannels were not open to the extracellular medium prior to opening to couple the cells. At the arrow, a second channel opened. The dotted lines indicate the substate conductances of the two channels. Similar results are obtained with the first opening of newly formed channels when dissociated cells are pushed together while recording. (a) From Valiunas V, Bukauskas FF, and Weingart R (1997) Conductances and selective permeability of connexin43 gap junction channels examined in neonatal rat heart cells. *Circulation Research* 80: 708–719.

Pharmacological block of gap junctions An important tool in functional analysis is the use of specific blockers. Although numerous blockers are available, such as heptanol, octanol, halothane, carbenoxolone, glycyrrhetinic acid, flufenamic acid, anandamide, and oleamide, they are not very specific. Octanol and heptanol are widely used but affect many membrane channels. Carbenoxolone and glycyrrhetinic acid are more specific but may also affect excitability properties. Mefloquine is quite selective for Cx36 junctions, common between neurons. Where measured, conductance is reduced to zero by the slow gating mechanism. Low cytoplasmic pH (Figure 11) and high Ca^{2+} block most if not all gap junctions. The sensitivity to pH varies with the connexin and possibly the tissue. Domains involved in pH sensitivity are being identified. In some instances, conductance is close to maximum at resting pH, and small degrees of acidification markedly depress it. Here intracellular acidification is a plausible mechanism for cellular control of junctional conductance. In the few cases analyzed quantitatively, the sensitivity to Ca^{2+} appears to be less than that to H^+. Calcium ions would, however, act to uncouple from its neighbors a cell whose surface membrane became leaky. 'Healing over' of an injury to cardiac muscle is thought to involve a decrease in junctional conductance due to an effect of this kind, although scrape loading and retention of a gap junction-impermeant molecule indicates that ruptured cells can indeed heal over.

One can pretty reliably infer that if several gap junction blockers do not block a particular response, then the response is not mediated by gap junctions. At this time, it is much less reliable to infer that gap junctions mediate a response because gap junction blockers reduce or prevent it. So-called connexin- (or pannexin-) mimetic peptides with sequences corresponding to regions of the extracellular loops, as well as molecular approaches using siRNAs, should be quite specific in preventing junction formation and will be useful where gap junctions turn over rapidly enough for an effect of loss of function to be observed (see the section titled 'Formation and turnover'). Connexin knockout by recombinant techniques is and has been extremely useful but suffers from poor time resolution.

Phosphorylation Probably most connexins are phosphoproteins. There are consensus sites for phosphorylation in the cytoplasmic C-terminal domain that vary among connexins. Cx43 has at least 14. Phosphorylation may result in an increase or decrease in macroscopic conductance associated with altered single-channel conductance or open time. For example, gap junctions between hepatocytes are increased in conductance by cAMP-increasing agents; conversely, conductance of the junctions between horizontal cells in the retina is decreased by the same treatments. Nitric oxide mediates synaptic modulation of gap junction synapses at several sites. Because these changes are relatively rapid and are likely to involve changes in single-channel properties rather than formation or removal, they may be considered a form of gating. Phosphorylation can also affect insertion and removal.

What Do Gap Junctions Do for Neurons?

Transmission between neurons In the equivalent circuit of Figure 9, transmission of small potentials is governed by the steady-state relations described

Figure 15 Removal of gap junction channels involves internalization of both junction membranes by one cell and transfer of a small volume of cytoplasm from one cell to the other. Successive stages of internalization of an entire junction are indicated, but small areas from the center of a junction can also be internalized. Between (b) and (c), the protrusion from cell 2 into cell 1 has pinched off from cell 2, and its membranes have resealed. Between (c) and (d), cell 1 has endocytosed the protrusion from cell 2 and resealed its membranes to include a small volume of extracellular material as well as the content of the protrusion.

above, and g_j values can be determined. Generally, voltages in neurons are too small or brief to engage voltage dependence of g_j, and the principle neuronal connexin, Cx36, is relatively insensitive to voltage. Because the membrane capacity of the nonjunctional membrane is much greater than that of the junctions, gap junction synapses act like a low pass filter (Figure 9). The postsynaptic potential is slowed because some of the junctional current goes to change the charge on the postsynaptic capacitance. Steady state coupling does not depend on capacity, but coupling is less for faster presynaptic potentials; peak amplitude is reduced, and the peak is delayed (Figures 8 and 9). One important consequence is that the measured synaptic delay can be as great at an electrical synapse as at a chemical synapse; although the electrical synapse starts to transmit without delay, time is required for the postsynaptic potential to reach a level at which it can be detected. The delays tend to be more nearly alike in warm-blooded animals because the delay at chemical synapses is less at higher temperatures whereas the delay at electrical synapses is not very temperature sensitive.

Slowing of the postsynaptic potential is generally an obvious feature of neural signaling across gap junctions. Neuronal action potentials are usually considerably briefer than the input time constant and so are relatively attenuated compared with slower potential changes such as synaptic potentials or applied hyperpolarization (Figures 8 and 9). In coupled cells, presynaptic impulses can produce postsynaptic responses that have been termed spikelets or fast prepotentials. Spikelets are briefer than synaptic potentials, and one hypothesis has been that they result from spikes generated in a dendrite that fail to invade the soma. While this may be true in some cases, dendritic spikes are often longer lasting than somatic spikes and spikelets. A factor that may contribute to the relatively short time course of an electrical postsynaptic potential (PSP)/spikelet is that the

presynaptic action potential may have an afterhyperpolarization that reverses the current flow across the electrical synapse and shortens the postsynaptic response.

In Cajal's neuron, transmission is polarized. At a gap junction synapse, if $g_1 \gg g_2$, then $k_{12} \gg k_{21}$ and coupling is much stronger in one direction that the other. Although inefficient, electrical coupling could be made arbitrarily unidirectional by adjusting the cell conductances. Unidirectional impulse propagation can also be achieved where the junctional membrane rectifies (see the section titled 'Heterotypic channels, gating asymmetry, and rectification,' above). At electrical axosomatic or axodendritic synapses, either electrical or chemical, impulses need not propagate from axon to postsynaptic cell on a one-to-one basis. Transmission is bidirectional, but coupling is weak, and the postsynaptic cell is excited only when there are enough presynaptic impulses to depolarize the cell to threshold. Impulses in the postsynaptic cell may or may not invade the electrically coupled presynaptic axons.

In coupled groups of neurons, a significant part of the input conductance of a single cell can be due to the conductances into the junctions it makes with other cells, and there generally are multiple pathways connecting any two cells. Significant voltage drops can be developed along dendrites connecting the cells. Furthermore, active conductances in the coupling pathways can influence the measured coupling and calculated value of g_c.

Synchronization Dendrodendritic gap junctions are the most common type of electrical synapse in mammals; these synapses generally synchronize electrical activity of cells of the same kind. In synchronization, current flows from a more positive cell to depolarize a less positive cell, and the first cell is itself made less depolarized by that current flow; thus, the synchronizing function is both excitatory and inhibitory, and pre- and postsynaptic do not have an obvious, fixed meaning where electrical signals can go in either direction. Examples of these coupled systems include numerous types of inhibitory interneurons, such as fast spiking cells, low threshold spiking cells in the neocortex, comparable cells in the hippocampus and striatum, stellate cells in cerebellum, thalamic reticular neurons, and various subclasses of interneurons expressing somatostatin, parvalbumin, or calbindin. Like neurons tend to be coupled, and a coupled network can extend for quite long distances, although electrical spread is measurable only between close neighbors. In these systems, synchronization of the inhibitory neurons is not very precise, but the circuitry is made simpler by allowing reciprocal connections that transmit not only impulse activity but subthreshold potentials of either sign. Moreover, the cells can excite each other through their gap junctions and inhibit downstream cells as well as each other by chemical synapses, a problematic arrangement for chemical transmission.

Synchronization can be increased by mutual inhibition mediated chemically. In a rhythmically discharging pool of neurons that are electrically coupled, firing of one cell tends to fire its neighbors, but depolarization is immediately followed by inhibition, restricting the time at which those cells can fire and also preventing delayed firing so that they are more likely to fire the next time the first cell fires. Generally in these pools of neurons, the influence of one cell on a coupled neighbor is small, but if many cells are active simultaneously, the excitatory effect on coupled cells can be very strong.

A number of classes of synchronously active coupled cells have axons that project out of the brain region in which they are coupled. Mitral cells of the olfactory bulb project to olfactory cortex and are coupled in their dendritic regions in the olfactory glomeruli. Olfactory neurons expressing the same receptor project to the same glomerulus, and the innervating mitral cells tend to fire synchronously. Cells of the inferior olive, which give rise to climbing fibers exciting cerebellar Purkinje cells, are coupled. The olive is a relatively large structure and tends to be subdivided into regions that are synchronously firing; the subdivision may be under control of inhibitory inputs to the dendrites that decrease electrical current spread along the dendrites and decouple groups of cells from each other. Neurons of the striatum are coupled inhibitory neurons that project to other brain regions. Neurons of the hypothalamus that release neuropeptides in the median eminence can be coupled with like neurons to facilitate hormone release. Neurons of the locus coeruleus are coupled, fire more or less synchronously, and project to much of the cortex. The suprachiasmatic neurons are coupled and project to the paraventricular nucleus.

Many neurons in the retina are coupled, including type II amacrine cells and horizontal cells, where coupling can be both within and between classes. Coupling mediates lateral spread of excitation (rather than synchronization) that then causes recurrent inhibition. Electrical synapses may also involve other types of retinal cell. Rod bipolar cells excite type II amacrine cells that are electrically coupled to each other and to cone bipolar cells that then excite ganglion cells.

Pools of neurons connected by gap junctions differ markedly in the degree of coupling. At one extreme, an impulse initiated in one cell propagates to all the

other cells (not true of mammalian inhibitory interneurons). In less well coupled groups of cells, the synchrony of firing may be rather poor. However, even weak coupling can promote precise synchronization if other inputs are driving the cells to fire at about the same frequency.

Synchronization mediated by electrical coupling has been characterized in a number of lower vertebrate and invertebrate species. Examples include neurons controlling electric organ discharge in fishes, which in most species is highly synchronous; motor systems in which speed and synchronization are important, such as those mediating saccadic eye movements, and sonic muscles, in which the fundamental frequency of the emitted sound is the frequency of contraction. Other systems are less well synchronized; examples include neurons controlling cardiac ganglia in arthropods and supramedullary neurons, a group of autonomic effectors found in teleosts.

In the highly synchronized systems, the short delay possible at electrical synapses is required for the observed degree of synchronization. In other cases, synchronization could be mediated by drive from a higher center with fewer cells or by feedback mediated by chemical synapses.

When a pool of neurons has fired synchronously, additional adaptations are necessary to assure that the effector cells are active synchronously, if distances from the 'command center' to effectors are sufficiently different to introduce asynchrony if conduction is 'as the crow flies' and of fixed velocity. One solution is to have the pathway to the more distant effectors conduct more rapidly. Others are to have more devious pathways to the nearer effectors or to introduce compensatory delays along the pathways.

Escape! Most animals have a fast escape response to escape from predators and other dangers. An example that has been important in the study of synaptic transmission is the Mauthner cell system found in teleost fishes and some urodele amphibians. There are two Mauthner cells, one on either side of the medulla. Their axons decussate and descend the spinal cord to excite the axial motor neurons on the side contralateral to the Mauthner cell body, and firing of one Mauthner cell mediates a tail flip escape response away from the stimulated side. Large myelinated fibers from the sacculus, a hearing organ, form 'club endings' on the lateral dendrite of the Mauthner cells that transmit both electrically and chemically; the electrical component is of shorter latency and presumably reduces the latency of the escape response. Excitation of the axial motor neurons by the Mauthner axons is chemically mediated, as is transmission at the peripheral neuromuscular junction. The Mauthner cells also inhibit each other through interneurons that act electrically (see the section titled 'Electrical inhibitory synapse') and then chemically so that firing of one cell rapidly inhibits the other; clearly, it would be counterproductive for swimming if muscles on both sides contracted simultaneously. (Each Mauthner axon also inhibits the contralateral motor neurons through crossed inhibitory interneurons on its side of the cord. Excitation of the inhibitory neurons is electrical so that in a given motor neuron, the chemical excitation from one Mauthner axon and the crossed chemical inhibition from the other have about the same latency, preventing simultaneous contraction of muscles on the two sides, should the Mauthner cells fire at the same time. In contrast, there is a bilateral component of the Mauthner cell escape reaction which closes the mouth and adducts the pectoral fins. Interneurons mediating these actions are excited by both Mauthner cells at chemical synapses and then transmit electrically to the motor neurons.)

The lateral giant axons controlling the tail flip of many crustaceans, including lobsters and crayfish, are made up of multiple segments, one neuron per segment coupled together end to end to make in effect a single giant axon. (The gap junctions connecting the segments are presumably pannexin based.) The lateral giant axons conduct impulses at a comparable speed to the medial giant axons, which are true single axons arising from a single pair of cell bodies in the supraesophageal ganglia. One can appeal to developmental factors to account for the structural difference. The medial giants are excited by synapses in the head region, and the lateral giants can be excited in many of the abdominal ganglia. The two systems give somewhat different escape responses. The giant axons of many annelids are segmental and mediate the fast withdrawal. The septa between segments contain gap junctions. The gap junctions in all the invertebrates are presumably pannexin based; the pannexin mediating the escape jump reflex in *Drosophila* is known.

How important is electrical transmission in these systems? Synaptic delays can be less at electrical synapses, particularly at lower temperatures. In an escape response, shorter latency is better, which may account for the high incidence of electrical transmission in escape systems of poikilotherms. There remains an obligatory chemical synapse to the muscle fibers, and one appeals to as yet undefined developmental constraints to account for the lack of electrical neuromuscular junctions. The time for muscle contraction is greater than the delay at a chemical synapse, but a small percentage increase in escape probability could provide powerful selection pressure. However, as an organism gets bigger, conduction times get

longer, the time required for movement becomes greater, and the saving at an electrical synapse a smaller fraction of the response time.

Electrical synapses are is found in the vestibular nuclei and mesencephalic nucleus of the trigeminal nerve of rodents, where it may reduce response latency. In mammals, where transmission in motor systems has been characterized, there are few instances of electrical transmission. However, anatomical studies of Cx36 distribution indicate that it may be much more common that realized hitherto.

Spatial and temporal summation If many axons form gap junction synapses on a postsynaptic cell, the postsynaptic response is graded with the number of presynaptic axons activated, and firing of the postsynaptic cell depends on the summation of inputs from the presynaptic axons, just as at a cell receiving many excitatory chemical synapses. In the classic sense, the system shows spatial summation of the excitatory synaptic potentials. A second classical form of short-term interaction is temporal summation. Electrical as well as chemical PSPs can change the charge on the postsynaptic capacity, which requires time to decay back to the resting value. Electrical synapses can show temporal summation, when the postsynaptic time constant is comparable to or greater than the interval between presynaptic impulses. Furthermore, presynaptic action potentials can be prolonged or decreased in amplitude as a result of repetitive firing, both of which can modulate both electrical and chemical postsynaptic potentials.

Other forms of plasticity Coupling between neurons can be regulated in a number of ways. Inhibitory synapses along a dendrodendritic path coupling cell bodies can short-circuit coupling between them and allow them to fire independently in response to excitatory inputs closer to their cell bodies. This form of regulation has been proposed for the mammalian inferior olive and for buccal motor neurons in a mollusk.

Gap junctions may be regulated by second messengers, as in retinal horizontal cells and amacrine cells. Transmitters, such as dopamine, acting through G-protein-coupled receptors, lead to increase in cytoplasmic cAMP, which is followed by decrease in junctional conductance. It remains to be determined whether phosphorylation sites on the connexins are involved. Long-term potentiation and depression of both electrical and chemical components have been demonstrated at the club endings on the Mauthner cell. As more electrical synapses are examined, more instances of this class of regulation are likely to appear.

Coupling of cortical neurons is very widespread and promiscuous in early development but then decreases to the less frequent and more precisely targeted level seen in the adult. The roles of this early coupling are obscure. It may mediate synchronous firing that helps guide axons to their appropriate targets, or it may mediate chemical communication for differentiation. Mice with targeted deletion of any one of a number of connexins expressed in brain still exhibit relatively normal central nervous system (CNS) structure and function, suggesting either redundancy or relative unimportance.

Electrical Inhibitory Synapses

As noted, gap junction synapses mediating synchronization are both excitatory and inhibitory. Furthermore the postsynaptic potential generated by a presynaptic action potential with an afterhyperpolarization is biphasic, depolarization followed by hyperpolarization. Depending on the cell, the mean potential can be hyperpolarizing, and the result of a train of action potentials is an initial excitation followed by a prolonged inhibition with small superimposed depolarizations associated with each presynaptic spike.

A completely different kind of electrical inhibitory synapse occurs at the initial segment of the Mauthner cell. Interneuron axons converge on a structure termed the axon cap, a specialized region around the initial segment, which is where the impulse arises. Presynaptic action potentials in the inhibitory neurons generate a positivity in the extracellular space of the axon cap, the time course of which is like that of an action potential (Figure 16). It is likely that the axonal membrane acts simply as a fixed battery with a series resistance. The axons may go on to form chemical inhibitory synapses on the nearby soma of the Mauthner cell. The positivity, or 'extrinsic hyperpolarizing potential,' causes current to flow inward through the initial segment membrane (hyperpolarizing it) into the cell soma (and axon), along the cell cytoplasm and out through more-distant membrane (causing depolarization of this membrane). Since the conductance of this latter pathway is large compared with that of the initial segment membrane, most of the external potential is developed across the initial segment membrane, and impulse initiation is inhibited.

When the Mauthner cell is active, it generates a large negativity in the axon cap region. This current tends to hyperpolarize the excitable membrane in the inhibitory interneurons and inhibit them. The current flows and equivalent circuit during inhibitory neuron and Mauthner cell activity are diagrammed in Figure 16.

The electrical inhibition is a specialization for speed. Electrical inhibition reduces the latency of onset of inhibition by one chemical synaptic delay. The electrical component is brief, but it is followed by long-lasting chemical inhibition. As noted (see the

Figure 16 Diagram of an electrical inhibitory synapse at the initial segment of the Mauthner (M) cell. (a) Impulse activity of the inhibitory interneurons (I cell) produces outward current through their axon terminals (r_t) that divides to (1) flow across the external resistance (r_e) of the axon cap or (2) enter the M cell through its impulse initiation site, hyperpolarizing it and inhibiting M-cell firing. The current entering the M cell leaves through the resistance of dendritic (r_s) and axonal membrane, but the resulting depolarization does not significantly affect impulse initiation. The circles with impulses drawn in them represent the impulse-generating membranes. Conversely, impulse activity of the M cell causes current that hyperpolarizes and inhibits the impulse-generating membrane of the I cell. Reciprocity of the inhibitory interaction is made clearer by the redrawn equivalent circuit in (b). From Bennett MVL (1977) Electrical transmission: A functional analysis and comparison with chemical transmission. In: Kandel ER (ed.) *Cellular Biology of Neurons*, pp. 357–416. Baltimore: Williams and Wilkins.

section titled 'Escape!') a requirement for an effective escape response is that the Mauthner cells do not fire simultaneously and each inhibits the other. There is evidence for similar electrical inhibition at the axon hillock of mammalian cerebellar Purkinje cells.

Gap Junctions and Genetic Disease

Given the size of the connexin gene family (and Murphy's law that anything that can go wrong, will), one would expect there to be diseases caused by mutations in these genes. The first discovery was that mutations or deletions of Cx32 cause X-linked Charcot–Marie–Tooth disease, a peripheral neuropathy. Only after positional cloning demonstrated the involvement of Cx32 was it shown that this connexin is expressed by Schwann cells that form myelin. The effects of the mutations on Cx32 junctions may be subtle, such as minor changes in voltage sensitivity or permeability, or marked, leading to perturbed trafficking or complete loss of the protein. Light microscopic immunocytochemistry shows Cx32 at perinodes and Schmidt-Lanterman incisures, but their arrangement has not been clearly resolved in thin section or freeze-fracture electron microscopy. The gap junctions are apparently reflexive, that is, between different parts of the same cell, and are presumed to facilitate the interchange of small molecules between the periaxonal cytoplasm and the outermost part of the Schwann cell. The question remains as to what is communicated from outside to inside or vice versa. And it is unclear why loss of this communication, which has no apparent effect on myelin formation during growth and development, leads eventually to demyelination and degeneration of nerve fibers. Furthermore, there is no obvious pathology in other tissues expressing Cx32, either because Cx32-mediated communication is unimportant in these tissues or because another connexin takes over the function of Cx32. Some minor effects are seen in central nerve conduction and in the Cx32 knockout mouse in the liver and pancreas.

Mutations in Cx26 are the most common cause of nonsyndromic deafness (deafness without other defects). Cx26 is expressed in the cochlear epithelium, not including the hair cells, and the pathogenesis may involve impaired communication between supporting cells. In any case, degeneration of the hair cells occurs early in the development of hearing but after the major structures of the inner ear have developed. As for Cx32, few other symptoms are reported, although a minority of patients exhibit defects in skin. Mutations of Cx31, which is expressed in skin, cause erythrokeratodermia, a thickening and reddening of the skin. Cx30 mutations cause deafness or skin disease; differential effects of the mutations at different points in the life cycle of the connexin may account for these differences. Mutations in the lens connexins, Cx46 and Cx50, cause congenital cataract. Mutations in Cx43 cause oculodentodigital dysplasia, a disease involving multiple defects, including in the nervous system. Cx36 is implicated in juvenile myoclonic epilepsy, but mechanisms are obscure.

Targeted gene disruption (knockout) in mice reveals other potential genetic diseases involving mutations in connexins. Knockout of Cx32 is quite benign, but the double knockout of Cx32 and Cx47 causes loss of central myelin and early death. Knockout of Cx43 is lethal at birth because of cardiac malformation, and there are subtle abnormalities in cortical layering.

Knockout of Cx26 is embryonic lethal because of defects in the trophoblast, but conditional knockouts using various strategies to permit knockout of a gene in a specific tissue are becoming important tools for analysis of gene function that will be relevant to human disease.

Evolution

Vertebrate connexins have been grouped into alpha and beta (or group II and group I, respectively). Assignment into further divisions, gamma and delta, may be justifiable, but deep branches of the evolutionary tree are less reliable at this time. The zebra fish, *Danio rerio*, has 37 connexins, almost twice as many as mammals have, probably because teleosts have undergone a whole genome duplication. Connexins are also found in ascidians. The number of connexins in the common ancestor of ascidians and vertebrates may be no more than one. Most vertebrate connexins have a single coding exon, and alternative splicing is limited to noncoding regions. Cx36 is an exception and has two coding exons. Ascidian connexins have several coding exons, as do pannexins/innexins.

The ancestral connexin is uncertain. Occurrence in hemichordates has not been investigated. The sea urchin genome has been sequenced and is reported to lack both connexins and pannexins. The anatomical basis of coupling in this group, reported in several studies, is thus unknown. Although there were early inferences of connexins in Cnideria based on antibody labeling and Western blotting, genomic sequencing has yet to demonstrate a connexin. Their gap junctions, coupling, and electrical synapses are likely to be pannexin/innexins based.

What is the survival value of having multiple gap junction-forming proteins? Functional differences between connexins in gating, permeability, and trafficking have been demonstrated and provide one explanation for the observed diversity. There are the obvious functional differences in permeability, gating, and posttranscriptional regulation of formation and degradation. Differences in transcriptional and translational control may be more important than the functional differences in the connexins themselves.

Convergence between Connexins and Pannexins

Although differences in the gene sequences indicate that connexin-based and pannexin-based gap junctions are separate evolutionary adaptations, there is a remarkable degree of functional convergence, including block by many of the same pharmacological agents, by low cytoplasmic pH, and by high cytoplasmic Ca^{2+}. Fast V_j gating to a substate and slow gating to the completely closed state are also found in both classes, although dependence on membrane potential ($V_{i\text{-}o}$) is more pronounced in at least one pannexin junction. In pannexin junctions, the channel diameter is a little bigger, the gap is a little wider, and the number of channels per unit area is a little lower. Some pannexin junctions under specific uncoupling conditions may split, with each membrane taking its own hemichannels, which can then be reused. Pannexins do mediate coupling when expressed in *Xenopus* oocytes, but it is not yet clear whether they do so in mammals. Like connexins, pannexins form hemichannels that can open in the surface membrane without contact with a hemichannel in an apposed membrane.

Hemichannels That Open

The life history of a connexin molecule includes some time in the membrane as a hemichannel without a partner (**Figure 13**). Because of the predicted high conductance and lack of permselectivity, it was thought that these hemichannels should not open because they would stress the cells by letting in excess Ca^{2+} and Na^{+} and permitting loss of K^{+} and metabolites. Furthermore, measurements during junction formation indicated that channels were not open before connecting with hemichannels in an apposed membrane (see **Figure 14**). This conventional wisdom was confirmed when expression of Cx46, which is expressed only in lens and forms hemichannels when expressed in *Xenopus* oocytes, killed the oocytes unless Ca^{2+} in the bathing solution was kept at relatively high levels to keep the hemichannels closed. Now it is clear that hemichannels formed of a number of connexins can open to the extracellular space and can mediate both physiological and pathological responses. The open probability is generally very low, and cells can release significant amounts of signaling molecules, such as ATP, without impact on viability. Conversely, under pathological conditions hemichannels can speed death of the cells expressing them. Also, the molecules they release, such as glutamate from astrocytes, can have a toxic action on neighboring cells, in particular neurons.

A number of criteria indicate that connexins can form hemichannels. Different treatments, such as bathing in low Ca^{2+} solution, cause uptake of dyes to which gap junctions are permeable but normal cell membranes are not, and this uptake requires expression of connexins. The uptake is also blocked by gap junction blockers. Furthermore, single-channel activity can be recorded that has the predicted conductance of about twice that of the cell–cell channel formed by the same connexin. Moreover, their gating properties correspond to those of the cell–cell channels.

Pannexins in mammals may form only hemichannels, and one mode of opening is through activation of purinergic receptors. The linkage between purinergic activation and pannexin hemichannel opening is unclear. As with connexins, pannexin hemichannel opening may result in release of signaling molecules, such as ATP.

Gap Junctions and Hemichannels in Glia

Introduction

Gap junctions (GJ) are unique large channels that connect the cytoplasm of two adjacent cells. Half GJs, called connexons or hemichannels (HC), expressed by individual cells may also be functionally active, and when open would connect a cell's cytoplasm to extracellular space. Gap junctions mediate a primitive and important form of intercellular communication that is seen across phyla. Discovered in 1952 in heart muscle cells, GJs are expressed in most mammalian cells; mature skeletal muscle cells, spermatozoa and erythrocytes are the only exceptions. Gap junction mediated coupling between glial cells was first noted in the leech central nervous system (CNS) by Stephen Kuffler and colleagues in 1964. In the mammalian CNS, connexins, the proteins that form GJs and HCs, are most abundantly expressed by glial cells. All subtypes of glia express connexins and GJs, with the possible exception of the newly defined NG2 cell. The characteristics and possible functions of GJs and HCs in glial cells are the focus of this review. First, however, some important general principles about these channels and the proteins that make them will be discussed.

Connexins Form Gap Junctions

Gap junctions (GJs) are so named based on their appearance in electron micrographs. At GJs, the width of the extracellular space is narrowed to a small 'gap' of ~2.5 nm (normal width ~20 nm; Figure 1). In mammals, GJs are formed from connexins, a protein family with ancient origins and containing >20 members (Figures 1 and 2). The molecular mass of cloned connexins ranges from 25 to 62 kDa, and they are named on this basis (e.g., the 43 kDa connexin is called Cx43; Figure 2). Most cells express at least two connexin subtypes, although one is likely to predominate. Invertebrates form abundant GJs but do not express connexins. Instead, their GJs are composed of proteins called innexins that are analogous, but not strongly homologous, to connexins. Curiously, innexin-like proteins called pannexins have been detected in mammals and may mediate coupling between hippocampal pyramidal neurons. Pannexins, in contrast to connexins, however, are more likely to form hemichannels (HCs) than GJs.

Each GJ is composed of two HCs, one embedded in each of the closely opposed membranes (Figures 1 and 3). Each HC consists of six connexin molecules, and these can be aggregates of six identical connexins or a mixture of different connexins. Functional GJs can form between HCs composed of different connexins. For example, astrocytes and oligodendrocytes form GJs composed of Cx43 and Cx47, respectively. Connexins and related proteins have four transmembrane domains, and the N-terminal (NT) and C-terminal (CT) segments are both intracellular, resulting in two extracellular loops (ELs) and one cytoplasmic loop (CL). When two HCs 'dock' to make a GJ, the extracellular loops mesh to form a structural 'tight seal,' guaranteeing that the channel will not leak to the extracellular space. Covalent bonds are not involved in the formation of this tight seal. Curiously, connexin proteins have a very high turnover rate; the average half-life of these proteins is several hours.

Macroscopic GJs are aggregates of many, usually hundreds, of tightly packed GJ channels. In the mammalian central nervous system (CNS), GJs are most numerous between glial cells, especially between astrocytes. They are also seen between certain populations of neurons, including cortical interneurons and certain brain stem neurons. More detail about the expression of connexins and GJs in glial cells is given in the following sections.

Biophysical Properties of GJs

The biophysical properties of GJs can be partly understood based on their structure. Open GJs have a very large limiting pore diameter of 1.5 nm and are permeable to a much wider range of ions and molecules than are typical ion channels (typical pore diameter, ~3–5 nm). Consequently, GJ pores can admit molecules up to a molecular mass of about 1 kDa, largely independent of charge. Coupled cells, therefore, are able to exchange a wide range of biologically important molecules, including cyclic nucleotides, small molecules of intermediate metabolism, vitamins, and inorganic ions. Obviously, strongly coupled cells will have a tendency to have similar concentrations of those cytoplasmic constituents that easily pass through GJs. This principle has been conclusively demonstrated for the concentration of intracellular Na^+ in astrocytes. GJs composed of different connexins, however, vary considerably in what can pass through them. For example, GJ channels composed of Cx32 and Cx43 show marked differences in permeability to adenosine, which is 12-fold more permeable through Cx32 versus Cx43 channels.

Figure 1 Gap junction and hemichannel structure. (a) Schematic drawing of a gap junction as visualized by electron microscopy. The distance between neighboring cells narrows to about 2 nm in the junction. (b) Gap junctions are formed by two aligned hemichannels or connexons, one in each adjacent cell. Hemichannels are unopposed connexons. This is the only possible configuration when a connexon is inserted into the membrane outside the junction area. (c) Schematic drawing of a hemichannel. Each hemichannel is composed of six connexin molecules. An exploded view of a connexin molecule is shown on the right. Each connexin has four-transmembrane-spanning domains. Both the C-terminal (CT) and N-terminal (NT) portions of the connexin are located within the cell. This creates a single cytoplasmic loop (CL) and two extracellular loops (EL1 and EL2). Modified from Ransom BR and Ye ZC (2005) Gap junctions and hemichannels. In: Kettenmann H and Ransom BR (eds.) *Neuroglia*, 2nd edn., pp. 177–189. New York: Oxford University Press.

Figure 2 Phylogenetic 'tree' of known gap junction proteins in vertebrate (connexin and pannexin) and invertebrate (innexin) animal cells. More than 20 distinctive gap junction proteins have been identified (note that some of the 39 proteins listed here are only slightly different from one another and therefore do not count as distinctive proteins).

Electrophysiological analysis of single GJ channels indicates that, like other ion channels, they abruptly open and close. The permeability of GJ channels is influenced by physiological variables, including membrane potential and the intracellular concentrations of H^+ and Ca^{2+}. As a general principle, the permeability of GJs is greatest when there is no voltage difference across the junction; this corresponds to the situation when the two coupled cells have the same resting potential. Increases in intracellular concentrations of either H^+ or Ca^{2+} rapidly decrease junctional conductance (i.e., increase electrical resistance) and permeability to large molecules. Coupling conductance is sensitive to intracellular pH changes that are within the physiological range of this variable (i.e., pH 6.5 ± 0.5). Because neuronal activity can cause fluctuations of intracellular pH in astrocytes, this variable may be an important modulator of GJ function. Gating by pH depends on the connexin CT. Truncation of the CT eliminates pH sensitivity. It is believed that pH changes induce the CT to interact with a portion of the CL to close the channel, in a

fashion analogous to a 'ball and chain.' The increases in intracellular $[Ca^{2+}]$ ($[Ca^{2+}]_i$) that decrease junctional conductance are high (e.g., $\geq 10\,\mu M$), and this variable is not likely to affect coupling under normal physiological conditions; cell injury causes large increases in $[Ca^{2+}]_i$ that could lead to uncoupling.

GJ coupling is decreased by a wide range of drugs, including lipophilic agents such as the higher-order alcohols heptanol and octanol, and the anesthetic halothane. The mechanism of blockade by these agents is not clearly understood.

Hemichannels

HCs have not traditionally been thought of as 'stand-alone' ion channels. The presumption was that these channels existed only transiently in membranes before being incorporated into GJs. Moreover, to the extent that unpaired HCs existed, they would predominantly be in the closed state because of high extracellular $[Ca^{2+}]$ ($[Ca^{2+}]_o$) (Figure 3). A structural explanation for this was provided by the discovery of a site sensitive to near-millimolar $[Ca^{2+}]$ that is located on the extracellular portion of the HC pore. This site would not affect the permeability of GJs, however, because it would be inaccessible due to the tight meshing of the extracellular loops necessary to form a GJ. Because of their large pore diameter and presumed high permeability and low level of selectivity, open HCs could dissipate ion and metabolite gradients would seemingly threaten cellular integrity. This reasoning, and the fact that HCs have proved difficult to study for technical reasons, may explain why relatively little attention has been paid to HCs. Their involvement in brain function and pathology remains controversial. Because HCs connect cell cytoplasm to the extracellular space, the roles of HCs and traditional GJs are fundamentally different.

Unlike gap junctions, HCs are directly exposed to extracellular ions and thus can be effectively gated by extracellular, as well as intracellular, ion changes. A wide range of factors influence HC gating. For example, Ca^{2+}-free solution rapidly opens these channels in astrocytes and other cells. Unexpectedly, and in contradistinction to GJs, some HCs may also open in response to modest increases in $[Ca^{2+}]_i$. Open HCs are detected by uptake of appropriate marker dyes and by the release of molecules such as glutamate and ATP.

Most factors that regulate gap junctions, but probably not all, have similar effects on HCs. The ELs of an unopposed HC, for example, are far more exposed than are the same loops of two aligned HCs forming a GJ, making these ELs a prime candidate site for differential modulation (see earlier). For now, however, caution is needed when interpreting results obtained with agents that block gap junctions, because these would probably also block HCs. HCs may also be confused with other membrane ion channels that have very large pores, such as the P2X7 purinergic receptor channel.

Gap Junctions in Glial Cells

Connexins are variably expressed by all the main types of mammalian glial cells, with the possible exception of NG2 cells. Even microglial cells, felt at one time to be devoid of connexins, can express Cx43 and form gap junctions. Astrocytes are the most robustly coupled glial cells. Astrocytes of various types (e.g., protoplasmic, fibrous, Bergmann glia) form homotypic gap junctions with other astrocytes and heterotypic junctions with oligodendrocytes and ependymal cells. Astrocytes, as well as other glial cells, express several different connexins (Table 1) that may be regulated during development and affected by injury or cellular environment. Physiological variables

Figure 3 Schematic diagram of gap junctions and hemichannels in astrocytes. Gap junctions are typically open because they are exposed to low intracellular $[Ca^{2+}]$; they mediate diffusion of molecules up to 1000 Da. Hemichannels (i.e., unopposed connexons) are gated closed under normal conditions by high extracellular $[Ca^{2+}]$ (see text). When opened, hemichannels allow intracellular contents to equilibrate with extracellular fluid (e.g., glutamate leaves and Na^+ enters).

Table 1 Gap junction coupling in mammalian glial cells

Glial cell pair	*Relative coupling strength*[a]	*Connexin pairings*[b]
Astrocytes	++++	Cx43–Cx43, CX43–Cx30, Cx30–Cx30, Cx30–Cx26, Cx26–Cx26
Astrocyte–oligodendrocyte	++	Cx43–Cx47, Cx30–Cx32, CX26–Cx32
Oligodendrocytes	++	Cx32–Cx32, Cx29–Cx29
Schwann cells	++	Cx32–Cx32, Cx29–Cx29
Microglia	+	Cx43–Cx43
Müller cells	++	Cx43–Cx43, Cx43–Cx45, Cx45–Cx45
Müller cell–astrocyte	++	Cx43–Cx43, Cx43–Cx45, Cx45–Cx45
Ependymal cells	+++	Cx43–Cx43

[a]Relative coupling strength is shown as a semiquantitative score between + and ++++, with + being the lowest strength of coupling.
[b]Connexin pairings are shown in order of decreasing frequency. For example, Cx43–Cx43 is the most frequent connexin pairing for gap junctions between astrocytes.

such as glutamate application or depolarization can increase, while inflammatory cytokines decrease, astrocyte GJ coupling. The predominant connexin expressed by these cells is Cx43, but its expression varies by brain region. Not surprisingly, Cx43 is the most abundantly expressed connexin in the CNS. There are intriguing reports indicating that astrocytes form gap junctions with neurons. However, these junctions may be limited to immature cells and occur only during development. Mammalian astrocytes *in situ* typically show widespread dye coupling with each other. When the GJ-permeable dye Lucifer Yellow is injected into individual cortical astrocytes, as many as 100 adjacent cells are stained.

Oligodendrocytes primarily form gap junctions with astrocytes. The coupling between oligodendrocytes and astrocytes is mainly mediated by GJs composed of Cx43 (astrocytes) and Cx47 (oligodendrocytes) (Table 1). Although functional coupling between oligodendrocytes is readily detected *in vitro*, actual GJs are only rarely seen using electron microscopy on freshly prepared whole brain. Based on the scarcity of morphological GJs, it has been suggested that communication between oligodendrocytes might be mediated by connections through the astrocytic syncytium. 'Coupling strength' measured electrically and by dye passage is much greater between astrocytes than between astrocytes and oligodendrocytes.

In the peripheral nervous system, proliferating Schwann cells during development, or after peripheral nerve crush injury, primarily express Cx46 and are coupled to one another. When Schwann cells begin myelinating axons, they stop expressing Cx46 but increase expression of Cx32, which is confined to paranodal regions and Schmidt–Lanterman incisures. These so-called reflexic gap junctions connect the paranodal folds, perhaps facilitating ion and small-molecule movements to and from the tight, periaxonal space. The X-linked form of the hereditary neuropathy known as Charcot–Marie–Tooth disease is associated with mutations in the Cx32 gene.

Other specialized glial cells, such as ependymal cells, Müller cells of the retina, and Bergmann glia of the cerebellum, express connexins and GJs (Table 1). Activated, but not resting, microglia express Cx43 and show dye coupling *in vitro*. Interestingly, activated microglia can downregulate Cx43 expression and coupling in nearby astrocytes, probably via cytokine secretion, suggesting that astrocyte communication may be modulated by CNS inflammation mediated by microglia.

Functions of GJs and HCs

The functions of connexins, and the channels that they form (both GJs and HCs), are still debated and undoubtedly vary by cell type. This uncertainty about function is especially true for GJs and HCs in glial cells. The following comments about function are directed mainly at astrocytes. In general, GJs may serve to coordinate the electrical and metabolic activities of cell populations, act to amplify the consequences of signal transduction, control intrinsic proliferative capacity, and help to orchestrate the complex events of embryonic morphogenesis. Roles of GJs in astrocytes include equilibrating intracellular ions among coupled cells (Figures 3 and 4(a)), regulating cell proliferation, participation in signal dispersion (Figure 4(b)), participation in Ca^{2+} wave propagation (Figure 4(c)), and involvement in brain injury. Because astrocytes are strongly coupled, they can experience GJ-mediated signal dispersion (or amplification). Consider a cell stimulated to produce an intracellular second-messenger molecule (e.g., cAMP, inositol 1,4,5-trisphosphate, Ca^{2+}) by binding a specific ligand (Figure 4(b)). If the cell is not connected to its neighbors by gap junctions it will act in isolation. If the cell is widely coupled to other cells, however, the diffusible junction-permeable second messenger has the potential of affecting many cells, effectively amplifying the initial signal.

Astrocyte Ca^{2+} waves are propagated waves of elevated intracellular Ca^{2+} that may be elicited by

Figure 4 Illustration of possible functions of gap junctions and hemichannels. (a) In strongly coupled cell aggregates, the intracellular concentrations of ions and molecules less than ~1000 Da in size (including amino acids, sugars, and second-messenger molecules) will tend to be similar due to free exchange across gap junctions. (b) Glial cells express many receptors for signaling molecules (e.g., neurotransmitters, cytokines). Coupling can amplify the physiological consequences of a chemical signal acting upon a single cell. Such stimuli often evoke production of second-messenger molecules, such as Ca^{2+}, inositol 1,4,5-trisphosphate (IP_3), and cAMP, that can diffuse into adjacent cells via gap junctions; the coupled cells are then recruited to respond. (c) Gap junctions and hemichannels participate in astrocyte Ca^{2+} waves. Astrocyte Ca^{2+} waves are provoked in many ways, such as by the application of glutamate. Effective stimuli activate intracellular signaling pathways, such as those involving phospholipase C (PLC) and IP_3, which cause Ca^{2+} release from Ca^{2+} stores. IP_3 and Ca^{2+} diffuse to adjacent cells through gap junctions, creating a 'Ca^{2+} wave'. Astrocytes also release ATP upon activation, probably through hemichannels. In turn, ATP activates purinergic receptors on nearby astrocytes, the predominant mode by which Ca^{2+} waves propagate. Increase in astrocyte $[Ca^{2+}]_i$ causes glutamate release, which modulates the excitability of neighboring neurons. Reproduced from Ransom BR and Ye ZC (2005) Gap junctions and hemichannels. In: Kettenmann H and Ransom BR (eds.) *Neuroglia*, 2nd edn., pp. 177–189. New York: Oxford University Press, with permission.

glutamate application, mechanical perturbation, or ischemia (Figure 4(c)). As the wave passes through astrocytes it can elicit glutamate release and alter the behavior of adjacent neurons; in essence, this event is a slow form of signaling (slow compared to action potentials and synaptic transmission in neurons). Ca^{2+} wave propagation is dependent on both gap junctions and extracellular signaling pathways, including hemichannel-mediated ATP release; the relative contribution of these two mechanisms may vary in different brain regions.

Gap junctions tend to restrict cell proliferation. During neoplastic transformation, gap junctions are usually lost and most malignant cells are not coupled. Most primary brain tumors derive from glial cells, and loss of GJs could plausibly contribute to

CNS neoplasia. How GJs suppress mitotic activity is not clear.

Genetic manipulation is one method of assessing the function of connexins. Animals null for Cx43 die at birth because of a cardiac defect. Conditional mutants have been created in which Cx43 is suppressed only in astrocytes. These animals live to adulthood and exhibit subtle neurological changes, including increased exploratory behavior, an anxiolytic-like state, and impaired motor capacities. In humans, mutations in Cx43 cause an autosomal-dominant syndrome called oculodentodigital dysplasia (ODDD). At least half of these patients have neurological abnormalities, including spastic paraplegia and neurodegeneration (i.e., marked changes in cortex and white matter on magnetic resonance imaging), in addition to craniofacial and limb dysmorphisms. The exact pathophysiology of this condition remains uncertain and some mutations may cause a toxic gain of function or disturb the normal interactions known to occur between connexin and nonconnexin proteins.

The roles of glial HCs are mainly a matter of speculation at this time. Possible roles include (1) release of signaling molecules such as ATP or glutamate, (2) modulation of membrane potential or ion gradients in a manner similar to conventional ion channels, and (3) mediation of cell injury under pathological conditions such as ischemia. HCs can open under pathological conditions, perhaps due to oxidative stress, and may release glutamate, which could contribute to excitotoxic injury.

Conclusions

Connexins and the channels they form have been the focus of intense investigation for greater than a half century since their discovery. As more information about these fascinating channels has emerged, more questions have appeared. This is especially so in the brain, where these channels are widely expressed in glial cells. We lack conclusive insight about how they participate in brain function and pathological conditions. We are at a point, however, where critical hypotheses about their function can be formulated and tested using improved research techniques, including regional and cell-type-specific genetic manipulation of connexin expression.

Gap Junctions and Neuronal Oscillations

M O Cunningham and F E N LeBeau, Newcastle University, Newcastle upon Tyne, UK

Introduction

In addition to neuronal chemical neurotransmission, electrical transmission via gap junctions, which are protein channels that directly link the cytoplasm of adjacent cells, is now known to constitute an important type of cell-to-cell communication. Although initially thought to be important mainly in development, it is now clear that electrical signaling via gap junctions plays an important role in the adult central nervous system (CNS).

Considerable advances have been made in understanding the contribution of electrical signaling, via gap junctions, to neuronal signaling, most notably the role of synchronizing oscillatory or rhythmic activity. Oscillatory neuronal activity underlies the production of the signals recorded with an electroencephalogram (EEG) and reflects the coordinated activity of large populations of neurons. An EEG of the brain reveals rhythmic oscillatory activity in distinct frequency bands that occur during different behavioral states, and can be altered in a number of neurological and psychological diseases. Work from many research groups over the past decade has highlighted the role of electrical signaling via gap junctions in the generation, and/or spread, of synchronous oscillatory network activity. Electrical coupling via gap junctions can occur in both neurons and glial cells throughout the CNS. However, in this article, we focus on electrical coupling in excitatory principal cells and inhibitory interneurons, mainly in the neocortex and hippocampus. We provide an overview of the role of electrical signaling via gap junctions in the generation of oscillatory network activity and discuss briefly the importance of gap junction function in neurological conditions such as epilepsy.

Historical Background

The idea that neurons can form an interconnected network via direct cell-to-cell connections is not a novel concept. Proposed by Camillo Golgi in the late nineteenth century, the 'reticular theory' postulated that the nervous system could form a syncytium consisting of nerve fibers forming an intricate connected network and that the nerve impulse could propagate along such a diffuse network. However, at the same time, Ramón y Cajal's 'neuron doctrine' hypothesized that the nervous system was composed of anatomically and functionally independent units (neurons) with chemical synapses connecting them. Today we understand that in the adult mammalian brain, each of these theories reflects an important aspect of the communication in neuronal networks.

Structure and Properties of Gap Junctions in the CNS

Gap junctions form a continuous link between two separate neuronal structures (Figure 1) that allows the direct transmission of electrical signals between neurons. Neurons can be coupled together via gap junctions connecting soma-to-soma, dendrite-to-dendrite, or soma-to-dendrite. More recently, evidence has appeared of gap junctions linking neurons via axon-to-axon connections. The major proteins that form gap junctions are termed connexins (Cxs). Different Cx subtypes are defined by their molecular mass (in kilodaltons). A number of different Cx subtypes have now been identified in the vertebrate CNS, including Cx26, Cx32, Cx36, Cx43, and Cx45, but of these only Cx36 forms have been shown to be specific for neurons. A functional channel connecting two different neurons is formed by the apposition of two connexons, one in the plasma membrane of each neuron. Each connexon contains six Cx proteins. A functional gap junction is thus composed of 12 Cx subunits. Diversity in the composition of connexons in a gap junction can arise, as hemichannels can either consist of the same Cx subtype (homomeric) or different Cx subtypes (heteromeric).

Recently, a new family of gap junction proteins, the pannexins, has been identified in the CNS. Related to innexins, an invertebrate family of gap junction proteins, the so-called pannexins (Px) have been demonstrated to form functional gap junctions in recordings from paired *Xenopus* oocytes. Three Px subtypes have been described in the rat and human genome, with Px1 and Px2 expressed solely in the CNS. There are strong expression patterns for Px1 and Px2 in the cortex and hippocampus, but their functional role in network activity is unknown.

Gap junctions are not simply inert pores between neurons, as they can be dynamically modulated in a number of ways. Evidence suggests that the number of gap junctions, the pattern of expression of Cx proteins, and conductance properties of the individual channels can all be modified by neurotransmitters, second messengers, calcium ion concentrations, intra- and extracellular pH, and transmembrane voltage. This sort of modification occurs during development

Figure 1 Structure of a gap junction, showing a cluster of gap junctions (yellow) spanning two opposing plasma membranes (blue sheets). The intercellular space narrows at the point of the gap junction, bringing the two membranes into close contact. A gap junction consists of two hemichannels (one in each plasma membrane) that form a continuous channel between the two cells. Each hemichannel contains six connexin proteins, which, as a unit, are called a connexon. Insets show that a conformational change in the connexin proteins allows the gap junctions to open and close in response to modulators such as pH, calcium, and cAMP.

and in response to a variety of factors in the adult. Modulation allows for the complex, connexin-specific regulation of electrical signaling via gap junctions, although to date little is known about the mechanism.

Approaches to Studying Gap Junctions

Evidence for electrical coupling mediated via gap junctions in the CNS comes from using a multidisciplinary approach. The CNS consists of excitatory principal cells and inhibitory interneurons, and there is evidence for electrical signaling in both neuronal populations. Electron microscopy and freeze-fracture studies have anatomically demonstrated gap junctions between both interneurons and pyramidal cells in the cortex.

Early electrophysiological evidence for electrical signaling via gap junctions was obtained by recording from principal cells in the cortex and hippocampus. These studies also showed that certain dyes (e.g., Lucifer yellow) could pass from one principal neuron to another via gap junctions. In dye coupling experiments a specific dye is injected into one cell, and if that cell is coupled to other cells, dye transfer may be detected in the connected cells. However, dye coupling studies are complicated because different connexins may have different permeabilities to dyes, and dye transfer depends on the time for filling and the locations of the gap junctions. For this reason a lack of dye coupling does not completely exclude the presence of functional gap junctions.

Interneurons represent only 10–20% of the neuronal population and are thus difficult to record 'blind' with intracellular sharp electrode techniques. In order to surmount this issue experimentalists have utilized infrared differential interface contrast (IR-DIC) microscopy and whole-cell patch recording techniques. This has made it possible to identify interneurons visually from their basic morphology and thus conduct simultaneous whole-cell patch recordings from two or more interneurons. Using this technique electrical coupling between pairs of interneurons has been demonstrated. When current is injected into one cell to change the membrane potential, a potential change is also seen in the coupled cell (Figure 2). The ratio of the potential change in cell 1/cell 2 is termed the coupling coefficient or coupling ratio. As with the dye transfer studies, the absence of electrical coupling potentials cannot totally exclude the possibility that gap junctions may be present at sites too distant for current transfer to be detected with somatic recordings.

Electrically coupled interneurons have now been shown to be widespread in many areas of the vertebrate CNS, including the hippocampus and neocortex. However, elucidating the functional significance of electrical signaling via gap junctions has been made difficult by the lack of specific agents to block gap

Figure 2 Electrical coupling potentials, showing electrical coupling between fast-spiking interneurons. Paired whole-cell recordings of two fast-spiking interneurons from the hippocampal dentate gyrus region in the mouse are depicted. Traces show the voltage responses in cell 1 following depolarizing (upper) and hyperpolarizing (lower) current injections; voltage responses were also reflected in cell 2 but were smaller in amplitude.

junctions. Uncoupling agents that are currently used include heptanol, octanol, halothane, carbenoxolone, and 18α-glycyrretinic acid. However, these agents will block all gap junctions (including glial gap junctions), making it impossible to clearly identify the importance of any specific gap junctions. Recently, blockers for Cx36 have been described, including quinine and the more specific mefloquine. However, all of these compounds have been reported to have a range of nonspecific effects that could also affect neuronal activity. New strategies have been developed to study the role of electrical signaling via gap junctions using genetically engineered mice that lack specific connexin proteins (see later).

Evidence for Gap Junctions between Principal Neurons

Dye coupling studies show that when one principal cell is injected with dye, often one or two other cells also fill with dye, suggesting direct coupling between the cells. Procedures that increase gap junction conductance (e.g., reduced extracellular calcium) tend to increase the number of dye-coupled neurons. Conversely, the degree of dye coupling is diminished when gap junction conductance is reduced by the application of gap junction blockers. In these and earlier studies, potentials resembling small action potentials (<10 mV) were observed in recordings from the soma of principal cells. Termed fast prepotentials (FPPs), and first observed *in vivo*, these events were initially believed to arise from electrogenesis in dendrites. Subsequent experimental studies, however, suggested that FPPs or spikelets (presently the more commonly used term) represent action potentials in electrically coupled neurons.

The location of the gap junctions that mediate coupling between principal cells has yet to be conclusively demonstrated. Paired whole-cell patch recording techniques have failed to demonstrate significant electrical coupling between the somas of principal cells. However, recent intracellular recordings with sharp electrodes show high levels of coupling between pyramidal cells in the hippocampus. There is evidence to suggest that electrical signaling via gap junctions could be axo-axonic in principal cells. Computational studies first proposed that the fast kinetics of the spikelets seen in pyramidal cells could only be explained if the gap junctions were located between axonal compartments. If the gap junctions were located at remote sites on the dendrites of pyramidal cells, then the electrical-filtering properties of the dendrites would result in slower kinetic properties of the spikelets. Experimental evidence was subsequently provided when one study, using paired recordings from the soma and axon hillock/axon initial segment of the same cell, showed that following antidromic stimulation of the relevant fiber tract, the evoked spikelet appeared first in the axon hillock/initial segment and then in the soma. Subsequent visualization experiments revealed that the path taken by dye loaded into one cell could be followed in real time, as it was observed first filling in the axon and then subsequently in the soma of a second neuron. One recent electron microscopy study has found ultrastructural evidence for gap junctions between pairs of mossy fiber axons in the CA3 region of the hippocampus. However, the identities of the proteins that compose the putative axo-axonic gap junctions are not fully known, although the pannexins and Cx36 have both been proposed as possible candidates.

Evidence for Gap Junctions between Interneurons

Perhaps the greatest advance in our understanding of the role of electrical signaling via gap junctions has come from studies of interneurons. Interneurons in the hippocampus and neocortex consist of a number of distinct subtypes that can be identified on the basis of their morphology, physiological properties, and their expression of specific chemical markers such as peptides or calcium-binding proteins. Early anatomical studies clearly demonstrated evidence for the existence of dendrodendritic or dendrosomatic gap junctions between interneurons in the cortex.

Recent physiological studies have also shown that interneurons can be electrically connected. Electrical coupling between interneuron pairs has been shown to be bidirectional, with current usually flowing equally in both directions. In addition, gap junctions function as low-pass filters in that they preferentially transmit low-frequency signals. Fast signals, such as action potentials, are not transmitted as well and appear in the coupled cell as a truncated spikelet. Nonetheless, spikelets can still facilitate the generation of action potentials in the coupled cell and so enhance the spread of activity. The traditional view of electrical signaling via gap junctions as important for mediating fast excitation is an oversimplification. Gap junctions can transmit depolarizing and hyperpolarizing current equally well. For example, the afterhyperpolarization that follows an action potential is also transmitted to the coupled cell, so a spikelet can be followed by a significant hyperpolarization. Thus electrical signaling can be both excitatory and inhibitory.

A key feature of gap junction coupling observed between cortical interneurons is that it is mainly between interneurons of the same class (e.g., fast-spiking basket cells, multipolar bursting cells, neurogliaform cells, and low-threshold spiking cells). As it has long been postulated that different classes of interneurons are involved in different functions, this specificity of connectivity leads to the formation of distinct networks of electrically coupled interneurons, each of which could be involved in a separate function. In the neocortex, at least five different interneuron networks of electrically coupled cells have now been identified (Figure 3). Interneurons belonging to the same morphological class exhibit gap junction coupling, often with a high incidence (e.g., 50% of basket cells coupled). However, only a few cases of electrical coupling between different interneuron classes have been reported. Paired whole-cell patch recordings reveal that electrical coupling between all inhibitory interneurons so far studied is mediated by the same connexin (Cx36). In mice (though not in rats), Cx36 is expressed only in interneurons, and mice that lack Cx36 exhibit no functional electrical coupling between pairs of interneurons. As yet we know nothing about the mechanisms that regulate the specificity of interneuron coupling so as to ensure that connections only form between interneurons of the same type. This remains an important issue to address in the future.

There is strong evidence for the developmental refinement of the cell-specific distribution of gap junctions. The degree of electrical coupling in both rodent and human brain declines with maturation. This decline in the extent of electrical coupling was one reason that electrical signaling via gap junctions

Figure 3 Five networks of distinct electrically coupled γ-aminobutyric acid (GABAergic) interneurons in the cerebral cortex. Numbers indicate cortical laminae. Pyramidal cells are shown in black. Different colored circles represent different interneuron classes that are electrically coupled (jagged lines). Some interneuron classes are also chemically synaptically coupled, and all form synapses onto the pyramidal cells. CB, calbindin; CB_1 IS, cannabinoid receptor-1-expressing irregular-spiking cell; FS, fast-spiking cell; LS, late-spiking cell; LTS, low-threshold spiking cell; MB, multipolar bursting cell; PV, parvalbumin; SST, somatostatin.

was thought to be important mainly in development. However, a number of studies have demonstrated that electrical coupling persists in the adult brain, and computational studies predict that low levels of coupling (e.g., one to two gap junctions per cell) are in fact sufficient to enhance network synchronization.

Gap Junctions and Oscillations of Cognitive Relevance

Oscillatory, or synchronized, network activity occurs in the EEG in different frequency bands during specific behavioral states in mammals, including humans. Oscillations can occur at from less than 1 Hz to several hundred hertz. This broad range of activity is tightly linked to higher cognitive function such as memory formation, sensory perception, and integration. Two types of oscillatory activity in which the role of electrical signaling via gap junctions has been particularly well studied are the gamma frequency (20–80 Hz) and ultrafast (>80 Hz) or very fast oscillations (VFOs). Gamma frequency activity can be recorded in many brain areas but is particularly prominent in the neocortex and hippocampus. It is associated with a number of functions such as sensory perception, attention, learning, and memory. Ultrafast oscillations in the hippocampus are also associated with memory functions, particularly the consolidation of declarative memories.

Role of Electrical Signaling via Gap Junctions in Generating Fast Network Oscillations

A major methodological advance in the study of gamma frequency oscillations has been the ability to study this activity *in vitro*. Persistent gamma oscillations can be induced and sustained in brain slices of hippocampus and cortex by the bath application of drugs that can depolarize both pyramidal cells and interneurons such as kainate, muscarinic, or glutamate metabotropic receptor agonists. Gamma frequency activity cannot be generated in the absence of inhibitory neurotransmission, and several studies have identified specific interneuron classes, particularly fast-spiking basket cells, that fire at gamma frequency during the oscillation and so contribute to the generation of this activity. However, in addition to its role in GABAergic inhibition, electrical signaling via gap junctions also appears to be important for the generation of gamma frequency oscillations. Recent work suggests that electrical coupling between both interneurons and pyramidal cells is important for the generation of gamma frequency activity.

It had been known for some time that application of gap junction blockers (halothane, octanol, and carbenoxolone) can abolish gamma frequency oscillations, but these studies could not distinguish the contribution of electrical signaling via gap junctions in interneurons versus pyramidal cells. However, it is possible *in vitro* to generate a gamma frequency oscillation in which pyramidal cell activity has been blocked – the so-called interneuronal network gamma (ING). Computational modeling studies initially suggested that, along with chemical inhibitory transmission, electrical signaling via dendritic gap junctions between interneurons was important for synchronizing gamma frequency activity. Using the *in vitro* ING model it was found that blockade of gap junctions markedly reduced the synchrony of the oscillations, although some gamma frequency activity still remained.

The contribution of electrical coupling between interneurons to fast network oscillations was tested further using Cx36 knockout mice that specifically lack functional electrical coupling between interneurons. Using the Cx36 mice, in which excitation is intact, it was found that the ability of hippocampal neuronal networks to generate gamma frequency activity was significantly reduced. Reductions in gamma frequency activity were seen both *in vitro* and *in vivo*. At a cellular level, recordings from principal cells and interneurons *in vitro* showed a disruption in the amplitude, rhythmicity, and coherence of inhibitory inputs. Under normal conditions, spikelets in interneurons increase the likelihood of full action potentials being generated in the coupled cells, thus enabling a network of interneurons to fire synchronously. These synchronous inhibitory outputs impinge on the postsynaptic principal cells and control the timing of the spike output, as the principal cells can only fire once the inhibition has decayed. The inability of interneurons in the Cx36 knockout mice to synchronize properly their firing via gap junctions leads to a reduction in the precision of their action potential timing and thus their rhythmic inhibitory output. Behavioral studies have shown that mice lacking Cx36 exhibit learning and memory impairments, an observation consistent with the idea that normal gamma frequency activity is important for these cognitive tasks.

Importantly, the loss of Cx36 did not lead to the complete abolition of gamma frequency activity. A residual gamma oscillation was still present both *in vivo* and *in vitro*. *In vitro* it was shown that this remaining gamma frequency oscillation was blocked by the putative gap junction blocking agent, carbenoxolone. This suggested that some other form of

gap junction-mediated signaling is also required for the generation of the gamma frequency activity, and this is now thought to arise from the pyramidal cell population.

Electrical signaling via gap junctions between pyramidal cells was initially proposed to underlie the generation of certain types of ultrafast or 'ripple' activity. Using an *in vitro* brain slice model, high-frequency oscillatory activity, or 'ripples,' occurring at ~80–150 Hz can be generated in the hippocampus in the absence of chemical synaptic transmission when using a nominally calcium-free bath medium. The lack of chemical synaptic transmission in these experiments supports the hypothesis that this activity is dependent on direct electrical connections between neurons. The 'ripple' activity is abolished in the presence of pharmacological blockers of gap junctions, such as halothane or carbenoxolone. At the level of individual neurons, intracellular recording from principal cells revealed that, concomitant with the extracellular field potential 'ripple,' the cells discharged either a full-action potential or a spikelet. The kinetic properties of these spikelets (as discussed earlier) were too fast to be due to dendrodendritic gap junctions, and so axo-axonal connections were proposed. In addition, in the Cx36 knockout mice, this ultrafast oscillatory activity was normal both *in vivo* and *in vitro,* suggesting that interneuronal electrical coupling did not underlie this activity.

More recent work has now demonstrated that the ultrafast oscillations coexist with the gamma frequency activity. Ultrafast oscillations can be generated in the axon plexus of pyramidal cells in the hippocampus. It is currently thought that these high-frequency oscillations occur as a result of random ectopic action potentials (action potentials arising from regions other than the axon hillock) in the axon plexus. This random activity spreads throughout the axon plexus, via axo-axonic gap junctions, resulting in a barrage of fast excitatory synaptic potentials that can be recorded in the interneurons, and provides the necessary excitatory drive for the interneurons. The combination of chemical and electrical connections between the interneurons then allows a synchronized output back to the pyramidal cells at gamma frequency. Gap junctions are therefore required between the pyramidal cells to generate the drive to the interneurons, and the gap junctions between the interneurons are needed to temporally coordinate their activity.

Gap Junctions and Epilepsy

The EEG is an important test in the diagnostic process of treating epilepsy. Traditionally, this approach has been noninvasive, using small, metal electrodes attached to the scalp. This approach is satisfactory for the medical evaluation of the seizure activity. However, there are limitations to this approach. The advent of digital recordings and invasive human studies using depth electrode recordings or subdural electrode mats now allows the measurement of electrical signals with frequencies greater than those recordable with conventional EEG equipment. Using these techniques, ultrafast oscillatory activity has been observed in close proximity to seizure onset zones in both animal models and humans. Indeed, it has been suggested that this type of activity is a reliable electrophysiological marker of epileptogenicity. A common feature of focal epileptic seizure activity, in both humans and experimental models, is the presence of ultrafast oscillations. Thus fast ripples associated with interictal spikes currently provide information on localization and epileptogenicity of the tissue involved in their generation. Evidence from developmental studies further supports a role of gap junctions in epilepsy. Thus genetic linkage mapping demonstrates that Cx36 is a high-ranking positional and functional candidate gene for juvenile myoclonic epilepsy.

A number of molecular biology studies have demonstrated that in neuronal tissue obtained from animal models and human cases of epilepsy there are obvious alterations in the abundance of connexins. Most of this work concerns the expression of connexins, which is limited to astrocytes. Several studies have examined protein and or mRNA expression, but the results from these studies yield conflicting results, with some reporting increases in connexin expression and others reporting decreases. Differences in a number of the experimental parameters applied could account for these discrepancies. It is obvious that more work is required to determine whether Cxs are modified in epileptic tissue, and if so in what directions. Moreover, if putative axo-axonic gap junctions are composed of pannexins, then attempts should be made to examine the expression and localization of such proteins in both human epileptic tissue and tissue from animal experimental models of epilepsy.

Conclusions

Recent advances over the past decade have demonstrated that both chemical signaling and electrical signaling play a central role in cortical communication. It is generally widely accepted that chemical signaling allows for highly complex, specific, and modifiable neuronal communication. However, it is now apparent that electrical signaling mediated via gap junctions can also demonstrate a high degree of functional specificity. Thus, the combination of

multiple coexistent synaptic and electrical networks serves to greatly enrich the processing capabilities on neuronal networks.

Introduction

One of the first roles assigned to astrocytes was the supply of energetic compounds to neurons, since astrocytes form the first cellular barrier encountered by glucose as it enters the brain. In fact, astrocytic end-feet surround intraparenchymal blood vessels and astrocytic processes are in close contact with neurons. Thus, astrocytes are physically located between the capillaries and neuronal elements. In addition, astrocytes are ideally suited for such a nutrient role: they store glycogen, to the point where they can be identified at the ultrastructural level by the presence of glycogen granules. In addition, astrocytes process glucose glycolytically and release lactate, which serves as a metabolic fuel for neurons. Thus, due to their typical morphology, their intimate ensheathing of blood capillaries and synaptic contacts, and their specific metabolic activity, astrocytes can sense synaptic activity, evaluate the neuronal need for energetic metabolites, and dispatch metabolites for the maintenance of energy balance in neurons.

This metabolic role of astrocytes may be played by single and independent astrocytes, but a characteristic feature of astrocytes is communication through intercellular gap junctions. Since these intercellular channels allow diffusion of molecules between adjacent cells, it seems more likely that functionally coupled astrocytes are involved in metabolic trafficking. According to this hypothesis, two or more astrocytes can form a 'shuttle system' between blood vessels and neurons, and therefore the participation of gap junctions in metabolic trafficking should be considered. The aim of this article is to put together the evidence obtained so far, regarding diffusion of metabolic substrates through astrocytic gap junctions that can support this hypothesis. In addition, we focus on the effects of disrupting gap junctional communication on glucose uptake and metabolism and its relation with proliferation.

Permeability of Astrocytic Gap Junctions for Metabolic Compounds

Classically, most studies performed to demonstrate the occurrence of gap junction-mediated intercellular communication have been carried out using either electrophysiological techniques or intracellular loading of low molecular mass (up to 1000–1200 Da) tracers or fluorescent dyes. Although initial studies led to the conclusion that the junctional channel is an aqueous pore of large diameter and low selectivity, several authors reported that channels composed of different connexins (Cx) have different permeability properties. In fact, the rate of permeation of metabolites through gap junctions clearly differs according to the Cx composition. Therefore, the diffusion of metabolic compounds through astrocytic gap junctions needs to be addressed by using astrocytes, or at least cells that communicate through gap junctions composed of Cx43, since this is the main Cx expressed in astrocytes *in vivo* and *in vitro*.

The diffusion of various energetic metabolites through astrocytic gap junctions has been evaluated by adapting the scrape-loading dye transfer technique, using several radioactive metabolic compounds and following their intercellular spreading by autoradiography. This method, which must be performed with a confluent cell population, results in the loading of a large number of cells after they have been transiently opened to an extracellular medium devoid of calcium ions and containing a high concentration of the probe used to test gap junction permeability. After washing, if the junctional channels are functional, an intercellular diffusion of the dye is observed, provided the probe used does not leak through the plasma membrane to the outside. Such a technique is well suited for a membrane-impermeant dye such as Lucifer yellow, but has to be modified when metabolic compounds are used. Thus, to prevent the diffusion of metabolites through the plasma membrane, the experiments must be carried out at low temperature (4 °C) in the presence of a saturating concentration of the same nonradioactive metabolite. Moreover, after a given time (1–2 min) allowed for intercellular diffusion, preparations are fixed by drying the cells on a hot plate (100 °C). Prints of the distribution of the labeled compounds are finally obtained by exposing the dried coverslips to an X-ray-sensitive film, which is then photomicrographed and scanned for quantification (Figure 1).

Passage of Glutamine and Glutamate through Astrocytic Gap Junctions

Using the aforementioned technique, passage of glutamine and glutamate through astrocytic gap junctions has been achieved. In addition, passage of glutamate between Cx43-transfected C6 glioma cells has been documented. Diffusion of these metabolites

Figure 1 Adaptation of the scrape-loading dye transfer technique to measure the diffusion of radiolabeled substrates. (a) Passage of radiolabeled glucose-6-phosphate through astrocyte gap junctions. Astrocytes in primary culture growing on coverslips were scrape-loaded in the presence of 50 mM glucose and 20 μCi ml^{-1} of [^{14}C]U-glucose-6-phosphate. (b) Gap junctional communication was inhibited by the addition 100 μM endothelin-1 to the solutions used in the experiment. Dried coverslips were autoradiographed and the images were digitalized for quantification.

is inhibited by octanol or carbenoxolone, well-known inhibitors of gap junction permeability, suggesting that glutamine and glutamate can be distributed throughout the brain by passage through astrocytic gap junctions. In fact, glutamine is an excellent energetic substrate for both neurons and astrocytes in primary culture. Glutamine crosses the blood–brain barrier and its carbons are readily decarboxylated in the tricarboxylic acid cycle, consistent with the idea that glutamine is a very important energetic substrate. Although glutamine is a poor substrate for lipid synthesis in both neurons and astrocytes, its carbons can also be used to replenish tricarboxylic acid cycle intermediates in neurons. The passage of glutamine and glutamate through astrocytic gap junctions may also play an important role in the operation of a glutamine–glutamate cycle between neurons and astrocytes (Figure 2).

Passage of Glucose and Glucose-6-Phosphate through Astrocytic Gap Junctions

In agreement with the idea that astrocytic gap junctions are freely permeable to glucose, both radiolabeled glucose and radiolabeled 3-*O*-methylglucose, which cannot be metabolized, diffuse through gap junctions, indicating that it is glucose *per se* which

Figure 2 Syncytial metabolic operation of astrocytes coupled by gap junctions. Brain blood capillaries are surrounded by astrocyte processes through which energy substrates are taken up. To reach brain areas distant from the blood supply, energy substrates must cross astrocytic gap junctions (GJ) using an on/off mechanism that may be regulated by ATP concentrations through the ATP-sensitive potassium channel. Indeed, astrocytic gap junctions are permeable to glucose, glucose-6-phosphate (glucose-6-P), lactate, glutamate, and glutamine. Owing to the scarce presence of glucose-6-P in astrocytes, glucose-6-P from glycogen breakdown is converted into lactate, which can be used by neurons both as an energy substrate and as a lipid precursor. Astrocyte gap junctions may also participate in the glutamate/glutamine cycle that takes place between neuron and astrocyte.

passes through gap junctions. In addition, Goldberg and colleagues have reported radiolabeled-glucose diffusion through gap junctions in C6 glioma cells transfected with Cx43. More recently, Blomstrand and Giaume have shown that fluorescence-labeled glucose (2-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl) amino]2-deoxy-D-glucose) can diffuse through astrocytic gap junctions. This molecule allows online visualization of glucose diffusion in living astrocytes. All of these results serve to demonstrate the passage of glucose through astrocytic gap junctions.

The first and compulsory step in glucose metabolism is its phosphorylation, forming glucose-6-phosphate. Interestingly, the phosphorylated form of glucose also crosses astrocytic gap junctions. Since the plasma membrane is not permeable to glucose-6-phosphate, gap junctions may be the only way to transfer glucose-6-phosphate between neighboring astrocytes. In conclusion, astrocytes that communicate through gap junctions can operate as a metabolic syncytium, since gap junctions are permeable to low molecular weight phosphorylated compounds that otherwise cannot pass through the plasma membrane (Figure 2).

Passage of Lactate through Astrocytic Gap Junctions

The main product from glucose and probably from glycogen metabolism in astrocytes is lactate, which is synthesized in both normal and pathological situations. Although both neurons and astrocytes can use lactate as a substrate to provide energy and carbon skeletons, an attractive hypothesis for this substrate has been proposed in which lactate is supplied by astrocytes to neurons for metabolic purposes, depending on synaptic activity. Astrocytic gap junctions are permeable to lactate, which may contribute to its diffusion through brain structures (Figure 2). This helps to explain why lactate is able to support neuronal activity.

Metabolic Exchange between Astrocytic Gap Junctions: Relevance for Distribution of Glycogen Breakdown Products

The passage of glucose-6-phosphate and lactate through gap junctions may play a role in the trafficking of glucose carbons between astrocytes. Although brain glycogen is mainly confined to astrocytes, these cells lack glucose-6-phosphatase activity. Therefore, glucose-6-phosphate must be confined within astrocytes. Since the plasma membrane is not permeable to phosphorylated compounds, glucose-6-phosphate can be channeled to adjacent astrocytes through gap junctions, or it can be transformed into lactate through the glycolytic pathway for release to neurons. Indeed, it has been reported that the main product of glycogen breakdown in cultured astrocytes is lactate, which is released into the medium, presumably for use by neurons. It should be noted that glycogen has been proposed as a source of energy for memory processes. If so, the aforementioned mechanism for trafficking glycogen products through brain structures should be considered very relevant (Figure 2).

Regulation of Astrocytic Gap Junctional Communication: Contribution to Regulation of Metabolic Syncytial Operation

Astrocytes have the equipment to receive, integrate, and transmit signals, since they express a broad variety of membrane ionic channels, transporters, and receptors linked to most known signal-transduction pathways. One consequence of the activation of several astrocytic membrane receptor subtypes is the up- or downregulation of gap junction permeability, which indicates that junctional communication in astrocytes may exhibit some degree of plasticity and remodeling. For instance, endothelin-1, a peptide produced by several brain cell types, including endothelial cells, astrocytes, and certain neurons, is a potent inhibitor of astrocytic gap junctions. The regulation of gap junctional communication between astrocytes promoted by these molecules can affect the passage of metabolites through gap junctions, because endothelin or its second messenger, arachidonic acid, inhibit gap junction permeability for glucose and its derivatives. This suggests that the passage of metabolites through astrocytic gap junctions can be regulated through a paracrine mechanism. In fact, gap junction permeability is controlled by the activity of the K-ATP channel, which is composed of two subunits, KIR (inwardly rectifying K^+ channel) and SUR (sulfonylurea receptor), the latter conferring the channel sensitivity to ATP, sulfonylureas, and to an endogenous ligand, endosulfine. The existence of the K-ATP channel has been reported in the central nervous system (CNS), and this channel is sensitive to sulfonylureas and to endosulfine. Actually, sulfonylureas significantly decrease the inhibitory effect of Ca^{2+} on gap junctional permeability in astrocytes, suggesting that the K-ATP channel may control permeability through gap junctions in astrocytes. Sulfonylureas still decrease the effect of Ca^{2+} in the presence of the Ca^{2+} ionophore A-23187, suggesting that the effect of the K-ATP channel on gap junction permeability is not associated with changes in cytosolic free-Ca^{2+} concentrations. Instead, membrane depolarization caused by the inhibition of the K-ATP channel would prevent the inhibition of gap junction permeability caused by Ca^{2+}, suggesting that the K-ATP channel may regulate gap junction permeability by controlling membrane potential through a

mechanism that is independent of, but mandatory in, the Ca^{2+} effect. This hypothesis is in agreement with the finding that the increase in external K^+ concentration, which leads to depolarization, increases gap junction permeability in astrocytes.

Because sulfonylureas mimic the effects of ATP on the K-ATP channel, it is proposed that intracellular ATP concentrations might regulate gap junction permeability controlling the K-ATP channel. Therefore, the energy status of the astrocyte would be able to regulate intercellular communication through gap junctions. When the energy status of the astrocyte is sufficient to sustain its own metabolic machinery, gap junction permeability would increase, to allow the passage of metabolites to adjacent cells. However, if the energy reserves of the astrocyte were compromised, ATP concentrations would decrease, resulting in a drop in gap junction permeability. Therefore, astrocytic gap junctions may play an important role in 'pipelining' metabolic substrates through the CNS, by acting like waterway locks that allow establishment of a cell-to-cell metabolite gradient, which then fuels the transport of substrates to targeted neurons. Accordingly, ATP concentrations may regulate the open/closed state of the 'locks' by controlling the activity of the K-ATP channel. Once the incoming substrates have fulfilled the energy requirements of the cells, gap junction permeability would increase, to allow spared metabolic substrates to pass to adjacent cells, thus distributing energy and carbon skeletons through the CNS (Figure 2). Therefore, it is reasonable to suggest that the K-ATP channel plays an important role in controlling the transport metabolites and signals through the CNS, thus regulating the crucial collaboration between astrocytes and neurons.

Besides these metabolic substrates, important endogenous metabolites have been reported to be able to diffuse through gap junctions. In particular, ATP and ADP can be transferred through Cx43 channels, indicating that gap junctional communication may contribute to the maintenance of the energy status of the astrocytic network.

Inhibition of Gap Junctional Communication Increases Uptake of Glucose in Astrocytes

Several lines of evidence suggest that the inhibition of gap junctional communication increases the uptake of glucose in astrocytes (Figure 3). Thus, structurally unrelated inhibitors of astrocytic gap junctional communication, such as endothelin-1 (ET-1), arachidonic acid, oleic acid, carbenoxolone (CBX), or α-glycyrrhetinic acid (AGA), promote an

Figure 3 Gap junction (GJ) inhibition increases the rate of astrocyte proliferation. Gap junction inhibition increases glucose uptake by increasing the activity of glucose transporter 1 (GLUT-1) and type I hexokinase (HK). The increase in glucose uptake is maintained by the upregulation of GLUT-1 and type I HK and the appearance of different isoforms of glucose transporter (GLUT-3) and HK (type II). Glucose-6-phosphate (glucose-6-P) is then transformed to ribose-5-P through the pentose phosphate pathway (PPP), which is used for DNA synthesis to account for the increase in the rate of astrocyte proliferation.

increase in the rate of glucose uptake. The effect of these compounds on glucose uptake seems to be related to their ability to inhibit gap junctional communication. For instance, changes in their structure affecting their role in gap junctional communication, such as the esterification of oleic acid to form methyl-oleyl ester, abolish their role in glucose uptake. Other fatty acids, such as stearic acid, which does not affect gap junctional communication, do not increase glucose uptake either. The intensive coupling of astrocytes through gap junctions is required for the effect of the inhibitors of gap junctional communication on glucose uptake to be exerted, because their effect depends on the level of Cx43 expression and on the extent of gap junctional communication. In fact, in dissociated astrocytes, the gap junction channels of which are not functional, the inhibitors of gap junctional communication do not affect glucose uptake. Moreover, these compounds also fail to affect glucose uptake in C6 glioma cells, which are known to be poorly coupled through gap junctions. Finally, when the inhibition of gap junctional communication is prevented by tolbutamide, the inhibitors of gap junctional communication are not able to increase glucose uptake. Altogether, these results strongly suggest that the inhibition of gap junctional communication promotes an increase in the rate of glucose uptake in astrocytes. It can be speculated that the purpose of increasing the uptake of glucose is to compensate the decrease in the entry of glucose and other metabolites through astrocytic gap junctions.

Effect on Glucose Transporters

Glucose transport by astrocytes is mainly brought about through the energy-independent facilitative glucose transporter GLUT-1. The inhibition of gap junctional communication promotes a rapid translocation of GLUT-1 from an intracellular pool to the plasma membrane, which may be responsible for the increase in the V_{max} for glucose uptake found when gap junctional communication is inhibited. Similar changes in GLUT-1 distribution have been reported in response to some growth factors, indicating that this system may be designed to rapidly increase glucose uptake to meet cellular metabolic requirements.

In addition to this short-term regulation, the level of GLUT-1 is increased after 24 h of treatment with inhibitors of gap junctional communication, indicating that the inhibition of gap junctional communication also triggers a long-term regulation of glucose transport. In fact, GLUT-3, which is not normally present in astrocytes, although its expression can be induced under several circumstances, is induced after the inhibition of gap junctional communication. The upregulation of GLUT-3 has been associated with an increase in glucose uptake because this isoform exhibits a higher capacity for glucose transport than does GLUT-1. In fact, the K_m for glucose uptake is significantly reduced after treatment with the inhibitors of gap junctional communication.

Effect on Glucose Phosphorylation

The method of estimating glucose uptake with 2-deoxy-[U-^{14}C]glucose includes glucose entry and phosphorylation to 2-deoxy-[U-^{14}C]glucose-6-phosphate, which is confined inside the cell, where it is not further metabolized. Therefore, glucose uptake includes not only glucose transport but also glucose phosphorylation, which in the brain is mainly catalyzed by type I hexokinase. This enzyme can undergo rapid and reversible changes in subcellular compartmentation between mitochondria and the cytosol. In astrocytes, most of the type I hexokinase is associated with mitochondria. Interestingly, the inhibition of gap junctional communication promotes a rapid detachment of a significant proportion of type I hexokinase from mitochondria. This is rather unexpected, since it is generally accepted that the activity of hexokinase bound to mitochondria is greater than that of cytosolic hexokinase. However, the inhibition of gap junctional communication increases the translocation of type I hexokinase toward a specific subcellular location (i.e., to the microtubules). In this context, it has been reported that the binding of hexokinase to microtubules increases the activity of the enzyme. Consequently, the inhibition of gap junctional communication promotes a rapid translocation of type I hexokinase from mitochondria to microtubules, which could be responsible for the rapid increase in the activity of the enzyme. Thus, both glucose entry and phosphorylation are rapidly increased, probably to compensate the closure of an important route of metabolite supply (i.e., gap junctions). However, in addition to this rapid activation of the enzyme, longer exposure to inhibitors of gap junctional communication (24 h) induces a significant increase in the amount of type I hexokinase and the induction of type II hexokinase. It should be mentioned that type II hexokinase is not normally present in astrocytes but it is specifically induced in tumoral cells, contributing to their high rate of glycolytic activity.

Fate of Glucose after Inhibition of Gap Junctional Communication

As previously mentioned, prolonged inhibition of gap junctional communication in astrocytes induces the expression of isoforms characteristic of highly proliferative cells, such as GLUT-3 and type II hexokinase, suggesting that these phenotypic changes are designed to sustain a higher rate of cell proliferation.

In fact, analysis of the metabolic fate of glucose reveals that the inhibition of gap junctional communication specifically increases the flux of glucose through the pentose phosphate pathway (PPP). This pathway provides the ribose-5-phosphate needed for nucleic acid synthesis. In agreement with this, the inhibition of gap junctional communication increases the synthesis of nucleic acids from glucose, because glucose incorporation into both DNA and RNA increases (Figure 3).

Prolonged Inhibition of Gap Junctional Communication Induces Astrocyte Proliferation

For decades, gap junctions have been proposed to be required for an adequate rate of cell proliferation. In fact, the inhibition of gap junctional communication increases astrocyte proliferation (Figure 3). Thus, the presence of several inhibitors of gap junctional communication almost doubles the rate of 5-bromo-2-deoxyuridine (BrdU) incorporation in astrocytes. This effect is abolished by preventing the inhibition of gap junctional communication with tolbutamide, or when astrocytes are poorly communicated through gap junctions (i.e., only after 10 days in culture or in astrocytes after 21 days in culture, replated at half the density to avoid the establishment of gap junctional communication).

The percentage of astrocytes found in the S, G2, and M phases increases significantly after the inhibition of gap junctional communication, with a concomitant decrease in the G0 and G1 phases. In addition, the levels of Ki-67, a protein present during all active phases of the cell cycle but absent from resting cells, increases after the inhibition of gap junctional communication, indicating that the inhibition of gap junctional communication promotes the entry of astrocytes into the cell cycle.

In G0 and early G1, retinoblastoma protein (pRb) exists in a hypophosphorylated state but is sequentially phosphorylated on several residues; as a consequence, the cell passes through G1 and enters the S phase. The inhibition of gap junctional communication promotes the phosphorylation of pRb on Ser780. It should be mentioned that Ser780 has been identified as belonging to the sites that are initially phosphorylated in the G1 phase. Once pRb has been phosphorylated on Ser780 it loses its ability to bind and inhibit E2F, a family of transcription factors that activate the genes required for progression from the G1 to the S phase. pRb is phosphorylated on Ser780 by Cdk4/6, which is modulated positively by D-type cyclins. As a consequence of the inhibition of gap junctional communication, the levels of cyclins D1 and D3 are increased, suggesting that these cyclins may be responsible for activating the phosphorylation of pRb on Ser780 and hence for the transition of astrocytes from the G0/G1 to the S phase observed after the inhibition of gap junctional communication. Together, these results provide evidence for the involvement of cyclins D1 and D3 as sensors of the inhibition of gap junctional communication in astrocytes and suggest that they could be mediators in the mitogenic effect observed in these circumstances. These findings also suggest that D-type cyclins, apart from their classical role as sensors of growth factors, can respond to changes in the cellular context, such as the interruption of cell-to-cell communication.

Increase in Gap Junctional Communication Is Associated with a Decrease in Both Cell Proliferation and Glucose Uptake in Glioma Cells

Gliomas are the most common brain tumors and are generally highly malignant, with a poor prognosis. The neoplastic phenotype of gliomas and several other tumors includes the absence of gap junctional communication. Thus, the expression of Cx43, the main protein forming gap junction channels in astrocytes, correlates inversely with the degree of glioma malignancy. In addition, when Cx43 is overexpressed in glioma cells, the rate of cell growth decreases, indicating that Cx43 behaves as a tumor suppressor protein for gliomas. In this sense, tolbutamide increases gap junctional permeability and Cx43 expression in poorly coupled C6 glioma cells. This effect was similar to that found with dbcAMP, a well-known activator of gap junctional communication in tumor cells. Furthermore, the increase in communication promoted by tolbutamide or dbcAMP is concurrent with the inhibition of the proliferation of C6 glioma cells (Figure 4). Thus, tolbutamide significantly decreases the rate of C6 glioma cell proliferation, estimated by BrdU incorporation, and this effect is additive with that of dbcAMP. In addition, the percentage of cells in different cell cycle phases is affected by these two agents. In fact, tolbutamide and dbcAMP decrease the level of Ki-67, a protein expressed when cells are proliferating. These effects are accompanied by a reduction in the phosphorylation of pRb, mainly on Ser795, a residue critical for the control of cell proliferation. The decrease in the phosphorylation of pRb is probably due to the upregulation of the Cdk inhibitors p21 and p27. When Cx43 is silenced by siRNA, neither tolbutamide nor dbcAMP is able to upregulate p21 and consequently to reduce glioma cell proliferation, as judged by Ki-67 expression. In

Figure 4 The enhancement of gap junctional (GJ) communication decreases the rate of C6 glioma cell proliferation. The enhancement of gap junctional communication decreases glucose uptake by decreasing hexokinase (HK) activity. Concomitantly, the rate of C6 glioma cell proliferation declines (PPP, pentose phosphate pathway).

conclusion, tolbutamide and dbcAMP inhibit C6 glioma cell proliferation by increasing Cx43, which correlates with a reduction in pRb phosphorylation due to the upregulation of the Cdk inhibitors p21 and p27.

The ability to take up glucose at high rates is one of the most characteristic biochemical features of neoplastic cells and transformed phenotypes. The high glycolytic rate and increased glucose uptake by tumors were first reported by Warburg. Increased glucose uptake by tumor cells is exploited in cancer imaging using the positron-labeled glucose analog [^{18}F]fluoro-2-deoxy-D-glucose (FDG), which is transported into cells and then phosphorylated, but undergoes little further metabolism. The FDG accumulated can then be detected using positron emission tomography (PET). Several reports have indicated that FDG PET assesses the degree of tumor malignancy, since high-grade gliomas exhibit a higher glucose uptake than do low-grade tumors. In agreement with this, tolbutamide and dbcAMP, in addition to decreasing glioma cell proliferation, trigger a rapid decrease in the rate of glucose uptake. In addition, the effects of tolbutamide and dbcAMP on the rate of glucose uptake are additive, like their effects on gap junctional communication. Consequently, the increase in gap junctional communication is associated with a decreased rate of glucose uptake.

In C6 glioma cells, glucose phosphorylation is mainly catalyzed by type I and type II hexokinase. This enzyme can undergo rapid and reversible changes in subcellular compartmentation between the mitochondria and the cytosol. In C6 glioma cells, most type I and type II hexokinase is found associated with mitochondria. Interestingly, the presence of tolbutamide or dbcAMP promotes the rapid detachment of a significant proportion of type I and type II hexokinase from the mitochondria to the cytosol, together with a decrease in hexokinase activity. This is in agreement with several reports that the activity of hexokinase is higher when the enzyme is bound to mitochondria than when it is soluble in the cytosol. This seems to be the mechanism through which tolbutamide and dbcAMP decrease glucose uptake, since the activity of glucose transporters is not modified. In agreement with this, one of the mechanisms involved in regulating hexokinase activity in tumor cells is the shift of hexokinase between the cytosol and mitochondria. In fact, a strong correlation between growth rate and mitochondrial hexokinase activity has been reported for several types of tumors. In tumor cells, the release of hexokinase from mitochondria is associated with the inhibition of cell proliferation and is therefore a target for anticancer therapy. Taken together, these data show that the

increase in gap junctional communication in glioma cells reduces the exacerbated rate of glucose uptake characteristic of tumor cells by releasing hexokinase from the mitochondria. This is concurrent with a decrease of the rate of proliferation.

Summary

It is reasonable to suggest that astrocytic gap junctional communication is an important element for maintaining brain metabolic homeostasis. In fact, the inhibition of gap junctional communication induces the increase in the uptake of glucose through specific transporters in the plasma membrane, probably to compensate the lack of the diffusion of glucose and other substrates through gap junctions. However, prolonged inhibition of gap junctional communication induces an alteration of the astrocytic phenotype toward the phenotype of a highly proliferative cell. In fact, gliomas are an example of a pathology in which glial cells lose their ability to communicate through gap junctions. The upregulation of Cx43 in glioma cells decreases both cell proliferation and the exacerbated rate of glucose uptake, indicating that these events are closely linked. Knowledge of cellular and molecular events that associate them should contribute to a better understanding of the role of astrocytes in brain dysfunction and should lead to the identification of new targets for reversing pathological situations.

Gastrointestinal Signals: Satiety

T H Moran, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In many mammalian species, food intake occurs in distinct bouts or meals. Although meal initiation is determined by a variety of factors, especially food availability, meal termination is primarily the result of feedback signaling from the gastrointestinal (GI) tract. During a meal, ingested nutrients stimulate the activation or release of a variety of afferent neural and peptide signals. Many of these signals engage mechanisms that facilitate nutrient GI transit and nutrient digestion and absorption. A subset of these provide information about the quality and quantity of ingested nutrients and serve as feedback mediators controlling food intake within and between meals. Meal size can be highly variable and alterations in meal size appear to be a major determinant of overall food intake.

The clearest evidence for GI feedback controls on food intake comes form experiments involving sham feeding. Various models have been used, but the most common involves a gastric fistula that can be opened or closed (Figure 1). When closed, ingested food collects in the stomach and is gradually emptied into the upper intestine. Intake stops at a point where feedback inhibition exceeds any signals that are driving intake. When the fistula is opened, ingested nutrients drain from the stomach at the same rate that they are consumed. With such sham feeding, food does not accumulate in the stomach and does not pass into the upper intestine. Under these circumstances, feeding continues for much longer time intervals and much larger 'meals' are consumed. The fact that sham feeding does eventually stop suggests pregastric contributions to satiety. The amount sham fed depends upon the degree of experience with the sham-feeding paradigm. Although the first time rats sham feed, their intakes double, continued experience with sham feeding significantly increases intake. These data demonstrate the presence of a conditioned inhibition on food intake that is due to an association between oral stimulation and postingestion negative feedback. Only with continued experience is this conditioned inhibition on intake overcome. With experience, sham-fed meals can be 6–10 times the size of meals consumed with the fistula closed.

In normal ingestion, consumed nutrients contact mechano- and chemosensitive receptors in the stomach and the intestine. The potential range of feedback mechanism that could contribute to meal termination is dependent upon the distribution of ingested nutrients during the meal. Studies of gastric emptying suggest that this distribution during a meal is extensive. In both rats and monkeys, filling the stomach at rates mimicking normal ingestion results in rates of gastric emptying that are much more rapid than those that occur following the filling period. Such data demonstrate that a significant portion of ingested nutrients (in the rat as much as 30%) enters the duodenum, contacts duodenal receptors, and is available for absorption during the meal. Thus, the stomach and a significant proportion of the upper intestine are potential sites for within-meal feedback signal generation.

Neural Afferent Signaling

The vagus (X cranial) nerve is the major neuroanatomical link between the GI tract and brain. Vagal afferent fibers with cell bodies in the nodose ganglion innervate the stomach and various intestinal segments. In the rat, afferent fibers constitute the majority of vagal fibers, accounting for greater that 75% of subdiaphragmatic vagal nerve fibers. The subdiaphragmatic vagus has two major trunks that travel along the esophagus. In the rat, the ventral trunk bifurcates into the left gastric, the hepatic, and the accessory celiac branches. The dorsal trunk bifurcates into the right gastric and the celiac branches. The nomenclature implies a specificity of innervation. However, branches often innervate additional organs. For example, the hepatic branch provides the major innervation to the proximal duodenum and some duodenal innervation also derives from the gastric branches. Although there are also significant spinal gut neural connections, the response properties of this system have not been well characterized.

The response properties of vagal afferents depend in part upon the target organ from which they arise. Vagal afferents innervating the stomach have terminations in the gastric musculature. These afferents are primarily mechanosensitive – that is, they increase their firing rates in response to increasing gastric load volume. There are multiple mechanoreceptive response patterns. Slowly adapting mechanoreceptive fibers increase their response rate with increasing gastric volume. The fibers remain active while load volume

Figure 1 Increased food intake in sham feeding. Reproduced from Smith GP, Gibbs J, and Young RC (1974) Cholecystokinin and intestinal satiety in the rat. *Federation Proceedings* 33: 1146–1149, with permission.

is retained and show an off response in which activity briefly drops below baseline levels when the load volume is removed. Individual afferents are differentially tuned such that there are differences in their dynamic range. Some afferents reach their maximal activity at small intragastric volumes while others do not begin to respond until a significant gastric load is present. Another class of mechanosensitive fibers increase their firing rate during a volume increase but then return to baseline rates when the new load is achieved. Gastric mechanoreceptive vagal afferents do not respond directly to the chemical character of the gastric load. Response rates are similarly increased by nutrient and nonnutrient load volumes. Although gastric vagal activity is not directly responsive to intragastric nutrient character, gastric afferent responsivity can be altered by duodenal nutrient. Thus, the degree to which a gastric load activates gastric vagal afferent activity is modulated in the presence of duodenal nutrients.

Duodenal vagal afferents are activated by both intraluminal load volume and nutrient character. Duodenal slowly adapting mechanoreceptive fibers have been identified. Similar to gastric mechanoreceptive fibers, activity increases with increases in load volume. Other duodenal vagal afferents are directly responsive to nutrient character. For example, both intestinal casein and lipid infusions have been shown to result in increases in vagal afferent activity. Vagal afferent terminations have been identified within the duodenal mucosa. Although fine afferent fibers have been localized within the intestinal villa, the terminations do not appear to penetrate into the duodenal lumen, leading to the view that any direct nutrient stimulation would be postabsorptive rather than preabsorptive. Alternatively, nutrient absorption could stimulate local chemical release and activate vagal afferents secondary to such release.

Vagal afferent fibers project to the nucleus of the solitary tract (NTS) in the dorsal hindbrain following a rough viscerotopic representation of the alimentary canal. Activation of vagal afferent fibers results in a modulation of activity of NTS neurons. This can be shown electrophysiologically or through the detection of immediate activation of early genes such as c-*fos*. Just as the presence of intestinal nutrients can modulate the mechanoreceptive response to gastric load volume, meal-induced activation within the NTS reflects response integration. Studies that have provided stimulation to individual or multiple GI compartments have demonstrated that nutrient stimulation of one GI compartment can either enhance or reduce the activation produced by stimulation of another compartment.

Elimination of aspects of vagal afferent feedback can result in significant alterations in the way that rats pattern their food intake. Surgical vagal deafferentation results in alterations in meal patterns in rats maintained on a liquid diet, in that such rats consume larger meals than sham-operated controls do. Meal frequency is reduced in response to these meal size increases such that overall food intake is unchanged. Similar alterations in meal size have been reported in response to capsaicin-induced chemical vagal deafferentation. Although these data demonstrate a role

for vagal afferent feedback in the controls of meal size, the particular signal(s) that is being blocked by the vagotomy procedures has yet to be identified.

Within-Meal Peptide Satiety Signaling

As well as resulting in the stimulation of vagal afferent fibers, nutrients in the GI tract stimulate the release of a number of gut peptides that play various roles in food intake. Different peptides have different patterns of release during and following food intake and the patterns of release are consistent with their proposed roles in controlling the size of a current or in influencing subsequent meals.

A number of peptides are released into circulation at the onset of eating or shortly thereafter. A few of these have been demonstrated to play feedback roles in the control of the size of the meal that stimulates their release. Among these are the intestinal peptide, cholecystokinin (CCK), and the pancreatic peptides, glucagon and amylin (Figure 2). These peptides share a number of properties, including relative brief durations of action, the ability to produce reductions in meal size following their exogenous administration, documented roles for the endogenous peptide in limiting meal size, and signal transduction involving either the vagus nerve and/or the dorsal hindbrain.

The best characterized of these peptides is CCK. Exogenously administered CCK was originally demonstrated to decrease food intake over 30 years ago. The feeding inhibitory actions of CCK and CCK agonists have been demonstrated in a variety of species, including nonhuman primates and humans. Exogenously administered CCK reduces meal size and results in an earlier appearance of a behavioral satiety sequence. Consistent with its rapid release from the proximal intestine and short duration of effective bioactivity, the actions of CCK are specific to terminating an individual meal. Repeated, meal-contingent CCK administration consistently reduces meal size without producing a significant change in overall daily food intake.

Figure 2 Within-meal gut peptide feedback (CCK).

The satiety actions of CCK depend upon interactions with multiple receptor sites. Local arterial CCK administration aimed at the proximal gut results in increases in vagal gastric mechanoreceptive afferent activity similar to those produced by intragastric load. Combinations of gastric load and CCK produce greater degrees of activity compared to either load or CCK alone. CCK also modifies responses to subsequent intragastric load such that load volume results in greater degrees of activity following CCK administration than prior to it, even at times when the initial response has disappeared. Duodenal vagal afferents also are activated by CCK, and combinations of load and CCK combine to produce greater duodenal vagal afferent activity compared to either load or CCK alone, and CCK affects the response to subsequent load volumes. CCK also plays a role in the response of duodenal afferents to nutrients. Administration of a CCK antagonist blocks the increase in vagal afferent activity produced by intraduodenal casein. CCK-induced changes in gastric vagal afferent activity appear to result from a direct action of the peptide on the vagal afferent fibers. Vagal afferents contain CCK receptors, and CCK induces decreases in intragastric pressure that by themselves decrease rather than increase vagal afferent activity.

Surgical or chemical disruption of subdiaphragmatic vagal afferent innervation significantly affects the ability of CCK to inhibit food intake. The nature of this disruption is a rightward shift in the CCK satiety dose-response curve. Low doses of CCK that inhibit food intake in intact rats are ineffective following vagal afferent lesions. Higher doses inhibit intake, but to a smaller degree. CCK's feeding inhibitory actions also depend upon interactions with pyloric CCK receptors, and the effect appears to be additive to that relayed through vagal CCK receptors. In contrast to the effect of vagotomy, surgical removal of the pyloric sphincter does not affect the ability of low doses of CCK to inhibit intake, but instead truncates the dose-effect curve such that the additional suppression that normally accompanies higher CCK doses is eliminated. Results such as these have led to the proposal that the satiety actions of CCK have

multiple mediations and are, in part, secondary to its local GI effects.

A role for endogenous CCK in satiety is supported by data demonstrating that administration of CCK antagonists with specificity for the CCK1 receptor results in increases food intake. In the primate, the effects have been demonstrated to be dose related, with a maximum increase of around 40% in daily food intake in monkeys with 4-h daily food access. This increase is almost completely accounted for by an increase in the size of their first meal. Alterations in meal patterns are also evident in rats lacking CCK1 receptors. Otsuka Long–Evans Tokushima Fatty (OLETF) rats, which have a ~6-kb deletion in the CCK1 receptor gene spanning the promoter region and the first and second exons, lack functional CCK1 receptors. Consistent with this deficit, OLETF rats consume significantly larger meals and do so when maintained on either solid or liquid nutrients.

Satiety actions for the pancreatic peptides glucagon and amylin have also been demonstrated. Eating rapidly elicits an increase in pancreatic glucagon secretion. Because an increase in plasma glucagon is also stimulated by sham feeding, this appears to be a cephalic-phase response. Glucagon is rapidly cleared from the circulation by the liver and the liver appears to be the site of glucagon's satiety action. Hepatic portal infusions of glucagon at meal onset elicit dose-related reductions in meal size. Consistent with a hepatic portal site of action, glucagon-induced feeding inhibition is prevented by transection of the vagal afferent fibers that innervate the liver. In contrast to CCK, glucagon's satiety action requires the presence of other forms of ingestional consequences. CCK inhibits sham feeding but glucagon does not. A role for endogenous glucagon in the control of meal size is supported by data demonstrating the ability of hepatic portal infusions of a glucagon antibody to increase meal size.

Amylin inhibits feeding in a dose-dependent and behaviorally specific manner following either peripheral or central administration. Amylin is obligatorily cosecreted with insulin by pancreatic β cells. Thus, amylin levels rise rapidly with meal onset and remain elevated for a significant period of time during and following meals. Similar to CCK and glucagon, meal-contingent amylin administration reduces meal size and meal duration without affecting intake in subsequent meals. A physiological role for endogenous amylin in feeding controls is supported by experiments demonstrating increases in food intake in response to administration of amylin antagonists. Although overall food intake of amylin knockout mice does not differ from controls, whether meal patterns are altered in these mice has not been reported. However, the anorectic effect of CCK was abolished in amylin knockout mice and this effect was reversed by the administration of doses of amylin that by themselves did not affect food intake. These data have been interpreted to suggest a role for endogenous amylin in the satiety actions of CCK.

In contrast to the satiety actions of CCK and glucagons, amylin feeding inhibitory effects are not vagally dependent. Amylin's feeding inhibitory actions are mediated by the area postrema (AP), a circumventricular organ with a porous blood–brain barrier that lies adjacent to the NTS, the site of vagal afferent terminations. The AP contains amylin receptors, AP lesions block the ability of amylin to inhibit eating and amylin administration activates cells in both the AP and underlying NTS. Mediation through the NTS is a shared property of all three peptides. NTS lesions block the ability of both CCK and glucagon to inhibit food intake. This similar hindbrain mediation suggests that the three peptides may be interacting with a common substrate at this level of the neural axis.

Across-Meal Peptide Signaling

Recent work has demonstrated the ability of a number of additional gut peptides to inhibit food intake following their peripheral administration, and the dynamics of their nutrient-stimulated release and feeding effects are consistent with actions that may extend beyond the individual meal (Figure 3). Thus, peptides such as glucagon-like peptide-1 (GLP-1),

Figure 3 Across-meal gut peptide feedback (PP, pancreatic polypeptide; PYY(3-36), peptide YY(3-36); GLP-1, glucagon-like peptide-1).

pancreatic polypeptide (PP), and peptide YY (PYY) (3-36) have actions in feeding that do not appear to solely depend upon terminating the individual meal that stimulated their release.

GLP-1 is a posttranslational product of proglucagon that is released from L cells in the distal intestine upon ingestion of nutrients. Circulating levels of GLP-1 rise within minutes of food ingestion and remain elevated for over 3 h. The rapid rise in plasma GLP-1 following meal initiation makes it unlikely that this is a local response to nutrients in the ileum. Duodenal nutrients likely stimulate endocrine and neural mediators that activate GLP-1 secretion. Consistent with this view, pharmacological or surgical vagotomy significantly attenuates meal-stimulated increases in GLP-1 secretion. GLP-1 functions to help regulate blood glucose. Exogenous administration of GLP-1 reduces blood glucose in both normal and diabetic individuals by stimulating insulin synthesis and secretion and by suppressing glucagon secretion. GLP-1 is also involved in the ileal brake. Gastric inhibitory and intestinal motility actions of ileal nutrients are in part mediated through GLP-1 release. In humans, peripheral GLP-1 infusions have been reported to reduce food intake in lean, obese, and type 2 diabetic patients. However, peripheral bolus injections of GLP-1 into the rat have little or no effect on food intake. The short half-life of peripheral GLP-1 provides a potential explanation for the inability of exogenous GLP-1 to elicit an effect on food intake in the rat. Prolonged GLP-1 infusions prior to and during meal periods have been shown to reduce amounts consumed. The availability of a peptide GLP-1 agonist with a longer duration of action has allowed a more complete assessment of the effects of increased GLP-1 signaling on food intake. Peripheral bolus administration of such a compound potently suppresses food intake and does so for extended time intervals. The role of endogenous GLP-1 in feeding control has yet to be completely assessed. Although central administration of a GLP-1 antagonist has been shown to increase food intake, similar findings for peripheral administration have not been reported.

The mechanisms underlying the feeding inhibitory actions of intestinally derived GLP-1 are beginning to be understood. Vagal afferent denervation abolishes the actions of central and peripheral GLP-1 on gastric emptying, and vagotomy has recently been demonstrated to also prevent the feeding inhibitory actions of GLP-1. A second possible mode of action for peripheral GLP-1 to exert its effects is via specific carriers or endothelial leaks that allow peripheral GLP-1 access to central binding sites. Evidence supporting this idea comes from data demonstrating that when radiolabeled GLP-1 is injected peripherally, it can be identified in the AP and other circumventricular organs. These data suggest that peripheral GLP-1 gains access to dorsal hindbrain sites to inhibit food intake. Consistent with this view, administration of GLP-1 to the hindbrain does inhibit food intake.

PP is a member of the neuropeptide Y (NPY) and PYY family of peptides that interacts primarily the Y4 receptor subtype. PP is produced in endocrine cells in the pancreas and released into the circulation in response to food intake. The release of PP has multiple components with an early cephalic peak followed by a prolonged plateau. PP exerts a variety of regulatory actions in the GI tract, including inhibition of pancreatic exocrine secretion, gall bladder contraction, modulation of gastric acid secretion, and stimulation of GI motility. A role for PP in food intake was first suggested in studies in mice demonstrating that twice daily peripheral PP injections into obese mice reduced food intake and body weight. Recent work has suggested a role for PP in both food intake and energy expenditure and identified PP-induced decreases in the expression of NPY, orexin, and ghrelin as potential mechanisms for these actions. A vagal mediation has been suggested based on experiments demonstrating PP-induced increases in vagal afferent activity and the blockade of the feeding inhibitory actions by vagotomy. Exogenous PP administration has also been shown to result in reductions in food intake in human subjects. A role for endogenous PP in feeding control has not yet been demonstrated. Paradoxically, combined Y2/Y4 receptor knockout protects against high-fat-diet-induced obesity.

PYY and PYY(3-36) are also members of the NPY family of peptides; like GLP-1, they are secreted from I cells in the distal intestine. PYY and PYY(3-36) are synthesized through differential posttranslational processing of proPYY. The peptides are found throughout the GI tract, with the highest concentrations found at distal small and large intestinal sites. PYY(3-36) has been shown to be released into the plasma in response to a meal. Although little work has been done on the dynamics of PYY(3-36) release, its pattern of release has been inferred from data that measured postprandial plasma levels of PYY. The temporal pattern of PYY release is different from that of other GI peptides with suggested roles in feeding control. Plasma levels of PYY gradually rise following meal initiation, reaching a peak at about 60 min, and high levels are maintained for a number of hours following a meal. Such a pattern of release suggests the potential for a role in the control of food intake across meals rather than in meal termination. PYY has long been identified as a peptide involved in the ileal brake. PYY inhibits gastric emptying and mediates the effects of ileal fat on gastric motility.

Batterham and colleagues first reported significant suppression of food intake in rodents in response to peripheral bolus PYY(3-36) administration and significant decreases in food intake in humans in response to PYY(3-36) infusions. Originally, peripheral PYY(3-36) was proposed to affect feeding by directly inhibiting hypothalamic arcuate nucleus NPY-containing neurons by activating presynaptic Y2 receptors. Consistent with this proposal, peripheral PYY(3-36) was shown to decrease arcuate NPY mRNA expression. However, recent work supports the view that rather than directly accessing brain sites, PYY(3-36) may inhibit feeding through alterations in vagal signaling. The vagus contains Y2 receptors, and PYY(3-36) administration activates gastric vagal afferent fibers. Furthermore, vagotomy blocks the ability of peripheral administration of PYY(3-36) to inhibit eating and to activate NPY neurons.

It is not yet clear whether feeding inhibition is a physiological action of meal-induced PYY(3-36). There has been some controversy over the reproducibility of PYY(3-36)-induced feeding inhibition in rodents. In addition, doses of PYY that inhibit food intake in mice also produce a conditioned taste aversion. Finally, infusions that reduce food intake in primates produce plasma levels greatly in excess of those found following a meal. However, there is a recent suggestion that combining PYY(3-36) and GLP-1 may allow feeding inhibitions at plasma levels of each closer to those found following a meal.

An additional peptide that may play a role in controlling food intake is the recently identified novel peptide obestatin. Obestatin is derived from the prepropeptide that codes for the gastric orexigenic peptide ghrelin. In opposition to the actions of ghrelin, obestatin suppresses food intake and decreases body weight gain. Obestatin has been shown to act at a separate receptor site from ghrelin, suggesting a novel role for a gastric peptide in inhibiting food intake.

Summary

Gut vagal afferent neurons and peptide signaling modulate eating, providing feedback inhibition within individual or across multiple meals. The peptides involved have different sites of release along the GI tract and different patterns of release that are consistent with their actions. Vagal afferent neurons and/or hindbrain signaling appear to mediate the feeding actions of many of these peptides.

Introduction

The role of the gut in the digestion and absorption of nutrients is well established. The gut is not only involved in the assimilation and storage of nutrients, but is also an important endocrine organ, secreting a number of factors informing the brain about the nutritional status of the organism. Thus, the gut plays an essential role in the regulation of food intake and energy balance. These gastrointestinal (GI) signals are released from specialized enteroendocrine cells that are localized along the GI tract. For this action the gut uses neural and endocrine pathways to communicate with controllers of energy balance in the hypothalamus and hindbrain. Interestingly, many of the signals secreted by the GI are also found in the central nervous system, supporting a role for these signals not only peripherally but also at the central level. Most of these factors possess anorexigenic actions; however, some of them increase food intake.

The first hormone to be discovered in the GI tract was secretin, isolated from duodenal mucosa. Some years later, two additional GI hormones were described, gastrin and cholecystokinin (CCK). Over the past few decades a number of other gut peptides have been discovered. Several of these peptides, glucagon-like peptide-1 (GLP-1), pancreatic polypeptide (PP), and peptide YY (PYY), to name a few, have been reported to decrease food intake. However, in this article we focus on the few GI tract-secreted peptides which have been demonstrated to stimulate food intake, and discuss their regulation under different physiological conditions.

β-Casomorphin

Enterostatin is a pentapeptide produced by trypsin cleavage of pancreatic procolipase in the intestine during the absorption of fat. Enterostatin has been demonstrated to decrease food intake regardless of whether it is administered peripherally or centrally, and several studies have proposed that it interacts with opioid receptors in this regard. The opioid receptors involved in feeding are subdivided into the μ and κ subtypes. Opioid receptor agonists stimulate food intake, and one such example is β-casomorphin (β-CM), an agonist for the μ receptor. This peptide is a cleavage product of milk casein and has only seven amino acids. There is a high homology between the sequences of β-CM and enterostation, which consist of five amino acids, each peptide having proline residues in positions two and four. However, these two agents have opposite effects. β-CM stimulates food intake when given peripherally, and this effect is lost when the three C-terminal amino acids (Gly-His-Ile) are removed.

One study investigated the effect of several isoforms of β-CMs (β-CM1–β-CM7, β-CM1–β-CM5, and β-CM1–β-CM4) on food intake. The intracerebroventricular (icv) injection of isoforms 1–7 stimulated intake of a high-fat (HF) diet in animals, but isoforms 1–5 and 1–4 failed to promote intake of this diet. Peripheral injection of isoforms 1–7 also resulted in a dose-dependent increase in consumption of a HF diet, but reduced the intake of a high-carbohydrate (HC) diet in satiated rats with a similar dose-dependent relationship. Enterostatin (icv) inhibited the stimulation of HF intake by isoforms 1–7, as did the general opioid antagonist naloxone. These data suggest that at high doses, enterostatin and isoforms 1–7 may interact with the same low-affinity receptor to modulate intake of dietary fat. Consistent with this, it was observed that when rats with a gastric cannula were given a choice of a HF and a low-fat (LF) diet, enterostatin caused a dose-dependent reduction in the intake of the HF diet for the first 2 h after infusion, but had no effect on the LF intake. β-CM isoforms 1–7 stimulated intake of the HF diet, but had no effect on the LF diet, and blocked the inhibitory effect of enterostatin on HF intake in fasted rats.

To clarify the relationship between enterostatin and β-CM at different doses, K Berger and collaborators investigated the effect of intravenous (iv) administration of enterostatin in the presence and absence of β-CM, on HF intake in rodents. At low doses, enterostatin decreased HF intake in rats, whereas high doses stimulated food intake during the first hour after injection, compared to control rats. Contrary to this finding, iv β-CM increased HF intake at all concentrations. When enterostatin and β-CM were administered together at a low dose, there was no effect on food intake; however, at a higher dose an increase in food intake was detected, compared to

controls. These findings demonstrate that enterostatin and β-CM act in an antagonistic way at certain doses, and that β-CM is capable of abolishing the anorexigenic effect of enterostatin.

Motilin

Based on structural and effect-related similarities, motilin, a 22-amino-acid GI peptide, and ghrelin, the natural ligand of the growth hormone secretagogue receptor (GHS-R), are considered to represent a novel GI hormone family. Motilin is secreted from the endocrine cells of the mucosa of the upper part of the small intestine. This peptide stimulates GI motor activity especially in the antrum and upper duodenum, and it is widely acknowledged that motilin is involved in the regulation of interdigestive motility.

The production of motilin in the brain has been debated. Early studies suggest that motilin immunoreactivity is present in the Purkinje cells of the cerebellum in mice, rats, pigs, monkeys, and humans, as well as in the cerebrum, pituitary body, hypothalamus, and epiphysis in mice, rats, dogs, pigs, cows, monkeys, and humans. Motilin is also reported to excite neurons in the cerebral cortex and spinal cord of rats. Using longitudinal muscle/myenteric plexus (LMMP) preparations and cultures of myenteric neurons of the guinea pig ileum, it was observed that most of the motilin-immunoreactive and motilin receptor-immunoreactive neurons were also positive for neuronal nitric oxide synthase, with only a few being positive for choline acetyltransferase. In contrast, ghrelin was mainly co-localized with choline acetyltransferase. Motilin, ghrelin, and ghrelin receptor mRNA transcripts were found in LMMP preparations and in cultured myenteric neurons, suggesting that both peptides may play a role in the activation of the enteric nervous system and in the regulation of GI motility.

Motilin has been reported to possess orexigenic actions. A significant increase in food intake was observed after acute icv administration of motilin in both mice and rats. This effect was attenuated markedly by the motilin receptor antagonist GM-109. These results are consistent with the possibility that motilin receptors are present in the brain and may have a role in the regulation of food intake. Furthermore, peripheral administration of motilin has also been found to stimulate feeding in rats. In agreement with the effect of motilin on food intake it was reported that circulating motilin levels rise progressively during fasting and fall to a nadir within an hour of refeeding.

In addition to its actions on food intake, motilin is also considered to be an important factor in the control of the interdigestive migrating motor complex in the upper GI tract. In the fasting state, exogenous administration of motilin has been reported to induce a contraction pattern in the gastric antrum of both dogs and humans, and motilin also contracts the porcine gastric fundus *in vitro*. Moreover, administration of motilin causes a contraction of the proximal stomach in humans and increases meal-induced satiety in clinical studies.

Ghrelin

In 1999, the endogenous ligand for the GHS-R was discovered and named ghrelin. Its highest expression was found in the stomach, and more recently substantially lower amounts have been found in the bowel, pancreas, pituitary, kidney, and placenta. Ghrelin takes its name from the proto-Indo-European word *ghre*, which means 'grow,' and *relin*, relating to its role in the release of growth hormone (GH). Ghrelin results from the cleavage of a precursor called preproghrelin, which is composed of 117 amino acids. Preproghrelin contains a 23-amino-acid signal peptide and the 94-amino-acid proghrelin, which includes the 28-amino-acid mature ghrelin and a 66-amino-acid tail.

Ghrelin has potent growth hormone secretagogue activity and also stimulates food intake in humans and rodents. One peculiarity of this peptide is the *n*-octanoylation in the serine-3, because this modification of a peptide by esterification with a fatty acid is unique in mammalian biology; yet this modification is essential for ghrelin's biological functions. The attached acyl group enables the binding of ghrelin to the GHS-R and is responsible for the observed effects on appetite and energy intake. However, the main circulating form of ghrelin is not the active form, but the desacylated ghrelin, which constitutes about 80–90% of total ghrelin. Desacyl ghrelin cannot activate GHS-R1a, but it was recently reported that this isoform has cardioprotective, antiproliferative, and adipogenic properties, and that it can antagonize octanoyl-ghrelin-induced effects on insulin secretion and blood glucose levels in humans. However, the receptor that mediates those actions is not known. Desacyl ghrelin is not known to be directly involved in the regulation of appetite or food intake.

Another isoform of ghrelin that misses the Gln residue at position 14 of the molecule was also purified in rat and was named des-Gln14-ghrelin. This 27-amino-acid des-Gln14-ghrelin is produced by alternative splicing of the ghrelin gene. It also has an acylated and a nonacylated form, the last one being the most abundant. The acylation appears to be essential for the release of GH in both natural forms of ghrelin, although desacyl ghrelin may also be

biologically active in the cardiovascular system, in the promotion of adipogenesis, or in the regulation of insulin sensitivity. Other minor forms of ghrelin are present in human plasma and stomach, measured as the total immunoreactivity by conventional radioimmunoassay (RIA) based on the C-terminal fragment of ghrelin.

Regulation of Ghrelin by Nutritional Status and Obesity

Gastric ghrelin production is regulated by nutritional status and various hormonal factors. Ghrelin is an important factor in meal initiation; levels rise prior to the onset of meal ingestion and then decline following consumption. The postprandial suppression of ghrelin may require a postgastric factor, since the intragastric administration of saline or glucose did not modify ghrelin levels when gastric emptying was prevented. This profile is also independent of any meal-related cues. When all external cues indicating the onset of a meal were removed, this 'typical' profile of ghrelin release was still observed. In addition, ghrelin levels were positively associated with subjective hunger ratings. Intravenous infusion of ghrelin significantly increases food intake, and ghrelin levels were highly correlated with self-reported hunger. Preprandial increases in ghrelin release have also been reported to have a learned component, related to habitual meal pattern in sheep trained to consume one, two, or three meals per day. Accordingly, in each group ghrelin increased preprandially in contrast to the lower ghrelin levels observed in the *ad libitum*-fed control animals.

The meal-related suppression of plasma ghrelin requires postgastric stimulation. The energy content of the ingested meal is also an important factor in postprandial ghrelin suppression, since it has been reported to decline in proportion to the ingested caloric load. The macronutrient composition of the ingested meal has also been reported to influence postprandial ghrelin secretion. Meals rich in carbohydrate have a more profound effect. The postprandial suppression of ghrelin correlates with a rise in insulin, and this may partially explain the greater suppression of ghrelin by HC meals. Circulating ghrelin levels are low in obese patients and higher after fasting. However, obesity may not be characterized by ghrelin resistance, since obese individuals have been reported to respond to peripheral administration of ghrelin by increasing food intake. Obese individuals also have been reported to have an attenuated postprandial suppression of ghrelin regardless of the energy content of the meal. The low ghrelin levels in obese individuals are reversed by diet-induced weight loss.

Patients with Prader-Willi syndrome (PWS), a disorder characterized by cognitive deficits, GH deficiency, extreme hyperphagia, and obesity, do not have low ghrelin levels. On the contrary, ghrelin levels are elevated in these patients and thus may contribute to the insatiable levels of hunger observed in these patients. However, when somatostatin, a potent suppressor of ghrelin secretion, was administered to patients with PWS, plasma ghrelin was suppressed but no changes of food intake were observed, thus questioning the role of hyperghrelinemia in hyperphagia observed in PWS patients. It is clear that ghrelin plays a complex role in appetite regulation and overall energy balance, yet the precise mechanism for the orexigenic effect of ghrelin is not completely understood.

Pharmacological Effects of Ghrelin on Energy Balance

Central (icv) administration of ghrelin induces c-fos expression in regions of primary importance in the regulation of feeding, primarily in the hypothalamus, including arcuate nucleus (ARC), paraventricular nucleus (PVN), and dorsomedial and ventromedial hypothalamic nuclei. Depending of the exact site of administration, c-fos was stimulated in several nuclei. Ghrelin-containing neurons are localized in the ARC and these neurons project efferent fibers onto neuropeptide Y (NPY)- and agouti-related protein (AgRP)-expressing neurons to stimulate the release of these orexigenic peptides, and onto proopiomelanocortin (POMC) neurons to suppress the release of anorexigenic factors from these cells. Most NPY/AgRP-containing neurons and POMC/cocaine- and amphetamine-regulated transcript (CART)-containing neurons also express leptin receptors, and both types of neurons are regulated by leptin in a reciprocal manner. Leptin inhibits ghrelin-induced feeding, and ghrelin substantially reverses the anorexic effect of leptin. However, the hypothalamus is not the only site of action for ghrelin, as brain stem areas have also been implicated in the stimulation of food intake by ghrelin. Administration of ghrelin into the fourth ventricle or directly into the dorsal vagal complex resulted in a hyperphagic response with a magnitude similar to that obtained with administration in the third ventricle. Moreover, GHS-R is expressed in neurons of the nucleus of the solitary tract, the dorsal motor nucleus of the vagus, the rostral ventrolateral medulla, and the caudal ventrolateral medulla. It has been reported that injection of ghrelin into the hippocampus or dorsal raphe nucleus also evokes an increase in food intake, suggesting that, in addition to areas of ghrelin control in the hypothalamus, ghrelin exhibits

orexigenic activity in various zones of the central nervous system, especially in the caudal brain stem. Ghrelin also directly acts at GHS-Rs expressed in ventral tegmentum neurons of the midbrain. Since such circuitry is known to be important for reward and addiction, it has now been proposed that similar to leptin, ghrelin directly targets the hedonic as well as the homeostatic drive for food intake.

The role of the vagus nerve in the orexigenic effects of ghrelin still remains to be fully elucidated. The detection of ghrelin receptors on vagal afferent neurons in the rat nodose ganglion suggests that ghrelin signals from the stomach are transmitted to the brain via the vagus nerve. However, it was recently suggested that the preprandial increase in ghrelin occurs independently of vagal afferent signaling, suggesting that circulating ghrelin likely acts directly at target neurons of the mediobasal hypothalamus, the ventral tegmentum, and the brain stem.

In addition to its effects on food intake and body weight, intravenous ghrelin dose-dependently increases gastric acid secretion and stimulates gastric motility and emptying. Intracerebroventricular ghrelin also increases gastric acid secretion in a dose-dependent manner and induces c-fos expression in the nucleus of the solitary tract and the dorsomotor nucleus of the vagus nerve.

Physiological Functions of Ghrelin: Lessons from Targeted Mouse Mutagenesis

Early investigations examining ghrelin and GHS-R knockout mice failed to identify effects on food intake, bodyweight, or body composition, although mice lacking ghrelin signaling were found to be smaller. Notably though, it was reported that these mice had a reduced respiratory quotient when fed a HF diet, suggesting that endogenous ghrelin may be an essential regulator of substrate utilization. Later investigations have revealed that ghrelin-deficient as well as GHS-R-deficient mice are resistant to diet-induced obesity, indicating that endogenous ghrelin does have an essential function in the control of body fat mass. More recent reports indicate that endogenous ghrelin may be of crucial importance for insulin sensitivity and maintenance of glucose homeostasis. This function appears to become most apparent in the absence of both leptin and ghrelin, where ghrelin gene deletion seems to partially rescue the diabetic state of leptin-deficient mice.

In summary, ghrelin or ghrelin analogs are orexigenic and adipogenic agents with the largely untested potential to treat human cachexia or anorexia. On the other hand, GHS-R antagonists may be useful candidates for the pharmacological treatment of obesity or type 2 diabetes. The multifaceted character and pleiotropic action profile of ghrelin will continue to represent a major challenge for the development of specific and safe therapeutics until the molecular underpinnings of ghrelin action are better understood.

Gastrointestinal Tract Role in Neural Control of Metabolism, Food Intake and Body Weight: A Summary

W Jänig, Christian-Albrechts-Universität zu Kiel, Kiel, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neural and endocrine regulation of metabolism and food intake by the brain is the main integrative function in which the gastrointestinal tract (GIT) is involved. Closely related to this regulation is the regulation of hunger, satiety, and body weight. The neural machineries that are important in this regulation are situated in the lower brain stem (in particular in the dorsal vagal complex (DVC) consisting of the nucleus tractus solitarii (NTS), the dorsal motor nucleus of the vagus nerve (DMNX) and the area postrema (AP)) and in the hypothalamus. The afferent neural signals from the GIT that are important in this regulation project through the vagus nerves to the nucleus tractus solitarii. The endocrine signals derive from endocrine cells in the mucosa of the GIT (most of them in the anterior part), pancreas, and adipose tissue, and they act on the brain mainly via the area postrema in the medulla oblongata and/or via the arcuate nucleus (ARC) in the hypothalamus.

A Model of Regulation of Metabolism and Food Intake

Regulation of metabolism and food intake is homeostatic and consists of a long-term regulation and a short-term regulation, both of which are closely integrated (Figure 1):

- The adipose tissue is the main energy store of the body. A normal human male of 75 kg body weight stores approximately $5–6\times10^5$ kJ in his fat tissue (15% of his body mass). Neural regulation of this energy store is a long-term regulation. The size of the body fat mass is proportional to the body weight. Regulation of the body fat mass (and therefore also body weight) is quantitatively precise and normally stable to <1% over months and years. The control centers, located in the hypothalamus and in the lower brain stem (mainly the DVC), receive two signals that are proportional in their blood concentration to the size of the body fat mass – leptin and insulin, also called adiposity-related (or adipositas) signals. Leptin is synthesized and released by adipocytes, and the hormone insulin is released by B cells of the endocrine pancreas. Increase of both hormones in the blood (e.g., during ample food availability and fat stores) leads to decreased energy (food) intake and of endogenous glucose production by the liver, increased energy expenditure, and a mobilization of fat stores (catabolic state of the organism). Decrease of both hormones in the blood (e.g., during starvation) leads to increased energy intake, decreased energy expenditure, elevated fat stores, and increased glucose production by the liver (anabolic state of the organism). Genetically engineered changes of these adipositas feedback signals, their receptors, or their postreceptor pathways result in changes predicted by this hypothesis.
- Neural regulation of food (energy) intake (regulation of meal size and meal frequency) is a short-term regulation. The regulation centers are situated in the DVC of the medulla oblongata and in the hypothalamus. This regulation is fast but quantitatively not precise. It is dependent on distinct neural, hormonal, and nutritive afferent signals to the brain. The DVC receives signals in vagal afferents encoding in their activity mechanical and/or intraluminal chemical events of the GIT, signals in taste afferents, and hormonal signals from the GIT via the area postrema (cholecystokinin (CCK), glucagon-like peptide 1, pancreatic polypeptide, and peptide YY (PYY)). However, it probably also receives hormonal signals that are important in the regulation of metabolism, namely leptin and insulin, as well as nutritive signals (glucose and lipids in the blood). Neurons in the ARC of the hypothalamus receive hormonal signals and nutritive signals. The hormonal signals are ghrelin from the oxyntic cells of the mucosa of the stomach that initiates food intake and PYY from the mucosa cells of the hindgut and ileum. With the exception of ghrelin, all afferent signals (neural, hormonal, or nutritive) are satiety signals; that is, they terminate, delay, or reduce food intake.

The homeostatic regulation of metabolism and food intake interact with other homeostatic regulations represented in the hypothalamus (body core temperature, reproduction, growth, fluid matrix, etc.). Furthermore, this regulation is under the control of the cerebral systems. This control is nonhomeostatic and is related to satiety and hunger as well as to reward and hedonic control of food intake.

Neural Components of Regulation of Metabolism and Food Intake

The central neural components that are involved in the regulation of metabolism and food intake are summarized in Figure 2.

Figure 1 Homeostatic long-term regulation of energy stores and short-term regulation of food intake by the brain. Homeostatic control centers are located in the hypothalamus and the lower brain stem. Long-term regulation of the main energy store (fat tissue) is slow but quantitatively precise, leading to a precision of the regulation of fat stores and body weight in the range of $\leq$1%. The main feedback signals are the peptides leptin (from the fat stores) and insulin (from the endocrine pancreas) to the hypothalamus. Short-term regulation of food intake (meal size and frequency of food intake) is fast and quantitatively relatively inaccurate. The main feedback signals are activity in vagal afferents from the GIT, hormones from the GIT, and nutritive signals (level of glucose and free fatty acids (FFA) in the blood) to the lower brain stem and/or the hypothalamus. The control centers involved in this regulation are integrated with other homeostatic regulations represented in the hypothalamus (regulation of body temperature, reproduction, fluid matrix, etc.). The homeostatic control centers in hypothalamus and brain stem are under the control of the cerebral systems responsible for the general sensations of hunger and satiety and represent the endogenous hedonic system. These cerebral controls are not homeostatic. GIT, gastrointestinal tract.

As already mentioned, the control centers of regulation of metabolism and food intake are represented in neural networks of the hypothalamus and the lower brain stem. The functioning of these centers and their interaction cannot be explained by a hierarchical model in which the hypothalamic centers take the lead, via command signals in descending projecting neurons, over the lower brain stem (mainly the DVC). In fact, the sensorimotor circuits in the lower brain stem can generate the full patterns of ingestive behavior involving the GIT and somatomotor systems. The way afferent neural, hormonal, and nutritive signals are translated by these circuits into coordinated behavior involving autonomic systems to the GIT, other autonomic systems, and somatomotor systems is poorly understood. Finally, the communication between hypothalamic and lower brain stem centers is reciprocal. Details of this communication are just beginning to be worked out, and the description given here is a somewhat simplified view.

1. Leptin and insulin in the blood activate, via leptin and insulin receptors, neurons in the ARC of the hypothalamus, which contain proopiomelanocortin (POMC), the precursor of α-melanocyte-stimulating hormone used by these neurons as transmitter. These neurons activate the parvocellular neurons in the paraventricular nucleus of the hypothalamus (PVH) via the melanocortin-3 and -4 receptors (Mc3R and Mc4R). The parvocellular neurons contain either oxytocin (Oxt), corticotropin-releasing hormone (CRH), or thyrotropin-releasing hormone (TRH). Activation of these neurons generates a catabolic state of the organism, with weight loss and decrease in food intake.

2. Decrease of food intake and the accompanying changes of the GIT (decrease of motility, endocrine and exocrine secretion; inhibition of hepatic glucose production) are generated, at least in part, by the activation of oxytocinergic neurons in the PVH that project to the DVC. This activation enhances the effect of neural and hormonal satiety signals from the GIT to the DVC. The changes in the GIT, including the inhibition of hepatic glucose production, are mediated by vagal preganglionic neurons in the DVC.

3. Interruption of the specific signaling chain leptin–insulin–POMC neurons–PVN neurons (e.g., by deletion of the leptin or insulin receptor in the neurons of the ARC, in transgenic mice lacking the functioning peptide leptin or by blockade of the Mc4 receptor in the PVH nucleus) results in an anabolic state of the organism with an increase of body weight and food intake. This view does not

Figure 2 Centers in the hypothalamus and lower brain stem involved in the regulation of metabolism (anabolism and catabolism) and food intake. Long-term regulation of fat tissue and short-term regulation of food (energy) intake are integrated. Adipositas signals (leptin from fat tissue and insulin from the endocrine pancreas) activate neurons containing the peptides proopiomelanocortin (POMC) and α-melanocyte stimulating hormone (α-MSH) and inhibit neurons containing neuropeptide Y (NPY) and agouti-related peptide (AgRP) in the arcuate nucleus (ARC) of the hypothalamus. Stimulation of POMC neurons in the ARC of the hypothalamus activates parvocellular neurons in the paraventricular nucleus of the hypothalamus (PVH, containing either oxytocin or CRH or TRH) via melanocortin receptors (Mc3R and Mc4R). This activation generates a catabolic state of the organism. Stimulation of NPY/AgRP neurons in the ARC (e.g., by decrease of concentration of leptin and insulin in the blood and the subsequent decrease of inhibition of NPY/AgRP neurons) activates neurons in the lateral hypothalamic area (LHA) and parafornical area (PFA), which contain orexin or melatonin-concentrating hormone (MCH), via the Y1 and Y5 receptors. This activation generates an anabolic state of the organism. Both catabolic (anorexigenic) circuits (red) and anabolic (orexigenic) circuits (green) inhibit each other reciprocally. This inhibition is exerted by GABAergic neurons or by AgRP acting as an endogenous antagonist at the Mc4 receptor of the neurons in the PVH. Fast (neural and hormonal) signals from the GIT and nutritional signals in the blood (glucose and lipids) act either on neurons in the dorsal vagal complex (DVC; in the nucleus tractus solitarii (NTS) or via the area postrema (AP)) or on the NPY/AgRP neurons in the ARC. The hormone ghrelin stimulates food intake. With the exception of ghrelin, the signals are involved in short-term regulation and satiety signals. They lead to a reduction of food intake and further catabolism by the inhibition of NPY/AgRP neurons. +, excitation; −, inhibition; CCK, cholecystokinin; CRH, corticotropin-releasing hormone; DMNX, dorsal motor nucleus of the vagus nerve; GABA, γ-aminobutyric acid; GIT, gastrointestinal tract; GLP-1, glucagon-like peptide 1; mech., mechanical; PP, pancreatic polypeptide; PYY, peptide YY; TRH, thyrotropin-releasing hormone; Ⅹ, vagus nerve. exclude leptin and insulin also acting on neurons in the DVC, POMC neurons in the ARC projecting to the DVC, and similar reaction patterns also being generated independently of the PVH from the DVC.

4. Activation of a second group of neurons in the ARC of the hypothalamus generates an anabolic state of the organism with an increase of food intake and gain of body weight. These neurons contain neuropeptide Y (NPY) and the peptide agouti-related peptide (AgRP). Their excitation activates neurons in the lateral hypothalamic area (LHA) and the parafornical area of the hypothalamus (PFA) via the Y1 and Y5 receptors. Neurons in the LHA and PFA contain the peptides orexin or melanin-concentrating hormone (MCH). NPY and AgRP neurons in the

ARC are inhibited by leptin, insulin, and PYY and are excited by the peptide ghrelin.

5. Activation of the orexin and MCH neurons attenuates the response of the neurons in the DVC to the neural and hormonal satiety signals from the GIT. Injection of orexin or MCH into the third ventricle or overexpression of MCH in transgenic mice generates an anabolic state in the animals. Targeted deletion of MCH or its receptor leads to weight loss and a hypermetabolic (catabolic) state of the animals. Nutritive signals (glucose and lipids in the blood) also inhibit NPY and AgRP neurons in the ARC through specific intracellular pathways.

6. Neurons whose activation generates a catabolic state of the organism (red in **Figure 2**) and neurons whose activation generates an anabolic state of the organism (green in **Figure 1**) inhibit one another reciprocally. This inhibition is mediated by the transmitter γ-aminobutyric acid (GABA) in the ARC. In the PVH nucleus, AgRP acts as an endogenous antagonist at the Mc4 receptor, thus blocking the signal transmission from the POMC neurons to the Oxt, CRH, and TRH neurons. In the lateral hypothalamus, the inhibition of orexin and MCH neurons is probably mediated by GABA too. This reciprocal inhibition between neurons of the catabolic and neurons of the anabolic system means that activation of a catabolic state is also produced by the disinhibition of POMC neurons and of Oxt, CRH, and TRH neurons generated by the inhibition of NPY and AgRP neurons by leptin, insulin, PYY, and/or nutritive signals.

Future experimental investigations will elaborate the details of this complex neural regulation system, in the center of which is the GIT. These investigations will work out the relationship of this homeostatic regulation with cortical systems, such as the insular cortex, the anterior and middle cingulated cortex, and the prefrontal cortex, that are responsible for reward, hedonic aspects of food intake, and the sensations of hunger and satiety. Unraveling these nonhomeostatic cerebral control mechanisms may give us better insight into the mechanisms of the failure of regulation of food intake and body weight in higher vertebrates, in particular humans.

Gene Expression Dysregulation in CNS Pathophysiology

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

Pathophysiological changes in the brain include the deterioration or degeneration of specific brain regions, alterations in cell morphology, changes in the relative size of different brain regions, and the reorganization of neuronal connections. These changes in physiology often reflect more subtle changes in brain chemistry, signaling processes, and, underlying all else, changes in the levels of gene expression. While signaling processes in the developing and adult brain may have direct effects on cell behavior through influences on the cytoskeleton or on cell adhesion, most signals culminate in the nucleus and result in the activation or repression of specific sets of genes. Any neurological disorder that has a significant genetic component must in some way reflect the abnormal activity of such genes, and it is becoming increasingly clear, therefore, that pathophysiological changes are intricately linked to changes in the level of gene expression. In some cases, such changes are a direct reflection of mutations in specific genes, while in others they reflect the overactivity or underactivity of signaling pathways or regulators caused by particular external stimuli, such as stress or drug use. Some changes in gene expression are short-lived and easily reversible, while others lead to long-lasting effects which must be addressed with long-term therapies. The regulation and dysregulation of gene expression can mediate both the transient and the stable maladaptations in the brain that lead to pathophysiological changes.

Causes of Gene Dysregulation

Mutations with *cis*-Acting Effects on Single Genes

Conceptually the simplest way for gene expression to become dysregulated is for a mutation to occur in the regulatory elements of a particular gene. Devastating single mutations are rare, but in a number of cases the predisposition to a particular disease has been shown to reflect the presence of mutations in the promoter or occasionally in the sites that regulate splicing, resulting in quantitative rather than qualitative differences in the level of mRNA. In some cases, it is not the total level of mRNA that matters, but rather the balance of alternative transcripts where a primary transcript undergoes alternative splicing.

Examples of *cis*-acting mutations that affect individual genes with pathological consequences include promoter mutations upstream of the *APP* gene, increasing the risk of Alzheimer's disease; a mutation in the acetylcholine receptor ε-subunit promoter, causing congenital myasthenic syndrome; and single-nucleotide polymorphisms in the apolipoprotein E promoter, which affect the phenotype of primary open-angle glaucoma.

A more complex example which involves the dysregulation of splicing and therefore modulates the ratio of alternative transcripts has been described for the *NRG1* gene, encoding neuregulin 1 (NRG1). At least six different isoforms of NRG1 have been described, with a diverse range of functions in the nervous system and links to several diseases, including schizophrenia. A recent association study using the Icelandic deCODE database yielded a high-risk haplotype at the 5′ end of the *NRG1* gene (SNP8NRG243177) that enhances the expression of type IV NRG1 in the brains of schizophrenic patients.

The transcript levels of key genes can also be modified by segmental deletions and duplications, as occurs in Charcot–Marie–Tooth disease when the dosage of the *PMP22* gene is increased from two to three copies, and in Alagille syndrome, which results from haploinsufficiency for the gene *JAG1*.

Mutations with *trans*-Acting Effects on Multiple Genes

The function of certain genes is to regulate other genes, and, depending on the number of downstream targets, mutations affecting such genes may cause significant dysregulation of expression. Examples of genes in this category include those encoding signaling proteins, transcription factors, or proteins that control RNA processing and protein synthesis. Importantly, there is scope here for wide-ranging changes because the affected genes might also encode regulatory proteins, which go on to have further knock-on effects on the nervous system.

A good example of this phenomenon is mutations affecting the activity of PAX6. The *PAX6* gene is expressed in the developing retina, iris, lens, and surface ectoderm, as well as in discrete regions of the forebrain, hindbrain, neural tube, pituitary gland, and nasal epithelium. It encodes a transcription factor that plays a critical early role in the developing nervous system and the effects of which are dosage critical. Mutations in *PAX6* are responsible for a range of neuroectodermal defects, including aniridia. The expression of *PAX6* is complicated by the presence of

two promoters and six enhancers, and the fact that alternative splicing yields three isoforms that recognize different DNA sequences. Genomic sequencing and microarray analysis have identified a number of downstream targets that become dysregulated following mutation of the *PAX6* gene. Interestingly, these include many further regulatory factors, such as transcription factors involved in neurogenesis (AP-2γ, Bhlhb5, NeuroD6, Nfia, Ngn2, Satb2, and Tbr2) and the retinoic acid signaling molecule Rlbp1. These have additional downstream targets that would also become dysregulated. From this example, it is clear that a single mutation in a critical master gene can impact on the expression of potentially hundreds of other genes by affecting the availability of other transcription factors and signaling proteins.

Epigenetic Changes Affecting Many Genes

Mutations by definition achieve dysregulation by changing the DNA sequence of a gene, and these effects are described as genetic. In contrast, epigenetic changes modify gene expression without modifying the gene sequence. This is achieved by altering the way DNA is packaged in the cell, principally by altering the structure of chromatin. Chromatin remodeling is brought about by a combined process of histone modification and DNA methylation.

Histones are the proteins that package DNA into chromatin in the nucleus, and they are subject to various forms of posttranslational modification, some of which are clearly linked to transcriptional accessibility. In particular, histone acetylation usually corresponds to active chromatin whereas the loss of acetylation correlates with inactive, silenced chromatin. Histone modification may also result in the specific recruitment of certain transcriptional activators and repressors, or proteins that sequester DNA into higher-order structures. Histone modification is mediated by specific enzymes, and those controlling acetylation are the best understood. Histone acetyltransferases (HATs) catalyze the acetylation of lysine and/or arginine residues, whereas histone deacetylases (HDACs) catalyze the removal of acetyl groups and associate with transcriptional repressors. The actual state of chromatin in any region of the genome depends to a large extent on the balance of these two opposing enzyme activities.

Transcriptional repression is also associated with the methylation of DNA at the 5′ position of cytidine residues in the context of the dinucleotide sequence CpG. The methylation of DNA is catalyzed by DNA methyltransferases (DNMTs), which transfer the methyl group from an *S*-adenosylmethionine (SAM) donor. As might be expected, patterns of DNA methylation correspond to patterns of histone modification that establish inactive chromatin. This is achieved through the presence of methyl-CpG-binding proteins (MeCPs) that associate with protein complexes containing HDACs and histone methyltransferases. DNA methylation, histone methylation, and histone deacetylation are therefore intrinsically linked in order to facilitate transcriptional silencing, establish epigenetic markers, and allow the silenced state to persist through DNA replication and cell division. Since chromatin remodeling is a general rather than gene-specific phenomenon, it is easy to see how altering the activity of histone-modifying enzymes, DNA methyltransferases, or other chromatin components could have a profound impact on the expression of many genes. It is becoming clear that a number of complex neurological disorders, including psychiatric disorders, may reflect gene dysregulation caused by the perturbation of chromatin remodeling, rather than specific defects in individual genes.

To exemplify the role of epigenetic modifications in pathological gene dysregulation, there is now a lot of evidence that epigenetic mechanisms underlie disorders such as schizophrenia. Microarray analysis of postmortem brains suggests that significant numbers of genes are misexpressed. Histone remodeling has been implicated in schizophrenia because antipsychotic drugs, such as the dopamine receptor antagonist haloperidol, induce rapid phosphoacetylation of histone H3 in the c-*fos* promoter in mouse striatal neurons. Similarly, an anticonvulsant and mood stabilizer, valproic acid, is able to increase expression of the *reelin* gene by demethylating the *reelin* promoter and inhibiting the activity of HDACs. Reelin is a glycoprotein with a main function to control neuronal migration during brain development, although it is also expressed in γ-aminobutyric acid (GABA-)ergic neurons in the adult brain. Reelin is significantly underexpressed in schizophrenic brains, and treatment with agents that either promote or inhibit methylation of the *reelin* promoter can repress or elevate its expression, respectively. These data suggest that disturbances in the levels of DNMTs, and histone-modifying enzymes could contribute to schizophrenia by altering the degree of methylation in the promoters of genes such as *reelin*, causing a generalized disruption in genes involved in the GABA and glutamate systems.

Detecting Gene Dysregulation

Traditional Methods

Traditional methods for studying gene regulation are difficult to apply on a large scale and therefore tend to be used to look at specific candidate genes. Analysis

at the RNA level invariably relies on the specificity of nucleic acid hybridization, with the target mRNA recognized either directly using a complementary labeled probe, or indirectly through amplification of cDNA using the polymerase chain reaction (PCR) and specific primers. The methods also differ considerably in their sensitivity. The easiest methods, the Northern blot and RNA dot blot, simply involve the transfer of RNA from a complex source to a membrane either without prior fractionation (dot blot) or after fractionation by electrophoresis (Northern blot), followed by probing with a complementary nucleic acid and detection of the signal. This allows rough quantitation and, in the case of the Northern blot, size determination. However, it is difficult to detect rare transcripts because of the lack of sensitivity.

More sensitive techniques include nuclease protection and reverse transcriptase PCR (RT-PCR). In nuclease protection, a labeled antisense RNA probe is hybridized in solution with a complex RNA population. If its target is present, it forms a duplex and is thus protected from degradation with a nuclease specific for single-stranded RNA and can be visualized on a sequencing gel. In the RT-PCR method, a population of mRNA molecules is reverse-transcribed to generate an equivalent population of cDNAs, which are then amplified by the PCR. Through the incorporation of suitable labels, this reaction can be rendered semiquantitative or fully quantitative, and moderate multiplexing is possible.

High-Throughput Methods

The aforementioned traditional techniques are not suitable for large-scale analysis because of the materials and labor involved. Two new methods have been devised which allow the simultaneous monitoring of all genes – one based on the high-throughput sampling of cDNA sequences and one based on miniature devices called microarrays, which allow mRNA levels to be measured by hybridization. Sequence sampling is based on the principle that a strongly expressed gene will be abundantly represented in the mRNA population of a particular cell or tissue, and will be similarly represented in an unbiased cDNA library or sequence database derived from that population. Therefore, random sampling will tend to pull out clones or sequences of strongly expressed genes much more frequently than those of poorly expressed genes. Relative expression levels can be determined simply by counting the score for each sequence pulled out during sampling, and because these data are in the form of real numbers, they are digital. A method called serial analysis of gene expression (SAGE) accelerates the sampling process by reducing each cDNA to a short tag 9–15 bp in length, and allowing up to 200 such tags to be concatemerized prior to sequencing.

Microarrays are miniature devices comprising a collection of immobilized DNA sequences arranged in a grid. Each address on the grid corresponds to a unique gene, or at least to a unique mRNA if the gene undergoes alternative splicing. These arrayed targets are hybridized (interrogated) with a complex mRNA or cDNA probe, that is, a probe comprising many different sequences representing the entire population of mRNAs from the cell or tissue under investigation. In this case, quantitative data are obtained not by counting, but rather by measuring the strength of the hybridization signal at each address. If the source mRNA/cDNA probe is universally labeled, the most abundant mRNA/cDNA molecules in the population will generate quantitatively stronger signals on the array, as long as hybridization does not reach saturation. Both sequence sampling and microarrays can be used for comparative expression profiling, in one case by comparing the representation of different sequences in two different tissues (e.g., prefrontal cortex from normal brain and schizophrenic brain) and in the other case by using two complex probes, labeled with different fluorophores, and comparing the signal intensity of each fluorophore for each gene.

Gene Expression in Normal Aging Brain

T E Morgan, University of Southern California, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Genes, lifestyle, and life circumstances all contribute to aging. Impairments in cognitive and motor skills commonly occur with increasing age. These progressive changes in cognition are subtle but become apparent later in life. Aging is a major risk factor for numerous neurological disorders. Cognitive and motor impairments resulting from neurodegenerative diseases are distinct from age-related changes and are influenced by peripheral diseases, such as diabetes and cardiovascular disease. In fact, there are strong associations between cardiovascular disease, diabetes, and Alzheimer's disease (AD).

The complex process of brain aging involves multiple systems, cells types, and cellular pathways. As with aging in general, numerous mechanisms have been proposed to underlie brain aging, including instability of nuclear and mitochondrial genomes, neuroendocrine dysfunction, production of and damage from reactive oxygen species, altered calcium metabolism, and inflammation-mediated neuronal damage. The common thread woven through all of these mechanisms is changes in gene expression.

Minimal Neuron Loss with Age

Prior to advances in stereological procedures for estimating neuron number it was widely believed that brain aging was accompanied by significant neuron death. Today, as verified by electron microscopy, stereologic counts, and gene expression data, brain aging is not due to loss of neurons. Instead, loss of synapses, morphologic changes in dendritic arbors and spines, and changes in myelination contribute to age-related cognitive and motor impairment. The causes of these changes are not known. Molecular studies with transgenic mouse models indicate that specific genetic manipulation can lead to defects in long-term potentiation (LTP) and learning in the absence of degenerative changes (e.g., *N*-methyl-D-aspartate receptor subunits and calcium- and calmodulin-dependent kinase II). These studies support the important role that specific genes have in brain aging.

Gene Alleles: Single Nucleotide Polymorphisms

Brain aging is not only influenced by changes in gene expression but is also affected by the particular gene allele one inherits. Specific sequence variations (single-nucleotide polymorphism, or SNP), which make people more or less susceptible to certain diseases, have also been shown to influence age-related cognitive changes. An SNP in the coding or regulatory region can affect transcription, translation, and ultimately function. For example, in humans, there are three unique alleles for the apolipoprotein E (*APOE*) gene (designated *APOE* $\varepsilon 2$, $\varepsilon 3$, and $\varepsilon 4$). *APOE* $\varepsilon 3$ allele is most prevalent, followed by *APOE* $\varepsilon 4$, with rare occurrence of *APOE* $\varepsilon 2$. Genetic linkage studies indicate that the inheritance of *APOE* $\varepsilon 2$ is associated with increased longevity. The neurotrophic activities of *APOE* are allele specific, with $\varepsilon 2 > \varepsilon 3 > \varepsilon 4$. Furthermore, inheritance of *APOE* $\varepsilon 4$ increases the risk for AD. Another example is brain-derived neurotrophic factor (BDNF), a neurotrophin that is essential for neuronal growth, survival, and function. In addition, BDNF is a critical factor in learning and memory. An SNP identified in the coding region of BDNF (Val66Met), which affects the pro-region of the protein, is associated with age-related cognitive deficits.

Gene Expression

Most studies that examine age-related gene expression compare mRNA levels in brain tissue of different age groups. A number of important caveats must be acknowledged when interpreting these studies. First, gene expression is highly selective to different brain regions and specific cell types. Second, alterations of mRNA levels may represent changes in gene expression or mRNA stability or turnover. Third, changes in mRNA levels may not ultimately reflect translational or functional changes. Fourth, aging changes can be quite subtle, which requires confirmation of each potential age-regulated gene by multiple methods and labs, and even in a variety of species. Unfortunately, most studies do not look at the 'middle years' of a species' life span, and results are generally reported from only two age groups, young and old. Careful examination at multiple ages throughout the life span is necessary for identifying potential intervention strategies.

Age-related pathways that may contribute to aging are difficult to ascertain in humans. Since gene expression in the human brain can only be examined at autopsy, the changes measured may be causing aging or may be a consequence of aging. Due to this difficulty, animal models provide a reasonable approach to studying brain aging. In addition, specific pathways can be modeled *in vitro* but these studies are complicated by the fact that neurons are postmitotic.

Some of the first studies documenting changes in gene expression with age showed declines in specific pre- and postsynaptic markers which are often correlated with age-related decline of cognition and motor skills. Synaptophysin, a presynaptic vesicular protein that is often used as a marker for synaptic plasticity and integrity, decreases with increasing age in hippocampal and cortical regions. Specific subunits of *N*-methyl-D-aspartate (NMDA) receptors (e.g., NR1, NR2), which have critical roles in learning and memory, decrease with age. Also, dopamine receptor (D2R) levels decrease with increasing age. The decline in expression of these synaptic components effectively reduces synaptic transmission, which contributes to age-related cognitive and motor changes.

In addition to these neuronal changes, age-related gene expression also occurs in glia. Glial fibrillary acidic protein (GFAP) is an astrocyte-specific intermediate filament that consistently shows elevation in aging brain. Beginning at middle age, the increased expression of GFAP ranges from 1.5 to 4 times normal, depending on brain region. Widely accepted as an indicator of astrocyte activation, the consequence of the progressive increase during aging is not known. Recent data suggest that the age-related increase of GFAP may contribute to the loss of synaptic plasticity during aging. Astrocytes originating from aged rat brains possess elevated GFAP and are less able to support neurite outgrowth. Experimental manipulation of GFAP levels (increase with complementary DNA; decrease with small interfering RNA) demonstrates a direct correlation between GFAP levels and neurite outgrowth. This exciting line of discovery implicates astrocytes as a driver of age-related cognitive changes.

Myelin-associated oligodendrocyte basic protein (MOBP) is increased with age in oligodendrocytes. Although MOBP is the third most abundant protein in myelin, its exact physiological function is not known. Based on its localization to compact myelin, it is proposed to have a role in stabilization of the myelin. White-matter integrity declines with increasing age. In addition, a decline in the volume of brain white matter had been shown with magnetic resonance imaging (MRI). The impact of these age-related changes in the ultrastructure of the myelin sheath may have a profound effect on neuronal function.

Another glial gene that is increased with age is apolipoprotein D (ApoD). As with many of the age-regulated genes, the exact function of ApoD is not known. It is widely expressed by both astrocytes and oligodendrocytes. The ApoD protein can transport small hydrophobic ligands, including cholesterol, pregnenolone, and sterols, but it is not known if these are its physiological ligands. Importantly, the *Drosophila* homolog has been shown to increase stress resistance and extend life span. In studies of transgenic flies that overexpress the homolog of human ApoD, the protein named glial Lazarillo (GLaz), the flies were less susceptible to hyperoxic conditions, had improved motor and behavioral activities when subjected to sublethal oxygen exposure, and lived 29% longer. Therefore, the age-associated increase in ApoD expression may be a compensatory response to the age-related progressive increase in oxidative stress.

Genotypic changes in microglia are believed to underlie their activated phenotype which appears with increasing age. One indication of this is the increased expression of CD68 (the mouse homolog is macrosialin). CD68 is a lysosomal/endosomal-associated membrane protein with characteristics of scavenger receptors. Its function is not known but is believed to play a role in phagocytosis. Under normal conditions CD68 is predominantly found in microglia residing in white matter. Since oxidized lipids induce CD68 expression, it may be playing a role in age-related myelin changes.

Studies examining the expression of individual genes that change with age are vital to advancing our knowledge of the molecular mechanisms underlying aging; however, such studies do not address the polygenetic component of brain aging. This need is met by large-scale microarray analysis, which allows simultaneous examination of thousands of genes in a single sample. This type of analysis has been performed on brains from many mammalian species, including humans, chimpanzees, and rodents. There is significant change with age in a relatively small percentage (<5%) of the >20 000 genes examined. Although specific genes across all species may not be identical, classes of genes emerge (Table 1). The greatest percentage of genes that are upregulated consists of those involved in inflammatory processes and the stress response. Downregulated genes concentrate in synaptic function and plasticity. A comparison of gene classes in different species suggests that inflammatory and oxidative pathways are at the center of age-related cognitive and motor deficits.

An important group of inflammation-related genes that are increased in the aging brain includes components of the complement cascade. Resident brain cells

Table 1 Functional gene classes showing consistent changes with brain aging

Age change	*Functional class*	*Gene family*
Increase	Inflammatory and stress response	Complement subunits, heat shock proteins, cathepsins, inflammatory mediators
Decrease	Synaptic function and plasticity	Presynaptic and postsynaptic proteins, neurotransmitter receptors

produce each member of the complement cascade. Activation of the complement cascade initiates innate immune responses such as phagocytosis, chemotaxis, and cytolysis. The initial components, C1q, C3, and C4, are commonly shown to be increased in the aging brain, suggesting that activation of the complement cascade occurs during aging.

Brain Aging across Species

A new informatics tool to compare microarray results from different specifies and/or different laboratories is the web database and analysis platform, Gene Aging Nexus (GAN). GAN is freely accessible online (see 'Relevant website' section), where new datasets can be uploaded, queries can be run on existing datasets, and extensive integrative analysis can be performed to identify differentially or co-expressed genes with functional annotation. The database currently has data for the aging brain in humans, mice, and rats. Seven genes are identified to be increased with age across these three species (Table 2).

This cross-species comparison identifies known age-changers such as *GFAP* and *APOD*, but also identifies age-regulated genes that have not been documented prior to the microarray analysis. For example, annexin A3 (gene *ANXA3*) increases in human, mouse, and rat brains. Annexin A3 is a member of the annexin family of proteins that have calcium-dependent phospholipid-binding activities. The function of annexin A3 is not known; it is expressed in activated microglia in response to neuron injury. Carbonic anhydrase IV (gene *CA4*) expression is decreased in the aged brain. Reduced levels of carbonic anhydrase IV may contribute to age-related declines in synaptic transmission, since this protein is responsible for buffering the alkaline pH shifts associated with neuronal activity.

It should be noted that some of the individual genes identified as age changers were not shown to be changed during aging in the microarray studies. Detection of individual genes is influenced by the specific set of oligonucleotide probes used on a particular microarray chip, which may explain these differences. Also, differences could arise due to the complex statistical considerations microarray analysis requires.

Brain Aging and Insulin-Like Growth Factor

A discussion of aging is not complete without including insulin-like growth factor-1 (IGF-1). The importance of the insulin/IGF-1 pathway in aging and longevity is apparent from the vast experimental literature documenting a central role for IGF-1 pathways in regulating the life span of diverse organisms, including yeast, worms, flies, and mice. IGF-1 pathways orchestrate cell metabolism, growth, and survival. Systemic IGF-1 decreases with increasing age. IGF-1 crosses the blood–brain barrier and resident brain cells express IGF-1. Correlational and experimental observations suggest that IGF-1 has a generally positive influence on cognitive performance. At the cellular level, IGF-1 is neurotrophic and neuroprotective while participating in the stress response. The influence IGF-1 has on cellular activities predicts a critical role for IGF-1 pathways in brain aging.

Table 2 Age-regulated genes common to human, rat, and mouse brain: fold change (*p*-value)

Human gene nomenclature/protein	*Human*	*Mouse*	*Rat*
ANXA3/annexin A3	+2.2 (0.006)	+1.4 (0.04)	+1.3 (0.002)
APOD/apolipoprotein D	+2.0 (0.000 05)	+2.6 (0.000 03)	+1.4 (0.003)
CA4/carbonic anhydrase IV	−1.5 (0.01)	−1.9 (0.009)	−1.3 (0.009)
EGR2/early growth response 2	−1.6(0.04)	+1.6(0.04)	+2.8(0.000 9)
GFAP/glial fibrillary acidic protein	+1.5(0.01)	+2.1(0.000 1)	+1.7(0.05)
MOBP/myelin-associated oligodendrocyte basic protein	+2.1(0.03)	+1.8(0.007)	+1.6(0.02)
QDPR/quinoid dihydropteridine reductase	+1.4(0.04)	+1.3(0.04)	+1.6(0.000 003)

Age-regulated genes identified from three brain aging datasets of gene expression microarray analysis in Gene Aging Nexus.
Human data from B Yankner, Harvard Medical School; mouse data from T Prolla/R Weindruch, University of Wisconsin-Madison; rat data from P Landfield, University of Kentucky.

Regulation of Gene Expression

Gene expression is regulated through transcription, translation, and posttranslational means. Transcriptional factors, which are at the center of gene regulation during development, may also have a major role during aging. Generally, transcription factors exist in an inactive form and become active through phosphorylation, ligand binding, or removal of inhibitory subunits. Likely candidates involved in regulating age changes include activator protein-1 (AP-1), glucocorticoid receptor (GR), cyclic AMP response element-binding protein (CREB), peroxisome proliferator-activated receptor (PPAR), and nuclear factor-kappa B (NF-κB). Each transcriptionally activates unique signal transduction pathways that are implicated in learning and memory. The promoter region of the age-regulated gene *GFAP* contains putative transcriptional binding sites for all of these transcription factors. Although transcriptional regulation of *GFAP* through these sites has been extensively documented, it is still unresolved which ones are responsible for increasing *GFAP* expression with age. Additional levels of regulation have recently been identified. These include the silencing RNAs, microRNAs, and chromatin acetylation pathways. The contribution each of these has in aging is not known.

Attenuation of Brain Aging

Dietary restriction (DR; also called caloric restriction, or CR), which is achieved through restricted caloric intake, is the most powerful and general manipulation of aging processes in laboratory animals. In addition to extending life span, DR attenuates many of the age-related changes that occur in the brain. Depending on the brain region, 30–75% of the age-associated gene expression changes are either completely or partially prevented by DR. In the neocortex, DR prevents the age-related increased expression of 65% of those genes involved in the inflammatory response.

In addition to DR, specific dietary nutrients that possess anti-inflammatory and antioxidant properties have beneficial effects on brain aging. For example, supplementing rodent diets with strawberry, blueberry, or spinach extracts attenuates age-related motor and cognitive declines. Polyphenolics, such as the flavonoids found in these dietary supplements, are believed to underlie this beneficial effect. The omega-3 unsaturated fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), improve cognitive performance. The phytoalexin, resveratrol, also has anti-aging properties. Since resveratrol is concentrated in the skin of red grapes, one has an additional reason to savor that glass of burgundy.

Brain Aging and AD

Since aging is the primary risk factor for AD it should not be a surprise that age-regulated genes are also found in AD. In fact, inflammatory and oxidative pathways are implicated in AD progression. Activated astrocytes and microglia are integral components of AD-related pathologies. Furthermore, using transgenic mouse models of AD, experimental reduction in disease progression occurs with many of the methods shown to be beneficial for brain aging (e.g., DR, DHA, blueberry extract, and resveratrol).

Technologic Advances

New technologies will soon advance our understanding of brain aging significantly. Microarray analysis is now available for screening microRNAs and SNPs. Laser capture microdissection (LCM) will allow researchers to perform molecular analysis of pure cells from specific microscopic regions of the brain; in addition, the synergism of molecular and computational biology disciplines is poised to make major contributions to the complex, multifaceted process of brain aging.

Open Questions

Some of the critical issues that remain to be addressed include the unique roles that transcription, translation, and posttranslational modification (which currently is a major target of drug development) have in orchestrating age-related changes in motor and cognitive skills. The delineation between normal age-related changes and disease-related changes, such as those that occur in AD and Parkinson's disease, will identify unique molecular mechanisms underlying normal brain aging. Also, careful consideration must be given to the specific contributions made by vascular aging in the aging brain.

Summary

Underlying normal age-related cognitive and motor deficits are gene expression changes that define the aging brain. The specific changes in gene expression that occur in each type of brain cell contribute to subtle dysfunctions in brain activities. A comparison of gene classes in the different species supports the belief that the aging brain experiences progressive increases of inflammatory and oxidative stress pathways, and that this results in the accumulation of altered or damaged proteins that interrupt normal synaptic functions. The current status of age-related gene expression supports an important role for glia in orchestrating these age changes in the brain.

Gene Expression in the Evolution of the Human Brain

M C Oldham and D H Geschwind, UCLA School of Medicine, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Humans and chimpanzees diverged from a common ancestor within the past 5–7 My. During this relatively brief evolutionary time period, humans have acquired a number of singular characteristics, including a bipedal gait, the widespread use of tools, and a vastly expanded neocortex. Above all else, it is our unique cognitive abilities that separate us from other primates, endowing us with the specific epithet *sapiens*: the 'wise' or 'intelligent' human. What changes precipitated the remodeling of the human brain? Although we may never know with certainty the selective forces that shaped the recent evolution of our species, the telltale signature of natural selection must exist in the finite number of DNA sequence differences that distinguish our genome from those of our closest living relatives.

The first detailed molecular comparisons between humans and chimpanzees were performed in the 1960s and 1970s and produced a remarkable conclusion that holds true today: the overwhelming majority of macromolecules are nearly identical between the species. The degree of similarity between human and chimpanzee proteins suggested that, despite our overt phenotypic differences, we are as similar to one another molecularly as sibling species. Furthermore, these observations suggested that the evolution of many human-specific traits may have been driven by changes affecting the regulation of gene expression, in addition to changes in protein-coding sequences. The recent completion of the human and chimpanzee genome sequences and the advent of high-throughput technologies for surveying gene expression have begun to extend and refine these ideas.

Comparison of the human and chimpanzee genomes has revealed that they are approximately 96% identical, with about 1% of the differences resulting from single base substitutions and about 3% of the differences resulting from numerous insertions, deletions, duplications, inversions, and rearrangements of DNA sequences of various size. The majority of these differences exist outside of protein-coding regions, which is not surprising, since exonic sequence comprises only a small fraction of primate genomes. At present, it is difficult to discern on the basis of sequence data alone which of these changes have arisen through positive selection and which are the result of neutral evolution (i.e., genetic drift). For example, one commonly used metric assesses the ratio of single nucleotide changes that result in nonconservative amino acid differences and single nucleotide changes that do not affect coding sequence. However, this metric ignores many types of evolutionary change that may have significant functional consequences, including changes in introns that may alter splicing, changes in 3′-untranslated regions that may alter messenger RNA (mRNA) stability or trafficking, and changes in promoter regions that may alter the level of gene expression. Because many functionally significant changes in noncoding regions of DNA exert their effects by altering the regulation of gene expression, a new approach to the study of human brain evolution involves large-scale comparisons of gene-expression levels between human and chimpanzee brains. Here, we discuss what we have learned about brain evolution from these studies.

Comparing the Transcriptomes of Human and Chimpanzee Brains

The transcriptome is broadly defined as the set of all mRNA molecules that are transcribed in a given organism in a given tissue (or cell type) at a given time. In reality, no technique currently exists to survey all transcripts in any multicellular organism, as no complete set of transcripts, expressed across all developmental time points, is definitively known. However, existing techniques can measure the expression levels for upward of 20 000 transcripts in a single experiment. The most popular of these techniques involves the use of microarrays. A microarray consists of thousands of molecular probes arranged in a small grid, each designed to hybridize to a specific mRNA, thereby providing a quantitative measure of the abundance of that mRNA in a sample (i.e., the degree of gene expression). Recently, investigators have begun to use microarrays to compare expression levels for thousands of genes in adult human and chimpanzee brains, as well as other tissues. Below, we review the results of these initial studies and discuss some of the challenges that must be addressed to enable proper interpretation of the data produced by this promising experimental approach.

Initial Findings

As with humans, it is considered unethical to sacrifice a great ape for the sole purpose of obtaining tissue samples. As a result, microarray experiments

Figure 1 Outgroup data are required to infer the direction of evolutionary changes in gene-expression levels. (a) Mean expression levels are shown for a hypothetical gene in human, chimpanzee, orangutan, and gorilla. Although the gene is expressed higher in humans relative to chimpanzees, without outgroup data it is unclear whether expression levels have increased on the human lineage or decreased on the chimpanzee lineage. Comparison with orangutan and gorilla suggests an increase in expression on the human lineage. (b) Mean expression levels for another hypothetical gene are shown. The difference between humans and chimpanzees is comparable to that in (a). However, comparison with orangutan and gorilla suggests a decrease in expression on the chimpanzee lineage.

comparing gene expression between humans and chimpanzees have been carried out using mRNA extracted from postmortem tissue samples from individuals who have died of natural causes. Certainly, the cause of death or the process of death itself may influence gene expression, which is a potential confound in these studies. However, it is reassuring that gene-expression levels from postmortem tissue that has been rapidly frozen correlate strongly with gene-expression levels derived from tissue extracted during surgical biopsies from living human subjects, lending confidence to the integrity of this experimental approach. Microarray studies comparing gene expression in human and chimpanzee brains have focused primarily on cerebral cortex, although comparisons have also been performed for cerebellar vermis, caudate nucleus, and some nonneural tissues. An initial and perhaps somewhat counterintuitive observation is that humans and chimpanzees appear to have fewer gene-expression differences in prefrontal cortex than they do in nonneural tissues. This observation was first made in comparison to liver and subsequently extended to heart, kidney, and testis. These data have been interpreted to suggest that the brain may impose greater functional and evolutionary constraints on gene expression than other tissues. However, there are technical obstacles and other explanations that challenge this interpretation, which are discussed below.

An important question is whether gene-expression differences between humans and chimpanzees reflect evolutionary changes that have occurred on the human lineage, the chimpanzee lineage, or both. To answer this question, it is necessary to compare human and chimpanzee gene-expression levels with those of another closely related species (or outgroup), such as gorilla or orangutan (Figure 1). Unfortunately, tissue samples from these species are extremely scarce, often necessitating the use of more distant relatives for which captive colonies exist in large numbers, such as rhesus macaque. Comparisons of human/chimpanzee gene-expression differences with outgroup data have yielded another interesting observation: in the brain, but not in other tissues, a greater proportion of gene-expression differences between humans and chimpanzees seems to have occurred on the human lineage. Thus, although the brain appears to show fewer gene-expression differences overall between humans and chimpanzees compared with other tissues, relatively more of those changes are human specific.

Is there any pattern to the gene-expression differences between human and chimpanzee brains? *A priori*, one might expect that approximately equal numbers of genes would show higher expression in human and chimpanzee brains, respectively. However, there is some evidence to suggest that the distribution of gene-expression differences might be skewed, with more differentially expressed genes showing higher expression in human cerebral cortex relative to chimpanzee. Interestingly, among genes with higher expression levels in the human brain, several functional categories are enriched, including cell growth and maintenance, protein folding, and energy metabolism. The last category is especially noteworthy, as multiple lines of evidence are beginning to

converge upon the idea that genes involved in energy metabolism, including several members of the electron transport chain, have experienced accelerated evolution in anthropoid primates. In light of the massive expansion of the neocortex that has occurred on the human lineage within the past 5–7 MY, it is reasonable to expect that solutions to newly imposed energetic demands must have emerged concurrently.

Another important question is whether gene-expression differences between human and chimpanzee brains are ubiquitous or whether they are confined to a particular brain region or cell type. A comparison of four cortical regions (Broca's area, anterior cingulate cortex, prefrontal cortex, and primary visual cortex), caudate nucleus, and cerebellar vermis by Khaitovich and colleagues is the only study that has attempted to address this question directly. These authors observed very little variation in gene expression between cortical regions in individuals of either species (although there is some evidence to suggest that primary sensory cortex is distinguishable from areas typically termed 'association' cortex). In contrast, clear differences in gene expression exist between cortex, caudate nucleus, and cerebellum within individuals from both species. Analysis of genes that are differentially expressed between humans and chimpanzees reveals that the vast majority of gene-expression differences between the species are found in all of the brain regions surveyed. Among those genes that show expression patterns specific to a single brain region (cortex, caudate nucleus, or cerebellum), there appears to be a slightly greater percentage of human-specific cortical genes than there are human-specific caudate nucleus or cerebellar genes. However, the absolute number of these genes is quite low. Furthermore, direct comparison between humans and chimpanzees in Broca's area, a region of cortex known to be critically involved in a human-specific phenotype (language), did not identify any major differences in gene expression between the species.

Challenges to Data Interpretation

An important caveat is that, owing to the scarcity of human and chimpanzee tissue samples, all of the findings described above have been derived from comparisons of 3–6 individuals from each species. Because cortical gene expression can vary significantly between individuals (indeed, differences between individuals are typically greater than differences between cortical areas from the same individual), 'outlier' samples have the potential to significantly alter data interpretation. For example, it has been suggested that the apparent acceleration of gene-expression changes in the brain on the human lineage might result from greater variability in gene expression among the analyzed human samples relative to the chimpanzee samples, which could reflect true individual differences or differences in postmortem mRNA quality. In addition, many of the studies described above used samples from related chimpanzee individuals, depressing their degree of genetic diversity compared to the unrelated human individuals. Dissociating individual variability from technical variability will require many more samples representing different regional populations, genders, and ages. Thus, caution is required when attempting to generalize these findings. The issue of sample size and composition also holds true for the use of outgroup species. When outgroups have been used to infer the directionality of changes in gene expression between humans and chimpanzees, they have consisted of a handful of individuals (from one to four orangutans, gorillas, or rhesus macaques).

The use of outgroup species highlights another challenge to data interpretation – the effect of interspecies sequence differences on hybridization efficiencies between microarray probes and their mRNA target sequences. Because the probes have been designed from human mRNA sequences, they will not match perfectly with their mRNA targets in closely related primate species (including chimpanzees). Conservation between human and chimpanzee coding regions is ~99%, implying that one out of every four 25-mer probes (the probe length on Affymetrix microarrays, which have been used in all of the studies discussed above) will have a mismatch. A sequence mismatch can reduce the hybridization efficiency between a probe and its mRNA target, resulting in expression levels that appear 'decreased' in nonhuman primate species or 'increased' in humans. This effect clouds the observation that genes differentially expressed between human and chimpanzee brains are skewed toward higher expression in humans (although skewing of gene-expression differences was not evident in nonneural tissues such as heart or liver). However, this problem can be mitigated by using available sequence data to mask probes with sequence differences between species before calculating gene-expression values. Because each transcript on an oligonucleotide microarray is queried by multiple probes, eliminating ~1/4 of the probes (as might be done for chimpanzee samples) does not preclude data collection. Indeed, application of this approach to chimpanzee gene-expression data appears to preserve the skewing of gene-expression differences between the species. Unfortunately, this approach is untenable for more evolutionarily distant outgroup species, for which most probes are expected to possess sequence differences with their intended

targets. Ultimately, the solution to this problem may depend upon the development of species-specific microarrays with probes designed to match orthologous exons.

Microarray studies comparing human and chimpanzee brains pose several additional challenges. First, all studies to date have surveyed gene expression in tissue samples from adult individuals, although many of the most important evolutionary adaptations must manifest during fetal development. It is unclear to what extent such adaptations will persist into adulthood at the level of gene expression. Furthermore, it is unlikely that fetal chimpanzee tissue samples will become available anytime soon; therefore, additional strategies aimed at elucidating the unique aspects of the transcriptional program in the developing human brain will be required. Second, interpretation of microarray data derived from brain samples is complicated by the issue of cellular heterogeneity. Within any given sample of brain tissue there are anywhere from dozens to hundreds of different cell types; each of these cell types is expected to vary in terms of the number and degree of expressed genes. In effect, the level of expression for a given gene measured by microarray in a sample of brain tissue represents the breadth of expression (across cell types) multiplied by the representation of each cell type in the sample. Seen in this light, it may seem less surprising that gene expression appears to show less divergence between humans and chimpanzees in the brain than it does in other, more homogeneous tissues such as liver, heart, or testis. The genes that are detected by microarray in samples of brain tissue are more likely to be genes that are broadly expressed across a variety of cell types; expression in a wide variety of cell types, in turn, is expected to impose greater functional and evolutionary constraints than expression in a few cell types, as would be the case in a more homogenous tissue. Clarification of this issue will require cellular resolution (i.e., comparisons of gene-expression levels for specific cell types). Finally, most current analyses of microarray data focus on identifying genes that show differential expression between two conditions. Since gene-expression levels in human and chimpanzee brains represent population averages across cell types and individuals, these comparisons offer a rather severe method of data reduction that do not extract all of the available information present in microarray data. It is likely that gene-by-gene assessments of differential expression will be supplanted by more comprehensive analytic techniques such as network-based approaches, which we discuss below. These approaches study gene expression in the context of the whole biological system. As such, they enable understanding of the relationships between genes and the relative importance of a gene within the system being studied.

Application of Network Theory to Gene-Expression Data

Recently there has been a great deal of interest in the application of network theory to biological systems. Many biological systems exhibit properties of complex networks, such as scale-free topology, in which the probability that a given node (a gene or its product) in the network has a certain number of connections follows an inverse power law (this property predicts that certain 'hub' nodes will have many connections and serve as convergence points in the network, whereas most nodes will have very few connections). Network analysis of gene-expression

Figure 2 Analysis of gene co-expression relationships provides insights that comparison of average gene-expression levels cannot identify. (a) Comparison of average gene-expression levels for *GABRD* and *DKFZP564O0823* suggests that neither gene is differentially expressed between human and chimpanzee cerebral cortex. On the basis of these comparisons, there is no reason to suspect that these genes have anything in common. (b, c) Network analysis reveals that *GABRD* and *DKFZP564O0823* are highly co-expressed in human cerebral cortex (b) ($r = 0.99$, $p = 6.45e{-}10$), but not in chimpanzee cerebral cortex (c) ($r = 0.11$, $p = 0.73$). *GABRD* encodes the delta subunit of the $GABA_A$ receptor, while the function of *DKFZP564O0823*, which also encodes a membrane protein, is unknown. The strength of co-expression in human cerebral cortex suggests that these genes may be co-regulated and participate in similar biological processes, while the absence of co-expression in chimpanzees suggests that coregulation of these genes may have disappeared during recent chimpanzee evolution or appeared during recent human evolution. H1, Human 1, C1, Chimp 1, etc.; Brocas, Broca's area; acc, anterior cingulate cortex; prv, primary visual cortex; prf, prefrontal cortex. Raw data are from Khaitovich P, Muetzel B, She X, et al. (2004) Regional patterns of gene expression in human and chimpanzee brains. *Genome Research* 14: 1462–1473. (d) By searching for other genes that are highly co-expressed in human cerebral cortex with both *GABRD* and *DKFZP564O0823*, a module of gene co-expression relationships is revealed. The hub genes in this module are highlighted in pink: *GNB5*, *SCN2B*, *G3BP2*, and *KLHDC3*. *GABRD* and *DKFZP564O0823* (highlighted in turquoise) are seen to be highly correlated with one another by virtue of their mutual association with the hub gene *GNB5*. (e) By comparing the strength of the connections depicted in (d) between humans and chimpanzees, it becomes possible to apply a filter such that only the most human-specific connections are retained as is depicted here. So, the network module shown in (e) represents human-specific connections. This pattern suggests that this module is poorly conserved in chimpanzee cerebral cortex. The lack of conservation is largely due to the differential connectivity of the hub genes. Such detail and knowledge of which genes are the focal points of evolution cannot be obtained from simple analysis of differential gene expression.

data proceeds by treating each probe set on the microarray as a node and modeling the connections between nodes as a function of the correlations between gene-expression levels. By searching for clusters of nodes that are densely interconnected, one can identify groups of genes (modules) that are highly co-expressed. Modules of co-expressed genes may be expressed in the same cell type(s) or be involved in similar biological processes, providing an excellent method for generating 'guilt-by-association' functional hypotheses about genes for which little is known. In addition, the position of each gene in the network can be described by its connectivity (k), which is a quantitative summary of its connection strengths to all other genes in the network. Genes with high k (hub genes) are critical to the integrity and proper functioning of the network. Comparisons of k between species can thus serve to place changes in gene expression or protein sequence in an appropriate functional context and may aid in discerning between changes that are adaptive and changes that are evolutionarily neutral. Similarly, comparisons of gene co-expression relationships between human and chimpanzee brains have the potential to identify genes with vastly different patterns of connectivity. Importantly, a gene may differ dramatically in its degree of co-expression with other genes, yet have the same average expression level in both species (Figure 2). By considering genes only in terms of differential expression, a world of available information goes unnoticed. Network-based approaches can thus provide a more sensitive method for comparing transcriptomes and are likely to become increasingly prevalent in large-scale analyses of microarray data sets in the future.

In Search of a Theoretical Framework

What forces govern the evolution of gene-expression differences between primate species? The answer to this question is not yet clear, and probably will not be for some time. One view holds that most genes are under stabilizing selection and expression levels should therefore be largely conserved across species; where differences exist, they are thought to be adaptive. An alternative theory posits that most gene-expression differences between species are evolutionarily neutral or nearly neutral. This theory predicts that gene-expression differences between species should accumulate approximately linearly with time. Although limited evidence has been produced in favor of both arguments, it is clear that much more data will be required to answer this question with any certainty. It is also evident that the search for a theoretical framework governing the evolution of gene expression must take place within appropriate species and tissue contexts. Can one assume that the rules governing the evolution of gene expression are the same in human appendix as they are in human brain, or the same in fly brain as they are in human brain? In addition, the question of selective pressure cannot be disentangled from the technical hurdles described above. The gene-expression 'levels' typically used to promote various theoretical frameworks represent population averages across cell types and individuals. Consequently, individual differences and differences in cellular composition have the potential to significantly impact data interpretation, especially when considering so few samples. Moving forward, the challenge for researchers in the field will be to assign differences in gene expression levels and gene co-expression relationships to specific cell types in the human brain. It is only at this level that a clear picture of the evolutionary forces that have shaped gene-expression changes in the human brain will begin to emerge.

Summary

Over 30 years have passed since it was first proposed that changes in the regulation of gene expression may underlie many human-specific traits. Today, with the availability of the human genome sequence, draft sequences for chimpanzee and rhesus macaque, and the impending availability of genome sequences for orangutan and gorilla, we are closer than ever to zeroing in on the parts of our DNA that make us unique as a species. While this goal is within our reach, it will in many ways mark a new beginning, as researchers attempt to determine which of these sequence differences have contributed to the emergence of uniquely human traits. High-throughput techniques such as microarrays that enable transcriptomic comparisons between species offer great promise to identify functionally significant molecular phenotypes that may underlie species-specific adaptations. Application of these techniques to larger data sets consisting of increasingly refined brain regions or specific populations of cells, combined with new analytic approaches, have the potential to discern between evolutionarily neutral and functionally significant differences in gene expression between humans and other species. Understanding these differences may enable the cultivation of a theoretical framework governing the evolution of gene expression in the human brain and simultaneously reveal the critical evolutionary changes that have contributed to the emergence of our singular cognitive abilities.

Gene Expression Regulation: Activity-Dependent

E D Nelson and L M Monteggia, University of Texas Southwestern Medical Center, Dallas, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Regulation of gene expression changes is thought to be the basis for long-lasting forms of synaptic plasticity in the brain. Paradoxically, synaptic activity can regulate the transcription of some of the genes responsible for the changes in synaptic plasticity. Synaptic activity can effect gene expression through the direct control of transcription factors, both activators and repressors, as well as through the regulation of epigenetic mechanisms important for controlling gene transcription, such as DNA methylation and histone acetylation. The common starting point by which synaptic input can regulate gene expression is through the enhancement of postsynaptic Ca^{2+} influx through *N*-methyl-D-aspartate (NMDA)-type glutamate receptors and/or voltage-gated Ca^{2+} channels (particularly of the L type). This rise in intracellular Ca^{2+} levels leads to the activation of signaling pathways important for regulating certain transcription factors (Figure 1). Most often, Ca^{2+} will bind either directly to kinases that can phosphorylate substrates important for controlling gene expression, or to proteins that can then activate downstream kinases in a Ca^{2+}-dependent manner. Activation of particular kinases depends upon the temporal and spatial properties of the Ca^{2+} signals in response to synaptic inputs.

Regulation of Transcriptional Activation by Synaptic Activity

One of the best-understood examples for how activity-driven signaling pathways can induce the activation of gene expression is the phosphorylation of the transcriptional activator cyclic AMP response element (CRE)-binding protein (CREB). Upon synaptic stimulation by excitatory neurotransmitters, increased intracellular Ca^{2+} binds to the protein calmodulin, which activates a number of different stimulus-dependent protein kinases that can all lead to the phosphorylation of CREB at serine 133. Immediately after receiving synaptic stimulation, Ca^{2+}-activated calmodulin can translocate from the cytoplasm to the nucleus, where it can then activate Ca^{2+}/calmodulin-dependent kinase IV (CaMKIV), which in turn phosphorylates CREB. Ca^{2+}-bound calmodulin can also activate additional CaM kinases within the cytoplasm or other signaling cascades, such as the mitogen-activated protein (MAP) kinase and protein kinase A (PKA) pathways. After phosphorylation of CREB by one of these kinases, it can bind to CRE sequences in the promoters of certain genes and activate their transcription (Figure 2). However, phosphorylation of CREB alone is not sufficient to activate gene transcription. Increased nuclear Ca^{2+} must also activate the transcriptional coactivator CREB-binding protein (CBP), which then associates with phosphorylated CREB and leads to the expression of target genes. Many of the targets of activity regulated transcription factors are gene products known to have effects on neuronal activity. The transcriptional activator CREB controls the expression of genes such as brain-derived neurotrophic factor (BDNF) and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptor 1 (GluR1). BDNF, a growth factor important for neuronal survival, can mediate changes in long-term potentiation (LTP), a form of synaptic plasticity. GluR1 is an excitatory neurotransmitter receptor subunit required for LTP to occur at synapses.

Ca^{2+}-dependent shuttling of transcription factors between the cytoplasm and the nucleus is another mechanism by which activity can drive changes in gene expression. Two different transcriptional activators, nuclear factor of activated T cells (NFAT) and nuclear factor-κB (NF-κB), are relocalized from the cytoplasm to the nucleus in response to signaling cascades activated by a variety of stimuli. The activation of the Ca^{2+}-dependent phosphatase, calcineurin, leads to the dephosphorylation of NFAT, allowing NFAT to translocate to the nucleus where it can then turn on the expression of specific target genes. In contrast, NF-κB is kept inactive in the cytoplasm by inhibitor proteins, IκBs, until they are phosphorylated and degraded in response to increased intracellular Ca^{2+}. NF-κB is then free to relocate into the nucleus and activate gene transcription. The nuclear translocation of these proteins in response to synaptic activity suggests that their specific localization within the cytoplasm may influence the transcriptional response to cellular stimuli, thus making them possible regulators of gene expression-dependent localized processes such as synapse-specific modulation and/or axon guidance. Indeed, it is known that NFAT controls the expression of the inositol 1,4,5-trisphosphate receptor type 1 (IP_3R1) gene that encodes an endoplasmic reticulum Ca^{2+} channel important for releasing Ca^{2+} from intracellular stores in response to synaptic activity.

Figure 1 Example of a postsynaptic mechanism by which activity can regulate gene expression. In response to neurotransmitter release from presynaptic neurons, ligand- and voltage-gated ion channels open up and allow the influx of Ca^{2+} into the postsynaptic compartment. Two channels that are critically important for mediating this rise in intracellular Ca^{2+} are *N*-methyl-D-aspartate receptors (NMDAR) and voltage-gated Ca^{2+} channels (VGCC). The rise in Ca^{2+} concentrations can be sensed by the binding of Ca^{2+} to the protein calmodulin (CaM), which then becomes ready to activate further downstream the proteins important for the regulation of gene expression. Two such proteins are Ca^{2+}/CaM-dependent kinases II and IV (CaMKII and CaMKIV). These kinases then go on to phosphorylate transcriptional activators or repressors and thereby have an effect on gene transcription.

Figure 2 Gene transcription is activated upon synaptic stimulation via the phosphorylation of cAMP response element (CRE)-binding protein (CREB). The rise in intracellular Ca^{2+} after synaptic activity leads to the activation of various kinases that can phosphorylate the transcriptional activator CREB. Upon phosphorylation, CREB dimerizes and binds to CRE sequences in the upstream promoter regions of target genes. The coactivator, CREB-binding protein (CBP), must also bind to CREB before the recruitment of proteins important for gene transcription, such as RNA polymerase II, can turn on the expression of these genes.

Regulation of Transcriptional Repression by Synaptic Activity

Though much work has been done demonstrating the activation of gene expression through synaptic activity, there is accumulating evidence that activity can regulate transcription repression as well. One example is through the direct binding of intracellular Ca^{2+} to the downstream regulatory element antagonist modulator (DREAM). DREAM represses transcription by binding to downstream response element (DRE) sequences found in the untranslated regions of target genes. Upon synaptic stimulation, Ca^{2+}-binding domains within the DREAM protein bind Ca^{2+}, causing a conformational change and the release of DREAM from DRE-containing genes, thereby relieving the repression of transcription. DREAM has been shown to repress the transcription of a specific Na^{2+}/Ca^{2+} exchanger, NCX3, important for controlling intracellular Ca^{2+} homeostasis.

Another example of the activity-dependent regulation of transcriptional repression is through the Ca^{2+}-induced phosphorylation of the methyl-CpG-binding protein 2 (MeCP2). MeCP2 is a unique transcriptional repressor protein that links two different epigenetic mechanisms for controlling gene expression, DNA methylation and histone deacetylation. Under unstimulated conditions, MeCP2 associates with methylated CpG dinucleotides in the promoters

of target genes and recruits histone deacetylases (HDACs) 1 and 2. In response to neuronal activity, CaMKII phosphorylates MeCP2 at serine 421, causing its release from methylated promoters and relieving its repression of target genes (Figure 3). Recent work has demonstrated that MeCP2 controls the expression of BDNF in neurons by repressing its transcription in the absence of synaptic inputs.

Activity-Dependent Regulation of Epigenetic Mechanisms

The mention of MeCP2 introduces a manner by which changes in the interpretation of epigenetic markers can be regulated through alterations in neuronal activity. There is recent evidence that epigenetic mechanisms can be regulated by synaptic activity. The previously mentioned CREB-associated protein, CBP, can also be phosphorylated by the specific kinase Ca^{2+}/calmodulin-dependent kinase IV and likely increases transcription through its histone acetyltransferase (HAT) activity. CBP's activation by intracellular calcium is only one mechanism by which synaptic stimulation can cause chromatin remodeling that can then lead to changes in gene expression.

Activity-dependent increases in gene expression can also be regulated by the activation of another transcriptional activator, myocyte-enhancer factor 2 (MEF2), and the subcellular localization of HDACs. In quiescent cells, phosphorylated MEF2 is bound to the promoters of target genes and interacts with class II HDACs (4, 5, 7, and 9). HDAC activity represses the expression of MEF2-regulated genes until the cell receives a large enough stimulation to induce Ca^{2+} influx. The activation of CaMKs then phosphorylates the class II HDACs, causing them to be shuttled from the nucleus to the cytoplasm, therefore relieving their repression of gene transcription. Activity can then induce the dephosphorylation of MEF2 through the Ca^{2+}-dependent regulation of calcineurin, which results in active transcription of MEF2 target genes. Activity-dependent activation of the transcription factor MEF2 leads to an increase in the expression levels of activity-regulated cytoskeletal-associated protein (arc) and synaptic Ras guanosine triphosphatase activating protein (synGAP). The products of the *ARC* and *SYNGAP1* genes control synapse number and therefore have impacts on neuronal excitability.

There is recent evidence that DNA methylation, an epigenetic mechanism for controlling transcriptional repression, can also be regulated by neuronal activity. A commonly used learning and memory paradigm, contextual fear conditioning, increases the levels of DNA methyltransferase (DNMT) enzymes in the brain and alters promoter methylation patterns in two genes associated with synaptic plasticity. The molecular signaling mechanisms that drive these changes in DNA methylation are still not understood, but they are likely to involve similar increases in postsynaptic calcium levels.

In summary, there are many ways in which changes in synaptic activity result in the regulation of gene expression. Interestingly, there are known neurodevelopmental disorders associated with deficits in the activities of some of these transcriptional regulators, making their understanding of great clinical relevance. In humans, mutations in the transcriptional activating protein, CBP, cause Rubinstein–Taybi syndrome, a disorder associated with both growth and mental retardation. Mutations in the gene *MECP2* have been shown to lead to another mental retardation disorder, Rett syndrome. Future studies of these transcription factors will hopefully lead to a better understanding of how neuronal activity can alter gene expression and may give some mechanistic insights into how their malfunctions can lead to neurodevelopmental defects.

Figure 3 Transcriptional repression by methyl-CpG-binding protein 2 (MeCP2) is relieved following synaptic activity. In the absence of activity, MeCP2 is bound to methylated CpG sequences in the promoters of certain genes. The expression of these genes is repressed due to the inability of transcriptional activators to bind to promoter regions as well as to the deacetylation of histones by histone deacetylases 1 and 2 (HDAC1/2), which are recruited to chromatin by MeCP2 and the corepressor Sin3a. Upon stimulation, Ca^{2+}/calmodulin-dependent kinase II phosphorylates MeCP2, causing release of the repressor complex from CpG islands, allowing subsequent binding of transcriptional activators that can enhance gene expression.

From the Nucleus to Synapse: Transcriptional Regulation of Synaptic Function

In addition to synaptic activity-dependent regulation of gene expression, alterations in gene expression can in turn have significant impact on neurotransmission. Acute or chronic changes in the levels of activity-dependent genes can alter the degree of synaptic plasticity as well as baseline neurotransmission. The most salient example of this type of regulation is the activity-dependent alteration in levels of the brain-derived neurotrophic factor, a target gene for CREB-dependent transcription and MeCP2-dependent transcriptional repression. BDNF, via its binding to TrkB receptors, can exert several effects on neurotransmission by acting on postsynaptic as well as presynaptic mechanisms. On the postsynaptic site, BDNF action can increase the activity of the NMDA subtype of glutamate receptors and it can be a potent cofactor facilitating long-term synaptic plasticity. BDNF can also augment neuronal excitability by directly acting on voltage-gated ion channels. In the case of presynaptic nerve terminals, however, BDNF action has been proposed to target neurotransmitter release machinery directly in addition to its more global effect on presynaptic excitability. Due to its intimate association with multiple forms of synaptic plasticity and robust activity-dependent regulation through gene expression, BDNF has been a focus of several studies on the transcriptional regulation of neurotransmission.

Regulation of neuronal gene transcription via CREB or MeCP2 can have multiple, albeit specific, effects on neuronal excitability and synaptic transmission, which may not be solely attributable to alterations in BDNF levels. For instance, expression of constitutively active CREB or CaMKIV in the CA1 region of hippocampus causes a concomitant increase in NMDA receptor-mediated synaptic responses and in the extent of long-term potentiation. This increase in synaptic plasticity is attributable to a parallel increase in the number of 'silent synapses' that possess functional NMDA responses but no detectable AMPA receptor-mediated currents. As silent synapses are considered to be excellent substrates for synaptic plasticity, an increase in their number can substantially augment the dynamic range for ensuing plasticity. In addition, *in vivo* expression of active CREB in the nucleus accumbens medium spiny neurons causes a substantial increase in the excitability of these neurons and modifies cocaine-induced neuroadaptations.

Studies on loss-of-function phenotypes of MeCP2 have revealed several changes in baseline synaptic transmission as well as synaptic plasticity. Loss of MeCP2 causes impairments in long-term potentiation as well as long-term depression. This phenotype becomes evident in aged MeCP2-deficient mice at a time when the mice begin to manifest behavioral phenotypes akin to those seen in human patients with Rett syndrome. Synaptic connections formed between dissociated hippocampal neurons extracted from MeCP2-deficient mice also display several abnormalities, suggesting that MeCP2 is a *bona fide* cell-autonomous regulator of synaptic function. In this reduced system, loss of MeCP2 causes a specific decrease in the frequency of unitary excitatory neurotransmission coupled to a small increase in evoked neurotransmitter release from excitatory nerve terminals. Interestingly, treatment of wild-type control cultures with a drug that impairs histone deacetylation induces a similar decrease in unitary excitatory neurotransmission, but this decrease is occluded in MeCP2-deficient neurons. Furthermore, neither the loss of MeCP2 nor the drug treatment results in changes in inhibitory neurotransmission. Taken together, these findings suggest a role for MeCP2 in control of excitatory presynaptic function through regulation of gene expression.

The studies on CREB- and MeCP2-dependent alterations in synaptic function indicate a strong interaction between the regulatory mechanisms that tightly control gene expression in neuronal nuclei and the postsynaptic and presynaptic signaling elements. Therefore, activity-dependent regulation of gene expression forms a closed-loop system, which underlies potent feedback regulation of synaptic plasticity and neuronal homeostasis. Strong reciprocal feedback regulation of gene expression and synaptic function is clearly a key factor in sustained stability of synaptic networks, despite their vast capacity of information storage and processing.

Gene Expression Regulation: Chromatin Modification in the CNS

Introduction

Epigenetic gene mechanisms are widely studied in the developmental and cancer biology fields but are relatively new to neurobiology. Nevertheless, many emerging discoveries suggest the importance of epigenetics in the central nervous system (CNS), which is the subject of this article. Historically studied in simple genetic model systems such as plants and invertebrates, and once considered in the realm of strange and unexplained gene expression phenomenon, it is now generally regarded as a fundamental mechanism of gene regulation comparable to genetic mechanisms. Although there are several definitions of epigenetics, the most commonly used one applies to meiotically and mitotically heritable changes in gene expression that is not encoded in the DNA sequence. Using biochemical modifications of chromatin, this allows genotypically identical cells to behave phenotypically different. Two well-documented epigenetic mechanisms are chromatin packaging and DNA methylation. From biochemical approaches and the use of simple model organisms, much of the basic cellular chromatin and transcriptional machinery has been worked out; however, a full understanding of the mechanisms that regulate gene expression in complex organs such as the mammalian brain is still in its infancy. This article discusses current ideas regarding epigenetic mechanisms of neural development and plasticity in both normal and disease states.

Chromatin Structure and Histone Modifications

Chromatin is a complex of nucleic acid and protein made up of nucleosome repeats of 147 bp of DNA wrapped around two copies each of histones H2A, H2B, H3, and H4. One of the most exciting breakthroughs in chromatin biology in the past decade is that the amino (N)-terminal tails of core histones are subject to many types of covalent modifications including acetylation and methylation that control the activation or repression of gene expression on the associated DNA (Figure 1). Some histone modifications, such as acetylation of histone H3 on lysine 9 and 14, dimethylated or trimethylated at lysine 4, and phosphorylated at serine 10, are associated with active gene expression. Other marks, such as dimethylated or trimethylated histone H3 on lysine 9, are associated with inactive chromatin. These histone modifications are regulated by specific enzymes; histone acetyltransferases (HATs), histone deacetylases (HDACs), and histone methyltranferases (HMTs) are just some of the chromatin-modifying enzymes that have emerged to play central roles in cell growth and differentiation.

Among the growing list of chromatin-modifying enzymes, the HATs and HDACs have been extensively studied. HATs induce histone acetylation which usually results in relaxation of the nucleosomes and increased transcription, whereas HDACs catalyze the reverse reaction; in the deacetylated state, nucleosomes are more condensed, preventing access of transcriptional activators to their target sites, which results in transcriptional repression. HDAC proteins fall into three classes. Class I and class II are based on their homology with yeast HDACs Rpd3p and Hda1p, respectively. Class III HDACs represent a distinct class and are similar to yeast Sir2. In terms of the brain, global changes in histone modifications have been observed in different regions, particularly after traumatic brain injury, electroconvulsive seizures, or drugs of abuse. Although these findings are intriguing, the role of cell type-specific histone-modifying enzymes in neural development and function remains to be determined. Even though one class of tissue-specific HDACs (class II) have well-documented roles in cardiac hypertrophy and other tissue types, despite the fact that they are highly enriched in the developing and adult brain, little is known regarding their specific function in neurobiology. One important clue regarding the role of class I and class II HDACs comes from small molecule HDAC inhibitors such as trichostatin A or valproic acid. HDAC inhibitors can induce neuronal differentiation in embryonic and adult hippocampal neural stem cells. Moreover, HDAC inhibitors are becoming one promising class of potential therapeutics with apparent neuroprotective effects in Huntington's disease, amyotrophic lateral sclerosis, Friedreich's ataxia, spinal muscular atrophy, ischemic brain injury, seizure disorders, and even brain cancer cells. The future application of HDAC inhibitors for treating CNS disorders remains an exciting possibility. Our own studies suggest that one of the most commonly prescribed antiepileptics, valproic acid, appears to block seizure-induced aberrant neurogenesis and hippocampal-related cognitive deficits through a mechanism involving HDAC inhibition. Although these global studies of histone modifications and HDAC inhibitors in neurological disorders and brain function remain intriguing, detailed studies are needed to understand how specific genes are regulated

Figure 1 Epigenetic mechanisms involved in neural development. (a) Example of histone H3 acetylated (Ac), methylated (Me), and/or phosphorylated (P) in the promoter of a neuronal gene before ('silenced') and after lineage specification ('activated'). (b) Methyl-CpG-binding domain protein (MeCP2) binds to a methylated CpG site in DNA in the promoter of a neuronal gene and recruits repressor complexes containing HDACs and Sin3A/3B to mediate gene silencing. (c) An SWI/SNF chromatin-remodeling complex containing a Brm/Brg1 subunit and HAT activity to activate neuronal gene expression.

to control neural cell growth and plasticity. The mechanism for regulating HDAC activity in the cell can involve export from the nucleus and de-repression of gene expression or, more commonly, the recruitment of HDACs to gene-specific promoters by association with DNA-binding proteins, a process that is discussed in the next section.

Chromatin Complexes in the Brain

During cortical development, neural stem cells first undergo limited expansion through rounds of symmetric divisions and then undergo neurogenesis, mainly through asymmetric division. Toward the end of neurogenesis, cortical progenitors switch back to symmetric divisions and give rise to astrocytes and oligodendrocytes. Genes that specify one lineage must be repressed when a stem cell generates a different lineage. Thus, neuronal genes must be silenced until the onset of neurogenesis, and gliogenic genes must be inhibited during neurogenesis. This is coordinated through both transcriptional and epigenetic regulatory mechanisms that determine the potential of the cell to respond to extrinsic signals. Many elegant studies collectively describe the existence of transcriptional codes involving the spatial and temporal expression of cell type-specific transcriptional activators and repressors that control neuronal subtype specification and patterning in the developing CNS. Many of these factors have been studied in terms of their regulation of individual target genes during neural specification; however, a unifying mechanism that controls the process of neural cell fate specification through maturation has not been found.

A candidate master regulator of neurogenesis and gliogenesis is the transcriptional regulator NRSF (neuron-restrictive silencing factor, also called REST) (Figure 2). Initially described as a repressor of neuronal genes in nonneuronal cells, NRSF is a zinc finger protein that binds to a conserved 21–23 bp motif known as NRSE (neuron-restrictive silencing element, also called RE1). The NRSE sequence is found throughout the genome; many are found in the regulatory regions of neuron-specific genes, including neuronal growth factors, ion channels, neurotransmitter receptors, and guidance/migration molecules. The mechanism by which NRSF mediates transcriptional regulation of its target genes is becoming more complicated and appears to be context dependent. Emerging evidence suggests that NRSF functions by recruiting other corepressor complexes, usually through interaction of its N- or C-terminal domains, such as the mSin3A/B, N-CoR, CtBP, or CoREST complexes, which in turn may recruit class I HDACs. Nakagawa and colleagues showed that NRSF also interacts with class II HDACs in ventricular myocytes, although it remains to be determined whether the interaction is direct or indirect. Bioinformatic analyses

Figure 2 NRSF/REST is a context-dependent regulator of gene expression. Originally discovered as a repressor of neuronal gene expression in nonneuronal cells by both the Anderson (called NRSF) and Mandel (called REST) labs, cumulative data over many years have arrived at the consensus that the activity of NRSF/REST is dependent on cellular context and the nature of the specific target gene and its many possible interacting proteins. There is accumulating evidence to suggest that NRSF/REST splice variants, small modulatory RNAs, protein dimerization, cellular localization, and posttranslational modification may affect the function of the transcription factor, giving it the ability to spatially and temporally regulate its hundreds to thousands of putative target genes in both neuronal and nonneuronal cells. BRAF, B-raf; RILP, REST/NRSF-interacting LIM domain protein; SWI/SNF, switching/sucrose nonfermenting; TBP, TATA-binding protein.

have identified hundreds to thousands of NRSE sites throughout the mammalian genome, supporting the idea that NRSF functions as a master regulator of neuronal gene expression in neural stem/progenitor cells as well as in mature neurons. To add to the intrigue, NRSF function has also been implicated in various pathological states in brain as well as outside the brain, such as in different kinds of neural and neuroendocrine cancer cells, Huntington's disease, ischemic insults, epilepsy, and cardiovascular disease.

In addition to neuronal gene regulation by NRSF and recruitment of histone-modifying enzymes, evidence suggests that members of the switching/sucrose nonfermenting (SWI/SNF) and polycomb family of chromatin remodeling complexes have important roles in neural development and cancer and stem cell biology. SWI/SNF complexes use ATP hydrolysis to disrupt histone–DNA associations and contain different combinations of proteins that include both conserved and nonconserved components. They also interact with HATs or HDACs and/or sequence-specific transcription factors to activate or repress target genes. Typically, SWI/SNF complexes contain either ATPase Brahma (Brm) or Brahma-related protein 1 (Brg1). Chromodomain proteins, which possess the ATPase domain found in SWI/SNF proteins, are also recruited by polycomb repressors and are involved in homeotic gene silencing to control tissue patterning. Collectively, Brm, Brg1, and the polycomb repressor protein Bmi-1 have all been implicated in some aspect of neural development and function. Regulation of the sex-determining region Y (SRY)-related, high-mobility group (HMG)-box-containing protein (Sox-2), a key transcription factor in neural stem cells, is associated with the recruitment of Brm and appears linked to its role in stem cell maintenance. Brg1 is also required for *Xenopus* neurogenesis; loss of Brg1 correlated with increased neural progenitor proliferation and an expansion of Sox2-positive cells in embryos at later stages of neurogenesis. Brg1 function appears to be linked to the regulation of two proneural bHLH proteins, Neurogenin (Ngn)-related 1 and NeuroD. Moreover, the polycomb group proteins are emerging to play fundamental roles in stem cell maintenance and cancer. Bmi-1 is required for the self-renewal of stem cells in the CNS and peripheral nervous system; mice lacking Bmi-1 experience neurological defects, presumably due to a postnatal

depletion of their neural stem cells. Together, these data indicate the important role of chromatin remodeling factors in brain development and function.

The Role of DNA Methylation in the Brain

One classic epigenetic modification is DNA methylation, where mammalian DNA can be covalently modified through methylation of the carbon at the fifth position on the pyrimidine ring of the cytosine residue. This typically occurs at symmetrical CpG dinucleotides. DNA methylation is mainly involved in the establishment of parental-specific imprints during gametogenesis and gene silencing of the inactivated X chromosome and retrotransposons. *De novo* methylation of DNA is catalyzed by DNA methyltransferases, Dnmt3a and Dnmt3b, which add methyl groups onto unmethylated DNA. When cells divide, the methyltransferase Dnmt1 preferentially recognizes hemimethylated DNA and maintains DNA methylation. Interestingly, Dnmt3a and Dnmt3b have both been shown to associate with the regulatory regions of genes during the initial specification of neurons and glia, as well as during later stages of neuronal maturation and function. Dnmt1 is also very important in the brain and is involved in Janus kinase-single transducer and activator of transcription (JAK-STAT) signaling to control the timing of when precursor cells switch from neurogenesis to gliogenesis during development. Site-specific methylation of DNA has been shown to be important for astrocyte differentiation and activation of the glial fibrillary acidic protein (GFAP) promoter. Activation of the GFAP promoter requires binding of the STAT3 in response to leukemia inhibitory factor (LIF) signaling. Early cortical progenitors are refractory to astrocyte fates, even in the presence of LIF and STAT3 activation, likely due to methylation of the STAT3 binding site. At later stages, this site becomes demethylated and gliogenesis can proceed. A similar case was observed in the STAT3 binding site of the S100β promoter, a calcium-binding protein expressed in astrocytes.

In addition to DNA methylation, histone methylation has also been found to be important for the regulation of the GFAP gene in cortical progenitors. Using chromatin immunoprecipitation assays, Song and Ghosh showed there was increased histone H3 lysine 9 methylation, a mark associated with gene silencing, at the STAT3 binding site within GFAP at progenitor stages, when GFAP was repressed. Stimulation with basic fibroblast growth factor (FGF-2) potentiated the ability of CNTF (ciliary neurotrophic factor) to induce astrocyte differentiation. Strikingly, FGF-2 induction caused lysine 9 to become demethylated but lysine 4, the active mark, to become hypermethylated, resulting in STAT3 binding and activation of GFAP. By contrast, mature neurons had low levels of both lysine 9 and lysine 4 methylation. This leaves open the question of how GFAP is repressed in neurons. These studies highlight the diverse transcriptional and epigenetic mechanisms that control lineage-specific gene expression for the generation of different neural cell types.

Epigenetics and Neurodevelopmental Disorders

As described previously, DNA methylation-mediated silencing can be mediated by inhibition of transcription factor binding to target genes by methylation at CpG sites. Another mechanism by which DNA methylation leads to transcriptional gene silencing is the binding of methyl-CpGs by methyl-CpG-binding proteins (MBDs), which further recruit HDAC repressor complexes, resulting in a repression of chromatin. MBDs comprise a family of proteins, two of which (methyl-CpG-binding domain protein (MeCP2) and MBD1) play key roles in the nervous system. MeCP2 is found highly enriched in postmitotic neurons, and mutations in MeCP2 have been linked to the neurological disorder Rett syndrome. Rett syndrome is characterized by normal development until 1 year of age, most commonly seen in females, and is followed by a rapid deterioration, involving loss of speech and motor skills, microcephaly, seizures, autism, ataxia, and stereotypical hand wringing. The exact role of MeCp2 in neurons is unclear. There is evidence that MeCP2 is a key regulator of the essential CNS protein, brain-derived neurotrophic factor (BDNF). Interestingly, membrane depolarization of neurons by exposure to elevated levels of extracellular potassium resulted in the phosphorylation of MeCP2 and transcriptional de-repression of the BDNF promoter. Zhou and colleagues showed that phosphorylation of MeCP2 at a specific amino acid residue, S421, occurs selectively in the nervous system and is important for regulating dendritic growth and spine maturation, explaining, at least in part, the neural-specific pathology of Rett syndrome. Other MBD proteins may also play roles in the brain; MBD1 knockout mice have diminished hippocampal neurogenesis, defects in spatial learning, and a reduction in long-term potentiation in the dentate gyrus of the hippocampus.

Fragile X is another commonly inherited mental retardation. Patients have excessive expansion of the CGG sequence from the 5′ untranslated region (UTR) of the *Fmr1* gene, resulting in transcriptional silencing of the gene. When the CGG repeats exceed 200, the region is hypermethylated, preventing the binding of transcriptional machinery. Treatments with DNA demethylating drugs result in increased histone

H3 methylation at the lysine 9 residue, increased H3 and H4 acetylation, and decreased methylation at H3 lysine 4, resulting in the activation of *Fmr1*. This finding strongly suggests a role for chromatin remodeling in the silencing of *Fmr1*. Even more supportive is the observation that MeCP2 and Brm associate and jointly silence the *Fmr1* gene. RNA interference knockdown of MeCP2 and Brm resulted in increased mRNA transcription of *Fmr1*. Taken together, these results present a compelling case for epigenetic factors underlying neurological disorders such as Rett syndrome and fragile X mental retardation.

Disorders in genomic imprinting have also been shown to have effects on the integrity of the CNS. Genomic imprinting has been defined as an epigenetic effect on a parental chromosome in the gamete or zygote that causes differential gene expression in the offspring's somatic cells. The main epigenetic effect in genomic imprinting is differential allele-specific DNA methylation, whereas the effects of DNA methylation were described previously. Two well-described imprinting diseases related to the CNS are Prader–Willi syndrome (PWS), which is characterized by hyperphagia, obesity during childhood, mental retardation, and behavioral abnormalities; and Angelman syndrome (AS), which is characterized by mental retardation, speech impairments, and behavioral problems. Both molecular defects seem to lie in an ~2 Mb imprinted domain at 15q11–q13 which contains both maternally and paternally expressed genes in humans. In PWS, no single gene defect has been shown to be responsible for the disease, whereas in AS the loss of a single gene is the defect. The maternally expressed UBE3A (ubiquitin protein ligase E3A) is only imprinted in the brain and is involved in the ubiquitin–proteasome degradation pathway; loss of function of this gene results in AS. Therefore, another body of evidence suggests that epigenetic mechanisms play an essential role in the CNS.

Epigenetic Control of Neural Plasticity, Learning, and Memory

In addition to regulating gene expression in mature neuronal or glial cells or their progenitors during lineage specification, epigenetic mechanisms have also been suggested to underlie certain forms of cellular and organismal memory. Histone modifications and chromatin remodeling factors have been observed in animal models of drug addiction as well as certain types of learning and memory. Since drug addiction has a long-term sustained effect, evidence is leading to alterations of chromatin structure in the brain as a possible underlying mechanism to mediate long-lasting changes in gene expression associated with the addiction state. c-*fos* and ΔFosB, members of the Fos family of transcription factors, are implicated in behavioral responses and synaptic plasticity induced by abused drugs. Interestingly, cocaine administration can induce H4 acetylation and H3 phosphoacetylation at the c-*fos* gene promoter in the striatum after acute administration but is desensitized after repeated exposure to cocaine. Regarding the FosB promoter, H3 acetylation is still observed under chronic cocaine treatment. ΔFosB, a product of the *FosB* gene, also known to accumulate under chronic cocaine exposure, increases the binding of Brg1 (a component of the SWI/SNF complex mentioned previously) with cyclin-dependent kinase 5, a gene implicated in neurogenesis, synaptic plasticity, learning, and memory. This evidence suggests that ΔFosB can recruit chromatin-remodeling factors such as HATs and Brg1-containing complexes to its downstream targets, thus regulating the expression of key genes involved in sustaining the long-term effects of drugs of abuse.

Epigenetic modifications have also been linked to changes in neural plasticity and long-term memory. Two different mouse models for Rubinstein–Taybi syndrome (RTS), which in human patients has well-defined multiple congenital anomalies – mental retardation syndrome characterized by postnatal growth deficiency, microcephaly, specific facial characteristics, broad thumbs, and big toes – were used to demonstrate that histone acetylation (since the syndrome is linked to mutations in protein (CBP), which has HAT activity) is required for long-term potentiation, learning, and memory. CBP heterozygotes exhibited normal levels of short-term memory; however, their long-term memory, as determined in contextual and cued fear conditioning and novel object recognition tasks, was abnormal. Interestingly, when the HDAC inhibitor suberoylanilide hydroxamic acid was delivered intraventricularly into CBP heterozygotes, the mice showed improvement in contextual fear conditioning. In a second mouse model bearing a hippocampal CA1- and dentate gyrus-specific inducible form of mutant CBP lacking HAT activity, there were long-term memory deficits, although short-term memory appeared intact. Similarly, when an HDAC inhibitor trichostatin A was used, or when the transgene was shut off, the memory deficits could be rescued, suggesting that pharmacological manipulation of HAT activity might be a potential therapeutic approach to treat RTS. Perhaps more important, the findings that genes such as CBP and MeCP2, which have global effects on gene expression, have specific phenotypic consequences in the brain suggest that epigenetic mechanisms may represent an untapped area for understanding and treating cognitive disorders. Many more examples of

neurodevelopmental and cognitive disorders linked to transcriptional regulators have been described and discussed elsewhere.

Transcriptional Silencing in the Brain and Emerging Role of Small RNAs

Small noncoding regulatory RNAs have emerged to be a central player in all of biology as well as in the mammalian CNS. Their small size and sequence complementarity allow extreme versatility to target mRNAs for repression or activation of gene expression or modify chromatin structures of targeted genes. Double-stranded RNA was originally found to silence genes by targeting their mRNA intermediates for degradation, but during the past several years, more mechanisms of action of small RNAs have been discovered and potential new classes of such RNAs have been revealed. Small regulatory RNAs fall into at least five major classes. Small interfering (si)RNAs and micro (mi)RNAs both silence gene expression; usually, siRNAs target mRNAs for degradation by sequence complementarity to a single site, whereas miRNAs can recognize numerous partially complementary binding sites that act synergistically within target mRNAs found to be abundantly distributed in the postnatal brain, suggesting they play important roles in neuronal function. Out of the ~250 miRNAs in mammals, it appears that at least 125 miRNAs are enriched or expressed in the brain. Those enriched in brain include miR9,-29,-124,-125a,-125b,-127,-128,-132,-137,-138, and -139. A CREB-induced miRNA, miR-132, was found to regulate neuronal morphogenesis in cultured cortical neurons. Another miRNA implicated in neuronal function is miR-134, which is dendritically localized and involved in the control of spine size. Besides siRNAs and miRNAs, newly discovered classes of short RNAs are emerging that are species specific (tiny 20–22 nucleotide noncoding RNAs in *Caenorhabditis elegans*), tissue specific (small 29 or 30 nucleotide noncoding RNAs that interact with the germ cell protein PIWI in germline), and activators, not silencers, of gene expression (short, double-stranded RNAs called NRSE (described later)).

The first demonstrated intersection of small RNAs and chromatin remodeling factors in the mammalian CNS was when a small dsRNA matching the binding sequence of NRSF, called NRSE small modulatory RNA (or just smRNA), was discovered in adult hippocampal neural stem cells. This smRNA appeared to mediate its function in an entirely novel way, unlike siRNAs or miRNAs, by interacting with the NRSF protein and inducing neuron-specific gene expression. Clearly, there will be many more studies regarding brain-enriched small RNAs in both physiological states and disease states. Interestingly, the protein product of *Fmr1*, FMRP, has also been shown to interact with miRNAs and Argonaute 2, although the exact function of this association in the pathogenesis of fragile X mental retardation has not been fully described. However, much more research is required to fully elucidate the effects of these and other small RNAs in the CNS.

Conclusions

What is amazing and still one of the life's major mysteries is how the brain balances a specific set of instructions to carry out cellular and tissue patterning but still retains plasticity to respond to the ever-changing environment. The brain must have a way to receive input with the outside world and relay environmental information down to the cellular and molecular level to affect changes in gene expression. Epigenetic and chromatin modifications of target genes in response to variations in environmental conditions might serve as a major source of variation in gene expression and function, and ultimately as a mechanism mediating neuronal plasticity and individual differences in behavior. We propose that chromatin remodeling conveys dynamic environmental experiences on a static genome, resulting in heritable and reversible changes in the CNS during development and throughout adulthood.

Introduction

The most extensive information regarding the distribution of estrogen receptor (ER) α and ERβ messenger RNA (mRNA) expression patterns in the central nervous system (CNS) has come from studies of the rat. In adult rats, cells expressing ERβ mRNA are more widely distributed throughout the brain than are those expressing ERα mRNA, although ERα-positive neurons are more numerous than those expressing ERβ. Within the hypothalamus, ERα is the primary ER in the arcuate and ventromedial nuclei, whereas in the paraventricular nucleus, ERβ is the predominant ER. Within the midbrain, pons, and brain stem, a predominance of ERβ has been observed in several of the major monoaminergic cell populations. These include the dopaminergic substantia nigra and ventral tegmental area, the serotonergic raphe nuclei, and the noradrenergic locus coeruleus. In the cerebellum, only ERβ mRNA was exclusively detected, both in the Purkinje cell layer and scattered within granule cells. Despite many differences in the distribution of ERα and ERβ mRNAs, considerable overlap was seen in the preoptic area and the bed nucleus of stria terminalis and throughout the lower brain stem. Studies also suggest considerable overlap in expression of ERα and ERβ mRNA in various regions of the forebrain, such as the cerebral cortex and hippocampus.

Comparison of ER mRNA expression patterns in rat, mouse, monkey, and human indicates that although the general distribution is similar, data cannot be extrapolated from one species to another. For example, in the mouse brain, ERβ mRNA is more abundant in the suprachiasmatic nucleus, raphe nuclei, and entorhinal cortex, whereas in these areas the ERβ mRNA expression is low in the rat brain. In contrast, levels of ERβ mRNA in the mouse supraoptic nucleus and preoptic area are low. The rat paraventricular nucleus has been reported to express only ERβ, but the mouse paraventricular nucleus contains cells that also express moderate levels of ERα. It is interesting that the human paraventricular nucleus has been reported to express mRNA for both ERα and ERβ; in fact, ERα appears to be the predominant subtype.

The distribution of ERα and ERβ protein in the CNS seems to coordinate relatively well with the mRNA distribution. However, some exceptions have been reported: In the suprachiasmatic nucleus of the mouse brain, only weak ERβ immunoreactivity has been detected, and in the nuclei of Purkinje cells and granular cells of the mouse cerebellum, ERβ was not detectable even though these regions are reported to abundantly express ERβ mRNA.

The differential distribution of ERs in the brain may provide a mechanism for selective modulation of physiological parameters involved with reproduction, as well as the regulation of learning and memory. ER expression in discrete brain regions depends on gender, reproductive status, age, and exposure to estradiol (E2). ERα expression is acutely reduced shortly after exposure to E2, whereas ERβ expression decreases after chronic E2 treatment (1–2 weeks) but not after short-term (2 h) E2 treatment of ovariectomized rats. A recent study indicates altered expression of ERβ in specific brain regions in the male ERα knockout ($ER\alpha^{-/-}$) mouse.

Estrogen Action in the CNS

Estrogens influence a wide variety of brain functions in mammals. In the adult CNS, these include the feedback regulation of hypothalamic and pituitary hormone secretion and the facilitation of feminine reproductive behavior via regulation of brain progesterone receptor levels. Furthermore, estrogen has an effect on the modulation of motor behavior. There is also an effect on mood and mental state by the control of central aminergic and peptidergic neurotransmission. Various experimental studies and clinical observations have shown estrogen to be effective in the preservation of cognitive brain function, suggesting that it could exert a neuroprotective effect in some neurological disorders such as Alzheimer's disease, Parkinson's disease, schizophrenia, and ischemic stroke. In schizophrenia, psychotic symptoms are exacerbated when estrogen levels are low, and estrogen treatment produces beneficial effects. Furthermore, abrupt changes in hormone levels such as those occurring at menopause or at parturition are associated with depression.

Multiple epidemiological reports have suggested that estrogen replacement therapy may delay the onset of and slow the cognitive decline associated with Alzheimer's disease. Accumulation of amyloid β is thought to be causal in the development of cerebral plaques, a characteristic in the neuropathology of Alzheimer's disease. A number of studies have reported that E2 reduces the generation of amyloid β peptides and protects against amyloid β-induced

cell degeneration in primary cell cultures. E2 also attenuates impairment of synaptic Na^+, K^+ adenosine triphosphatase activity and glucose and glutamate transport induced by amyloid β.

Whether estrogen replacement therapy can improve cognition and memory functions in neurological diseases remains an actively debated issue. It seems that there is a critical period around menopause when hormone replacement delays the onset of and slows cognitive decline. However, estrogen replacement at a later stage does not seem to improve cognitive function. It has been suggested that estrogen replacement may protect younger women from Alzheimer's disease or reduce the risk of early onset forms of Alzheimer's disease.

Estrogen as a Trophic Factor for Neurons

More than 20 years ago, it was found that estrogen enhances the growth and arborization of axons and dendrites in hypothalamic neurons grown in organotypic cultures. Initial studies concerning synaptic remodeling in developing and adult brain were performed on the arcuate nucleus, where neonatal estrogen treatment increases synapse formation during postnatal development in rats. Estrogen treatment was also shown to restore deafferentation-induced loss of axodendritic synapses in adult rats. Later on it was shown that synapses in the arcuate nucleus exhibit a phasic remodeling, which could be linked to the fluctuation in hormone levels during the estrous cycle. Growth-promoting effects of estrogen have now also been described in the midbrain, cortex, hippocampus, spinal cord, and pituitary.

One of the processes regulated by ovarian hormones is the cyclic formation and breakdown of excitatory synapses in the hippocampus. Estrogens do not act alone; in fact, ongoing excitatory neurotransmission is required for synapse induction, and activation of *N*-methyl-D-aspartate (NMDA) receptors by glutamate is an essential factor in the development of new excitatory synapses. Estrogen treatment has been shown to increase the density of NMDA receptors in the CA1 region of the hippocampus. Exactly how estrogen induces the formation of new synaptic contacts is not clear, but estrogen treatment has been shown to induce both pre- and postsynaptic markers in the spine synapses. In light of the critical role of dendritic spine synapses in hippocampal function, it is not surprising that it has been suggested that Alzheimer's disease, schizophrenia, and stress are all associated with a substantial pathological loss of dendritic spine synapses in the hippocampus.

It has been suggested that the effect of estrogens on neuronal growth may be mediated indirectly via regulation of other endogenous neurotrophic substances. Expression of several growth factors and their receptors has been shown to be estrogen regulated. The most studied are nerve growth factor (NGF) and its receptors in cholinergic neurons transforming growth factor in the hypothalamus, brain-derived neurotrophic factor in the cortex, NGF receptors in sensory neurons, and the insulin-like growth factor and its receptor in the hypothalamus. The effects of estrogen on growth factor signaling are reciprocated, and growth factors can influence estrogen signaling. Thus, NGF has been shown to regulate ER action in the forebrain, possibly via phosphorylation events. However, estrogen can also affect neurite elongation and differentiation directly through its regulation of cytoskeletal genes that are required for neurite growth.

Estrogen and the Sexual Differentiation of the CNS

The criteria that have been used to measure sexual differentiation in the brain are volumes of brain nuclei, cell numbers/densities, and synaptic morphology. The first morphological evidence of sexual dimorphism in the brain was the observation that three vocal control areas of songbirds are larger in males than in females. Size differences have since been found in the preoptic region in rat and human brains. Sex differences have also been reported in higher cognitive centers and in sensory and autonomic ganglia as well as structures of the limbic system.

Virtually all morphological differences between male and female brains and all sexually differentiated behaviors are thought to be influenced by embryonic exposure to gonadal steroids, a phenomenon called imprinting. The embryonic testes secrete testosterone that enters the brain and is converted to its metabolites 5α-dihydrotestosterone (DHT) and E2. There is a large body of evidence showing that E2 is the hormone which masculinizes the brain permanently. Although it has been the focus of much research effort, even today, little is known about how E2 exposure imprints the fetal brain. Besides acting as a growth-stimulating agent, estrogen has been suggested to influence neurogenesis and apoptotic cell death. There is still no detailed study of the profile of ERα and ERβ in the fetal brain, so it is not possible to pinpoint the cells which are the targets of E2 during this period.

Estrogen and the Cholinergic System

The basal forebrain contains cholinergic neurons that project to cerebral cortex and hippocampus, where they play an important role in cognitive function.

Experiments with ovariectomy and estrogen replacement therapy have revealed an induction of choline acetyltransferase (ChAT), the rate-limiting enzyme for acetylcholine formation, in basal forebrain of female rats. One possible candidate as a regulator of the cholinergic system of the basal forebrain is NGF, which is produced by the hippocampus and transported retrogradely to basal forebrain neurons to produce trophic effects. Although the effects of estrogen treatment on NGF levels in hippocampus remain to be investigated, ER has been reported to co-localize with low-affinity NGF receptors in cholinergic neurons of the basal forebrain of the newborn rat. Moreover, estrogen replacement in both young and aged female rats increases both NGF receptor mRNA and ChAT mRNA expression in basal forebrain.

Estrogen and the Serotonergic System

Serotonin neurons of the midbrain–brain stem raphe nuclei are among the earliest neuronal phenotypes to become differentiated during CNS development, and serotonin is believed to act as a regulatory-developmental agent. The serotonergic system is involved in the regulation of diverse functions such as reproduction, mood, sleep, and cognition. Serotonergic activity seems to be regulated by the ovarian steroids, but the mechanism by which such regulation occurs is not fully understood. It has been demonstrated that ovarian hormones increase the expression of tryptophan hydroxylase, the key enzyme in serotonin biosynthesis, and suppress expression of the serotonin transporter in the macaque raphe nuclei. Estrogen treatment has also been reported to affect the expression of certain subtypes (5HT2A, 2C, and 1A) of serotonin receptors in rat brain.

Estrogen's affecting serotonergic function is relevant to the effect of estrogen on mood and cognition. High doses of estrogen have been reported to have antidepressant effects in humans, and estrogen treatment influences the response to antidepressant drugs in animal models and in clinical studies.

Estrogen and Catecholaminergic Systems

Noradrenergic System

Brain stem catecholaminergic neurons contain ERs, and estrogen treatment after gonadectomy exerts complex, time-dependent effects on the level of tyrosine hydroxylase mRNA. In the rat locus coeruleus, galanin is co-expressed in many noradrenergic neurons, and estrogen treatment increases the expression of galanin mRNA. It is thought that estrogen treatment might reduce noradrenergic tone by enhancing the secretion of galanin, which in turn reduces noradrenaline release.

Dopaminergic System

Estrogen has been shown to modulate the binding of dopamine to its receptor. Estrogen also potentiates K^+-stimulated dopamine release from rat nucleus accumbens, and estrogen pretreatment increases the firing rate of neostriatal neurons in response to dopamine. Furthermore, estrogen has been shown to facilitate amphetamine- and apomorphine-stimulated dopamine release and locomotor activity in lesioned rats, and this activity is responsive to natural fluctuations in E2 levels and is generally increased during late proestrus and early estrus. Intrastriatal application of E2 rapidly causes rotational behaviors and enhances sensorimotor performance. One explanation of this phenomenon is reduced L-type Ca^{2+}-channel activity in striatal neurons via a G-protein-coupled receptor. Relatively high levels of estrogen, such as provided through oral contraceptives and estrogen replacement therapy, have been shown to exacerbate symptoms of Parkinson's disease, pointing to antidopaminergic actions that are the opposite of the actions of physiological levels of E2.

An Alternative Estrogen

More than 30 years ago, it was noted that 5α-androstane-3β,17β-diol (3βAdiol) is an estrogenic metabolite of DHT which has no affinity for the androgen receptor. The formation of 3βAdiol is catalyzed by several steroid metabolizing enzymes – 17β-hydroxysteroid dehydrogenase and 3α- and 3β-hydroxysteroid dehydrogenase – and like DHT, 3βAdiol is a local (autocrine/paracrine) hormone in the cells where it is synthesized.

The immature ovaries in prepubertal female rats do not synthesize E2, but substantial quantities of 3βAdiol and 5α-androstane-3α,17β-diol (3αAdiol) seem to be synthesized instead, and it has been suggested that these steroids may have a role in the onset of puberty. The immature testes also produce 3βAdiol and 3αAdiol in large amounts. It has been reported that until postnatal day 20, the main metabolite of DHT is 3αAdiol; thereafter 3βAdiol is the predominant testicular metabolite of DHT. In adult male rats, the plasma concentration of 3βAdiol is about 20 times higher than the E2 level. Treatment with 3βAdiol in male rats does not seem to affect the serum levels of gonadotropins, although both DHT and 3αAdiol depress the gonadotropin levels in serum. A recent report has stated that 3βAdiol treatment, as well as DHT treatment, depresses the corticosterone response to stress.

The enzymes responsible for the conversion of DHT to 3βAdiol are expressed in many regions of the rat brain throughout development, including the cortex, hypothalamus, thalamus, septum, hippocampus, and cerebellum. In the brain, the exact function of 3βAdiol is unclear, but in a neuronal cell type, HT-22, 3βAdiol has been shown to activate ERβ-induced transcription mediated by an estrogen response element with the same efficacy as E2. Also, the transcriptional selectivity for ERβ over ERα has been demonstrated to be much greater than its binding selectivity in these neuronal cells.

Moreover, 3βAdiol is further metabolized via hydroxylation to nonestrogenic androstanetriols, which are excreted in the urine. Oxidative conversions and metabolism of cholesterol and its steroid derivatives are performed by cytochrome P450s (CYPs), a family of heme-containing mono-oxygenases. Tissue levels and estrogenicity of 3βAdiol are regulated by CYP7B1, which was cloned from rat and mouse hippocampus in 1995. Before the complementary DNA of this enzyme was cloned, the tissue distribution of '3βAdiol hydroxylase' was assessed by its catalytic activity. The tissues with the highest activity were the ovary and testis, as well as the prostate, brain, and pituitary. With the cloning of CYP7B1, it was identified as a steroid/sterol B-ring hydroxylase with selectivity for hydroxylation at the 7α, 6α, and 7β positions. It accepts dehydroepiandrosterone (DHEA), pregnenolone, 25- and 27-hydroxycholesterol, and 3βAdiol, but 3αAdiol is not a substrate, and neither is E2 or testosterone.

Analysis of mRNA from various tissues shows CYP7B1expression in several tissues, such as brain, prostate, liver, and kidney. It is interesting that CYP7B1 mRNA expression and enzyme activity have been reported to be very high in the neuroepithelium of most brain areas during early to midgestation but to decrease in later stages of gestation, and in adults it has been detected only in a few specific regions of the brain, most notably the dentate gyrus. No expression of CYP7B1 in liver was reported at any point in gestation. In liver, CYP7B1 activity has initially been detected at 3 weeks of age, after which it increases gradually, then remains constant after 8 weeks of age. Sterol B-ring hydroxylation in the liver has been shown to be important for the metabolic elimination of oxysterol via conversion to bile acids. This is promoted by cholesterol 7α-hydroxylase (CYP7A1) and CYP7B1 operating in parallel with a liver-specific 24(S)-hydroxycholesterol 7α-hydroxylase. It has been suggested that in the brain, CYP7B1 activity may be important for neurosteroid synthesis and metabolism. Baulieu and colleagues originally used the term 'neurosteroid' to describe the steroids that were produced *de novo* within the brain. Nowadays the term is also used for steroids that are synthesized in the CNS from precursor steroid hormones secreted from peripheral endocrine organs. The understanding of neurosteroid synthesis and where neurosteroids act is still limited. It is interesting that a reduced level of CYP7B1 mRNA has been reported in the dentate gyrus and the CA1 hippocampal area of patients with Alzheimer's disease.

Knockout Models

In 1998, ERβ knockout (ER$\beta^{-/-}$) mice were produced, and the phenotype of ER$\beta^{-/-}$ mice is at present being investigated and compared with that of ER$\alpha^{-/-}$ mice. A part of the phenotypes present in the two knockouts relates to reproductive function and to other tissues, including the CNS, the skeletal system, and the cardiovascular system.

Phenotype of ER$\beta^{-/-}$ Mice

In contrast to ER$\alpha^{-/-}$ mice, the lack of functional ERβ does not impair adult sexual behavior. However, transient behavioral differences between wild-type (WT) and ER$\beta^{-/-}$ males during puberty have been described. At the time of puberty, but not in adult males, aggression is higher in ER$\beta^{-/-}$ than in WT males. Furthermore, ERβ has been shown to be involved in defeminization or the ability of males to display female-typical behaviors, such as lordosis (receptive mating posture).

Increased anxiety has been reported in ER$\beta^{-/-}$ females compared with WT mouse behavior. Local increase of the serotonin receptor 5-HT1A expression in medial amygdala of the brain has been suggested to contribute to these changes as well as to lower serotonin content in several brain regions including the bed nucleus of the stria terminalis, preoptic area, and hippocampus.

In the brain, estrogen has been suggested to influence spatial learning in females via ERβ. The results are puzzling, however: WT females were able to learn a spatial task with or without E2 replacement, but when given E2 replacement, ER$\beta^{-/-}$ females showed an impaired spatial learning ability in the Morris water maze. Without E2 treatment, the spatial learning was normal in ER$\beta^{-/-}$ females compared with WT females. Furthermore, ERβ has been shown to be involved in the estrogenic regulation of oxytocin and vasopressin mRNA levels in the paraventricular nucleus.

Phenotype of CYP7B1$^{-/-}$ Mice

CYP7B1 knockout (CYP7B1$^{-/-}$) mice have been generated in two independent laboratories, and both

lines show that CYP7B1 is not essential for viability of mice. CYP7B1$^{-/-}$ mice have been reported to accumulate 25- and 27-hydroxycholesterol in their plasma and tissues, while the levels of brain-derived 24(S)-hydroxycholesterol are normal. In addition to the abnormalities in certain plasma sterol levels, brain extracts from CYP7B1$^{-/-}$ mice fail to catalyze hydroxylation of DHEA and 3βAdiol.

In prostate, CYP7B1 has been suggested to play a role in epithelial cell proliferation by regulating the tissue level of 3βAdiol, which could be the quantitatively major estrogenic steroid and the most likely ligand for ERβ in this tissue. The ventral prostate, but not the other lobes of prostate, has a decreased number of proliferating cells in CYP7B1$^{-/-}$ mice before puberty and are smaller than those of their WT littermates at adulthood. Because CYP7B1 represents the major pathway for inactivating 3βAdiol in the prostate, it regulates, via ERβ, androgen receptor expression and epithelial cell proliferation.

It has been reported that the uteri and mammary glands of young CYP7B1$^{-/-}$ female mice have characteristics of tissues chronically exposed to estrogen. There is a precocious onset of puberty in female CYP7B1$^{-/-}$ mice, but at 15 months of age, the estrous cycling has stopped. These data suggest premature exhaustion of ovarian function in CYP7B1$^{-/-}$ females.

Why Study the Function of ERβ in the CNS?

Evidence suggests multiple roles for estrogen in the brain. It influences development, plasticity, and survival of neurons, with consequences for age-related neuronal degenerative diseases. Even though we have an anatomical framework of the distribution of the two ER subtypes in the CNS, the functional relevance of the two ERs in different cells remains a question. Distinguishing the effects of the different ER subtypes *in vivo* would give insight into the kind of ER-selective ligands that would exert positive effects on brain and bone but spare the uterus and breast. The estrogen replacement therapy of today is associated with serious unwanted side effects, including development of breast cancer and endometrial cancer. ERβ is highly expressed in the brain but very poorly in the adult uterus, and it is possible that ERβ-selective ligands would have the desired tissue specificity.

ERβ is important for neuronal survival, during both brain development and the following neuronal life span. In the brains of ER$\beta^{-/-}$ mice, a regional neuronal hypocellularity with a severe neuronal deficit is seen in the somatosensory cortex, especially layers II, III, IV, and V. Neuronal loss was also evident in certain regions of the hypothalamus, as well as in the amygdala and ventral tegmental area, but not in the cerebellum or hippocampus. Proliferation of astroglia was also detected in a regional manner; it was evident in the limbic system but not in the cortex. Regarding the hyperproliferation of astroglia in the limbic system, it is possible that in ER$\beta^{-/-}$ mice, it occurs in response to the neuronal loss as proliferation of astroglia usually is a reactive response to neurodegeneration or injury.

These morphological abnormalities in the brain of ER$\beta^{-/-}$ mice are evident as early as 2 months of age. As ER$\beta^{-/-}$ mice age, the neuronal deficit becomes more pronounced, and by 2 years of age, there is degeneration of neuronal cell bodies throughout the brain. At this stage, there is a gross atrophy of the brain, especially pronounced in the cortex. Neuronal shrinkage is particularly evident in the substantia nigra. However, no astrogliosis is evident in 2-year-old ER$\beta^{-/-}$ mice. One possible explanation is that ER$\beta^{-/-}$ mice lose both neurons and astrocytes as they age. It appears that ERβ is one critical factor for neuronal life span in CNS. No morphological changes have been reported in the brains of ER$\alpha^{-/-}$ mice, but some *in vitro* studies have suggested that ERα has a neuroprotective effect, whereas ERβ mediates apoptosis in neuronal cells. Further studies are needed regarding the actual role of the different ERs in the neuroprotective action of estrogen, but ERβ may well be a protective factor for neurons and could influence the development of degenerative diseases of the CNS, such as Alzheimer's disease and Parkinson's disease, as well as those resulting from trauma or stroke in the brain.

Because the morphological changes appear quite early in ER$\beta^{-/-}$ mouse brains, it is possible that the phenotype has resulted from defective embryonic brain development. During embryonic development, brain size is determined by proliferation of neural progenitor cells and by differentiation, survival, and migration of postmitotic neurons. A reduction in the number of neurons in the cortex could therefore occur via several possible mechanisms: decreased proliferation, increased apoptotic cell death, or abnormal migration and differentiation. In embryonic brains from ER$\beta^{-/-}$ mice, there are no differences in size or cellularity at embryonic day (E) 14.5; however, at E18.5, ER$\beta^{-/-}$ mouse brains are smaller than those of their WT littermates. Nissl staining of brain sections shows a thinner cortex, but no morphological differences are evident in the hippocampus, thalamus, or hypothalamus. Because the neuronal loss in the adult ER$\beta^{-/-}$ mouse cortex is more pronounced in superficial layers than in deeper layers, it may be that neurons in the deep layer would be affected little by

the lack of ERβ. When proliferating cells are labeled with 5′-bromodeoxyuridine (BrdUrd) on E12.5, when cortical neurogenesis in mice begins, and examined on E14.5, there is no difference between WT and ER$\beta^{-/-}$ mice in the number of labeled cells in the cortex. However, when BrdUrd is administered between E14.5 and E16.5, fewer labeled cells can be detected in the superficial cortical layers by E18.5 and postnatal day 14 in mice lacking ERβ, suggesting that neuronal migration could be defective. When one stains for radial glia, which are essential for guiding the migrating neurons, their processes appear to be truncated. The cytoarchitecture of ER$\beta^{-/-}$ mouse cortex also seems disorganized, and cells are not clustered in a clear radial pattern, as seen in WT littermates. The radial glia also have more branched end-feet at the marginal zone, and this might result in abnormal contact with Cajal–Retzius cells. These cells produce reelin, shown to be important for migration and positioning of neurons in the cerebral cortex. Although the number and morphology of Cajal–Retzius cells in ER$\beta^{-/-}$ mice appear normal, their functional abilities in the absence of ERβ need further investigation.

At E18.5, more apoptotic cells are in the ventricular zones in ER$\beta^{-/-}$ mice, indicating that the lack of ERβ promotes apoptosis. Regarding the regional astrogliosis of adult ER$\beta^{-/-}$ mice, few astroglia cells have been seen in either ER$\beta^{-/-}$ or WT mouse brains during the late gestational stage. Thus, a lack of ERβ does not hasten the maturation of glial cells into astroglia, and the increase in the number of astroglia in the adult ER$\beta^{-/-}$ mouse brain seems to occur postnatally. It has been reported that ERβ mRNA is detected from E10.5 in brain of mouse embryos, whereas the earliest detection of ERα mRNA is on E16.5. Although the exact distribution pattern of ERβ in the CNS during development is still unclear, data suggest that by influencing migration and neuronal survival, ERβ has an important role in the late embryonic development of the brain. However, it is unclear whether ERβ is ligand activated in the embryonic brain because of the limited exposure of the brain at this stage to E2. The placenta efficiently inactivates E2 by catalyzing its conjugation with sulphate. In addition, α-fetoprotein in the fetal circulation binds E2 with high affinity and prevents its entry into the tissues. One alternative ligand for ERβ could be 3βAdiol, an estrogenic metabolite of DHT. Although 3βAdiol activates both ERα and ERβ, it has no affinity for the androgen receptor. Recent studies report that the human placenta is capable of synthesis and metabolism of androgen during early gestation and is thereby able to synthesize 3βAdiol. To explore the function of 3βAdiol *in vivo*, CYP7B1$^{-/-}$ mice, in which the pathway for degradation of 3βAdiol is inactivated, have been examined, and their early postnatal brain is larger than that of WT littermates of the same body weight. Nissl staining of brain sections has shown all regions of the forebrain to be affected. The increased sizes of the cortex, caudate putamen, and preoptic area are all directly proportional to the increased overall brain size in CYP7B1$^{-/-}$ mice at 14 days of age. There is no change in cell density of either neurons or astroglia, and no apparent distortion in cytoarchitecture or cortical layering has been detected. However, the increased brain mass results in compression of the lateral ventricles in CYP7B1$^{-/-}$ mice.

When BrdUrd was administered on E12.5 and embryos examined on E13.5, no difference was detected between WT and CYP7B1$^{-/-}$ littermates in the number or pattern of S-phase-labeled neurons in the brain. The pattern of late-born neurons, generated and labeled with BrdUrd at E17.5 and observed at E18.5, was also normal. No difference in the number of M-phase-labeled progenitor cells lining the ventricles has been seen, and no abnormalities in neuronal guidance by radial glia or neuronal differentiation have been detected. However, a profound decrease in apoptosis is apparent in the ventricular/subventricular zone between E13.5 and E15.5 in CYP7B1$^{-/-}$ mice. At later gestational stage, no changes in cell death have been detected, indicating that the increase in brain size in CYP7B1$^{-/-}$ mice is most probably due to increased cell survival during early brain development. However, by the time mice were 3 months old, the brains of CYP7B1$^{-/-}$ mice and their WT littermates were indistinguishable on the basis of size and shape. Thus at some time in the late postnatal period, the excess cells must be removed. Competition for the limited access to target-derived neurotrophic substances may be involved in this later neuronal loss and needs to be investigated further.

These data are supportive evidence for a role for the ERβ-3βAdiol-CYP7B1 pathway in regulation of neuronal survival in the embryonic brain. By metabolizing steroids in the CNS, CYP7B1 could be important for the availability of steroids to their receptors, either by preventing or by potentiating receptor interactions. If 3βAdiol acts as an estrogen in the fetal brain, ERs are active earlier in fetal life than has previously been thought. It is now essential to have a thorough understanding of the expression and cellular localization of ERs in the developing brain.

Summary and Conclusions

A central finding is that ERβ is important for neuronal survival, during both brain development and the

following neuronal life span. Data of the phenotype in the brains of ER$\beta^{-/-}$ mice have strengthened the view that ERβ is a protective factor for neurons and could influence the development of degenerative diseases of the CNS, such as Alzheimer's disease and Parkinson's disease, as well as those resulting from trauma or stroke in the brain. The data suggest that by influencing migration and neuronal survival, ERβ has an important role in the late embryonic development of the brain. However, it is unclear, because of the limited exposure of the brain at this stage to E2, whether ERβ is ligand activated in embryonic brain. One alternative ligand for ERβ could be 3βAdiol, an estrogenic metabolite of DHT. The data of the phenotype in the brains of CYP7B1$^{-/-}$ mice are supportive evidence for a role for the ERβ-3βAdiol-CYP7B1 pathway in regulation of neuronal survival in the embryonic brain. By metabolizing steroids in the CNS, CYP7B1 could be important for the availability of steroids to their receptors, either by preventing or by potentiating receptor interactions. If 3βAdiol acts as an estrogen in the fetal brain, then ERs are active earlier in fetal life than has been thought previously. It is now essential to have a thorough understanding of the expression and cellular localization of ERs in the developing brain.

Gene Therapy and Protection from Stress-Induced Brain Damage

R Sapolsky, Stanford University, Stanford, CA, USA

Introduction

There are few challenges to health that can be more devastating than a major neurological injury. This is because of the ease with which such injury can cause extensive damage, the frequent irreparability of injury, our limited therapeutic skills, and because such an injury can compromise the essence of whom we are.

Amid this depressing picture, nonetheless, recent decades have brought tremendous insight into the mechanisms underlying neuron death following acute necrotic neurological insults such as seizure, stroke, cardiac arrest, severe hypoglycemia, and concussive head trauma. Central to such death is the 'excitotoxic' cascade, initiated by pathologically elevated concentrations of the highly excitatory neurotransmitter glutamate. Initially, this excess is due to depolarization-induced release of glutamate, but as the insult progresses, the bulk of the excess becomes due to failure of costly high-affinity uptake of synaptic glutamate by glia and the presynaptic neuron. This excess triggers a vast increase in free cytosolic calcium concentrations in the postsynaptic neuron; this is due to influx, via both the NMDA receptor and the opening of voltage-gated calcium channels, the release of calcium from the endoplasmic reticulum, and the failure of costly extrusion and sequestration. The calcium excess, in turn, triggers an array of unregulated and damaging consequences via calcium-dependent enzymes. This includes cytoskeletal degradation, damage to DNA, and, most important, the generation of reactive oxygen species (ROS). Finally, in a subset of neurons, activation of this cascade can activate apoptotic programs that, given sufficient energy, can trigger controlled, noninflammatory programmed cell death rather than the default state of chaotic and proinflammatory necrotic cell death.

Adverse Neurological Effects of Glucocorticoids

With this knowledge has come an understanding of factors extrinsic to the nervous system, which can modulate this pathway. A number of such modulators are endocrine. As one example that will become relevant later in this article, estrogen can strongly protect against necrotic insults, both by decreasing the likelihood of neuron death following an insult and by aiding recovery and compensation.

The focus of this article is on another case of endocrine modulation of necrotic neuronal injury, namely stress, and stress-induced secretion of glucocorticoids (GCs). These adrenal steroid hormones (e.g., cortisol in primates, corticosterone in rats, and synthetic versions such as prednisone and dexamethasone) are secreted in response to virtually all stressors, both physical and psychological. Their short-term actions typify the benefits of the stress response in the face of the acute insults typical of most mammals (e.g., evading a predator or pursuing a prey); they mobilize energy to exercise muscle; synergize with catecholamines in enhancing cardiovascular tone and thus energy delivery; enhance immunity; suppress unessentials such as growth, tissue repair, and reproduction; and enhance aspects of cognition and sensory processing (as well as the synaptic plasticity underlying such processing). However, when secreted in excess, typically in response to psychosocial stressors, GCs can increase the risk of adult diabetes, hypertension, obesity, immunosuppression, and reproductive suppression.

It is in this context that one can appreciate the array of adverse effects of GCs in the nervous system; these are most dramatic in the hippocampus, which contains high concentrations of receptors for GCs. Beginning hours after the first elevation of GC concentrations, hippocampal-dependent cognition and synaptic plasticity is impaired. Within a similar time span, there is inhibition of neurogenesis in the structure. Over longer time periods, the hormone will cause atrophy of the dendritic tree. Finally, over the course of days, the hormone will compromise the ability of neurons to survive necrotic neurological insults and, over the course of months to years, will cause overt neuron death in the hippocampus.

The final case of overt neurotoxicity is demonstrable in both rodents and nonhuman primates; however, it remains unsettled whether this is only a pharmacological effect, requiring elevations of GC levels above those seen physiologically, even in the case of major stressors. Far more reliable and studied is the 'endangerment' of neurons by GCs (i.e., the compromising of neuronal ability to survive insults).

One key step in such endangerment is the ability of GCs to decrease glucose uptake in the hippocampus. It has long been known that GCs inhibit glucose uptake throughout the body, with the exception of exercising muscle, constituting a means of diverting energy to such muscles during an acute physical stressor. This inhibition is protein synthesis dependent and involves the withdrawal of glucose transporter molecules from the cell surface. Inhibition of glucose transport occurs in hippocampal neurons and

Table 1 Adverse effects in the hippocampus of prolonged exposure to stress and/or elevated concentrations of glucocorticoids

Effect	*Comment*
Impaired cognition	Impairment of subsequent acquisition and retrieval of information; inconsistent effects on consolidation; effects are reversible.
Impaired synaptic plasticity	Disruption of long-term potentiation and primed burst potentiation; enhancement of long-term depression; effects are reversible.
Inhibition of adult neurogenesis	Mechanisms and consequences relatively unknown; effects are reversible.
Dendritic atrophy and reorganization of neural networks	Likely to result in decreased connectiveness of dentritic spines; effects are reversible.
Neurotoxicity	Rare and of questionable physiologic relevance; effects are essentially irreversible.
Impaired capacity of neurons to survive necrotic disruption of energetics, of the control of glutamate	Demonstrable with an array of insults; involves insults and calcium trafficking, and impaired antioxidant defenses; effects are reversible.

glia as well (albeit to a lesser extent than in, for example, adipose tissue). Although insufficient to cause a change in energy profiles in the absence of insult, it leaves the hippocampus energetically vulnerable, such that during necrotic insults, the declines in ATP concentrations and mitochondrial potential are exacerbated.

Containing the excitotoxic cascade of neuron death is highly energy dependent; as a result of the inhibition of glucose uptake by GCs, the energy-sensitive steps in the cascade are worsened. The GC-induced worsening of the energy profile biases the presynaptic neuron toward depolarization and thus increased glutamate release. Moreover, glutamate reuptake is impaired, as is uptake by glia, because of the expense of the process. The net result of these presynaptic effects is a greater mobilization of calcium in the postsynaptic neuron. This is exacerbated by the energy problems occurring at that neuron; depolarization will be worsened by GCs, enhancing calcium influx via the NMDA receptor and voltage-gated calcium channel, and there will be less energy for costly extrusion. The worsening of the insult-induced calcium mobilization by GCs will worsen the downstream consequences. This has been shown to involve generation of more ROS, more cytoskeletal damage (i.e., more spectrin proteolysis), and more microtubule abnormalities (i.e., increased levels of the abnormally phosphorylated tau microtubule protein).

A small number of studies have examined whether the consequence of these GC actions is an increase in the fraction of neurons that die necrotically and/or in the fraction that die apoptotically. Despite the well-established fact that GCs can trigger apoptosis in immune cells, there are roughly equal amounts of evidence for and against physiologically elevated levels of GCs worsening the apoptotic profile of neuron death.

Neurons are not passively pummeled by necrotic insults. Instead, there are a variety of defenses that are mobilized. The uptake of synaptic glutamate and the extrusion of calcium qualify as such, but they are rarely thought of this way. More recognized defenses include responses such as expression of heat shock proteins, upregulation of antioxidant genes, and release of inhibitory retrograde neurotransmitters. Although the subject has not been explored in great detail, there have been some reports of GCs impairing the upregulation of such antioxidant genes or curtailing the activity of antioxidant proteins. One such case involves glutathione peroxidase, in which its activity was decreased by GCs decreasing NADH levels (secondary to the hormone's energetic effects), thereby reducing the available pool of reduced glutathione.

These adverse effects of GCs are summarized in Table 1.

Potential Clinical Implications

The previously discussed findings raise a number of worrisome issues in the clinical realm, related to the possible damaging effects of excessive GCs and/or stress. To date, few data are relevant to the ability of GCs to worsen the outcome of neurological insults in humans, beyond some correlative findings (e.g., that GC levels predict the extent of cognitive impairment post-stroke or following electroconvulsive therapy). Instead, the human literature is more focused on instances of GC excess, independent of coincident neurological disease.

Administration of Synthetic GCs

Experimental work with healthy volunteers demonstrates that a few days of exposure to only moderately high doses of a synthetic GCs such as prednisone causes subtle neuropsychological impairments. Synthetic GCs are prescribed in enormous quantities for prolonged periods for a number of disorders, include autoimmune diseases, inflammatory disorders, and to prevent organ transplant rejection. This raises the issue of whether such prolonged GC treatment has

adverse cognitive effects. This has indeed been long recognized clinically, and recent case-controlled studies suggest that the GC treatment impairs hippocampal-dependent memory. As is the case with all of these human syndromes, there is currently no insight as to the cellular basis of these GC effects.

Cushing's syndrome arises from any of a number of tumors, which, as their commonality, result in secretion of supraphysiological GC concentrations. This has long been recognized to result in cognitive impairments, traditionally referred to as 'Cushingoid dementia.' Recent work reports selective hippocampal volume loss in Cushingoid patients, with the magnitude of atrophy correlating with the severity of GC hypersecretion and cognitive impairments. Whatever the underlying cellular basis of this volume loss, it reverses slowly with the correction of the GC excess.

Posttraumatic Stress Disorder

An array of studies report that posttraumatic stress disorder (PTSD) arising from combat trauma or childhood abuse is associated with hippocampal volume loss in adulthood, the magnitude of which correlates with the severity of cognitive deficits and of the trauma. This suggests a model in which the volume loss arises as a result of the GC excess during the trauma and/or the posttraumatic period. However, this view is controversial for two reasons.

First, does the volume loss emerge posttrauma or, for reasons unrelated to stress, does it precede and predispose toward PTSD (i.e., a vulnerability model, reflecting the fact that trauma results in PTSD in only a subset of victims)? There is evidence for both ideas. As particularly strong support for the predisposition model, Vietnam veterans with PTSD secondary to combat trauma demonstrated hippocampal volume loss. As an important feature of this unique study, these subjects were members of pairs of identical twins, in which the sibling had not gone to Vietnam nor suffered from PTSD for other reasons; however, the same degree of volume loss was observed in these siblings as well. As particularly strong evidence for the model in which atrophy emerges as a result of the trauma rather than precedes it, children with PTSD due to abuse do now show hippocampal volume loss; it only emerges later on, gradually over subsequent months to years.

Second, it remains unclear whether GC levels are, in fact, elevated in PTSD. One literature reports such elevations, whereas another reports lower than normal levels, accompanied by enhanced sensitivity to negative feedback and downregulation of GC receptors in lymphocytes. Confounding this is a great deal of uncertainty (due to minimal data) as to GC levels during the relevant traumas.

Regardless of the resolution of these controversies, there is little evidence that the volume loss is reversible with time.

Major Depression

Stress and GCs play a central role in understanding the onset of the first few episodes of major depression, the neurochemistry and symptomatology of the disorder, and its endocrine concomitants. Importantly, approximately half of individuals with major depression have elevated GC levels. Commensurate with this, long-term depression is associated with hippocampal volume loss, the extent of which is correlated with the duration of depression and severity of cognitive impairments. This literature is weakened by the lack of demonstration that the volume loss is only found among the depressives with the elevated GC levels. As with the other syndromes, the cellular basis of the hippocampal volume loss is not known. One controversial theory is that it reflects GC/stress-induced inhibition of hippocampal neurogenesis; currently, there are no definitive data for or against this idea. There is also only minimal evidence that the volume loss precedes and predisposes toward depression. Finally, whatever the underlying cellular mechanism, the volume loss is demonstrable long after depressions have been pharmacologically contained.

Occupational Stress

Currently, the notion that everyday stressors can lead to hippocampal atrophy is almost entirely speculative. One provocative study supporting this idea concerned the fact that airlines differ as to the length of time that flight crews are allowed to recover after flights that involve major circadian shifts. After controlling for length of time in the profession and the total number of such shifts, individuals from the airline that allowed the shortest recovery time had significantly smaller temporal lobes and worse hippocampal-dependent cognition relative to crews from the airline allowing the longest recovery time.

Adverse Effects of Stress in the Amygdala

As should be clear, the literature regarding the deleterious effects of stress and GCs in the brain has been heavily skewed toward the hippocampus. A recent literature, however, shows there to be different GC/stress effects in the amygdala, ones that can be argued to be deleterious as well.

An extensive literature implicates the amygdala in fear and anxiety-related behaviors, findings derived from both animal and human studies (in which, for example, brain imaging shows amygdaloid activation

in response to frightening faces, or hyperactivity of the amygdala in individuals with PTSD). Thus, whereas the pathologies of the hippocampus involve decreased function (impaired hippocampal-dependent cognition, synaptic plasticity, and dendritic atrophy), those of the amygdala involve the opposite for each of those endpoints. Recent work shows that stress and GCs augment this picture of the amygdala as 'hyperexcitable.' As such, both will enhance fear conditioning and the startle response, phenomena that reflect amygdaloid-dependent learning, and will enhance the underlying increases in synaptic plasticity. Most remarkably, stress augments the dendritic tree in amygdaloid neurons, which is a plausible contribution to long-term increase in excitability.

On the level of cell biology, these are instances in which stress and GCs improve the function of neurons, and it remains a fascinating mechanistic question as to how the same external stimulus (GCs) can cause diametrically opposite cellular effects in the hippocampus and amygdala. On the more integrative level, insofar as enhanced excitability of the amygdala helps mediate an array of maladaptive behaviors (e.g., PTSD), the effects of stress and GCs can be viewed as being adverse in the amygdala.

Strategies to Protect against Adverse GC Effects

The range of stress-related pathologies throughout the body has long emphasized the importance of minimizing activation of the stress response in psychosocial circumstances; the growing literature regarding the adverse neurobiological effects of stress add to this conclusion. Although interventions meant to minimize the stress response are predominately psychological in nature, more biological approaches have been tried as well (Table 2). For example, some investigators have attempted to decrease the impact of the elevated GC levels frequent in major depression (because one important consequence of the elevated levels is to increase the severity of the anhedonia in the disease). Such approaches have taken the form of treating individuals with adrenal steroidogenesis inhibitors or, more recently, antagonists to one type of GC receptor.

Some first tentative attempts at developing 'anti-stress' gene therapy approaches have been made as well. Gene therapy in the nervous system is a burgeoning field. The approach most typically involves the use of neurotropic viruses (i.e., viruses that can infect postmitotic cells such as neurons), including herpes simplex virus or adenovirus. Potentially protective genes are inserted into crippled (i.e., safe) versions of the virus, and the resulting vector is introduced into the nervous system, where the transgene is expressed. Nearly all such gene therapy studies have targeted the basic biology of neuron death or neuronal recovery in the context of neurodegenerative diseases and acute necrotic neurological insults. Considerable preclinical success has been reported with these approaches, and the first few clinical trials derived from those are in progress.

Making use of this technology, some gene therapy approaches have been designed to block the disruptive effects of GCs and stress. Two components of these vectors have been developed. The first is to use vectors that will only express in response to elevated GC levels. This has been accomplished with the introduction of glucocorticoid responsive elements upstream of the transgene to be expressed. The result is a vector that can be introduced into neurons in advance of a stressor and that will then be activated out of latency by a stressor.

The second element is to identify genes that, if overexpressed, will blunt GC action in some manner. To date, three have been tried. In the first two cases, the transgene expressed was either a renal enzyme that unidirectionally degrades GCs or a mutant transdominant version of the glucocorticoid receptor; both decrease the hormone's access to its receptors. The third represents an advance in gene therapy technology and takes advantage of the fact that estrogen, as discussed, is neuroprotective in many realms. This

Table 2 Approaches to block the deleterious effects of glucocorticoids in the nervous system

Intervention	*Rationale*
Metyrapone, aminoglutethimide	Blocking adrenal steroidogenesis
RU486 (Mifepristone)	Blocking glucocorticoid receptors
Gene therapeutic overexpression of	
• 11-β-Hydoxyrosteroid dehydrogenase	Degradation of glucocorticoids
• Transdominant glucocorticoid receptor	Outcompeting wild-type glucocorticoid receptor for ligand
• ER/GR chimera containing the hormone-binding domain of the glucocorticoid receptor and the DNA-binding domain of the estrogen receptor	Converting deleterious glucocorticoid effects into protective estrogenic effects

vector exploits the modular structure of steroid receptors by expressing a chimeric gene that is half a GC and half an estrogenic receptor; the hormone-binding domain is derived from the GC receptor, and the DNA-binding domain is derived from the estrogen receptor. The result is that GCs, when bound to this receptor, trigger its translocation to estrogen responsive elements in the DNA, triggering the expression of estrogen-regulated genes; as such, this vector transduces the endangering effects of GCs into the protective effects of estrogen. Recent work suggests that these 'anti-GC' vectors can not only protect against the endangering effects of GCs and stress in the context of neurological insult but also are protective against their disruptive effects on cognition and their enhancement of amygdaloid function.

Conclusions

We are now nearly three-quarters of a century into recognizing the potentially pathogenic effects of sustained stress, often via the excessive secretion of GCs. The past few decades have shown that this pathogenicity applies to the nervous system as well, and that this act may be relevant to understanding the maladaptive responses to trauma, the side effects of heavy pharmacological use of synthetic GCs, the extent of neurotoxicity following the most common acute neurological insults, and why some brains will age more successfully than others. However, the knowledge of the cell biology of how these adverse actions emerge is also paving the way for the development of some potential therapies against the neurological effects of stress.

Gene Therapy: Direct Viral Delivery

B K Kaspar, The Ohio State University, Columbus, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

As populations age, the burden of health-related diseases due to nervous system disorders rises. Given the challenge to deliver drugs to the complex structure and diverse cell types of the nervous system, new therapeutic approaches are being investigated. Recent progress in molecular biology and virology has allowed tremendous advancements in delivery of recombinant DNA to the brain. This article provides an update on the status of direct viral gene delivery and examines the challenges to advance this approach as a therapeutic modality.

Direct viral injections focused on treating or curing acquired and inherited disorders can be utilized through a variety of approaches, including (1) delivery of a gene in excess (such as a trophic factor), (2) suppression of a gene (via antisense or small interfering RNA), (3) swapping an abnormal gene with a normal gene through homologous recombination, (4) controlling the regulation of endogenous gene expression (via transcription factor or zinc finger approaches), or (5) modulating immune defense mechanisms by either activating or suppressing immune function. Furthermore, direct viral injection can be used to generate animal models of mutant or toxic gene expression or, using *loxP* technology, conditional gene deletions.

There have been tremendous advances in the development of recombinant viral vectors that transduce postmitotic cells of the central nervous system with no associated toxicity. Among the two most commonly used are recombinant adeno-associated virus (AAV) vectors and recombinant lentiviral vectors. Initial studies in rodents have shown that neurons are the predominant cells that are transduced, with little transduction of other central nervous system (CNS) cell types. Both adeno-associated virus and lentiviral vectors have also been utilized in larger species, including in the monkey CNS, demonstrating a neural tropism. Over the years, it has been shown that these vectors are very nontoxic, with little to no activation of astrocytes or immune reactions against the vector. Additionally, long-term gene expression has been achieved, lasting well over 1 year post-infection with no evidence of cell death.

Utilizing precise maps of the brain and spinal cord, direct injection provides an ability to specifically target regions of the brain. The dynamics of vector spread have been studied, and, given the structure of the target and well as the type of virus; vector spread may be confined or may spread several millimeters. It has become apparent in many studies that virus may be transported in a retrograde and anterograde fashion, thereby targeting multiple areas of the CNS. Therefore, in many situations a direct injection will target multiple projection pathways.

Delivery Platforms

Numerous viral-mediated gene delivery platforms exist, each having particular advantages and disadvantages. Two of the most common platforms utilized to target nondividing cells, such as neurons, are adeno-associated virus and lentiviral vectors. These two vectors are attractive since they deliver genes into postmitotic cells and have demonstrated long-term gene transduction with limited or no immune response to the vector. Retroviral vectors are used for direct injection into the brain to target dividing cells, such as astrocytes or neural progenitor cells. It has recently been shown that retroviral vectors could transduce neural progenitor cells in different regions of the brain, with long-term gene expression. In addition, adenoviral and herpes simplex viruses are advantageous for transducing all cell types in the CNS very efficiently. Both of these vectors have the potential to induce an immune response, but new modified, or 'gutless,' versions of the viruses have bypassed many of the immune responses. Adenoviral and herpes simplex vectors are commonly used in many brain-related cancer studies.

The following sections provide a brief description of the various viruses that are used most commonly for direct injections into the brain.

Adeno-Associated Viral Vectors

The AAV is a member of the genus *Dependovirus* of the family Parvoviridae, among the smallest of DNA animal viruses, consisting of a virion particle approximately 25 nm in diameter and composed of an icosohedron-structured protein capsid outer coat. The viral genome is linear, consisting of a single-stranded DNA molecule of approximately 4.7 kb which contains two open reading frames (ORFs) flanked by 145 bp inverted terminal repeats (ITRs). AAV requires adenovirus or herpes virus as helper virus to initiate and complete its viral life cycle of rescue, replication, and packaging. Recombinant AAV-based vectors have the viral genome deleted, other than the ITRs, allowing for insertion of vector

construct to a maximum of approximately 4.9 kb. In recombinant form, most of the AAV vectors persist as concatemers, forming linear and circular forms, which lead to long-term persistence of the viral genome in transduced cells.

Specifically, to make these vectors recombinant, the rep- and cap-coding regions are removed and a promoter with a respective cDNA and polyadenlyation signal is cloned in between the two ITRs. For viral production, this recombinant AAV plasmid, along with *a trans* rep and cap plasmid and helper adenovirus or adenoviral plasmid, is transfected into cells such as human embryonic kidney (HEK293) carcinoma cells. Viral production consists of lysing cells followed by gradient ultracentrifugation and/or column chromatography. Vector preparations of titers between 10^{12} and 10^{13} are now routinely produced. Viral packaging efficiency and purity are important for optimal transduction *in vivo*. Of importance, AAV vectors can target postmitotic cells such as neurons. Most serotypes are neurotropic; however, some have achieved astrocyte gene transfer. Most regions of the brain have been transduced by AAV, with expression lasting long term in rodents as well as nonhuman primates. Currently, the most widely utilized serotype of AAV has been based on AAV-2, which utilizes the heparan sulfate proteoglycan as the primary receptor as well as $\alpha v\beta 5$ integrin and fibroblast growth factor receptor 1 (FGF-1R) as coreceptors. This allows a wide host range of tissue and cellular types. Other serotypes have shown great promise for expression in ependymal cells as well as various regions of the brain.

In sum, recombinant AAV vectors offer high promise for direct *in vivo* injection. This is due to the high stability of the virus, including an ability to inject highly concentrated stocks. AAV vectors have shown the ability to infect a wide spectrum of cells, including postmitotic cells, leading to long-term expression. Furthermore, AAV vectors are nonpathogenic, induce no etiological factors, and have been safely demonstrated in a number of clinical trials. However, AAV has a smaller packaging capacity compared to other vectors and requires several weeks to reach the maximal level of gene expression. Additionally, the scale of virus production and the purification processes remain a challenge, though significant progress is being made. New approaches using self-complementary vectors may offer some benefits for improving the timing and level of expression in the brain.

Retroviral

Historically, retrovirus-mediated gene transfer methods have been the most commonly used in gene transfer techniques, based on the Moloney murine leukemia virus (MoMuLV) as the backbone. Retroviruses target dividing cells and involve integration of the proviral DNA into the infected cell, allowing stable transmission to subsequent generations of the infected cells. Retroviruses have several advantages, including the ease of manipulation, the ability to clone relatively large genes (up to 7 kb), and the ability to infect a variety of cell types from various species. The majority of viral genes can be removed from the vectors, requiring regions in and around the long terminal repeats (LTRs) for packaging the RNA genome into the viral coat and allowing reverse transcription and integration. Since the proteins necessary for the viral replication can be provided *in trans*, replication-defective viruses can be generated easily. Production of retroviral vectors typically utilizes packaging and producer cell lines in which the viral gag, pol, and env proteins are expressed.

Given the ability to stably infect dividing cells, current direct injections of retroviral vectors to the brain have focused on tumor cell injections as well as direct injections into regions of neurogenesis to target neural progenitor cells. This approach to label neural progenitor cells has provided a very useful tool to investigate the neurobiology and histology of neural progenitor cells *in vivo*. Furthermore, this approach may be very useful to target these cells for therapeutic options in a number of diseases. There are several problems with retroviruses, such as stability (very short half-life of the virus) as well as the difficulty in making concentrated high-titer stocks. Furthermore, promoter shutdown has been an issue; however, advances in vector and promoter design have proved successful.

Lentiviral

Since conventional retroviruses only infect dividing cells, considerable attention has been directed to vectors based on the human immunodeficiency virus (HIV) or equine infectious anemia virus (EIAV), species of the genus *Lentivirus*, which infect postmitotic cells. A generation of HIV-based retroviral vectors that are not limited to infection of replicating cells has gained considerable use as a means to deliver genes to the CNS. Unlike other retroviruses that rely on the breakdown of the nuclear membrane and passive diffusion into the nucleus during cell division to transport their genetic information, HIV can be actively transported to the host cell nucleus by the cellular nuclear transport mechanism. This HIV-based expression system can efficiently transfer genes into nondividing cells. The HIV-based vector has been developed through several generations, reducing the potential for recombination. Extensive studies selectively removing the HIV virulence genes (*tat*, *vif*, *vpu*, *vpr*, and *nef*) have

demonstrated that these new generations are helper-virus free. Lentiviruses have an advantage in that larger transgenes may be cloned into the vector, versus AAV vectors. Packaging of lentiviruses is very similar to that of retroviruses, in which the *gal–pol* gene is used, along with the *rev* gene in some packaging systems. In addition, the packaging system includes the pseudotyping of the envelopes with other viruses, such as the vesicular stomatitis virus glycoprotein (VSVG). One drawback in lentiviruses is that production in large quantities for *in vivo* studies remains cumbersome and also that purification techniques have not been fully developed for highly purified vectors. Recent advances in column chromatography may aid in the enhancing lentiviral purification. For human studies, it may be useful to develop vectors with nonhuman lentiviruses, such as EIAV, bovine immunodeficiency virus, or simian immunodeficiency virus.

Adenoviral

Adenoviral vectors have been one of the most widely used viruses in gene delivery. They are nonenveloped, double-stranded (ds) DNA viral vectors with a packaging capacity of approximately 35 kb. Over 50 different adenoviral serotypes exist, grouped into six species. Recombinant adenoviral vectors are commonly derived from types 2 and 5. Adenoviruses of these serotypes have not been associated with human malignancies. The majority of these vectors are *E1* gene-deleted to render the virus replication deficient, along with *E3* deletions to allow greater packaging space. Most of the serotypes are able to enter most cells via the cellular coxsackie/adenovirus receptor (CAR), for attachment, and utilize αv integrins for internalization. This ability is indeed a major strength of adenoviruses, enabling a broad tissue tropism and infection of many cell/tissue types, with a very fast expression profile. In addition, large genes can be inserted relatively easy and adenoviral vectors are produced with relative ease at high titers and are easily purified. Virus is produced typically in HEK293 cells that stably express the *E1A* and *E1B* genes, allowing for replication and packaging. Transgene expression from first-generation vectors is very strong, but is reduced and abolished 2–3 weeks following direct injection. These recombinant adenoviral approaches have been utilized for many direct brain injections for tumor cell killing. The adenoviruses are recognized by the immune system and therefore have problems with long-term gene expression. Second-generation vectors have been used in an attempt to decrease immune responses to the vector, by deleting early regions involved in DNA replication, such as the *E2A*, *E2B*, and *E4* regions.

In sum, adenoviral vectors can be produced in high titers that hold a large amount of foreign DNA with the ability to infect postmitotic and dividing cells. The major disadvantage is that adenoviral proteins are highly immunogenic and many people have circulating antibodies and cellular immune responses toward the virus. Other drawbacks are that transgene expression is relatively unstable because the virus remains episomal, and that the virus may be toxic at high doses. The recent development of new generations of adenoviral vectors might overcome the toxicity and immunogenicity issues experienced with the previously used adenoviral vectors in the nervous system. Helper-dependent ('gutless') adenoviral vectors have shown reduced toxicity and larger cloning capacity compared to the standard adenoviruses. However, these gutless adenoviral systems are difficult to produce in large quantities.

Herpes Simplex Virus

Recombinant herpes simplex virus (HSV-1) is a double-stranded virus that has been produced as a recombinant vector system based on a natural neurotropic virus. The two types that are being exploited for *in vivo* injection are the herpes virus amplicon and the recombinant virus. The virus has a large cloning capacity and has been shown to remain in a latent state within neurons. Recombinant HSV-1 vectors are created by deleting the nonessential viral genes and replacing them with a transgene or a construct of interest (up to approximately 50 kb). HSV-1 has a wide ability to infect different cells and tissues. The virus has the capacity to retrogradely transport from remote sites, affording HSV-1 the ability to target CNS sensory and motor neurons in a highly efficient manner. There is also evidence to support transsynaptic passage from neuron to neuron. Most neurons are efficiently infected by HSV-1 vectors; however, HSV-1 is not solely a neurotropic virus, and in fact it will infect astrocytes and oligodendrocytes. HSV-1 vectors have been predominantly utilized experimentally for tumor cell killing. There is, however, potential to develop an immune response to the vector, and at present, sustained transgene expression has been difficult to achieve.

Control of Vector Systems

There are numerous methods to gain control of vector systems. One method is to engineer cell type-specific promoters into the recombinant vector. In this case, known cell type promoters are cloned in front of the recombinant transgene, which leads to specific cellular expression. Numerous promoters have been utilized, including promoters specific for neurons and

for specific subtypes of neurons (such as motor neurons), as well as astrocytes. In addition to cell type-specific expression, numerous advances have allowed for regulated transgene expression. In this case, transgene expression can be turned on and off as well as regulated as to the level of expression. Technology of regulatable systems is growing, and new developments are under way that are currently being tested in a variety of vector systems. Virologists have also utilized another method to gain control of vector systems: each viral particle is coated or encapsidated, allowing researchers to modify the outer coat or capsid. Many viruses have numerous serotypes and are species specific. It has been determined that these different serotypes display different transduction profiles. Some serotypes work better than others in neurons. In addition, numerous viral vectors can be pseudotyped with various proteins that allow the virus to infect cells more efficiently. Also, specific engineering can be employed on the capsid by inserting peptides or mutating the capsid regions in specific or nonspecific regions to alter viral tropism and transduction properties.

The control of vector systems in the CNS is important for a number of reasons. First, any therapeutic approach will necessitate the therapy being delivered to the proper cell type at the right dosage. Furthermore, while the brain is normally immune privileged due to the blood–brain barrier, there is considerable evidence that immune responses to viral vectors need to be considered in the design of direct viral injections. In the case of AAV, approximately 80% of the human population is seropositive for antibodies to wild-type AAV 2 capsid protein. The presence of neutralizing antibodies may prevent effective infection of this serotype. While it was originally thought that the blood–brain barrier would prevent peripheral immune responses, it has been shown that direct viral delivery locally disrupts the blood–brain barrier. Vector redosing is not possible with the same serotype.

With the demonstration that viral vectors are highly efficient for delivering genes, with long-term gene expression in rodents exceeding 18 months and over 3.5 years in primate brain, it is apparent that gene delivery may be a useful modality for the treatment of progressive neurodegenerative disorders. The following sections describe recent preclinical research of direct viral delivery in a number of degenerative disorders.

Diseases of the CNS

While not exclusive to all disorders, direct viral injection to the nervous system has been studied in numerous diseases and injuries, including Alzheimer's disease (AD), Parkinson's disease (PD), amyotrophic lateral sclerosis, lysosomal storage disorders, and Huntington's disease (HD).

Alzheimer's Disease

Affecting approximately 20 million people worldwide, AD is the most prevalent neurodegenerative disease. The disease is characterized by progressive cell death in cortical structures, with progressive memory loss, impaired judgment, confusion, and personality changes. The disease is characterized by a neuropathological component of accumulated amyloid beta (Aβ) plaques and neurofibrillary tangles throughout the brain. Since AD affects multiple regions of the brain, including widespread structures such as the cortex, direct viral delivery has been difficult. To date, there are no effective drugs for AD, although several inhibitors of acetylcholinesterase are prescribed. New strategies have focused on the use of trophic factors and antiapoptotic factors to target the cholinergic neurons of the basal forebrain. Nerve growth factor (NGF) is the most potent neurotrophic factor for cholinergic neurons and has been tested by direct viral delivery of NGF to spare cholinergic neurons of the basal forebrain in animal models. Furthermore, NGF has been shown to increase acetylcholine levels, which leads to improved memory, and is therefore a major candidate being pursued in the clinic. New viral approaches have focused on using natural peptidases that hydrolyze Aβ. Using a number of different viral vectors, neprilysin has shown promise in decreasing Aβ levels in AD mice. Another approach at reducing amyloid plaques has focused on the use of developing antibodies to clear the plaques. The use of vectors that express Aβ has induced autoantibodies that have been shown to vaccinate against and thereby reduce the levels of Aβ. Still another method using viral vectors has focused on the Aβ proteolytic pathway to prevent the toxic form of Aβ. Using a small interfering RNA (siRNA) approach against a protease (BACE-1) in the cleavage of amyloid precursor protein, cleavage has also shown significant promise as a therapy. Delivering the therapy in AD to the right cells in a widespread manner and utilizing the most efficacious genes are current challenges in AD research.

Parkinson's Disease

PD is one of the most studied neurodegenerative diseases and is the second most common disorder following AD, with symptoms manifesting at approximately 60 years of age. This neurological disorder is due to a gradual degeneration of dopamine-containing neurons in the substantia nigra, leading to the loss of dopamine transmission in the striatum. In fact, when

symptoms of Parkinson's appear, approximately 80% of striatal dopamine is lost. The loss of striatal dopamine leads to a resting tremor, bradykinesia, and akinesia. The etiology of the idiopathic form of the disease is largely unknown, although there are certain forms of the disorder with genetic components. Currently the only pharmaceutical therapy is L-dopa (L-3,4-dihydroxyphenylalanine), a precursor of the neurotransmitter dopamine. As the disease progresses over 3–5 years, this treatment becomes ineffective. Numerous studies have focused on direct gene delivery to deliver factors to prevent the neurons from dying, or to serve in dopamine replacement strategies. Several studies have utilized antiapoptotic factors or neurotrophic factors, including glial-derived neurotrophic factor for potent neuroprotection and regeneration of dopaminergic neurons. Additionally, there have been studies for striatal L-dopa for dopamine delivery via intrastriatal gene delivery. Numerous genes have been employed, including those encoding tyrosine hydroxylase (TH), GTP-cyclohydrolase 1 (GTPCH-1; for tetrahydrobiopterin availability), and aromatic amino acid decarboxylase (AADC; to produce dopamine). Still another approach has targeted the subthalamic nucleus to modulate basal ganglia during the nigrostriatal dopamine degeneration. In this therapy, direct injection into the subthalamic nucleus of glutamic acid decarboxylase (GAD) has been tested to increase the inhibitory neurotransmitter γ-aminobutyric acid (GABA). All of these approaches are showing promise in rodent and nonhuman primate models of PD using direct viral injection into the CNS.

Clinical trials in PD A neurotrophic strategy is currently in clinical trials to treat PD. This approach has utilized a neurotrophic factor, neurturin, to restore lost motor function and protect against further losses of dopaminergic neurons. Using an AAV encoding this gene, the virus is delivered into dopamine neuron-rich regions of the brain. Phase I safety trials in 12 patients with advanced PD were injected with the virus into the putamen at two different doses. Patients that received the low dose of virus demonstrated approximately a 36% improvement in the Unified Parkinson's Disease Rating Score (UPDRS) while off their current drug therapies, which was detected at 9 months post-gene delivery. The group of patients receiving a fourfold higher dosage experienced similar improvements at 6 months postinjection. These patients had persistent improvements throughout the 1-year analysis. No untoward or serious adverse events were noted in the study, demonstrating that gene delivery was safe and well tolerated over long periods of time. Self-reports from patients demonstrated a 50% reduction in the time when normal medication was ineffective and a doubling of time without dyskinesias while on medication. Currently, a phase II trial of this treatment is underway, enrolling 51 patients with advanced PD, and will be studied for 12 months for safety and efficacy.

A second trial using AAV virus is currently underway to evaluate the safety and efficacy of a therapy designed to restore and extend the therapeutic effectiveness of L-dopa, the precursor to dopamine. This vector encodes aromatic amino acid decarboxylase and is currently administered bilaterally to the putamen of patients. As of 2006, four patients had received treatment. Positron emission tomography (PET) anlaysis showed an increase in the ratio of L-dopa to dopamine, demonstrating an increase in the AADC tracer fluoro-L-*m*-tyrosine (FMT) uptake at 1 month in all four patients following gene delivery, with slightly less uptake at 6 months. To date, there has been no report on changes in the average UPDRS motor score. Further recruitment is currently under way to evaluate this clinical study.

Another trial that has demonstrated safety and function of AAV has involved 11 men and one woman with PD, a disease noted for substantial reduction in the activity and amount of GABA in the brain; GABA is a major inhibitory brain neurotransmitter that suppresses excessive neuronal firing. In this trial approach, using an adeno-associated viral vector, the glutamic acid decarboxylase (GAD) gene was injected into a single site of the brain, the subthalamic nucleus, that is a key regulatory center within the motor circuit. In this procedure, only one side of the brain was injected with virus. Using the UPDRS and positron emission tomography scans, the investigators monitored patients for safety and the potential efficacy. They found that the injection was safe and well tolerated, and no adverse events were reported during the trial over 1 year. Interestingly, there was a 25–30% improvement in the UPDRS scores in patients taken off the standard drug therapies for a period of time, to evaluate effects of the gene therapy treatment alone. Similar improvements were found even while patients were on their normal medications. These improvements persisted over the course of the trial. Trends noted on reduced medication linked dyskinesias and improvements in daily living, though the data did not reach statistical significance. Furthermore, PET scans showed that the treated side of the brain had more normal levels of activity than did the nontreated side. Larger, efficacy-driven trials are planned to evaluate this therapy.

Amyotrophic Lateral Sclerosis

Also known as Lou Gehrig's disease, ALS is a degenerative disease of the motor system affecting upper

and lower motor neurons of the motor cortex and spinal cord. The disease is characterized by loss of skeletal muscle control, ultimately resulting in death due to loss of muscles involved in respiration. Currently there are no effective treatments for this disease, but significant progress and promise have been demonstrated by gene therapy approaches. Numerous strategies have evaluated viral-mediated gene delivery of neurotrophic factors – glial-derived neurotrophic factor (GDNF), insulin-like growth factor-1 (IGF-1), and vascular endothelial growth factor (VEGF) – as well as antiapoptotic genes using numerous viral vectors, including adenoviruses, AAV, and lentiviruses. In addition, there are developments to deliver antisense or siRNAs directed against one of the known genetic mutations accounting for the familial form of the disease in which patients have mutations within the superoxide dismutase 1 (*SOD1*) gene. Several different approaches have been utilized to deliver a therapeutic gene to the spinal cord. These approaches have utilized the concept of remote delivery by injecting the therapeutic vector intramuscularly; the virus is taken up by the axon terminal and transported in a retrograde fashion to the motor neuron cell body. This retrograde transport approach of the viral vector was accomplished using adenoviral and adeno-associated viral vectors as well as rabies glycoprotein pseudotyping of lentiviral vectors. Other approaches have investigated direct viral delivery by intraparenchymal delivery to the spinal cord. These studies have all showed the promise to significantly delay disease onset and/or progression in mouse models of the disease. Several of the approaches are being developed for clinical translation. Ultimately, as further genetic analysis of patients leads to new targets and mechanisms of the disease, the efforts gained in targeting spinal cord motor neurons and the surrounding cellular environment will lead to more efficacious therapies.

Lysosomal Storage Disorders

Over 40 known lysosomal disorders result from deficient enzymes, leading to accumulation of cellular proteins in the lysosomes. A deficiency of lysosomal acid hydrolases results in several lysosomal disorders, including mucopolysaccharidosis type VII (MPS VII), Niemann–Pick A, MPS IIIB, Krabbe disease, and Batten disease. Current therapies include enzyme replacement strategies. Human therapy for prenatally determined lysosomal disorders requires administration of the missing enzyme postnatally. Approaches to gene therapy have tested numerous enzyme replacement strategies utilizing viral vectors, and new approaches are investigating minimally invasive, yet widespread gene delivery to the CNS in addition to delivering the gene to peripheral organs. The CNS is targeted to treat the cognitive neural problems associated with the disease. A clinical trial for Batten disease is currently underway to transfer a correct version of the ceroid lipofuscinosis neuronal 2 (*CLN2*) gene into infants.

Huntington's Disease

HD is a fatal neurodegenerative disease classified by trinucleotide repeats of CAG in the first exon of the HD gene. These polyglutamine expansions require a specific length to trigger neurodegeneration, in which the mutant protein forms aggregate, leading to loss of GABA spiny neurons in the caudate putamen. The disease leads to cognitive defects and motor abnormalities. Trophic factor support utilizing a number of viral vectors is currently being tested to protect against the GABAergic cell loss. Furthermore, new approaches utilizing short-hairpin RNAs (shRNAs) to target the mutant huntington gene has shown significant promise for a therapeutic modality in this disease. Given that a number of diseases of the CNS are due to the expansion of polyglutamine repeats, this directed approach for silencing the mutant protein may be further applicable to other diseases. Proper delivery to target the affected cells in the disease and the optimal timing of delivery are challenges that researchers in the field are currently developing.

Conclusion

In addition to use in therapeutic approaches to the diseases discussed in this article, gene therapy by direct viral injection has shown significant promise for the treatment of brain disorders such as Canavan's disease, and in treating pain, epilepsy, stroke, and spinal cord injury; besides, there is interest in direct viral injection in a wide spectrum of studies on treating cancers of the brain, including neuroblastoma and glioblastoma.

Utilization of gene therapy by direct viral injection for nervous system disorders has the potential to revolutionize medicine in the near future. Indeed, there have been striking preclinical results demonstrating that viral vectors may be the only feasible therapeutic modality to target a specific region of the brain, or to deliver a therapy that can get past the blood–brain barrier. Many of these preclinical studies warrant clinical development. As additional genetic understanding for brain diseases develops, the ability to utilize the optimal vectors with the right gene, by the optimal injection parameter, will ultimately result in therapeutic benefit.

Truly one can see the challenges and struggles in the field of gene delivery as similar to those faced in the dramatic development of open heart surgery, when the early studies resulted in scientific challenges that were far beyond those ever imagined, including the loss of the earliest treated patients. The field of gene therapy, in particular as it relates to neuroscience, has recruited a diversity of specialists, ranging from molecular biologists to virologists, anatomists, physicians, and biotechnologists, to work together to revolutionize healthcare and ultimately to unburden patients from the effects of disease and injury of the nervous system. As clinical development of gene therapy ensues, the field will take the lessons learned and apply them to evolve genetic medicines to use in standard practice.

Gene Therapy: Genetically Modified Cells

U J Kang, The University of Chicago, Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Gene therapy has been introduced as a potential therapeutic modality that alters the genetic machinery of the cells and tissues to a desired end. The host or implantable cells are modified with externally provided genetic information so that they produce therapeutic molecules by utilizing endogenous mechanisms to transcribe the message and translate into protein products. Since the introduction of this concept for central nervous system (CNS) disorders in the late 1980s, significant progress has been made in understanding its potential and in the development of new techniques for genetic manipulation of various cell types in *ex vivo* and *in vivo* settings. This article reviews the methodological issues and examples of CNS application that have been studied.

Gene Therapy Methods to Produce Genetically Modified Cells

Two general approaches have been taken to introduce genes of interest and artificially produce a desired product in a therapeutically relevant part of the CNS: *ex vivo* and *in vivo* gene therapy. *Ex vivo* gene therapy involves genetically modifying cells *in vitro* to express relevant gene products in the cells and then delivering the modified cells to target areas *in vivo*. The cells are sometimes taken from the host and implanted back to the host after genetic modification. The *ex vivo* approach was developed first since early gene therapy vehicles such as retrovirus vectors required actively dividing cells for successful and stable integration of the genetic materials into the chromosomes and they were not efficient in transducing cells *in vivo*. *In vivo* gene therapy is discussed in a separate article; this article focuses on *ex vivo* methods utilizing genetically modified cells.

Cell Types Used for *Ex Vivo* Gene Therapy

The cell types that are genetically modified play a critical role in *ex vivo* gene therapy. Properties of the cells that are implanted can determine a significant part of the therapeutic effect of genetically modified cells. To avoid the detrimental effects of cell delivery, the potential of the genetically modified cells to form tumors or produce immunological reactions by the host must first be considered. Placing the cells within encapsulation polymers can also provide a physical barrier restricting further growth and limiting immunological reactions. Often, primary cell types such as fibroblasts, myoblasts, astrocytes, Schwann cells, and olfactory ensheathing glia have been used as cellular vehicles for these reasons. Particularly attractive cell types for genetic modification are various stem cells of both embryonic and adult origin, which may also provide a substrate for neurite outgrowth and have a tendency to migrate into the pathological areas such as tumor cells or sites of injury or degeneration.

Vectors Used for *Ex Vivo* Gene Therapy

Viral vectors are currently the most preferred method of gene transduction for gene therapy because of their high transfection efficiency for most cell types used for *ex vivo* gene therapy. Retroviruses derived from the Moloney murine leukemia virus transduce cells with high efficiency by integrating into the cellular genome of dividing cells. However, integration is apparently random and could disrupt important normal cellular function by insertional mutagenesis including oncogenesis. Lentiviruses are retroviruses derived from human immunodeficiency viruses and have the ability to transduce nondividing neurons *in vivo* with great efficiency. They have also been successfully used for transducing cells for *ex vivo* gene therapy. Adenovirus is a double-stranded DNA virus associated with human respiratory infections, conjunctivitis, and gastroenteritis. Adenovirus has been shown to infect both neurons and glia after direct intracerebral injection and is very efficient in transducing genes into primary neurons in culture.

The main issue in using viral vectors is whether expression levels can be sustained after many passages and after implantation of the genetically modified cells into the host animals. The long-term expression depends on the type of viral vectors, promoters, cells, and transgenes. Viral promoters have initial high levels of expression but tend to turn off their expression as the cells become quiescent in culture and after grafting. Constitutive promoters have been used and they show sustained expression, but at a very low level compared to viral promoters. For some transgenes such as tyrosine hydroxylase (TH), short-lived *in vivo* expression has become a major limitation of *ex vivo* gene therapy. However, other genes, such as choline acetyltransferase (ChAT) and nerve growth factor (NGF), have been shown to maintain their expression for as long as 1 year. Another issue is the ability to regulate the expression of the transgenes so that appropriate quantities of products

are delivered to exert intended biological effects. Various novel promoter constructs that can be regulated by external agents are being developed and tested.

Summary of *Ex Vivo* Gene Therapy Methods

The advantage of *ex vivo* gene therapy is the ability to characterize the genetically modified cells extensively and select them for desired phenotypes before using them for therapy. The property of the cells may also be chosen to enhance the therapeutic potential. They may produce trophic factors endogenously, provide substrates that are conducive for neurite growth, and be capable of migrating within the target brain area. Confining the genetic modification within the implanted cells may provide a measure of safety against unexpected detrimental effects that cannot be controlled in the host cells after viral vector-mediated direct *in vivo* gene therapy. Incorporation of a suicidal gene that could be controlled in genetically modified cells can be envisioned.

The disadvantages of *ex vivo* therapy include the extraneous graft mass of many cell types such as fibroblasts and astrocytes in the CNS that could be disruptive of normal host function. Another potential limitation of *ex vivo* therapy is that the genetic modification is most appropriate for secreted molecules that can act extracellularly and not for therapeutic molecules that need to gain entry into the target cells to intervene in the intracellular processes, which is better suited for *in vivo* gene therapy.

Application of Genetically Modified Cells

Genetically modified cells can serve as a biological minipump that delivers therapeutic molecules such as neurotransmitters or neurotrophic factors locally and in a continuous manner. Neurotransmitter replacement is a mainstay of neurological therapy in disorders such as Parkinson's disease. However, selective delivery into the target site in a physiological manner is not possible by pharmacological means. Therefore, a biological pump that can provide therapeutic products in a steady fashion appropriately targeted to selected brain areas has the potential for increased therapeutic efficacy with reduced side effects.

Neurotrophic factors are critical in the growth and survival of developing neurons. In addition, they can enhance certain neuronal phenotypes and promote the survival and regeneration of damaged adult neurons. For these reasons, neurotrophic factors have tremendous therapeutic potential for a wide range of neurological diseases. However, delivering appropriate concentrations of neurotrophic factors to target cells is not easily achieved by systemic administration. Neurotrophic factors generally have short half-lives, do not cross the blood–brain barrier, and have a wide range of effects on various targets. Intraventricular delivery could overcome the blood–brain barrier but lacks anatomic and cellular specificity. Intraparenchymal delivery is limited by short diffusion distance from the delivery site. Therefore, gene therapy represents one of the most promising means of providing continuous delivery of neurotrophic factors to specific anatomic and cellular targets.

The neurotrophin family, including NGF, brain-derived neurotrophic factor (BDNF), neurotrophin (NT)-3, and NT-4/5, has been extensively studied for its therapeutic potential, including use in gene therapy. Glial cell line-derived neurotrophic factor (GDNF) is a distant member of the transforming growth factor-β superfamily of trophic factors that also includes neurturin, artemin (neublastin), and persephin (Table 1).

Parkinson's Disease

Parkinson's disease (PD) is the second most common neurodegenerative disorder. PD is well suited for gene therapy to deliver neurotransmitters or neurotrophic factors because it is biochemically and pathologically well defined. The degeneration of the nigrostriatal dopaminergic system and ensuing dopamine loss underlie the majority of motor disabilities of PD. The clinical efficacy of dopamine replacement therapy in improving major aspects of motor

Table 1 Target genes delivered by genetically modified cells in animal models of neurological disorders

Disorder	*Neurotransmitter replacement*	*Neurotrophic factor delivery*
Parkinson's disease	TH, GTPCH1, AADC, VMAT	BDNF, GDNF, neurturin, persephin
Alzheimer's disease	ChAT	NGF
Huntington's disease		NGF, BDNF, NT-3, NT-4, GDNF, neurturin, CNTF
Amyotrophic lateral sclerosis		GDNF
Spinal cord injury		GDNF, NGF, BDNF, NT-3, NT-4/5

AADC, aromatic L-amino acid decarboxylase; BDNF, brain-derived neurotrophic factor; ChAT, choline acetyltransferase; CNTF, ciliary neurotrophic factor; GDNF, glial cell line-derived neurotrophic factor; GTPCH1, GTP cyclohydrolase 1; NGF, nerve growth factor; NT, neurotrophin; TH, tyrosine hydroxylase; VMAT, vesicular monoamine transporter.

disability has been well established. On the other hand, pharmacological therapy with dopamine precursor, L-3,4-dihydroxyphenylalanine (L-DOPA), or synthetic dopamine agonists is limited by development of motor response fluctuation and other side effects that develop over time. The emergence of motor response complications has been attributed to the supersensitivity of the dopamine signaling pathway and further maladaptive plasticity that result from nonphysiological chronic drug therapy. It has been hypothesized that steady levels of L-DOPA or dopamine may be more physiological than fluctuating levels that are typically achieved by intermittent oral administration of dopaminergic agents. Experimental studies have shown that maintaining steady levels of L-DOPA achieved by either intravenous or intraintestinal delivery reduces the likelihood of motor response complications. In addition, it is hypothesized that localized delivery would avoid cognitive side effects such as hallucinations that are attributed to excessive stimulation of dopamine system outside the pathogenic nigrostriatal system by systemic delivery of dopaminergic agents. Therefore, methods to deliver L-DOPA or dopamine continuously and locally have been sought. Transplantation of various cells that provide L-DOPA or dopamine has been attempted in patients and experimental animals. Fetal dopamine cells have been considered the gold standard for such vehicles. Stem cells and gene therapy have been proposed as alternative means to provide well-defined and readily available sources of localized and sustained dopamine.

Neurotransmitter replacement To deliver dopamine by genetically modified cells, one has to consider many genes depending on the cell types to be used as a vehicle. Some cell types, such as stem cells, can be coaxed into expressing some such phenotypes, but for most implantable cell types, artificial expression of transgenes is necessary or can supplement the phenotype. Dopamine synthesis is a two-step enzymatic process. The essential amino acid tyrosine is first converted into L-DOPA by the rate-limiting enzyme TH. TH requires cofactors such as iron, oxygen, and tetrahydrobiopterin (BH_4) for its activity. Although most of the initial studies employed only TH, the most efficient production of L-DOPA is achieved by adding the GTP cyclohydrolase 1 gene along with the TH gene. GTP cyclohydrolase 1 is the first and rate-limiting step of BH_4 synthesis. Both *ex vivo* gene therapies utilizing various cell types and *in vivo* gene therapies introducing genes directly into striatal cells have shown the necessity and effectiveness of using both TH and GTP cyclohydrolase 1 genes for significant production of L-DOPA and subsequent behavioral restoration in PD models of rats, mice, and nonhuman primates. The critical role of GTP cyclohydrolase 1 in dopamine synthesis is also demonstrated by hereditary progressive dystonia and parkinsonism (also termed DOPA-responsive dystonia), which results from the deficiency in GTP cyclohydrolase 1.

The second step in dopamine synthesis involves decarboxylation of L-DOPA to dopamine by aromatic L-amino acid decarboxylase (AADC). *Ex vivo* gene therapy experiments in which AADC is added to TH and GTPCH1 have provided interesting insight about dopamine regulation. When fibroblast grafts expressing three genes, TH and GTPCH1 to produce L-DOPA and AADC to convert L-DOPA to dopamine, were compared to those expressing only TH and AADC, both L-DOPA and dopamine levels were higher in those with two genes than those with three genes. The detrimental effect of AADC on synthesis of L-DOPA and dopamine in genetically modified fibroblast cells both in culture and *in vivo* was attributed to the end product – dopamine inhibition of TH activity. End-product inhibition is a well-established regulatory mechanism of TH, and dopaminergic neurons sequester dopamine into synaptic vesicles and thus accumulate high levels of dopamine in the cytoplasm that would inhibit TH. Therefore, AADC is marginally helpful given its endogenous expression in nondopaminergic cells and may even be detrimental depending on the parameters of its delivery.

Engineering cells with the vesicular monoamine transporter (VMAT) gene to increase storage capacity circumvents the feedback inhibition. Although typical synaptic vesicles are not present in most cell types used for *ex vivo* gene therapy, experiments on fibroblast cells have shown that even nonneuronal cells can incorporate VMAT into tubulovesicular structures and store dopamine at higher levels and release them over longer periods of time than cells without VMAT expression. *In vivo* gene therapy study also showed that engineering all four genes – TH, GTPCH1, AADC, and VMAT – produced higher levels of dopamine and better behavioral recovery than three gene constructs consisting of TH, GTPCH1, and AADC in a rat model of unilateral PD.

An alternative approach to providing either L-DOPA or dopamine by gene therapy is to graft cells that express AADC without TH or GTPCH1 to enhance the efficiency of converting systemically administered L-DOPA to dopamine. If one could achieve the same level of striatal dopamine using a lower dose of L-DOPA compared to those without grafts, this would decrease the diffusion of L-DOPA to other parts of the brain, notably the limbic system, and minimize side effects such as hallucinations and

confusion. Both *ex vivo* and *in vivo* gene transfers of AADC genes in the striatum have been employed to demonstrate enhanced dopamine production in the striatum in rodents and nonhuman primates. This approach also has the advantage of being able to regulate dopamine production by varying the amount of precursor, L-DOPA. A phase I clinical trial using adeno-associated virus (AAV)-mediated AADC gene therapy in PD patients is in progress. To further enhance the efficacy of dopamine conversion from L-DOPA, genetically modified fibroblasts containing both AADC and VMAT genes have been used for gene therapy. The addition of VMAT not only enhances dopamine levels but also prolongs the duration of dopamine release compared to AADC alone.

A major technical issue with the dopamine gene approach is the safety of regulating the level of dopamine replacement. The most feasible approach is to use regulatory promoters to control either TH or GTPCH1 expression or use a combination of precursor, L-DOPA regulation, and gene therapy with-AADC to enhance the production with or without VMAT to store dopamine. In the meantime, the rationale for central and continuous delivery of dopamine is being re-examined. First, limitations of treating only dopamine-associated symptoms are recognized as more widespread system degeneration in PD is being appreciated. Second, current gene therapy or cell replacement therapies may function mainly as a tool for tonic replacement of dopamine, whereas phasic activity of dopamine seems to be critical in many physiological functions. Lastly, the use of continuous dopamine stimulation to reverse fundamental mechanisms of motor response complication is largely untested beyond its pharmacokinetic effect. Of note is that most dopamine-related genes seem to be relatively unstable, achieving relatively short-term expression by genetically modified cells, and most long-term expression has been achieved by direct *in vivo* viral delivery.

Neurotrophic factor delivery A complementary approach to treating PD is neurorestorative therapy using genes that could prevent degeneration or promote dopaminergic phenotypes and survival. To do so effectively would require a good understanding of the etiology of PD, which remains largely unknown. Nonetheless, mitochondrial dysfunction, oxidative stress, and abnormal protein processing have been implicated in the pathogenesis. In addition, several approaches seem to be restorative to dopaminergic neurons, although these approaches may not be based on the precise etiology or pathogenesis of PD. For example, although it is not well understood whether neurotrophic factor deficiency plays a major role in the pathogenesis of PD, neurotrophic factors can still augment the function and retard degeneration of dopaminergic neurons in PD models.

Although many factors have been shown to promote the survival of dopaminergic neurons in experimental culture models, only a few have been effective *in vivo*. BDNF has been delivered by a variety of *ex vivo* gene therapy paradigms. Implants of BDNF-producing fibroblast cells protect against the toxicities of 6-hydroxydopamine (6-OHDA) and 1-methyl-4-phenylpyridinium. In addition, implantation of BDNF-expressing fibroblasts into the substantia nigra induced sprouting of dopaminergic fibers into grafts.

GDNF delivered to the substantia nigra by *ex vivo* gene therapy using neural stem cells and encapsulated cells has been found to protect dopaminergic neurons and terminals from 6-OHDA toxicity in rodents and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine in primates. Fibroblasts expressing neurturin and neuronal stem cells expressing persephin protected against 6-OHDA neurotoxicity. The timing and the location of GDNF gene therapy are important variables in experimental models of PD usually produced by dopaminergic toxins. Therefore, one would need to extrapolate the efficacy in these acute toxic lesion studies to the chronic neurodegenerative process of PD. The effect of *in vivo* viral gene therapy with GDNF in boosting the dopaminergic phenotype in aged monkeys demonstrates the feasibility of this approach in chronic human diseases such as PD.

Intraventricular and intraparenchymal deliveries of GDNF have been attempted in PD patients without significant benefit, most likely due to inefficient delivery to target areas. To overcome the delivery issue, *in vivo* AAV-mediated gene therapy of neurturin is in phase I clinical trials in PD patients.

Alzheimer's Disease

Alzheimer's disease (AD) is characterized by generalized cortical atrophy with characteristic pathology of neuritic plaques and neurofibrillary tangles. Although the degeneration is widespread, reductions in acetylcholine are most profound and associated with the loss of cholinergic neurons in the basal forebrain. Cholinergic deficits are thought to be responsible for memory loss and attention problems, but neurotransmitter replacement therapy using centrally acting acetylcholinesterase inhibitors has been only modestly effective in improving cognitive dysfunction.

Neurotransmitter replacement Acetylcholine is synthesized by ChAT from acetyl coenzyme A and choline. Once released from the nerve terminals, acetylcholine is rapidly metabolized by acetylcholinesterase and choline is taken backup to the terminal

by the choline transporter. Gene therapy targeted to replace ChAT by genetically modified fibroblasts cells has been tested in two different rat models of AD: the ibotenic acid lesion of the nucleus basalis of Meynert in the basal forebrain and the fimbria-fornix lesion that axotomizes the basal forebrain neurons. The cells were shown to express the transgenes at least for 1 year. Increased ChAT activity and acetylcholine levels were noted in these genetically modified cells grafted in the frontal and parietal cortex, and this increase was associated with improvement in their performance in the water maze task. The behavioral effects of the genetically modified cells were comparable to those of pharmacological treatment with acetylcholinesterase inhibitors or hippocampal grafts that contain cholinergic neurons. In addition, aging rats with cognitive deficits improved their water maze spatial memory performance when grafted with acetylcholine-producing fibroblast cells in cortex and hippocampus.

Neurotrophic factor delivery The effect of NGF on basal forebrain cholinergic neurons has been well demonstrated in rodent and primate animal models. Rat fibroblast cells that were genetically modified to express NGF protected against cholinergic degeneration following fimbria-fornix lesions in rats. The protective effects of NGF have been replicated in many *ex vivo* and *in vivo* gene therapy experiments in rodents and primates of AD models produced by lesions of basal forebrain as well as against age-related atrophy in rats and monkeys. The cells that have been modified include immortalized embryonic skeletal muscle cells, NT2N cells, and encapsulated Schwannoma cells. Intraventricular delivery of NGF was attempted in several AD patients but was limited by side effects such as weight loss and back pain. A phase I gene therapy study was conducted in which NGF-expressing fibroblasts were implanted near the nucleus basalis of Meynert in the brains of a small number of patients with early stage AD. After a mean follow-up of 22 months, no adverse effects were noted. Clinical assessment showed attenuation in the rate of cognitive decline, positron emission tomography scans showed an increase in cortical glucose uptake, and one autopsy showed robust sprouting of cholinergic axons into the NGF delivery site. Further studies including control groups will be critical for proper assessment of this approach, but these initial findings are promising and consistent with experimental data in animals.

Other Disease Models

For other diseases, neurotransmitter replacement strategy by genetically modified cells has not been explored much due to the fact that there is little clinical evidence for the efficacy of such an approach. Genetically modified cells that produce neurotrophic factors have been tested in animal models of several other neurodegenerative disorders.

Huntington's disease (HD) is an autosomal dominant disease characterized by abnormal involuntary movements, cognitive deficits, and psychiatric manifestations. The expansion of trinucleotide CAG repeat sequences results in abnormally long polyglutamine tracts in the huntingtin protein and degeneration of medium spiny neurons in the striatum and cortical neurons. BDNF levels are decreased by 45% in the frontoparietal cortex of HD brains. BDNF delivered by *ex vivo* gene therapy using fibroblasts has been shown to protect striatal projection neurons against quinolinic acid lesions. GDNF-expressing fibroblast cell lines protected GABA/substance P-positive neurons in the direct pathway but did not protect striatal projection neurons in the indirect pathway following quinolinic acid lesions. Interestingly, neurturin-expressing cell lines have the opposite effect, protecting striatal neurons in the indirect but not direct pathway. Polymer-encapsulated baby hamster kidney fibroblast cells expressing CNTF protected striatal neurons in rats against the toxicity of intrastriatal quinolinic acid injections and against the toxicity of 3-nitropropionic acid in monkeys. Few clinical trials using neurotrophic factors have been performed in HD.

Amyotrophic lateral sclerosis is a devastating disease of unknown etiology involving the progressive degeneration of motor neurons. Most applications of gene therapy using neurotrophic factors have utilized direct viral-mediated *in vivo* gene therapy.

Spinal cord injury is another major therapeutic target of genetically modified cells that express neurotrophic factors. A variety of growth factors have been studied in animal models of spinal cord injury, including GDNF, NT-3, NT-4/5, BDNF, and NGF, each with its distinct range of target neuronal populations. For instance, NGF-expressing fibroblasts induced growth of sensory axons and noradrenergic axons into the graft, whereas fibroblasts genetically modified to express NT-3 resulted in growth of corticospinal axons through host gray matter and distal to lesion sites following acute dorsal spinal cord hemisection and produced partial functional recovery. BDNF-expressing Schwann cells induced growth of coerulospinal and raphespinal axons, and BDNF-expressing fibroblasts into a partial cervical hemisection model resulted in partial regeneration of the rubrospinal tract axons and functional recovery and partially rescued axotomized red nucleus neurons from loss and atrophy. Fibroblasts expressing GDNF also promoted significant regeneration of dorsal

column sensory, propriospinal, and local motor axons when grafted into transected spinal rat spinal cord. Schwann cells expressing GDNF also promoted propriospinal axonal regeneration and myelination. Despite some success in the initiation of axonal growth, stimulating axons to grow beyond neurotrophic factor-secreting grafts has proved to be much more difficult since they are trapped at the graft with a high concentration of neurotrophic factors. It may be necessary to employ novel strategies such as turning off growth factor expression at the injury site and initiating expression at more distal sites or producing a gradient of neurotrophic factors.

Summary

Gene therapy using genetically modified cells provides an opportunity to understand the biology of disease by examining the effect of one gene at a time on restoration of functions of the diseased system. Genetically modified cells have the potential to effectively deliver neurotransmitters, neurotrophic factors, or a combination of factors in a wide range of neurological diseases. Some of these experiments have led to early phase clinical trials, such as *in vivo* viral gene therapy of aromatic L-amino acid decarboxylase, glutamic acid decarboxylase, or neurturin for PD and *ex vivo* therapy of NGF for AD. One must consider the specific advantages offered by gene therapy and balance them against the limits of current therapeutic modalities.

Introduction

Advanced genomics technologies allow neuroscientists to tackle more complex questions than ever before. Most of the new genomewide analysis methods concentrate on evaluating global gene expression or protein abundance differences. However, RNA-based methods are currently more popular because of their relative ease and the methodological difficulties associated with proteomic approaches. DNA microarrays enable the detection of gene expression profiles from small quantities of brain tissue or even from single cells. This ability is essential for most neurobiological applications because the brain is extremely complex tissue in which neighboring cells might have very different gene expression patterns.

Microarrays offer a tool for unbiased genomewide gene expression analysis. They work by hybridization of labeled RNA or DNA to DNA molecules attached at specific locations on a surface (Figure 1). The concept of DNA microarrays is more than 15 years old, and several different techniques emerged in the mid-1990s. Current arrays offer high sensitivity, reproducibility, and a large number of target genes. A wide variety of different arrays is commercially available. Therefore, the initial problems related to microarray technology have been largely overcome, although reliable identification of small differences in expression level between two samples (<20%) remains challenging. With the advancement of the technology, the need to independently replicate array-based results is disappearing as microarrays themselves are in many cases more sensitive than methods used to validate microarray results, such as quantitative real-time PCR or Northern blots. Several excellent reviews and book chapters discuss the technical aspects of gene expression profiling using microarrays.

Multifactorial or complex diseases are likely to be caused by some combination of multiple genetic and environmental factors. While a great number of genes that cause monogenic disorders are known, success in mapping susceptibility genes for multifactorial diseases has been limited because of several confounding factors, such as genetic heterogeneity, unknown mode of inheritance, classification of the phenotype, phenocopies, reduced penetrance, and high frequency of disease-predisposing alleles. The initial disappointments in gene mapping of complex diseases have led geneticists to use new methods, such as microarrays, in order to find genes predisposing to complex diseases. Moreover, it has been hoped that microarrays would provide information about pathogenetic mechanisms of both Mendelian and complex diseases. In the past 5 years, a large number of studies have been published using human brain samples and microarrays, and some of this work is discussed below. There is also an ongoing search for relevant animal models for complex behavioral traits. The major advantage of working with animals is that the environment can be entirely controlled, and one can concentrate on phenotypic differences resulting from genetic differences. Gene expression profiling has provided valuable information about disease mechanisms in various animal models, such as transgenic mouse lines or pharmacological models.

This article reviews some recent research aimed at the identification of genes with altered expression in human behavioral disorders. It also emphasizes the use of animal models in conjunction with new genomic methodology in trying to understand complex neurobiological diseases and behavior.

Gene Expression Profiling of Human Brain Tissue

Gene expression profiling has contributed to our understanding of the pathophysiology of many diseases, such as cancer. The progress in brain-related diseases has not been as rapid. In part, this is due to the poor availability of good-quality human brain samples. Although fresh tissue is always preferred, it is rarely available, with the exception of central nervous system tumors. They have been classified according to their cell type of origin as it is possible to obtain good-quality brain tissue from patients who undergo surgical treatment for brain tumors. However, for many other brain-related diseases, it is very difficult, and this has slowed the use of microarray-based technologies in the study of neurological and mental illnesses. Recently established human brain collections, such as the Stanley Foundation Brain Collection, which have collected and matched brains especially for gene expression profiling experiments, have already proven valuable. It seems that agonal status and the freezing of the tissue impact mRNA integrity more than postmortem interval does, and the mRNA in most regions of the brain appears to be surprisingly well preserved, at least up to 48 h postmortem. An essential requirement in

Figure 1 An overview of sample processing for microarrays. (1) First, a brain region or cells of interest are dissected. (2) Messenger RNA (mRNA) is extracted from the tissue/cells. (3) mRNA is converted to complementary DNA (cDNA) by a reverse transcriptase, and the resulting cDNA is converted back to RNA and labeled simultaneously. (4) Labeled RNA is then hybridized on a microarray, usually overnight. (5) Unbound probe is washed, and further staining is performed, depending on the type of microarray used. The signal intensities of bound probe are then read in a scanner. (6) The signal intensities of bound probe are then read in a scanner. A higher signal intensity generally means a larger number of the corresponding transcript in the original sample. Careful quality control assessment and statistical analysis are needed in order to determine the expression level of transcripts on the microarray. Pictures in 4–6 from www.affymetrix.com

studies using human brain samples is that a sufficient number of experiments be performed across multiple individuals and multiple tissue samples to account for individual variation due to age, sex, disease state, medication, and possible tissue inhomogeneity. This has been the major problem of most microarray studies of human brain tissue, and therefore interpretation of the results between different studies has been difficult. As studies of cancer have shown, it might be possible to use microarray profiling and cluster analysis to better define the subtypes of a given disease, identify target genes and pathways, predict optimal therapeutic interventions, and assess pharmacodynamic response. In the past few years, a growing number of studies have shed light on gene expression perturbations in various neurobiological diseases. The next sections provide an overview of some studies aiming to resolve the biology behind these complex brain diseases.

Recent Advances in Gene Expression Profiling of Behavioral Diseases

Alcoholism

Alcohol dependence is a complex disorder with an estimated lifetime prevalence of 10–15%. Genetic factors involved in alcoholism are largely unknown, but linkage and association studies have suggested the involvement of several genes in the etiology of alcoholism, such as alcohol dehydrogenases; cytochrome P-450, family 2, subfamily E, polypeptide 1; γ-aminobutyric acid receptor subunits; dopamine receptors; and serotonin receptors.

Several recent studies have investigated gene expression differences in various brain regions between individuals with alcoholism and controls. The most studied tissue has been the prefrontal cortex due to the most severe brain damage in this region in patients with alcoholism. Other profiled tissues include brain regions involved in reward and dependence, such as other mesolimbic brain structures. These studies have consistently found altered expression of genes involved in myelination, trafficking, ubiquitination, mitochondrial function, cell adhesion, and apoptosis. One recent study of 14 people who were alcoholic and 13 controls suggested that relatively small expression changes in the frontal cortex of brains of alcoholics are quite consistent across individuals and likely represent important alcohol-responsive genes. It is interesting that some of the differentially expressed genes in alcoholism studies are the same as those identified in Alzheimer's disease (AD), and others are the same as those identified in schizophrenia, suggesting that

these genes perhaps are involved in more-general brain malfunction.

Alzheimer's Disease

AD accounts for the majority of dementia in the older population. By means of linkage analysis in pedigrees with several affected individuals, genes predisposing to early-onset familial AD have been described: amyloid-β precursor protein (APP), presenilin 1, and presenilin 2. Also, one risk factor, the ApoE4-ε4 allele of the apolipoprotein E gene, has been described in late-onset AD. However, variation in these four genes accounts for only a fraction of the total genetic predisposition to AD.

In recent years, several studies have used microarrays to examine gene expression changes in brain aging and AD. Results from these studies, which have used both animal models and postmortem human brain tissue, vary considerably, which is not surprising given the variability in microarray platforms, statistical approaches, and tissue studied. However, these studies have identified some common pathways that might regulate brain aging and related pathological processes in both rodents and humans. There is an encouraging overlap between findings of microarray studies and pathological processes identified with more conventional neurobiological methods. Most microarray studies of brain aging have been performed in rodent models. Essentially all have found altered expression of genes related to inflammatory responses, oxidative stress, mitochondrial dysfunction, and glial processes.

The microarray studies of human postmortem AD brain tissue have compared either AD-affected brain structures across AD patients and matched controls or affected and unaffected tissue across AD patients and controls. Some studies have looked at early stages of disease, and others have concentrated on advanced stages. The results suggest downregulation of transcripts whose protein products are associated with neuronal function and upregulation of messages functioning as transcription factors and tumor suppressors.

Transgenic animal models for genes that are associated with AD show many characteristics similar to those seen in human AD patients. Microarray studies of these models (presenilin 1 and 2 and APP) have suggested changes in the expression of genes related to inflammatory response, lysosomal function, transcription machinery, synaptic or intracellular signaling, cell growth, extracellular matrix/cytoskeletal elements, energy transduction, and protein degradation, among others. It has been postulated that many of these changes relate to disorganization of the synaptic structure of extant neurons or loss of neurons. This dysfunction in the neuronal compartment might be accompanied by glial activation and inflammatory processes. Overall, microarray studies have provided new systems-level information about normal and pathological aging of the brain and have provided testable hypotheses for future functional studies.

Autism

Autism is a severe neurodevelopmental disorder with a prevalence of 10–20 per 10 000. Autism is the most severe form of a broad group of disorders known as autism spectrum disorders, which include also milder conditions such as Asperger syndrome, disintegrative disorder, and atypical forms of autism. Twin and family studies have repeatedly and unequivocally indicated a strong genetic component in autism spectrum disorders, but the underlying genetic mechanisms are still largely unknown.

Three studies investigating gene expression profiles of autism have been published to date. One of them studied mRNA extracted from cerebellum of ten patients with autism and 23 controls. Of the 30 genes differentially expressed between the patients with autism and the controls, the glutamate receptor system was targeted for further analysis. It was shown that the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid-type glutamate receptor density was decreased in the cerebellum of individuals with autism. The two other studies investigated gene expression profiles from lymphoblast cell lines. There is emerging evidence that the presence of chromosomal abnormalities may play a significant role in the etiology of autism, and chromosome 15 duplication in particular accounts for $\sim$1–3% of autism cases. Gene expression profiling in ten cell lines with the duplication and nine control cell lines revealed 112 genes that were differentially expressed between these two groups, including genes in several functional categories associated with macromolecular catabolic processes, especially the ubiquitin-dependent protein catabolism category. Another recent study of lymphoblast cell lines looked at gene expression differences between five pairs of monozygotic twins discordant or concordant for autism. Global analysis of the significantly differentially expressed genes based on functional classes identified genes involved in nervous system development and function as significantly enriched across the five gene expression data sets. It is interesting that *in silico* mapping of the most differentially expressed genes across as well as within the twin sets demonstrated that many of these genes are located in or close to chromosomal regions previously identified as autism susceptibility loci by genetic analyses. Even though the

sample sizes of these studies have been low, these initial experiments show that microarray analyses can identify interesting new candidate genes that might help investigators understand the pathogenetic mechanisms of autism.

Bipolar Disorder

Bipolar disorder (BPD) is a common psychiatric disorder of adulthood affecting about 1% of the population. It is characterized by episodes of abnormal mood (mania or hypomania and depression). Family and twin studies have demonstrated the importance of genetic factors in the etiology of BPD but have also suggested multifactorial inheritance. Several genomewide screens have been performed in families with multiple affected family members. Encouragingly, some chromosomal regions have been implicated in several studies, and specific susceptibility genes are being identified.

A growing number of microarray studies have compared postmortem brain tissue of patients with BPD and controls. The profiled regions include hippocampus, dorsolateral prefrontal cortex, and orbitofrontal cortex, all of which have been implicated in the pathogenesis of BPD. Lymphoblast cells from patients with BPD have also been profiled. Many of the studies have used samples from the Stanley Foundation Brain Collection. Comparison of results from different studies has been difficult because of slightly different diagnostic classification, statistical analysis methods with varying covariates, and different microarray platforms. However, several interesting processes that might be involved in the pathogenesis of BPD have been identified, such as mitochondrial dysfunction, regulation of oligodendrocytes and myelination, cell growth and development of the nervous system, apoptosis, the ubiquitin–proteasome pathway, regulation of synaptic function, G-protein-coupled receptor signaling, and immune response. As in the case of other diseases discussed in this article, it remains to be determined how these various processes coordinately contribute to the pathogenesis of BPD, which gene expression changes are causal, and which are reactive.

Major Depression

Major depression (MD) is one of the most common mental disorders, with a lifetime prevalence of at least 10%. Heritability based on twin studies is 40–50%, suggesting that it is a complex disorder with genetic and environmental risk factors. The potent environmental risk factors include childhood abuse and neglect and stressful life events. As in the case of other psychiatric disorders, genetic linkage and association studies have identified some susceptibility genes for MD, but replications of the results have been rare. However, one of the recent meta-analyses has shown that serotonin transporter gene polymorphism may be associated with MD. Other suggested susceptibility genes include serotonin 2A receptor, tyrosine hydroxylase, tryptophan hydroxylases 1 and 2, catechol-o-methyltransferase (COMT), and brain-derived neurotrophic factor.

A recent study investigated gene expression profiles of three brain regions, the orbital cortex, the dorsolateral prefrontal cortex, and the motor cortex in French Canadian individuals. The study included 24 people who had committed suicide, of whom 16 had a diagnosis of MD and eight did not. In addition, 12 controls were included. Twenty-six genes were differentially expressed between patients and controls, and one of these, spermine/spermidine N^1-acetyltransferase (*SSAT*), was targeted for further studies. The expression difference has been confirmed with other methods. It is interesting that an association analysis of genetic markers in the gene coding for *SSAT* revealed evidence of association in an independent cohort of males who had committed suicide. Therefore, this study suggests that SSAT, the rate-limiting enzyme in the catabolism of polyamines, might have a role in the predisposition to suicide and depression. Another recent study looked at gene expression profiles of eight patients with MD, six with BPD, and seven control individuals. The brain regions studied included anterior cingulate cortex and dorsolateral prefrontal cortex. Altered expression of a specific subset of genes encoding the glial high-affinity glutamate transporters, glutamate-ammonia ligase, and various subunits of glutamate receptors and γ-aminobutyric acid receptors was found in patients with MD compared with controls. Altered expression of fibroblast growth factor system-related genes in MD patients was also observed in this data set.

Schizophrenia

Schizophrenia is a severe and debilitating mental disorder characterized by so-called positive (psychotic) and negative (low levels of emotional arousal, mental activity, and social drive) symptoms. In general, the lifetime prevalence of schizophrenia is thought to be between 0.5% and 1.0%, but some geographical variation occurs. The evidence for a genetic predisposition to schizophrenia has been obtained from family, adoption, and twin studies. However, despite the effort of numerous groups, only a few susceptibility genes have been found by linkage analysis in families with several affected individuals. Genes that have been independently identified in several studies

include disrupted in schizophrenia 1, dystrobrevin binding protein 1, neuregulin 1, and D-amino acid oxidase activator, among others. In addition, multiple promising chromosomal loci have been found that are likely to harbor genes predisposing to schizophrenia.

With regard to gene expression profiling, schizophrenia is clearly the most extensively studied mental disorder. In the past few years, more than 30 reports have been published on gene expression profiles studied in either postmortem brain tissue or blood cells. As discussed above, there are many confounding factors that make the comparison of the different studies difficult, and the number of replicated findings is small. However, several well-replicated findings have emerged: dysregulation of genes involved in the function of mitochondria and energy metabolism, altered expression of genes that control oligodendrocyte function and myelination, and decrease of presynaptic markers. It is interesting that several genes in these pathways, not just single genes, show altered expression in schizophrenia patients. On the other hand, these changes do not seem to be specific for schizophrenia as patients with BPD or MD show similar alterations in brain gene expression patterns. It is encouraging that some genes that have been found differentially expressed between schizophrenia patients and controls, such as PDZ and LIM domain 5 and regulator of G-protein signaling 4, have also revealed evidence of genetic association.

Gene Expression Profiling of Mouse Brain Tissue

Progress in understanding the neurobiology of behavior has increased rapidly in recent years as result of several major advances, most notably advances in mouse genetics. The rapid pace at which new genes are being identified, the availability of the DNA sequence for several mouse strains, the extensive analysis of inbred strains of mice, and the use of induced mutations have created new tools for investigating the molecular and genetic basis of behavioral phenotypes. Highly parallel gene expression approaches allow one to look at the global interactions of genes and modifiers and their effects and will greatly enhance our ability to define the role of developmental alterations, mutations, and compensatory mechanisms in causing or modifying particular behaviors. Behavioral testing combined with microarray profiling has proven to be a powerful approach to identifying genes regulating mouse behaviors. Since the basic neuronal mechanisms are shared across mammalian species, the same set of genes likely regulates critical aspects of behavior in humans and mice. The advantage of studies in mouse is that when strict procedures are applied during animal and tissue handling, sample preparation, and array hybridization, overall assay variability can be minimized, and the false-positive rate can be kept extremely low. The drawback of using animals as models for human behavioral phenotypes is that it requires a well-characterized animal model for a given disease, and such models do not exist for many psychiatric diseases, such as schizophrenia. However, individual components of complex diseases can be studied separately, and in the case of schizophrenia, this has been done by studying prepulse inhibition (PPI). PPI is the suppression of the normal response to a startling stimulus when that stimulus is immediately preceded by a weak prestimulus or prepulse. PPI, measured using acoustic startle, differs between patients with schizophrenia and controls as well as among different inbred mouse strains. For some behavioral phenotypes, such as anxiety and substance abuse, animal models have been well characterized and widely used.

The advantage of working with mice is that the animals can be handled and the tissue dissections performed systematically and consistently. This consistency is extremely important in order to minimize sample-to-sample variation. Brain dissections can be performed by hand, by means of a sophisticated dissection microscope and very fine dissection tools, or by laser capture microdissection. It is important to dissect the exact anatomical structure of interest. Inclusion of too much additional material might 'dilute' a weak expression difference seen between two regions, and failure to include all small subnuclei might cause important differences to be missed. As in the case of human RNA, it is important to use stringent quality control measures at all steps of the procedure, from RNA extraction to the analysis of hybridized arrays.

Mouse Gene Expression Studies of Behavioral Phenotypes

Numerous transgenic mouse models show differences in behavioral phenotypes. Gene expression profiling of the brain tissue from these models has helped reveal molecular pathways affected by the transgene expression. However, this article concentrates on the genetic variation across a number of inbred mouse strains because it provides an excellent model to correlate various complex phenotypes with brain transcript levels in a genomewide unbiased manner. The involvement of the identified genes in behavior can then be studied further by means of various methods (Figure 2).

Figure 2 A gene expression-based approach to identifying genes involved in the regulation of behavior. (a) First, behavioral testing is carried out across inbred mouse strains to determine their phenotype (e.g., anxiety level). (b) Brain regions that regulate the behavior are dissected from the same strains. Messenger RNA extracted from the tissue is hybridized on a microarray to determine expression levels of all genes. (c) Statistical analyses are carried out to identify genes with an expression pattern that correlates with the behavioral phenotype across the strains. (d) The involvement of the candidate genes in behavior can be further studied by manipulating the gene expression and/or protein level(s) in mouse. (a–c) Reproduced from Hovatta I, Tennant RS, Helton R, et al. (2005) Glyoxalase 1 and glutathione reductase regulate anxiety in mice. *Nature* 438: 662–666.

Inbred mouse strains vary with regard to many behavioral phenotypes, such as anxiety, learning and memory, activity, alcohol preference, aggression, and PPI. Since animals within one inbred strain are genetically identical, interstrain differences result from genetic differences between the strains. Investigators have proposed combining behavioral testing in inbred mouse strains with gene expression profiling to find candidate genes for behavioral phenotypes. Gene expression differences that correlate with a given phenotype might be causal (i.e., directly regulate the phenotype in question) or reactive (i.e., are secondary changes due to the primary genetic defect). Causal genes can be directly tested as susceptibility genes for a given phenotype, and reactive changes may help illuminate the pathogenesis of the disease. Several groups are currently developing statistical methods to distinguish between these possibilities by combining single-nucleotide polymorphism (SNP) genotyping and gene expression profiling in populations that segregate the phenotype of interest.

In one recent study, gene expression profiles from the hippocampus of eight inbred mouse strains were compared with aggression phenotype from the Mouse Phenome Database, where information regarding many different phenotypes across several inbred mouse strains has been collected. It is interesting that the gene with an expression pattern across the strains that correlated most significantly with the aggression behavior was COMT. In humans, it has been shown that individuals with lower levels and activity of COMT are generally more aggressive than people who have an allele associated with higher activity.

Gene expression profiles of six inbred mouse strains have also been correlated with anxiety-related behavior measures from two behavioral tests, and follow-on functional studies have proven causality of a subset of identified genes. First, anxiety-related behavior of six inbred mouse strains was assessed through two pharmacologically validated behavioral tests. Concurrently, seven brain regions (amygdala, bed nucleus of the stria terminalis, cingulate cortex, hippocampus, hypothalamus, periaqueductal gray, and pituitary gland) that are known to regulate some aspects of anxiety were dissected from the same strains. The mRNA extracted from these tissues was hybridized on microarrays, and 18 genes with an expression profile that correlated significantly with the behavioral phenotype were identified. Further efforts concentrated on two of these genes: glyoxalase 1 and glutathione reductase 1, which are expressed at

a higher level in anxious mouse strains than in nonanxious ones. Both of these genes code for enzymes that are involved in the regulation of oxidative stress. Functional analyses using lentivirus-mediated gene transfer to overexpress or silence these genes in the cingulate cortex of anxious 129S6/SvEvTac mice or nonanxious C57BL/6J mice have shown that both these genes regulate anxiety-related behavior in mice. This study shows that inbred mouse strains differ markedly in behavioral phenotypes and that these differences are partially due to gene expression differences of genes regulating the phenotype. Moreover, these expression changes can be detected from appropriate brain regions by gene expression profiling.

Conclusions and Future Directions

In recent years, gene expression profiling has become one of the strongest methods for revealing the molecular basis of many neurobiological diseases. In studies with postmortem brain tissue, several new pathways have already been implicated in the pathogenesis of neurobiological diseases. It is interesting that many gene expression changes seem to be common to a group of brain diseases, while some changes are specific to individual conditions, perhaps as would be expected as some of these diseases share a subset of clinical symptoms. Many groups have also investigated gene expression profiles of blood cells from patients with various behavioral disorders. Even though only a small fraction of genes that are differentially expressed in the relevant brain region for the disease are expected to be differentially expressed in the blood, several groups have started to investigate whether blood-based gene expression profiling could be used as a diagnostic test for neurobiological disorders. It is assumed that some of the pathological changes in the brain are reflected in the blood as well and that this information could be used to classify patients into subgroups, much as in the case of various cancers.

However, simply measuring gene expression may not be enough to unravel the molecular underpinnings of a complex behavior or a disease state. Taking advantage of an increasing amount of DNA sequence information in the context of data sets on gene expression enables investigators to combine expression studies with sequence analysis and to move from phenomenology to causation. Since the sequences of the human and mouse genomes are known, it is relatively simple to look at the SNPs in the coding regions of the differentially expressed genes and identify SNPs that may either directly or indirectly lead to the expression differences. However, little is known about *cis*-acting elements outside the coding regions of the gene or *trans*-acting elements that regulate gene expression levels, and identification of such SNPs is time consuming. New approaches to solve these methodological shortcomings have been developed recently and should help in identification of susceptibility genes for complex diseases.

With large amounts of gene expression data emerging from various neurobiological studies, it is important to consider how to store and share the data. Clearly, a large database that would enable efficient sharing of data between laboratories would be desirable, but is difficult to realize in practice, as different studies have used widely varying sample collection procedures and microarray platforms, as discussed in this article. Moreover, there will be a need to incorporate data from other sources, such as SNP genotyping or proteomic or epigenetic experiments, in the same database with gene expression data. Combined analysis of genomewide data should lead to testable hypotheses about pathogenetic mechanisms of behavioral traits.

Genetic Regulation of Circadian Rhythms in *Drosophila*

R Allada, Northwestern University, Evanston, IL, USA

Drosophila Circadian Rhythms and the *period* Gene

The fruit fly, *Drosophila melanogaster*, is one of the preeminent genetic model organisms for the study of circadian rhythms. Because of its short generation time, the ease of screening large populations of mutant animals, its century long history of development of genetic and molecular tools and ultimately its conservation with higher organisms, especially humans, the fly has played an important role in both the discovery of new circadian rhythm genes and more importantly, the revelation of underlying principles in clock function. In the premolecular age, *Drosophila* had been used as a model for defining fundamental properties of circadian rhythms. Indeed, the genus name *Drosophila* comes from the Latin meaning 'dew loving' derived from the rhythm of eclosion (emergence of the adult from the pupal case) in the morning. The molecular era can be traced to behavioral genetic screens initiated by Seymour Benzer during the late 1960s and early 1970s. Benzer believed that the same genetic approaches used to elucidate the basic principles of cell and molecular biology could be used to analyze animal behavior. Among many behavioral screens, his laboratory screened for mutants that eclosed at different times of day. Three mutants were identified: one with short-period rhythms, one with long-period rhythms, and one with no discernable period. These mutants also displayed altered locomotor activity rhythms, the assay most commonly used today to monitor circadian behavior. All three mutants mapped to a single locus they termed *period* (*per*). Unfortunately the cloning of the *per* gene during the 1980s failed to immediately reveal underlying clock mechanisms. Ultimately, studies of the *per* transcript demonstrated daily oscillations in levels, and mutations in the *per* coding sequence that alter behavioral period length alter the period length of these molecular oscillations in a parallel manner. This led to the notion of a transcriptional feedback loop in which PER protein must feed back and regulate its own transcription to generate circadian oscillations that can persist even in the absence of any environmental cue. Studies in many organisms, including mammals, have identified similar transcriptional feedback loops at their core, suggesting that such loops are a conserved aspect of circadian clock function.

In addition to oscillatory transcription, PER was also found to undergo rhythms in protein levels, phosphorylation, and nuclear localization. As for transcript oscillations, circadian oscillations at the protein level have been defined subsequently in the core clocks of many other organisms. PER is not only found in the central nervous system (CNS) but in many other neurons and non-neuronal tissues, helping establish the notion of peripheral clocks (those outside the CNS). Indeed, most organs in mammals are known to harbor circadian clocks. Thus, studies of the *per* gene in *Drosophila* have elucidated many of the operating principles that have been subsequently found among circadian clocks throughout nature. Indeed, circadian gene discovery in the fly has often led to the discovery of new components and underlying mechanisms in mammalian, even human, circadian clock function.

The Molecular Circadian Pacemaker of *Drosophila*

Transcriptional Feedback

The transcriptional activators: CLK and CYC Early molecular studies demonstrated that the *per* gene is a central element of a transcriptional feedback loop that generates circadian rhythms in *Drosophila*. The positive elements of this loop are the transcription factors CLOCK (CLK) and CYCLE (CYC; Figure 1). These two transcription factors are members of the basic helix-loop-helix PAS family of transcription factors. Of note, PER is one of the three founding members of this family, with aryl hydrocarbon nuclear translocator (ARNT) and single-minded (SIM). CLK and CYC form a heterodimer that binds tightly to a DNA motif called the E-box (CACGTG) to activate transcription. An E-box is present in the *per* gene and is responsible for the circadian control of its transcription. Flies carrying inactive or null alleles of *Clk* and *cyc* express very little *per* and *tim* transcripts and are behaviorally arrhythmic. Thus, CLK and CYC are obligate heterodimers, at least for circadian rhythms.

The transcriptional repressors: PER and TIM The molecules responsible for blocking the activity of the CLK/CYC dimer are PER and its heterodimeric partner TIM (Figure 1). As for *per*, flies with a null mutation in the *tim* gene are arrhythmic. *tim* transcription

Figure 1 A model for the molecular circadian pacemaker in *Drosophila*. In the early night (a), the *per* and *tim* genes are actively transcribed under the positive influence of the transcription factors CLK and CYC. PER and TIM dimerize and begin to be phosphorylated in the cytoplasm. SGG phosphorylates TIM, CK2 and DBT phosphorylate PER, while PP2A counteracts the effect of these two kinases. In addition, DBT also associates durably with PER. In the early morning (b), PER and TIM are mostly nuclear, and highly phosphorylated. PER binds to the CLK/CYC dimer and reduces its affinity for the E-box, possibly with the help of DBT. This results in the repression of PER and TIM expression and the closing of a first transcriptional feedback loop. To restart the cycle, PER and TIM must be eliminated. PER and TIM degradation begins during the second half of the night. Hyperphosphorylated PER is targeted for proteasomal degradation by the E3 ubiquitin ligase SLIMB. TIM is also degraded, but the mechanism of its degradation is not clear. When the flies are exposed to light (b), the blue-light photoreceptor CRY is activated by light, binds to TIM, and greatly accelerates its proteasomal degradation. PER degradation is also accelerated since PER is no longer protected by TIM. Importantly, light is not required for this feedback loop to generate and maintain its circadian oscillations, but it is important to reset properly the phase of these oscillations every day. In addition, a second transcription loop controls CLK expression. In the early night, the *clk* gene repressor VRI, whose circadian expression is controlled by CLK, is highly expressed, while the circadian expression of the *clk* activator PDP1, also regulated by CLK/CYC, has not peaked yet. As a result, *clk* expression is low. However, at the end of the night and the early morning, PDP1 dominates and CLK expression is high. The role of this second transcriptional loop is still mysterious.

is also circadianly regulated by CLK/CYC, and TIM protein levels oscillate robustly during the day and night. TIM is thus an integral part of the transcriptional feedback loop that generates circadian oscillations.

While PER and TIM are heterodimeric partners, it is likely that PER is playing the dominant role in repressing CLK/CYC-activated transcription. PER and TIM are believed to repress transcription by reducing the affinity of CLK/CYC for the E-box. In the pacemaker neurons controlling circadian behavior (the LNv, see below), PER enters the nucleus before TIM. Moreover, PER does not need TIM to translocate into the nucleus when expressed at a high level. Finally, it appears that PER can inhibit transcription independently of TIM in a cell culture assay. The principal role of TIM appears to be protecting PER from proteasomal degradation, rather than a biochemically direct role in repressing transcription.

The precise mechanism by which PER represses CLK/CYC remains unclear. PER forms complexes with CLK/CYC and the formation of this complex coincides with a reduction in the binding of CLK/CYC to E-box DNA *in vivo*. Although PER and CLK/CYC share a PAS dimerization domain, this PAS domain does not appear to be required for PER repression of CLK. It is noteworthy that over 30 years after the isolation of the original short- and long-period alleles of *per*, we still do not have a clear explanation of how PER works and the molecular basis of these short- and long-period phenotypes.

In summary, the current model for the transcriptional loop involves four transcription factors: two

transactivators, CLK and CYC; and two repressors, PER and TIM (Figure 1). This 24 h feedback loop has turned out to be remarkably conserved in the animal kingdom. Homologs of CLK, CYC, and PER are also involved in the transcriptional feedback loop that generates circadian rhythms in mammals, but TIM's function in the mammalian clock is not yet clear.

In mammals, mammalian cryptochromes (*crys*) rather than *per*s are the primary transcriptional repressors of the CLK/CYC orthologs mClock and Bmal1. In flies, CRY is a circadian photoreceptor (see below) that is not required for circadian oscillations. Nevertheless, fly CRY does support robust rhythms in constant conditions in the antennae (the main olfactory organ) and the Malpighian tubules (insect kidneys). Moreover, in the eyes, CRY can repress CLK/CYC activation, although it is not required for the circadian oscillations of PER and TIM proteins. Interestingly, several non-drosophilid insects have two cryptochromes: one homologous to mammalian CRYs that represses CLK/CYC-mediated transcription and the other that resembles the photoreceptive *Drosophila* CRY. It therefore appears that drosophilids lost the repressive CRY during evolution, and that the photoreceptive CRY adopted some repressor activity.

The *Clock* Loop

In addition to *per* and *tim*, the CLK/CYC dimer activates multiple genes including the transcriptional activator PDP1 and the repressor VRILLE (VRI; Figure 1). These transcription factors, in turn, bind to the same DNA motif in the *Clk* promoter. Interestingly, the concentration of both factors oscillates but with distinct phases, with VRI peaking a few hours earlier. The differential oscillation in activator and repressor results in coordinated circadian oscillations in transcription of *Clk*. The function of this second transcriptional feedback loop remains uncertain. It is clear that this loop is not necessary for generating circadian rhythms, since flies in which *Clk* is overexpressed under the control of the *per* promoter display essentially normal circadian rhythms. Since very similar feedback loops are also found in mammals and fungi, it suggests that interlocked feedback loops are important for the circadian systems.

Posttranslational Regulation

Rhythmic protein phosphorylation appears to be a ubiquitous feature of core circadian clocks. There are accumulating data suggesting that rhythmic protein metabolism may not require rhythmic transcription and indeed may even drive rhythmic transcription. Rhythmic PER and TIM oscillations still occur even when they are driven by constitutive promoters. In cyanobacteria, rhythmic protein levels and phosphorylation persist in the absence of rhythmic transcription. A 24 h phosphorylation cycle can even be reconstituted *in vitro* using purified cyanobacterial clock proteins and ATP. These data suggest that transcriptional feedback may be dispensable and thus, may not be a central feature of the clockwork. On the other hand, these studies highlight a potential dominant role for rhythmic phosphorylation in driving circadian timing. Consistent with this hypothesis, the strongest period-altering alleles are of *per*, *tim*, and their associated kinases.

At least three protein kinases have been defined as important players in terms of period length: DOUBLETIME (DBT), the fly ortholog of CK1ϵ; Shaggy (SGG), the fly ortholog of glycogen synthase kinase 3 (GSK3); and casein kinase 2 (CK2; Figure 1). Taken together, these kinases modify the activity, subcellular localization, and stability of core clock components. In the case of PER and TIM, rhythmic phosphorylation has been assessed by Western blotting and observation of mobility shifts that can be reversed by phosphatase treatment. In both cases, disappearance of the proteins coincides with peak levels of phosphorylation, suggesting that phosphorylation serves as a signal for protein degradation.

DBT phosphorylation of PER is a key element in circadian timekeeping. *Dbt* orthologs (CK1δ and ε) also function in mammalian, including human, clocks. The most potent dominant period-altering alleles have been identified in *Dbt*, suggesting an important role in setting period length. Surprisingly, both short- and long-period alleles appear to reduce the DBT catalytic activity. In *Dbt* null mutant larvae, PER accumulates to very high levels in a hypophosphorylated state, while *per* mRNA is not strongly affected, suggesting that DBT destabilizes PER. Moreover, DBT can induce PER phosphorylation and degradation in cultured cells and DBT co-immunoprecipitates with PER *in vivo*, suggesting that PER is an *in vivo* DBT substrate.

DBT-induced phosphorylation of PER likely triggers its degradation by the ubiquitin proteasome system. Accumulation of hyperphosphorylated PER and TIM is typically followed by their degradation. In mutants of the E3 ubiquitin ligase, *supernumerary limbs* (*slimb*), these forms of PER and TIM accumulate. Moreover, SLIMB directly interacts with PER and DBT. Cell culture experiments suggest that SLIMB may specifically interact with DBT-phosphorylated PER, and thus signal its ubiquitination and subsequent proteasomal degradation.

DBT may also mediate negative feedback of PER onto CLK/CYC. Knockdown of DBT in tissue culture cells reduces PER repression of CLK activation. Indeed, DBT may also phosphorylate and destabilize CLK. Moreover, this phosphorylation may depend on PER. Thus, PER repression of CLK activation may be mediated through DBT phosphorylation of CLK. This is analogous to fungal clocks where changes in phosphorylation may mediate rhythmic repression of transcriptional activators.

CK2 and SGG are two kinases that phosphorylate PER and TIM, respectively and promote their translocation to the nucleus (Figure 1). The timing of TIM and PER nuclear translocation is delayed in long-period *sgg* loss-of-function mutants. Of note, *sgg* overexpression can increase TIM phosphorylation even in per^{01} mutant flies and can phosphorylate TIM *in vitro*, suggesting direct effects of SGG on TIM. Interestingly, GSK3 is also a target of lithium, a therapeutic agent for bipolar depression. Evidence suggests that defects in the circadian clock may contribute to bipolar disorder.

The CK2 holoenzyme is a heterotetramer consisting of two catalytic α subunits and two regulatory β subunits. Mutations that disrupt α- or β-function result in long-period behavioral rhythms. Both subunits are cytoplasmic in pacemaker neurons and the transition of PER from cytoplasm to nucleus is delayed in CK2 mutants. CK2 increases PER phosphorylation *in vivo* and can specifically phosphorylate PER *in vitro*. *In vivo* mutation of CK2 phosphorylation sites in PER recapitulates many aspects of CK2 mutants. These data implicate CK2 in phosphorylating PER in the cytoplasm and signaling its entry into the nucleus.

Both SGG and DBT are kinases that recognize and phosphorylate previously phosphorylated recognition sequences. The imposition of a requirement of prior phosphorylation for subsequent phosphorylation may introduce the necessary time delays to produce a 24 h phosphorylation rhythm. In this model, the phosphorylation of target substrates such as PER and TIM would be greatly facilitated by other kinases that prime their phosphorylation. The identity of the priming kinase is unknown.

A phosphatase that may mediate rhythms in phosphorylation state is PP2A (Figure 1). PP2A consists of three subunits: structural, regulatory, and catalytic. Two genes encoding regulatory subunits, *wiederborst* (*wdb*) and *twins* (*tws*) both appear to play a role in rhythms. Genetic manipulation of *wdb*, *tws,* and the catalytic subunit, *microtubule star* (*mts*), indicates that PP2A both stabilizes and promotes nuclear localization of PER. PP2A efficiently dephosphorylates DBT-induced PER phosphorylation, suggesting that PP2A may specifically antagonize this kinase. One of the transcripts of the regulatory subunit *tws* is clock-regulated. As none of the kinases thus far exhibit daily rhythms in activity or expression, rhythmic *tws* expression and consequent rhythms in PP2A activity may drive daily rhythms of PER phosphorylation. In this model, the 24 h posttranslational rhythm of PER phosphorylation and degradation is driven by the delicate balance between kinase and phosphatase action.

Synchronization of the *Drosophila* Circadian Clock

The period of circadian clocks only approximates 24 h. Therefore, circadian clocks need to be reset every day to remain synchronized with the environment. In *Drosophila*, three inputs are known to synchronize the clock: light, temperature, and social cues.

The Dedicated Circadian Light Input Pathway

The circadian clock responds quickly to light exposure. Light pulses as short as 1 min can shift the phase of circadian locomotor activity by 4 h. If the pulse is applied early during the night, the result will be a phase delay, while if it is applied late it will be a phase advance. The molecular correlate of this behavioral response to short light pulses is the proteasomal degradation of TIM, which will subsequently result in the reduction of PER levels, since TIM protects PER from degradation.

The photoreceptor responsible for TIM degradation is CRYPTOCHROME (CRY), a member of a family of blue-light sensitive proteins (Figure 1). Light pulses during the early night (when TIM levels are rising) delay TIM accumulation, resulting in delayed rhythms, while light pulses during the late night (while TIM levels are falling) accelerate TIM disappearance, advancing rhythms. While CRY binds directly to TIM, it is unknown how this event triggers TIM degradation.

CRY is expressed in almost all neurons and non-neuronal peripheral tissues that contain circadian clocks. Remarkably, these isolated peripheral organs can be synchronized to external light–dark cycles. In addition, flies that express CRY only in the pacemaker neurons controlling circadian behavior can respond to short light pulses behaviorally, but their peripheral clocks (with few exceptions, see below) remain blind, suggesting that CRY operates cell-autonomously. Of note, mammalian peripheral clocks do not appear to be able to synchronize to external light–dark cycles but rather respond to rhythmic humoral factors. Mammals are too large and opaque for light to reach internal organs, and thus the cell-autonomy of the light input pathway was lost during their evolution.

Other Light Input Pathways

CRY is not the only photoreceptor that can synchronize the circadian clock. Visual photoreceptive organs using rhodopsin as a photopigment (the eyes, the ocelli, and the Hofbauer–Buchner eyelets) can synchronize pacemaker neurons responsible for rhythmic behaviors in the absence of CRY. Nevertheless, in the absence of CRY, the phase of circadian behavior is not shifted by short light pulses and TIM is not acutely degraded, suggesting that CRY and rhodopsin synchronize the pacemaker by distinct mechanisms. However, the anatomic and molecular pathways by which visual input reaches the circadian pacemaker neurons are not clear. CRY-independent synchronization is also evident in some peripheral organs. In flies without functional CRY, the isolated antennae and the Malpighian tubules can still synchronize to external light–dark cycles. The nature of the photoreceptor, a rhodopsin or an as-yet-unidentified photoreceptor, remains unclear.

The utility of having different and partially redundant photoreceptor systems may be related to the fact that the spectrum of ambient light significantly changes during the sunrise and sunset. The combination of CRY and other photoreceptive organs may help the fly to monitor these changes in light spectrum, and thus more efficiently synchronize its circadian clock.

Nonphotic Environmental Cues That Synchronize the Circadian Clock

Temperature is an important synchronizing cue in animals, especially those that cannot maintain their own body temperature. The isolation of a mutant (*nocte*) with normal circadian light responses but insensitivity to temperature changes reveals a dedicated temperature input pathway in *Drosophila*. This pathway is likely cell-autonomous as dissected antennae or wings can be synchronized to temperature cycles. Nonetheless, the pace of the circadian pacemaker is protected from changes in ambient temperature, a phenomenon termed temperature compensation. A clock whose period changes with the weather would be useless. Since, the kinetics of biochemical reactions increase with temperature – usually doubling every 10 °C – there are compensatory mechanisms within the circadian pacemaker that prevent acceleration of the clock with increasing temperature. The mechanisms that underlie temperature compensation are unknown. While period is relatively insensitive to temperature, the phase of the circadian clock is temperature sensitive, perhaps mediating seasonal adaptations. A temperature-sensitive splicing in the 3′ untranslated region of *per* determines the phase of *per* mRNA and protein accumulation. Delayed PER accumulation at higher temperatures results in a later onset of behavioral activity in the evening, thus helping flies to avoid heat-mediated dessication during the middle of the day.

Olfactory social cues also influence circadian phase, suggesting the existence of a circadian pheromone. Surprisingly, when a small population of flies with a specific circadian phase is mixed with a larger population with a different phase, the larger population will shift its phase toward the phase of the smaller population, not vice versa.

Pacemaker Neural Network

Under 12 h light:12 h dark (LD) conditions, flies exhibit two peaks of activity, a morning peak around the time of lights-on and an evening peak around the time of lights-off. Flies anticipate each transition by increasing their activity, a process mediated by the circadian clock. Upon release into constant darkness (DD), flies continue to exhibit morning and evening peaks that gradually morph into a single broad peak of activity occurring approximately every 24 h.

Considerable progress has been made in understanding how these molecular oscillators function within cellular networks that control these rhythmic behaviors. There are roughly 200 neurons in the central brain that express core clock components. These can be subdivided into six main clusters: small ventral lateral neurons (sLNv), large ventral lateral neurons (lLNv), dorsal lateral neurons (LNd); and three groups of dorsal neurons (DN1, DN2, and DN3; Figure 2).

While molecular oscillators within these neurons largely keep time, network communication is essential to maintain synchrony between these intracellular clocks. The neuropeptide pigment dispersing factor (PDF) is a major synchronizing agent (Figure 2). PDF is selectively expressed in the LNv. The sLNv send dorsal projections toward the DNs. PDF is rhythmically expressed in these dorsal projections, presumably reflecting clock-controlled release. In addition, the lLNv send projections to their contralateral counterparts. Loss of *pdf* and its receptor *pdfr* result in changes in the core molecular oscillator of both PDF and non-PDF neurons. In the absence of PDF/PDFR, flies exhibit advanced timing of evening anticipation in LD and short (albeit weak) periods in DD. These behavioral changes are accompanied by changes in molecular oscillations within PDF and non-PDF neurons including phase advances, desynchrony, and reduced amplitude. Selective acceleration of the clock in the LNv speeds up the molecular oscillator in the LNd, DN1 and DN3 groups, strongly

Figure 2 The *Drosophila* pacemaker neural network. Top panel shows a schematic of the fly brain with small ventral lateral neurons (sLNv) indicated in orange, large ventral lateral neurons (lLNv) indicated in maroon, dorsal lateral neurons (LNd) indicated in yellow, and three groups of dorsal neurons (DN) indicated in green. The sLNv send projections dorsally and lLNv send contralateral projection. The ventral lateral neurons express the neuropeptide PDF. The bottom panel shows the locomotor activity behavior of a population of wild-type fruit flies. Location of morning and evening peaks is indicated. Cells that underlie morning and evening behavior are circled and indicated as M- and E-cells.

suggesting a role for PDF in resetting and synchronizing these other oscillators to the period set in the LNv. Of note, speeding up the oscillators of the non-PDF neurons does not drive faster behavioral or LNv rhythms, suggesting that the PDF neurons are at the top of a network hierarchy that controls circadian period.

Selective pacemaker neurons mediate morning and evening behavior. PDF is likely communicating to output neural circuits that ultimately drive morning behavior. *pdf*/*pdfr* mutants display little or no LD morning anticipation or DD morning peak. Of note, ablation of the PDF neurons have a similar phenotype suggesting that PDF is the principal LNv neurotransmitter, indicating that these cells are responsible for morning anticipation, acquiring the name 'morning cells.' Yet these large changes in morning behavior are not accompanied by similarly large changes in the molecular oscillators. These data suggest that PDF is playing a role downstream of the core oscillator to regulate morning behavior. In contrast to the role of the PDF neurons, the non-PDF neurons, particularly the LNd/DN1, are essential for evening anticipation and have been termed the 'evening cells.' In addition, they set the phase (but not period) of the evening peak relative to the morning peak under DD conditions.

In understanding the molecular mechanisms by which different circadian oscillators are synchronized requires elucidating how the core oscillator regulates neural outputs such as PDF and in turn, how PDF receptor signaling feeds back and resets target oscillators. Microarray studies have identified hundreds of rhythmically expressed transcripts, suggesting that clock-mediated regulation of transcription mediates clock outputs. One presumed neural target of clocks is membrane excitability. In a variety of systems, the function or activity of ion channels is under clock control. In flies, there is some evidence that clocks control resting membrane potential. Moreover, a novel voltage-gated ion channel, NARROW ABDOMEN, appears to play an important role in regulating pacemaker neuron output. Silencing of pacemaker neurons can abolish free-running rhythms suggesting an important role for membrane excitability in regulating core clock function.

Unlike most peripheral oscillators in *Drosophila*, molecular oscillators in the core pacemaker neurons exhibit long-term persistent rhythmicity in DD. Network connections between these neurons may serve to sustain rhythms in the absence of external cues. As loss of PDF results in altered neuronal oscillators, it suggests that PDF receptor signaling may play a role in synchronizing and sustaining core oscillators. Studies in heterologous systems demonstrate that the PDF receptor is coupled to $G\alpha_s$, assisted by the GTPase-activating protein, neurofibromatosis-1 (NF1), and its activation results in increases in cAMP-dependent gene transcription. In addition, calcium-dependent transcription is also promoted. However, the PDF-R signaling pathway still needs to be elucidated *in vivo*. In the mammalian circadian pacemaker, the suprachiasmatic nucleus (SCN), the neuropeptide, vasoactive intestinal peptide (VIP) plays an analogous role to PDF in synchronizing circadian neurons. Thus, the similarity between the mechanisms generating circadian rhythms in *Drosophila* and mammals is not limited to the molecular pacemaker, but also includes the neural network controlling circadian rhythms.

Circadian Rhythms in Mammals

As terrestrial beings living on a planet with an axial rotation of about 24 h, giving rise to rhythms in light and darkness, almost all living organisms display circadian rhythms in their behavior. It is this near-24 h, period that gives the name 'circadian' or 'about a day' to the system. In mammals the circadian timing system, or biological clock, is located in the suprachiasmatic nuclei (SCN) of the hypothalamus. This circadian pacemaker synchronizes many physiologic processes to cyclic changes in the external environment and also maintains the temporal organization of these processes to each other. The daily light and dark cycles entrain the circadian system which signals the appropriate time for activity and rest. The circadian activity/rest rhythm as well as other physiological, biochemical, and molecular processes are synchronized to the external environment in response to changes across the 24 h day. From an evolutionary viewpoint, this kind of circadian organization creates specific temporal groups of animals sharing times of the day in which to do certain activities, for example, diurnal or nocturnal. This may have developed in organisms in response to several needs: food, search for prey, protection from predators, and reduced competition for resources in a physical environment.

Although humans are diurnal animals, preference for certain times of the day, or chronotype, varies among individuals. Some people prefer activity in the early part of the day; others prefer night-time activity, while still others have no preference. Early types have been described as larks and late types as owls. Subjective measures of diurnal preference by questionnaire have been used to assess the morningness or eveningness of individuals for several decades, driven in large part by the desire to identify workers' abilities to adjust to changing work schedules such as shift work. A number of studies have shown that diurnal preference has, in part, a genetic basis yet there are certainly environmental, social, and behavioral influences on the preference for sleep/wake schedules. Different subjective chronotypes have been associated with objective measures of circadian rhythms, including body temperature and hormonal rhythms. Diurnal preference has also been correlated to a sleep/wake pattern and performance measures.

The expression of circadian behavior is also, in part, genetically determined. The first circadian mutant mammal identified, the *tau* mutant hamster, has a shortened endogenous period compared to the wild-type hamster. This altered circadian period of locomotor activity was seen in the offspring of mutant animals demonstrating the heritability of circadian behavior and was eventually associated with a specific genetic mechanism. The identification of other mammalian circadian mutants that show heritability of their altered circadian rhythms has led to the identification of circadian genes that comprise the molecular mechanism for the generation of circadian rhythms. Homologs of these circadian genes have been identified in numerous species, including humans, showing a remarkable conservation of the molecular mechanisms of the circadian pacemaker. Evidence in different model systems shows that circadian timing is regulated transcriptionally, translationally, and post-translationally by genes that make up the clock mechanism. They form autoregulatory feedback loops that drive the essential cycling patterns of daily rhythms and mutations in these genes result in alterations or abolition of properties of circadian rhythms.

Circadian Rhythm Sleep Disorders

Sleep is a physiological and behavioral state that is necessary for life and highly conserved in numerous species. There are several theories about the function of sleep and it appears likely that it fulfills multiple functions. It is also possible that sleep served one primordial function necessary for survival and that multiple purposes evolved. Moreover, the lower threshold for arousal that occurs during sleep, putting an organism at great risk, reflects its essential function. Sleep loss impacts general health, mood, and cognitive function. Results from acute and chronic sleep deprivation studies have shown that the consequences of sleep loss on health, determined by a number of physiological and endocrine measures, and cognitive function, assessed on several performance tasks, are severe and detrimental. In fact, the result of near-total sleep deprivation in rat models is death in about 3 weeks.

For optimal sleep, the desired sleep time should coincide with the timing of the circadian rhythm of sleep propensity. A misalignment between sleep and the 24 h social and physical environment results in circadian sleep/wake cycle disruption and circadian

Figure 1 Circadian rhythm sleep disorders. The colored bars represent the sleep pattern for each type and the gray areas represent typical sleep times. For the first two types the environmental schedule is shifted, relative to the internal circadian clock. Examples are shown for jet lag (green) where the typical sleep time is advanced by 7 h (trans-Atlantic flight) and for shift work (purple) where a day shift (sleep at night) is followed by two consecutive night shifts (sleep during the day) followed again by a day shift (rotating shift schedule). For the last four types the circadian clock is altered relative to the environmental schedule.

rhythm sleep disorders, shown in Figure 1. Two types of circadian rhythm sleep disorders, jet lag and shift work, occur when the physical environment is altered relative to the internal circadian clock. Four types of circadian rhythm sleep disorders may result when the endogenous circadian rhythm is altered relative to the external environment: advanced sleep phase (ASPS), delayed sleep phase (DSPS), irregular sleep/wake, and nonentrained types. These types of disorders are thought to occur because of chronic alterations in the circadian pacemaker that result in the inability of the individual to achieve or maintain a conventional phase relationship with the external world. Of these four types, the most common are DSPS and ASPS, in which the timing of the major consolidated sleep period is altered, delayed, or advanced, in relation to local clock time. Despite being apparent disorders of circadian timing, little is known about how the circadian system and the diverse rhythms under its control are affected. As increasing numbers of patients with ASPS and DSPS are diagnosed and studied, more can be discovered about the pathophysiology of these disorders and rational strategies for treatments developed. In this article, the focus is on the genetic basis for the circadian rhythm sleep phase disorders, ASPS and DSPS, because little is known regarding the genetic contributions to jet lag, shift work sleep disorder, irregular sleep/wake cycle, or nonentrained sleep/wake disorder.

Diagnosis

The diagnoses of both DSPS and ASPS are based on published clinical criteria. Their diagnosis requires a complaint of inability to fall asleep or to remain asleep at the desired bedtime. Diagnostic criteria also include an advanced or delayed sleep pattern that is stable, and normal sleep quality and duration when patients are allowed to choose their preferred sleep schedule. A stable advance or delay of the habitual sleep period must be demonstrated by either sleep log or actigraphic recording in combination with sleep log for a minimum of 1 week. These criteria exclude the existence of any other sleep disorder, medical or neurological disorder, mental disorder, medication use, or substance use that can better explain the altered sleep pattern.

DSPS, first described by Weitzman and colleagues, is characterized by bedtimes and wake times that are

delayed 3–6 h, relative to desired sleep/wake times. The patient typically finds it difficult to fall asleep before 2–6 a.m. and wake up earlier than 10 a.m.–1 p.m. Classic symptoms include chronic sleep onset insomnia and difficulty waking in the morning. Patients also report daytime sleepiness, primarily during the earlier part of the day. Patients with DSPS often report feeling most alert and active in the late evening and most sleepy in the morning. They typically score as 'evening' types on the Horne and Östberg questionnaire of diurnal preference and are described as night people, or owls. The delay of the sleep period, particularly of the wake time, results in the patient's complaint of difficulty maintaining early morning work times, school schedule, or social obligations. Enforced conventional wake times frequently result in chronic sleep deprivation as the patient forces him- or herself to awaken early but still cannot fall asleep until later than desired. Often sleep is extended on days when the individual has no obligations that require an early wake time, such as on weekends, days off, and vacations.

In contrast to DSPS, ASPS is characterized by habitual and involuntary sleep (6–9 p.m.) and wake (2–5 a.m.) times that are several hours earlier than desired. ASPS patients complain of early morning awakening insomnia or sleep maintenance insomnia and also of sleepiness in the late afternoon or early evening. They typically consider themselves larks and score as morning types on subjective questionnaires. They report feeling best and most alert in the morning; however, some patients who delay their bedtime due to familial or social pressures still experience early morning awakenings and as a result are chronically sleep-deprived. An advance in the phase of the sleep/wake cycle is commonly seen with aging; however, sleep is more fragmented in this population as well, and alterations of the sleep homeostat could account for this advanced phase. In the few reported cases of young ASPS patients, sleep duration and architecture appeared normal without the fragmentation or sleep disturbances commonly seen in aging.

Prevalence

The prevalence of DSPS and ASPS is estimated to be low in the general population. The prevalence of DSPS is about 0.13–0.17%. The number appears to be much higher among adolescents and young adults, with a reported prevalence of 7–16%. This is supported by a number of studies showing that the sleep/wake rhythm is delayed in this group. The prevalence of ASPS is estimated to be much lower than DSPS. One reason for this disparity could be due to underreporting of ASPS, since an early schedule may have advantages in fitting in with societal norms and schedules and therefore 'morning people' do not have complaints about their sleep habits or feel a need to seek treatment. Another possible explanation for the low prevalence of ASPS is the fact that many of the symptoms are commonly seen with aging; therefore, complaints of early morning awakening may be attributed to normal senescence by patients and clinicians alike.

Pathophysiology

Based on the fundamental properties of the circadian timing system and sleep, several mechanisms could account for a persistently altered phase relationship between the sleep/wake cycle and the environment. One possible explanation is that the endogenous period of the circadian pacemaker is unusually short in individuals with ASPS and long in individuals with DSPS. With respect to DSPS, there is evidence showing a greater frequency of longer periods in adolescents, the same demographic group to show a higher prevalence of the DSPS. A long period that lies outside the range of entrainment or is too long to make the necessary adjustments to maintain a 24 h day may cause non-24 h sleep/wake syndrome. A long endogenous cycle that is still entrained to a 24 h day may have an altered phase angle of entrainment, delaying the sleep period in relation to the light/dark cycle. Likewise, in the case of ASPS, a short period could have an effect on the phase angle of entrainment causing a subsequent advance in the sleep and wake times relative to the light/dark cycle. The report that one member with familial ASPS had a short circadian period supports this explanation and suggests that an alteration in the period of the pacemaker may be involved in the development of ASPS.

Another possible explanation underlying the phase advance or delay seen in ASPS and DSPS is the masking of the phase advance or delay regions of the phase response curve (PRC) to light due to the sleep schedule (Figure 2). ASPS patients who are consistently awakening early are likely to be exposed to light at the region of their PRC causing phase advances. If they are also going to bed earlier in the evening, they are less likely to be receiving light at the delay region, thereby reinforcing the advanced schedule. Similarly, DSPS patients who awaken later in the morning are presumably sleeping through the phase advancing portion of their PRC and are more likely to be receiving phase delaying light in the late evening hours. A longer interval between body temperature nadir and sleep offset has been described in a few patients with DSPS, suggesting that the sleep period extended into the morning may be masking the advance

Figure 2 Representative human phase response curve to light, double-plotted. The light dark bar shows a 'typical' sleep/wake schedule (midnight–8 a.m.). The black bars at the bottom of the colored areas, represent the sleep times for ASPS and DSPS subjects, respectively. The colored bars show the proposed 'masking' of the PRC by the sleep schedule.

portion of the PRC in DSPS patients and therefore preventing them from phase advancing their circadian rhythms. This behavior acts as a vicious cycle and perpetuates the already advanced or delayed schedule in ASPS and DSPS, respectively.

An alteration in the entraining effects of light is yet another explanation for the altered phase relationship between the sleep/wake rhythm and the light/dark cycle. This has been described as a weak or low-amplitude advanced or delayed portion of the light PRC. For example, DSPS patients may have abnormally small advance portions of the light PRC explaining the inability to advance the phase of their sleep. Decreased sensitivity to the photic cues may also have an effect on the ability to synchronize an individual's sleep/wake rhythm to the environment. An increased sensitivity to night-time light has been shown in DSPS patients and a reduced response to morning light was demonstrated in subjects with a long free-running period, suggesting the possibility of an altered responsiveness to light cues in these conditions.

Finally, an alteration in the phase relationship between the circadian clock and the sleep/wake rhythm may play a role in these disorders. There have been reports of changes in the phase relationship between sleep times and measures of the circadian clock: specifically, an altered phase relationship between the melatonin rhythm and that of the sleep/wake cycle. The most consistent finding was a prolonged interval between melatonin acrophase and sleep offset. A change in the phase relationship of melatonin rhythm and core body temperature with an individual's diurnal preference has also been described with an earlier circadian phase of melatonin and core temperature in morning types and a later phase in evening types. Furthermore, the interval between circadian phase and habitual wake time was longer in morning types than in evening types. Because DSPS and ASPS patients segregate into the two diurnal groups, evening types or morning types, this supports the explanation that an alteration in the phase relationship between the clock and the sleep/wake rhythm may affect the phase of the sleep episode. Interestingly, when the morning types were divided by age, there was a difference in this phase relationship. Older morning types who also had an earlier circadian phase showed a shorter interval between core body temperature nadir and sleep offset, opposite to that seen in the young morning types. This suggests that different mechanisms may be responsible for the earlier phase seen in association with aging and ASPS. Therefore, it is likely that not only changes in the free-running period but also entrainment mechanisms of the circadian system contribute to the alteration in the timing of sleep in DSPS and ASPS.

Though it is commonly accepted that both DSPS and ASPS are predominantly a result of alterations of circadian timing, there is recent evidence that alterations in the homeostatic regulation of sleep may play an important role in the pathophysiology of circadian rhythm sleep disorders and in diurnal preference. Polysomnographic recordings of sleep in DSPS patients showed that sleep architecture was not disrupted after the initiation of sleep when the subject was allowed to sleep until their desired wake time. However, following 24 h of sleep deprivation, DSPS patients, when compared to controls, showed a decreased ability to compensate for sleep loss during the subjective day and the first hours of subjective night. In addition, the phase angle between melatonin onset and sleep propensity was larger in DSPS patients. It is possible that poor sleep recovery perpetuates the inability of patients with DSPS to reset their sleep phase. In a recent study of morning and evening types, those with similar intermediate circadian phases showed significant differences in dissipation of sleep pressure. In contrast, the morning and evening types with extremely early and late circadian phases did

not show this difference, suggesting that both the circadian system and the sleep homeostat contribute to diurnal preference in addition to sleep regulation and timing.

Genetic Basis of Human Circadian Rhythm Sleep Disorders

Our current understanding of circadian rhythm sleep disorders indicates that alterations in the interaction between circadian and homeostatic processes that regulate sleep and wakefulness play an essential role in the pathophysiology of DSPS and ASPS. Animal work examining the genetic regulation of both circadian and homeostatic mechanisms has revealed a complicated interaction between these two processes in determining sleep duration and quality. Sleep studies of *Clock* mutant mice showed that they not only sleep less but also appear to need less sleep, suggesting that the *Clock* mutation alters the homeostatic drive in these mutants. Similarly, sleep studies of *Cry1* and *2* double knockouts showed an increased sleep drive in the mutants and suggest that the *Cry* genes play an important role in both circadian behavior and the homeostatic regulation of sleep. In contrast, sleep analysis of m*Per1* and m*Per2* mutants showed no significant difference in homeostatic sleep regulation relative to wild-type mice. The only difference between the genotypes of each mutation was seen in the distribution of sleep throughout the day expressing the circadian regulation of sleep timing with the m*Per2* mutants in particular, showing an advance of the activity rhythm. This negative result suggests an independence of the circadian and homeostatic processes regulating sleep. However, it has been proposed that changes in the sleep homeostasis have been demonstrated in mutants having no functional circadian rhythms, such as arrhythmicity in constant darkness (e.g., *Clock*, *Bmal1*, *Cry* double-knockouts, and m*Per1*and m*Per2* double knockouts). The evidence in rodents that mutations in circadian genes can alter both circadian rhythmicity and sleep homeostasis suggests the possibility that a similar genetic predisposition could be involved in the etiology of the circadian and sleep homeostatic changes of sleep regulation seen in circadian rhythm sleep disorders.

In the last few years, a genetic basis for ASPS and DSPS has been established. Familial cases of ASPS and one published family with DSPS demonstrate the heritability of these disorders. The ASPS and DSPS phenotypes appear to segregate with an autosomal dominant mode of transmission. Furthermore, a family history was reported in 11 out of 53 patients with DSPS from a clinic in Japan. Genetic analysis of a family with ASPS led to the identification of a mutation in the human *PER2* gene causing the disorder. However, other published cases of fASPS had not been found to carry this mutation and showed heterogeneity for fASPS. More recently, a mutation in the *CKIδ* gene was linked to another fASPS kindred.

Association studies in idiopathic cases of circadian rhythm sleep disorders have also identified mutations in several circadian genes associated with altered circadian properties. Structural polymorphisms in the human *PER3* gene have been associated with the affected status in DSPS patients and different polymorphisms in the same *PER3* gene were also identified and associated with DSPS and eveningness. A missense mutation in the *CKIε* gene showed an inverse association with circadian rhythm sleep disorders DSPS and non-24 h sleep/wake syndrome. Genetic analysis of diurnal preference to identify polymorphisms in circadian genes has yielded similar results. A polymorphism in the *CLOCK* gene was correlated with evening type although two other groups did not find this association with eveningness in their study populations. More recently, association studies of diurnal preference have identified polymorphisms in the human *PER2* and *PER3* genes associated with extreme morningness and eveningness, respectively.

Summary

The study of disorders of the circadian timing of the sleep/wake rhythm in humans provides valuable insight into the interaction and regulation of various neurobiological processes. Further phenotypic characterization of aspects to the circadian regulation of sleep in people with an altered circadian phase of sleep (i.e., ASPS and DSPS) may serve to elucidate important pathways and functions of photic regulation and entrainment. Thorough evaluation of the sleep in these disorders may also yield information about the underlying processes affecting and causing the expressed changes of sleep and sleep timing. Genetic analysis of ASPS and DSPS familial and idiopathic cases is likely to reveal the molecular and cellular processes generating and modifying the phenotype and behavior. Together, these endeavors will undoubtedly provide greater understanding of the mechanisms underlying circadian rhythm and sleep regulation.

Introduction

Recent advances in both molecular genetics and human neuroimaging have begun to provide the tools necessary to explore how individual differences in complex cognitive and emotional behaviors emerge and how such differences may confer vulnerability to psychopathology. With the publication of the reference human genome sequence, a major effort is underway to exhaustively identify common variations in this sequence that impact on gene function (i.e., functional polymorphisms) and subsequently to understand how such functional variations alter human biology. Because approximately 70% of all genes are expressed in the brain, many of these functional polymorphisms will influence how the brain processes information and, as a consequence, regulates both cognitive and affective behaviors. Human neuroimaging (e.g., magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), electroencephalography (EEG), magnetoencephalography (MEG), and positron emissions tomography (PET)), because of its capacity to assay detailed brain structure and function within individuals, has unique potential as a tool for characterizing functional genetics in neural circuitry. This article (1) describes the conceptual basis for imaging genetics and (2) outlines some major findings in imaging genetics related to aspects of human emotion and temperament. As a first step, we consider behavioral association studies relevant to the genetics of emotion regulation in healthy and clinical populations. These studies, with their challenges and limitations, provide a foundation for the imaging genetics approach, which aims to examine mechanisms at the neural-systems level that lead to individual variability in emotion regulation that is more proximal to genetic factors.

Behavioral Genetics

Why Study Genes?

Genes represent the 'Go' square on the monopoly board of life. They are the biological toolbox with which we negotiate the environment. Although most human behaviors, including emotion regulation, cannot be explained by genes alone, and certainly much of the variance in aspects of brain information processing is not genetically determined, variations in genetic sequence contributes some variance to these more complex phenomena. This conclusion is implicit in the results of studies of twins, which have revealed heritabilities of 40–70% for various aspects of cognition, temperament, and personality.

A powerful approach to understanding the nature of individual differences in emotion regulation revolves around genes because genes have an unparalleled impact on all levels of biology. In the context of disease states, particularly behavioral disorders, genes not only transcend phenomenological diagnosis, they represent mechanisms of disease. Moreover, genes offer the potential to identify at-risk individuals and biological pathways for the development of new treatments. In the case of psychiatric illness, genes appear to be the only consistent risk factors that have been identified across populations, and the lion's share of susceptibility to major psychiatric disorders is accounted for by inheritance. Although the strategy for finding susceptibility genes for complex disorders by traditional linkage and association methods may seem relatively straightforward (albeit not easily achieved), understanding the mechanisms by which such genes increase biological risk is a much more daunting challenge. How many genes contribute to a particular complex behavior or complex disease state? What genetic overlap exists across behaviors and diseases? How large are the effects of candidate genes on particular brain functions? And, perhaps most important, how does a gene affect brain information processing to increase the risk for a behavioral disorder?

Traditional Association Studies

The candidate-gene association approach has been a particularly popular strategy for attempting to answer these questions. Genetic association is a test of a relationship between a particular phenotype and a specific allele of a gene. This approach usually begins with selecting a biological aspect of a particular condition or disease, then identifying variants in genes thought to impact the candidate biological process, and next searching for evidence that the frequency of a particular variant (allele) is increased in populations having the disease or condition. A significant increase in allele frequency in the selected population is evidence of association. When a particular allele is significantly associated with a particular phenotype, it is potentially a causative factor in determining that phenotype. (There are caveats to the design and interpretation of genetic association

studies, such as linkage disequilibrium with other loci and ancestral stratification, that are beyond the scope of this review and that have been discussed at length elsewhere.)

A starting point for personality or psychiatric genetics is the findings of genetic influence through traditional behavioral genetics studies such as twin studies. By comparing the similarity of monozygotic and dizygotic twins on individual differences variables such as extraversion, such studies examine the extent to which variability is due to heritable (i.e., genetic) factors or to environmental factors. These studies indicate that genetic influences shape personality traits and do so across the life span.

Evidence that personality traits are heritable suggests that genes can be identified that account for their heritability. This is the foundation for genetic association studies of behavioral phenotypes. These studies, which take a molecular genetics approach, identify candidate genes of interest and examine their relation to a phenotype. The candidate genes included in these studies are typically those related to the patterns of brain function that putatively underlie personality style.

Association Studies of Genes Involved in Emotion Regulation

Behavioral and molecular genetics approaches have been applied to two topics that are relevant to stable emotional regulatory style: personality and affective disorders. Personality refers to stable normal individual differences, many of which pertain to emotional experience and expression. Affective disorders, although more in the realm of abnormal emotional experience, can be considered examples of pathological emotion dysregulation. These disorders – which include intense and long-duration depressed, manic, or anxious emotional states – involve reduced emotional flexibility. Presumably, difficulty with modulating the frequency, intensity, or duration of affective states underlies these disorders. For example, depression is characterized by sustained sadness and unusually low-frequency, low-intensity positive affect. The genes that predispose people to experience depression therefore may constitute genetic influences on healthy emotion regulation.

Molecular genetics approaches to emotion regulation have tended to focus on polymorphisms leading to variability in neurotransmitter availability or neurotransmitter receptor function. In general, this approach has been somewhat arbitrary and probably superficial. For example, the personality dimension of extraversion, which is characterized by measures of social dominance, novelty-seeking, and reward sensitivity, has been theorized to be driven by variability in function of the dopamine (DA) system. This has encouraged studies of association of variants in DA system genes and measures of extraversion. However, it is probable that many neurotransmitter systems influence aspects of brain function that impact on the extraversion personality style.

In spite of the oversimplification, two particular systems appear to be especially relevant to questions of emotion regulation: the serotonin (5-HT) system and the DA system. 5-HT has been implicated in the generation and regulation of emotional behavior, and the manipulation of 5-HT activity has effects on behaviors such as impulsivity and aggression. The DA system plays a critical role in reward processing and has been linked to normal individual differences in reward traits as well as to disorders involving enhanced reward-seeking such as addiction.

We address both neurotransmitter systems in our review of association studies here, and we focus specifically on the 5-HT system in our discussion of imaging genetics in the remainder of the article. In addition, although we address genetic factors in both normal and abnormal individual differences in the review of association studies, we emphasize normal individual differences in our treatment of imaging genetics. This is because the conceptual foundation for imaging genetics lends itself best to first examining normal variability in neural function.

Personality

There are a number of models characterizing stable and enduring aspects of personality, each involving different dimensions of character style. We believe that a five-factor model has the most established validity and is reflective of alternative styles of emotion regulation.

Extraversion, for example, is likely to involve an approach toward goals despite setbacks and assertion that serves to modify a current situation. Consequently, studies of the genetic underpinnings of extraversion have focused on polymorphisms related to DA function because of its critical role in shaping goal-oriented appetitive behaviors. Specifically, genetic variants of DA receptor subtypes, such as the D2 and D4 receptors, which mediate the myriad neuromodulatory effects of DA, as well as the DA transporter, which facilitates the active reuptake of DA from the extracellular space, have been examined in relation to the broad trait of extraversion and to one of its facets, novelty seeking. More recently, studies have begun to examine other genes that influence broader DA and other catecholamine availability, including catechol-*O*-methyltransferase (COMT) and monoamine oxidase A (MAO-A). As recent reviews and

meta-analyses have noted, the associations between specific DA polymorphisms and complex measures of personality have been inconsistent across studies, with null findings being relatively common.

Another significant line of related research from the field of personality genetics is the examination of 5-HT subsystem polymorphisms on emotional behaviors linked to the general experience of negative affect, such as neuroticism, impulsivity, and aggression. A variant of particular interest has been a common sequence-length polymorphism in the promoter or regulatory region of the 5-HT transporter (5-HTT) gene. Numerous studies have indicated that the short (S) variant of this gene, resulting in altered 5-HT signaling, is associated with higher levels of temperamental anxiety. Other investigators have established links between variation in the 5-HT genes controlling biosynthesis, receptor function, and metabolic degradation and additional dimensional measures of negative emotionality such as impulsive aggression and suicidality. Despite some replication, these lines of investigation have also been marked by frequent null findings, with several reports, including meta-analyses, emphasizing that the ability to detect associations depends on the personality instruments used, with broad-bandwidth personality measures (e.g., extraversion) typically representing constructs that are too heterogeneous to map meaningfully on to biological systems.

Affective Disorders

The leap from studies of genetic influences on dimensional indices of normal variability in personality and temperament to studies of genetic influences on affective disorders, such as depression and anxiety, is understandable given the correlation of these indices with the symptoms of these disorders and the genetic influences on such correlations. For example, depression and the personality trait neuroticism appear to share a genetic influence, and in addition, the correlation between depression and neuroticism appears to be influenced by genetic factors. Such attempts to link polymorphisms directly with clinical syndromes have been fueled by the suggestion that genes might have a more detectable influence at the extreme, pathological ends of the emotional trait distribution. A single gene, however, is not likely to account for a complex disorder such as major depression, and major gene effects on the expression of psychiatric disorders have not been found.

Studies of genetic influences on depression and anxiety in humans have emphasized the role of genes related to 5-HT and hypothalamic–pituitary–adrenal (HPA) axis function. Both the 5-HT and HPA systems play a critical role in emotional reactivity and regulation and are thus prime candidates for studies of these mood disorders. Many candidate polymorphisms in these systems have been linked to increased risk for mood disorders. Moreover, the existence of an association has been demonstrated to be moderated by the environment. In particular, social stress, such as maltreatment during childhood or divorce in adulthood, appears to unmask genetic vulnerability for depression and anxiety.

Limitations of Behavioral Association Studies

All the findings from traditional behavioral association studies based on clinical ratings or clinical diagnosis have been inconsistent, with an impressive amount of null findings for each gene studied. In many ways, this underscores the argument that, in the context of behavior and psychiatric illness, there are only susceptibility genes and not disease genes that clearly and specifically determine affective disorders and that the genetic origins of such disorders are heterogeneous and polygenic, involving gene–gene and gene–environment interactions. Association studies have important limitations, not least of which is the long chain of events from gene function to personality or psychiatric disorder. Additional limitations include the specificity of findings to particular personality instruments, the reliance on self-report rather than observed behavior, the failure to account for developmental effects, and the difficulties of defining and examining gene-by-environment interactions.

Conceptual Basis of Imaging Genetics

The failure of the genetic association strategy to link genotype to behavioral phenotype is ultimately not surprising given the fact that genes do not encode for complex behaviors, personality style, depression, or anxiety. Gene effects on behavior are mediated by their molecular and cellular effects on information processing in brain. Thus, examining gene effects on the brain represents a critical step in understanding their ultimate contribution to variability in behavior and is a biological readout with expected greater genetic penetrance.

Because genes are directly involved in the development and function of brain regions subserving specific cognitive and emotional processes, functional polymorphisms in genes would be expected to be more strongly related to the function of these specific neural systems than to the behavioral correlates of the function of these systems. This is the underlying assumption of our investigations examining the relation between genes and neural systems assayed with

neuroimaging techniques, what we initially called imaging genomics and more recently describe as imaging genetics because this approach is used to explore variation in specific genes and not in the genome broadly. Neuroimaging techniques, especially those that are noninvasive such as MRI and EEG/MEG, typically require no more than a few minutes of subject participation to acquire substantial data sets, reflecting the acquisition of many hundreds of repeated measures of brain structure or function within a single subject. The efficiency and sensitivity of these techniques makes it possible to investigate gene effects on multiple functional systems (e.g., prefrontal, striatal, and limbic) in a single subject in one experimental session. This capacity to rapidly assay differences in brain structure and information processing with enhanced power and sensitivity places neuroimaging at the forefront of available tools for the *in vivo* study of functional genetic variation.

The protocol for imaging genetics typically involves first identifying a meaningful variation in the DNA sequence within a candidate gene. For the variant to be meaningful, it should have an impact at the molecular and cellular level in gene or protein function (i.e., be a functional variant) and the distribution of such effects at the level of brain systems involved in specific forms of information processing should be predictable. For example, a polymorphism in the gene for the 5-HT transporter that impacts the availability of synaptic 5-HT would be expected to affect amygdala function because 5-HT is important in amygdala physiology. Alternatively, recent imaging genetics studies have taken the lead in exploring the functionality of candidate variants by first describing the *in vivo* effects at the level of brain systems. As such, imaging genetics can provide the initial impetus for the further characterization of molecular and functional effects of specific candidate genes in brain systems thought to be involved in behavior. In this manner, the contributions of abnormalities in these systems to complex behaviors and emergent behavioral phenomena, possibly including psychiatric syndromes, can then be understood from the perspective of their biological origins.

Selected Overview of Imaging Genetics Findings Related to Emotional Regulation

Converging evidence from animal and human studies indicates that 5-HT is a critical neuromodulator in the generation and regulation of emotional behavior. Serotonergic neurotransmission has also been an efficacious target for the pharmacological treatment of mood disorders, including depression, obsessive–compulsive disorder, anxiety, and panic. Moreover, genetic variation in several key 5-HT subsystems, presumably resulting in altered central serotonergic tone and neurotransmission, has been associated with various aspects of personality and temperament as well as susceptibility to affective illness. However, enthusiasm for the potential of such genetic variation to affect behaviors and especially disease liability has been tempered by weak, inconsistent, and failed attempts at replication of specific associations with psychiatric syndromes.

The inability to substantiate such relationships through consistent replication in independent cohorts may simply reflect methodological issues such as inadequate control for population stratification, insufficient power, and/or inconsistency in the methods applied. Alternatively, and perhaps more important, such inconsistency may reflect the underlying biological nature of the relationship between allelic variants in 5-HT genes, each of presumably small effect, and observable behaviors in the domain of mood and emotion that typically reflect complex functional interactions and emergent phenomena. Given that the biological impact of variation in a gene traverses an increasingly divergent path from cells to neural systems to behavior, the response of brain regions subserving emotional processes in humans (e.g., the amygdala, hippocampus, prefrontal cortex, and anterior cingulate gyrus) represents a critical first step in their impact on behavior. Thus, functional polymorphisms in 5-HT genes may be strongly related to the integrity of these underlying neural systems and mediate/moderate their ultimate effect on behavior.

Serotonin Transporter

The 5-HTT plays an important role in serotonergic neurotransmission by mediating the reuptake of 5-HT from the synaptic cleft. In 1996, a relatively common polymorphism was identified in the human 5-HTT gene located on chromosome 17q11.1–q12. The polymorphism is a variable repeat sequence in the promoter region (5-HTTLPR), resulting in two common alleles: a short (S) variant comprising 14 copies of a 20- to 23-bp tandem repeat unit and the long (L) variant comprised of 16 copies. In populations of European ancestry, the frequency of the S allele is approximately 0.40, and the genotype frequencies are in Hardy–Weinberg equilibrium (L/L = 0.36, L/S = 0.48, and S/S = 0.16). These relative allele frequencies, however, can vary substantially across populations.

Following the identification of this polymorphism, Lesch and colleagues demonstrated *in vitro* that the 5-HTTLPR alters both gene transcription and the

level of 5-HTT function. Cultured human lymphoblast cell lines homozygous for the long allele have higher concentrations of 5-HTT mRNA and express nearly twofold greater 5-HT re-uptake compared to cells possessing either one or two copies of the short allele. Subsequently, both *in vivo* imaging measures of radioligand binding to 5-HTT and postmortem calculation of 5-HTT density in humans reported nearly identical reductions in 5-HTT binding levels associated with the short allele as observed *in vitro* (but there were also negative reports).

In their initial study, Lesch and colleagues also demonstrated that individuals carrying the short allele are slightly more likely to display abnormal levels of anxiety compared to L/L homozygotes. Since their original report, others have confirmed the association between the 5-HTTLPR short (S) allele and heightened anxiety and have also demonstrated that individuals possessing the short allele more readily acquire conditioned fear responses and develop affective illness than do those homozygous for the long allele. Recent studies using pharmacological challenge paradigms of the 5-HT system suggested that these differences in affect, mood, and temperament may reflect 5-HTTLPR-driven variation in 5-HTT expression and subsequent changes in synaptic concentrations of 5-HT. Furthermore, reduced 5-HTT availability, as putatively indexed by the 5-HTTLPR S allele, has been associated with mood disturbances, including major depression and the severity of depression and anxiety in various psychiatric disorders. Intriguingly, it appears that exposure to stressful life events moderates the impact of the 5-HTTLPR on the development of depression.

The amygdala is a central brain structure in the generation of both normal and pathological emotional behavior. Furthermore, the amygdala is densely innervated by serotonergic neurons, and 5-HT receptors are abundant throughout amygdala subnuclei. Thus, the activity of the amygdala may be uniquely sensitive to alterations in serotonergic neurotransmission and any resulting variability in amygdala excitability is likely to contribute to individual differences in emergent phenomena such as mood and temperament. The response of the amygdala, however, occurs in the context of a distributed and interconnected network of cortical and subcortical brain regions for the generation, integration, and modulation of emotional behavior. Results from a series of imaging studies suggest that the dynamic interactions of the amygdala and prefrontal cortex may be critical in regulating emotional behavior.

Although the potential influence of genetic variation in 5-HTT function on human mood and temperament was bolstered by subsequent studies demonstrating increased anxiety-like behavior and abnormal fear conditioning in 5-HTT knockout mice, the underlying neurobiological correlates of this functional relationship remain unknown. Because the physiological response of the amygdala during the processing of fearful or threatening stimuli temporally precedes the subjective experience of emotionality, the 5-HTTLPR may have a more obvious impact at the level of amygdala biology.

In 2002, our research group at the National Institute for Mental Health (NIMH) used an imaging genetics strategy with fMRI to directly explore the neural basis of the apparent relationship between the 5-HTTLPR and emotional behavior. Specifically, we hypothesized that 5-HTTLPR S-allele carriers, who presumably have relatively lower 5-HTT function and higher synaptic concentrations of 5-HT (analogous to the 5-HTT knockout mice) and have been reported to be more anxious and fearful, would exhibit greater amygdala activity in response to fearful or threatening stimuli than those homozygous for the long allele, who presumably have lower levels of synaptic 5-HT and have been reported to be less anxious and fearful (analogous to the contrasting wild-type mice).

In our initial study, normal subjects from two independent cohorts ($n = 14$ in each) were divided into equal groups based on their 5-HTTLPR genotype, with the groups matched for age, sex, IQ, and task performance. During scanning, the subjects performed a simple perceptual processing task involving the matching of fearful and angry human facial expressions. Significantly, this task has been effective at consistently engaging the amygdala across multiple subject populations and experimental paradigms. Consistent with our hypothesis, we found that subjects carrying the less efficient 5-HTTLPR S allele exhibited significantly increased amygdala activity compared to subjects homozygous for the L allele. In fact, the difference in amygdala activity between 5-HTTLPR genotype groups in this study was nearly fivefold, accounting for 20% of the total variance in the amygdala response. This initial finding suggested that the increased anxiety and fearfulness associated with individuals possessing the 5-HTTLPR S allele may reflect the relatively increased reactivity of their amygdala to relevant environmental stimuli.

Subsequently, multiple independent functional imaging studies reported identical increased 5-HTTLPR S-allele-driven amygdala reactivity in cohorts of healthy adult volunteers as well as patients with social phobia, panic disorder and depression. Moreover, we also replicated our initial finding of 5-HTTLPR S-allele effects on amygdala reactivity in a large independent cohort of adult volunteers ($n = 92$) who were

carefully screened to exclude individuals with a past history of psychiatric illness or treatment. We again observed that 5-HTTLPR S-allele carriers exhibited significantly increased right amygdala activation in response to our fMRI challenge paradigm. In addition, our latest data revealed that 5-HTTLPR S-allele-driven amygdala hyperresponsivity is equally pronounced in both sexes and independent of S-allele load. The equivalent effect of one or two S alleles on amygdala function is consistent with the original observations of Lesch and colleagues on the influence of the 5-HTTLPR on *in vitro* gene-transcription efficiency and subsequent 5-HTT availability. The absence of sex differences suggests that the increased prevalence of mood disorders in females may be related to factors other than the direct risk effect of the 5-HTTLPR S allele.

A third study from the large NIMH cohort ($N = 114$) further captured the dynamic effects of the 5-HTTLPR on genes, brain, and behavior by examining effects on brain structure and corticolimbic functional connectivity. We found that, compared to the L/L genotype subjects, S-allele carriers showed a significantly reduced gray matter volume of the perigenual anterior cingulate cortex (pACC) and amygdala. Moreover, there was a positive correlation (structural covariation) between amygdala and pACC volume, and S-allele carriers showed significantly lower structural covariation between the amygdala and subgenual anterior cingulate than did L/L individuals. This suggests that the pACC and amygdala represent a functional anatomical circuit whose development is modulated by genetic variation in the serotonergic system.

We next explored the impact of these observed structural effects on the functional interactions of the amygdala and pACC in our fMRI data set. Independent of 5-HTTLPR genotype status, we found that the amygdala and pACC were significantly functionally connected. Two distinct regions of functional connectivity were identified within the pACC: (1) a positive coupling between the amygdala and the subgenual cingulate and (2) a negative coupling between the amygdala and the supragenual cingulate. This pattern of functional connectivity is consistent with anatomical tracing studies in nonhuman primates, which have defined a feedback circuit from the amygdala to the rostral cingulate and then from the dorsal cingulate back to the amygdala. These intrinsic cingulate regions also showed strong positive connectivity with one another, suggesting that the corticolimbic feedback loop is closed via local processing within the cingulate cortex. This intrinsic cingulate connection also is consistent with anatomical studies in nonhuman primates. Remarkably, 5-HTTLPR S-allele carriers showed a significant reduction of amygdala–pACC functional connectivity compared to L/L homozygotes. This difference was most pronounced in the coupling of the amygdala and subgenual ACC. These findings suggest that a disruption of this amygdala–pACC feedback circuitry could underlie the earlier observation of increased amygdala reactivity in S-allele carriers during the processing of biologically salient stimuli. More specifically, the data suggest that the increased activity of the amygdala associated with the 5-HTTLPR S allele may reflect more a relative failure of regulation of the amygdala response than an abnormal primary response *per se*. Taken together these data show that the 5-HTTLPR genotype affects the structure and putative wiring of a core region within the limbic system thought to be crucial for anxiety-related temperamental traits and depression.

The collective results of these imaging genetics studies reveal that the 5-HTTLPR S allele has a robust effect on human amygdala structure and function as well as the functional interactions of corticolimbic circuitry implicated in both normal and pathological mood states. Significantly, the absence of group differences in age, sex, IQ, and ethnicity in each of these studies indicates that the observed effects are not likely to be due to a bias resulting from population stratification. Rather, the data suggest that heritable variation in 5-HT signaling associated with the 5-HTTLPR results in structural alterations of the amygdala and pACC, accompanied by biased amygdala reactivity and functional coupling with the pACC in response to salient environmental cues. Furthermore, the emergence of these effects in samples of ethnically matched volunteers carefully screened to exclude any lifetime history of psychiatric illness or treatment argues that they represent genetically determined biological traits that are not altered by the presence of a psychiatric illness.

In contrast to the striking imaging genetics findings of 5-HTTLPR S-allele effects on amygdala reactivity and limbic circuitry dynamics, initial attempts to link these effects on brain function with measures of emergent behavioral phenomena, namely the personality trait of harm avoidance (HA), failed to detect any significant direct relationships. Specifically, in both our initial and replication studies we did not find any significant 5-HTTLPR genotype association with subjective behavioral measures of anxiety-like or fear-related traits as indexed by the HA component of the Tridimensional Personality Questionnaire, a putative personality measure related to trait anxiety and 5-HT function. This failure to find a behavioral association is not surprising given the relatively small sample sizes of each study, that the participants were screened not to have extreme scores on psychiatric inventories, thus

limiting the power to detect probably small (e.g., 1–5%) genetically mediated differences in behavior, and the theses of this paper – namely that genes do not directly predict behavior and their effect on behavior is mediated/moderated by their effects on distinct brain circuitry.

A convergence of evidence from animal and human studies clearly demonstrates that emotional behaviors, especially those as complex as HA, are probably influenced by a densely interconnected and distributed cortical and subcortical circuitry of which the amygdala is only one component. Thus, we were compelled to examine the relationship between HA and the observed 5-HTTLPR effects on the functional connectivity of the amygdala and pACC. We reasoned that if functional uncoupling of the amygdala–pACC affective circuit underlies reported associations of the 5-HTTLPR with emotional phenotypes, functional connectivity indices between these regions should predict normal variation in temperamental trait measures related to anxiety and depression such as HA. These analyses revealed a striking result; nearly 30% of the variance in HA scores was predicted by our measure of amygdala–pACC functional connectivity. This is particularly remarkable because approximately 50% of the individual differences in HA are estimated to be due to genetic effects, thus suggesting that the 5-HTTLPR effects on the amygdala–pACC coupling may account for as much as 60% of the genetically driven variance in HA. Consistent with our previous studies, functional (or structural) measures of single brain regions (i.e., the amygdala or pACC) were of no predictive value. Thus, 5-HTTLPR-mediated corticolimbic functional connectivity alterations are manifested in anxiety-related temperamental traits, possibly reflecting inadequate regulation and integration of amygdala-mediated arousal, leading to an increased vulnerability for persistent negative affect and eventually depression in the context of accumulating environmental adversity. Although investigations of localized structural and functional abnormalities have provided insights about depression, our data underscore the importance of studying the genetic mechanisms of complex brain disorders at the level of dynamically interacting neural systems. We suggest that such relationships capture more proximally the functional consequences of neurodevelopmental processes altering circuitry function implicated in human temperament and psychiatric disorders.

Monoamine Oxidase A

To the extent that the effects of the 5-HTTLPR variant on corticolimbic development and function related to emotion processing are 5-HT-mediated, it would be expected that other genes related to 5-HT function would show similar effects on the function of this circuitry. 5-HT neurotransmission is also regulated through intracellular degradation via the metabolic enzyme, MAO-A. A common polymorphism in the MAO-A gene, resulting in a relatively low-activity enzyme, has been associated with increased risk for violent or antisocial behavior, as well as for depression and anxiety. A recent fMRI study reported that the low-activity MAO-A allele is associated with relatively exaggerated amygdala reactivity and diminished prefrontal regulation of the amygdala. The magnitude of functional coupling between these regions predicted levels of temperamental anxiety, suggesting that the genetic association between the MAO-A low-activity variant and abnormal behavior may be mediated through this circuit. Interestingly, both the 5-HTTLPR S allele and MAO-A low-activity alleles presumably result in relatively increased 5-HT signaling and exaggerated amygdala reactivity. Because the directionality of these effects are consistent with animal studies documenting the anxiogenic effects of 5-HT, the imaging genetics data provide important insight regarding the neurobiological and behavioral effects of 5-HT.

Tryptophan Hydroxylase 2

Tryptophan hydroxylase 2 (TPH2) is the rate-limiting enzyme in the synthesis of neuronal 5-HT and thus plays a key role in regulating 5-HT neurotransmission. A recent study found that a single nucleotide polymorphism (SNP) in the regulatory region of the human TPH2 gene affects amygdala function. Specifically, the T allele of the relatively frequent G(-844)T polymorphism was associated with relatively exaggerated amygdala reactivity. In contrast to previous studies of genetic effects on brain function, in which the molecular and cellular effects of the candidate variants had been previously demonstrated (e.g., 5-HTTLPR, MAO-A, COMT, and brain-derived neurotrophic factor (BDNF)), these fMRI data provide the first evidence for potential functionality of a novel candidate polymorphism. In this way, the initial identification of a systems-level effect of a specific polymorphism provides impetus for the subsequent characterization of its functional effects at the molecular and cellular level. Building on this initial imaging genetics finding (and a subsequent replication), a recent molecular study demonstrated that the G(-844)T is in strong linkage with another promoter SNP that impacts the transcriptional regulation of TPH2 and may affect enzyme availability and 5-HT biosynthesis. Such scientific reciprocity between imaging and molecular genetics illustrates how the contributions of abnormalities in candidate neural systems to complex behaviors and emergent phenomena, possibly

including psychiatric illnesses, can be understood from the perspective of their neurobiological origins.

Brain-Derived Neurotrophic Factor

BDNF is a critical peptide neurotrophic factor involved in neuronal survival, differentiation, and synaptic plasticity. BDNF plays an important role in the expression of long-term potentiation (LTP) in the hippocampus and in learning and memory in animal models. BDNF is also regulated by serotonergic signaling and is involved in the developmental sculpting of serotonergic innervation patterns. A popular theory about the efficacy of selective serotonin reuptake inhibitor (SSRI) antidepressant/antianxiety drugs is that they act via stimulation of BDNF expression. The BNDF gene contains a common functional polymorphism, a valine (Val) to methionine (Met) substitution at codon 66 (Val66Met), which is associated with abnormal intracellular trafficking and the regulated secretion of pro-BDNF, the precursor to functional BDNF. This SNP also has been associated with mood disorders and with anxious temperament. Because of its abundant expression in the hippocampus and its role in learning and memory, BDNF has been studied using neuroimaging primarily in terms of hippocampal anatomy and memory processing. Consistent with the molecular effects of the Met66 allele, studies have documented relatively impaired episodic memory in human subjects carrying this allele. Converging evidence from several imaging genetics studies using different modalities suggests that the Met66 effects on memory are mediated in part by its impact on hippocampal structure and function. Most recently, a structural imaging genetics study revealed that the BDNF Val66Met can modulate the impact of the 5-HTTLPR S allele on corticolimbic circuitry. Specifically, reduced amygdala gray matter volume typically associated with the 5-HTTLPR S allele was absent in subjects also possessing the BDNF Met66 allele. The data suggest that the Met66 allele effectively blocks the relatively increased 5-HT stimulation of BDNF-mediated changes in brain morphology associated with the 5-HTTLPR S allele. As such, this functional genetic epistasis may partially account for the reduced risk of mood disorders associated with the BDNF Met66 allele.

Imaging Genetics, Development, and Developmental Psychopathology

It is important to emphasize that the 5-HTTLPR S-allele effect on amygdala structure, reactivity, and connectivity in our studies, as well as those of others, exists in samples of healthy adult volunteers with no history of affective or other psychiatric disorders. On the one hand, this is consistent with a recent fMRI study reporting that, although amygdala hyperexcitability reflects a stable, heritable trait associated with inhibited behavior, it does not by itself predict the development of affective disorders. On the other hand, more and more evidence is accumulating that the majority of psychopathology is rooted early in life, first emerging during childhood and adolescence. Thus, it is possible that the relevance of gene effects on corticolimbic brain circuitry will be more manifest during the development of individuals predisposed to psychopathology. Moreover, it is likely that exposure to environmental stressors impacts this gene–brain pathway, which in turn increases an individual's risk of developing psychopathology. The hallmark study of Caspi and colleagues and subsequent replication studies suggest that the existence of significant stressors in the environment of individuals carrying the 5-HTTLPR S allele is necessary to further tip the balance toward the development of psychopathology. Similarly, abnormal social behavior and 5-HT metabolism have been reported in rhesus macaques with the 5-HTTLPR S-allele homolog but only in peer-reared, and thus environmentally stressed, individuals. Emerging data from studies of the 5-HTT knockout mouse implicate similar early developmental phenomena interacting with genetically driven variation in 5-HT in shaping the neurobiological landscape contributing to emotional behaviors. It is pertinent to note that in many of these examples the genetic vulnerability has manifested as a consequence of environmental stressors that occurred early in development.

This shift from normal to pathological behaviors and when during the life span this shift occurs may reflect the effects of cumulative environmental stress on brain regions, most notably the prefrontal cortex, critical in the regulation of amygdala activity. For example, repeated exposure to environmental insults before the maturation of relatively late-developing prefrontal regulatory circuits may result in further biased amygdala drive in S-allele carriers. Such relative hyperamygdala and hypoprefrontal activity has been documented in affective disorders and thus, may represent a critical pathway or predictive biological marker for the future development of psychopathology.

Recent imaging studies demonstrating altered functional coupling of the amygdala and medial prefrontal cortex during affective processing in healthy adult S-allele carriers underscored that complex dynamic interactions of the amygdala and prefrontal cortex may be critical for normal behavioral responses in

individuals possessing this risk allele. These results suggest that individual differences in indices of complex emergent behaviors, such as HA, reflect the effects of genetic variation on a distributed brain system involved in not only mediating physiological and behavioral arousal (e.g., the amygdala) but also regulating and integrating this arousal in the service of adaptive responses to environmental challenges (e.g., the prefrontal cortex).

Summary

This article has reviewed efforts to parse human variation in anxious temperament and risk for affective disorders based on polymorphisms in genes implicated in development and function of neural circuitries mediating emotional arousal and regulation. We have outlined an experimental strategy by which genetic effects on brain function can be explored using neuroimaging, namely imaging genetics. This work is just in its infancy; the number of genes explored so far is very few and the strategies for looking at gene effects in brain are relatively simplistic. The studies cited provide compelling evidence that gene effects at the level of emotional neuroscience are much more robust (i.e., penetrant) than at the level of manifest behavior. This is consistent with the conclusion that genes related to emotional disorders and temperament do not encode for behavior but, rather, impact the development and function of neural systems that mediate emotional experience and behavior. Emotional responses are complex and not the result of variation in any single gene. Future studies will emphasize the interactions of genes and the interactions of genes with the environment. This is likely to add complexity but also a finer-grained resolution to the analyses.

Genomic Disorder and Gene Expression in the Developing CNS

C M Paczkowski and J Chun, The Scripps Research Institute, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

The central nervous system (CNS) is composed of billions of neurons with trillions of synaptic connections specifically designed for large amounts of information processing through parallel representational neural networks. The level of diversity required for higher order human cognition is, in large part, genetically regulated and, for this reason, highly susceptible to genomic instability resulting in neurological dysfunction. Cellular diversity is regulated by molecular mechanisms at multiple levels: DNA, RNA, and protein. This article focuses on the level of DNA – specifically, how genomic changes influence gene expression in the normal brain and in human genomic disorders.

Genomic Regulation of CNS Development

Development of the CNS requires an array of cellular processes to produce a functioning brain, including proliferation, programmed cell death, differentiation, migration, axonal/dendritic outgrowth, and synaptogenesis. A large number of genes are involved in the transition from neural stem cell to progenitor cell to postmitotic neuron, and in the age of microarrays and genome sequencing, new genes are constantly being discovered. Genomic and environmental regulation of gene expression determines the ultimate fate of individual neurons and their integration into functioning networks. Within the highly interconnected brain, each neuron has the potential to exert far-reaching effects on numerous other cells. Therefore, altered gene expression within even a single brain cell can impact nervous system development and function.

Neural stem cells lining the surface of the embryonic neural tube proliferate and give rise to lineage-committed neural progenitor cells, specifying neural patterning (see Figure 1). A large number of proneural transcription factors are involved in directing the fate of neural progenitor cells. In addition, epigenetic mechanisms (discussed below) are important in selectively silencing genes, committing cells to neuronal or nonneuronal lineages. As stem and progenitor cells divide, genomic instability can produce daughter cells with distinct genotypes.

Upon exiting the cell cycle, neurons and glia migrate away from their proliferative zone, guided by soluble and cell surface molecular cues. A host of factors can influence the subsequent maturation of neural populations, including those intrinsically encoded within the genome as well as an orchestrated milieu of activity-dependent intra- and intercellular signaling pathways.

Cell death is a prominent aspect of brain development, with substantial overproduction of neurons that are subsequently culled. Two waves of cell death occur over the course of nervous system maturation, the first during neurogenesis and the second during synaptogenesis, which together shape the final organization of the mature brain. Neuroproliferative cell death is likely a means of eliminating new cells with undesirable genotypes, resulting from a host of potential variables. Later in development, postmitotic cell death occurs as neurons are forging synaptic contacts. Competition, largely for limited neurotrophic factors, permits the survival of only a subset of neurons. The high rate of cell death in the developing CNS suggests that there is a selection process whereby neurons with more advantageous phenotypes (based on a combination of physiological environment and genotype) survive to populate the mature brain.

Genomic Changes That Alter Gene Expression

Multiple changes at the level of the genome have been shown to alter gene expression in neural cells. Genomic changes that occur during neurogenesis give rise to populations of cells with distinct genotypes. Altered genomes are often associated with brain malfunction; however, accumulating evidence points to genomic mosaicism as a feature of normal vertebrate brains.

The most extreme form of genomic change is aneuploidy – the loss and/or gain of whole chromosomes. Aneuploidy can occur as a result of missegregation during mitosis, through events such as lagging chromosomes, supernumary centrosomes, and nondisjunction (Figure 2(a)). With several hundred genes on each chromosome, loss or gain of a single chromosome leads to widespread changes in cellular gene expression. Changes in gene expression that result from aneuploidy include gene dosage effects and allelic variation. Increases or decreases in gene dosage for genes expressed on the aberrant chromosome (*cis* effects) and on other chromosomes (*trans* effects) have been reported in aneuploid neurons. Allelic variation results in the gain or loss of one parental allele, altering the balance of allele-specific gene expression. Allelic variation is due to genetic imprinting, expression of recessive mutated alleles (as seen in loss of tumor

Figure 1 Process of neurogenesis. Neural stem cells dividing within the neuroepithelium of the neural tube give rise to lineage-committed neural progenitor cells. Neural progenitors differentiate into multiple diverse cell types that constitute the mature nervous system.

suppressor genes in aneuploid cancer cells), and polymorphisms. This degree of genetic diversity will affect cellular function through changes in any number of signaling pathways and, in turn, influence nervous system development. Given the range of possible functional changes produced by aneuploidy, the implications of this recent finding extend to normal neuronal diversity, behavioral diversity (as seen in monozygotic twins with exactly the same genome yet individual personalities), and neuropsychiatric diseases.

Retrotransposons, primarily those within the long interspersed nuclear element 1, or LINE1 (L1), can cause genomic mutations by disrupting gene coding regions or noncoding promoters/regulatory elements (Figure 3). L1 protein binds to untranslated L1 mRNA and escorts it back to the nucleus where the L1 endonuclease nicks a single strand of DNA and re-inserts itself through reverse transcription. Both germ line and somatic transposition events have been noted. L1 retrotransposons have been recently reported as a mechanism for genomic alteration in neurons.

Genetic imprinting is a mechanism that can regulate gene expression without altering the DNA sequence, yet the specific modifications are heritable. A classic example that affects CNS function is Prader-Willi syndrome, in which partial deletion of chromosome 15 results in mono-allelic expression of a subset of genes, causing mental retardation. Specific genomic imprinting modifications include methylation of CpG sites within a gene or promoter region and histone modifications which are encoded during DNA replication and thus passed on in proliferating cells. Genetic imprinting likely contributes to other brain functions, as there are estimates of 100–200 known imprinted genes in humans. This mechanism plays an important role in determining maternal or paternal monoallelic expression of many genes involved in brain development.

Genomic Disorders Affecting CNS Development

Down Syndrome

Down syndrome (DS), or trisomy 21, is perhaps the best-known genomic disorder affecting the CNS. It is characterized by stereotypical craniofacial abnormalities, moderate to severe mental retardation, and an

Figure 2 Aneuploidy is one mechanism for altering the genome of individual neurons. (a) Missegregation events, such as nondisjunction, can result in daughter cells that have lost (monosomy) or gained (trisomy) chromosomes (yellow chromosome). Here, genetically distinct mature brain cells from an adult human cortex are shown to have different copy numbers of chromosome 21 (b–e). Nuclei are visualized with DAPI and chromosome 21 is detected with a whole chromosome-specific paint (green) and a locus-specific point probe. Arrowheads denote distinct chromosomes. Error bar = 10 μm.

Figure 3 Intrachromosomal mechanisms can also alter the genome of individual neurons. (a) LINE1 (L1) retrotransposons randomly insert their sequence into the genome. L1 proteins escort L1 mRNA into the nucleus, nick a single strand of DNA, and reverse transcribe the L1 sequence. The cell's replication and repair machinery incorporate the new sequence into the genome. (b) Methylation of cysteine nucleotides, particularly in CG repeat sequences, silences gene transcription. This epigenetic event is reproduced during DNA replication; thus, it is permanently imprinted on the genome.

increased risk for leukemia and cardiovascular disease. Patients with DS often live into the forth or fifth decade of life, during which they prematurely develop Alzheimer's disease (AD)-like amyloid plaques and neurofibrillary tangles. Edwards (trisomy 18) and Patau (trisomy 13) syndromes are other major trisomic disorders compatible with postnatal life, and they similarly show pronounced mental retardation and physical dysmorphism.

Much research has focused on defining the genotype-phenotype relationship in DS. Chromosome 21 contains roughly 360 known genes, and the main effects of trisomy are thought to be related to the 1.5-fold increase in gene dosage for genes on that chromosome. Gene expression studies on trisomic cells from DS individuals find that most genes on chromosome 21 are overexpressed, although the pattern of altered gene expression depends on tissue type and developmental stage. It has been noted that none of the features of DS are unique to DS, suggesting a shared etiology in disorders with overlapping symptoms. An example is the possible relationship that has been reported between DS and AD in which elevated gene dosage for the *APP* (amyloid precursor protein) gene on chromosome 21 has been implicated in amyloid plaque formation, although data linking trisomy with AD is lacking. Most phenotypic features do not appear to follow this single-gene/single-phenotype pattern, suggesting that *trans*-regulation of genes on other chromosomes could result in the disruption of many common signaling pathways. Such loss of genetic homeostasis, produced by aneuploidy in brain cells, could produce general neuronal dysfunction and result in mental retardation, common to all genomic brain disorders.

Chromosomal Deletion Disorders

A long list of chromosomal disorders in which partial deletions of various chromosomes exist: Miller-Dieker syndrome (del 17p13), Angelman and Prader-Willi syndromes (del chr 15q11–12; see previous discussion), DiGeorge syndrome (del 22q11), Cri-du-chat syndrome (partial del 5p-), and Wolf-Hirshhorn syndrome (partial del 4p-), among others. Invariably, these chromosome deletion syndromes are associated with brain malformation and/or mental retardation, supporting the idea that systemic genomic abnormalities disrupt general nerve cell function and brain development.

Turner syndrome (X0) is an intriguing disorder that results in females with normal verbal intelligence but impaired numerical and spatial cognition. In addition, social skills and emotion recognition are poorly developed in these patients, possibly related to structural abnormalities of the amygdalae. Since normal XX cells are known to inactivate one X chromosome early in development, much research has focused on gene expression in Turner syndrome. The phenotype is attributed to haploinsufficiency of genes with biallelic expression on chromosome X, representing up to 20% of the genes on that chromosome. It is not known how these biallelic genes are regulated in normal females and males, and to what degree biallelic expression is required in various cell types.

Fragile X Syndrome

Fragile sites are unstable chromosomal regions that are prone to double-strand breaks and rearrangements. The most common genomic disorder associated with a fragile site is the inherited disorder fragile X syndrome, in which a CGG trinucleotide repeat causes methylation-mediated silencing of the *frm1* gene on chromosome X. The gene product, FMRP, is a mRNA-binding protein that appears to traffic specialized mRNAs to the dendrites of neurons necessary for synaptic plasticity. CGG repeat length expands during germ line transmission and the full phenotype of fragile X syndrome does not manifest until there are more than 200 repeats. Mental retardation (IQs ranging from 20 to 60) is the main clinical phenotype in fragile X syndrome, although other symptoms can include autistic behaviors, anxiety disorder, attention deficit-hyperactivity disorder, and seizures. In addition to the predominant germ line mutations, repeat length instability has been reported in somatic tissues, including the developing brain, indicating that the phenotype may partially depend on neural genotypes distinct from the inherited genotype.

Ataxia-Telangiectasia

Ataxia-telangiectasia (A-T) is the best-known disorder resulting from disruption in a DNA repair pathway. The disorder is characterized by cancer predisposition and radiation sensitivity as well as progressive neurodegeneration. A mutation in the *atm* gene (A-T mutated) has been linked to the disorder. ATM phosphorylates multiple substrates involved in cell cycle regulation and genomic stability, playing an important role in genome surveillance. Loss of ATM function has been proposed to result in an accumulation of neurons with genomic abnormalities, leading to the progressive loss of neurons. Interestingly, mice lacking *atm* have an increase in aneuploid brain cells, suggesting that aneuploidy is one form of genomic instability associated with loss of genome surveillance mechanisms. It is notable that both defects in DNA repair and aneuploidy are also associated with medulloblastoma formation. Other

DNA repair disorders with neurological phenotypes include Nijmegen-breakage syndrome, Cockayne's syndrome, and xeroderma pigmentosa.

Mosaic Variegated Aneuploidy

Mosaic variegated aneuploidy (MVA) is a rare disorder characterized by mosaic aneuploidy in multiple somatic tissues, with the requirement of at least three distinct aneuploidies for diagnosis. Up to 65% of cases of MVA show premature centromere division, leading to a high frequency of different trisomies. In other cases, chromosome missegregation and mitotic checkpoint failure are suggested as mechanisms of aneuploidy. The gene *BUB1B*, which encodes the spindle checkpoint protein BUBR1, has been implicated in some forms of this disease. Rates of aneuploidy in blood lymphocytes and fibroblasts have been reported ranging from less than 10% to more than 80%, but no information is known about the effect of this high rate of aneuploidy on gene expression or cell function. Neurologically, the disorder is associated with microcephaly, mental retardation, and myoclonic seizures, presumably related to high levels of aneuploid mosaicism in the brain, similar to other chromosomal disorders.

Neuropsychiatric Disorders

It has been hypothesized that sporadic neuropsychiatric disorders may be the result of as-yet-undetected genomic changes. Evidence for this includes Tourette's syndrome, which has been linked to mutations in microRNAs that regulate gene expression; epilepsy, which has an increased risk associated with most chromosomal disorders, including DS; idiopathic mental retardation, in which *de novo* microdeletions have been identified in several cases; and neurodegenerative diseases, in which single gene mutations account for only a small minority of cases. Since many neuropsychiatric disorders present with clinical symptoms that overlap with known genomic disorders, it is not unreasonable to postulate that undetected genomic abnormalities may be present in these patients.

Recently, fragile sites have been implicated in some neuropsychiatric disorders. FRA13A is a fragile site that maps to chromosome 13q12–14, a region flanked by tumor suppressor genes and containing the neurobeachin gene *NBEA*. In humans, haploinsufficiency for NBEA has been linked to sporadic autism, suggesting that instability of FRA13A may be a contributing factor in some cases of autism. Interestingly, the unstable nature of the FRA13A site may be related to a high number of LINE1 elements within the region. Another known fragile site, FRA6E, maps to chromosome 6q26, which includes the *PARK2* locus. Mutations in *PARK2* have been associated with autosomal recessive early parkinsonism, and it is compelling to speculate that genomic instability of FRA6E could be a factor in sporadic forms of Parkinson's disease.

Genotype-Phenotype Variability within Genomic Disorders

The clinical phenotype of most genomic disorders is highly variable, especially regarding cognitive ability; however, the basis for this clinical presentation is unclear. Genomic mosaicism in the CNS is a compelling mechanism for explaining at least some degree of the phenotypic variability seen in neuropsychiatric disorders. Genomic mosaicism produced by multiple mechanisms (e.g., aneuploidy, genetic imprinting, and retrotransposons) exists within all human brains. The precise function of this mosaicism in normal and diseased brain is an area of active research, and will likely have repercussions for our understanding of many of the genomic diseases discussed in this section. Future research in this area will provide further insight into the link between genomic mosaicism and neurological phenotype.

Genomics of Brain Aging: Apolipoprotein E

D K Lahiri and B Maloney, Indiana University School of Medicine, Indianapolis, IN, USA

Introduction

Dementia is rapidly becoming a common diagnosis in the current aging population, and the numbers are expected to rise exponentially in coming years. Alzheimer's disease (AD) alone now affects over 4.5 million people in the United States. In addition, millions more are currently affected by vascular dementia, Lewy body disease, and frontotemporal dementia (FTD). Therefore it is critical to understand potentially modifiable risk factors and early disease markers and the application of new disease-specific diagnostic tools and treatment modalities for these age-related dementias. In the present review, we focus on the current state of knowledge and directions of research on the role of apolipoprotein E (ApoE), encoded by the *APOE* gene, on the major dementias, particularly AD.

ApoE has a major role in cholesterol transport and plasma lipoprotein metabolism. It is also an important cholesterol transporter in the brain, being involved in neuronal repair, dendritic growth, maintenance of synaptic plasticity, and anti-inflammatory activities. Cholesterol regulates amyloid production and its deposition. ApoE is associated with both plaques and tangles, which are the two major pathological hallmarks of AD. Importantly, plaque formation seems to require the presence of ApoE. It is essential for amyloid deposition in the β-amyloid protein precursor (APP) Val717 $\rightarrow$ Phe (V717F) transgenic model of AD, suggesting that the role of ApoE in AD is to increase the yield and/or toxicity of amyloid plaques. *APOE* is known to have three alleles, $\varepsilon 2$, $\varepsilon 3$, and $\varepsilon 4$. The risk of AD increases in accordance with genotype such that $\varepsilon 4 > \varepsilon 3 > \varepsilon 2$. The $\varepsilon 4$ allele has also been associated with anomic aphasia in FTD, while $\varepsilon 2$ may be a risk factor for FTD in general, with the $\varepsilon 2/\varepsilon 4$ genotype conferring greatest risk for primary progressive aphasia.

However, multiple factors in addition to ApoE play an important role in neurological pathogenesis, making ApoE only one of several important contributors. In transgenic mice, for example, *APOE* $\varepsilon 4$ expression causes neuropathology and behavioral deficits, but it is unclear whether the mechanism involves modulation of amyloid levels. ApoE is clearly an important and robust genetic risk factor for AD and other aging-related dementias. Perhaps the most important question in the area of age-related disorders concerns how ApoE accelerates dementia pathogenesis. In this regard, AD would serve as a model for ApoE's overall role, as this is currently the most extensively characterized relationship.

ApoE Expression in Different Tissues and Cell Types and during Aging

ApoE mRNA is most abundant in the liver, followed by the brain, where it is synthesized and secreted primarily by astrocytes, oligodendrocytes, activated microglia, and ependymal layer cells. The synthesis and secretion of ApoE also occur in some human neurons, in which ApoE is induced by brain injury. Central nervous system (CNS) neurons express ApoE at lower levels than do astrocytes. APOE protein and mRNA are detected in cortical and hippocampal neurons in humans and in transgenic mice expressing human ApoE under the control of the human *APOE* gene promoter. ApoE is expressed in primary cultured human CNS neurons and in several human neuronal cell lines. Cerebrospinal fluid (CSF) ApoE is a component of CSF high-density lipoproteins (HDLs), the major lipoprotein type in the CSF.

APOE expression is upregulated in astrocytes during aging. Macrophages are the major source of *APOE* among various cell types studied. Two distal enhancers that specify *APOE* gene expression in macrophages were reported in transgenic mice with specific constructs of the human *APOE/APOC1/APOC1′/APOC4/APOC2* gene cluster. A multienhancer-1 (ME-l) element consists of a 620-bp sequence located 3.3 kb downstream of the *APOE* gene and the multienhancer-2 (ME-2) element comprises a 619-bp region located 15.9 kb downstream of the *APOE* gene and 5.9 kb downstream of the *APOC1* gene. Both ME-1 and ME-2 elements drive *APOE* gene expression in astrocytes of the olfactory bulb, cerebellum, and hippocampus in transgenic mice.

ApoE and AD

Alzheimer's disease, the most common form of dementia among elderly, is a progressive, degenerative disorder of the central nervous system. The consequence of the disease is loss of memory; this and other cognitive and behavioral symptoms progressively impair function in the activities of daily living. Neurochemically, AD is characterized by selective neuronal cell death, the presence of amyloid deposits

in the core of neuritic plaques, and the formation of neurofibrillary tangles in the brain of afflicted individuals. Plaque and tangles are deposited extraneuronally and intraneuronally, respectively. Notably, ApoE protein has been reported to co-localize with both of these neuropathological lesions of AD.

An increase in ApoE mRNA was reported in the hippocampus in AD and in rats after entorhinal cortex lesioning. In both AD and the lesion model, investigators observed a shift in the location of astrocytes containing prevalent ApoE mRNA, from the neuropil to regions with densely packed neurons. The increased abundance of ApoE mRNA in astrocytes close to neuron cell bodies could be indicative of lipid uptake in regions where neurons are degenerating or where synaptic remodeling is taking place.

Protein Isoforms of ApoE and Their Role in AD

ApoE is a polymorphic 299-amino-acid protein with a molecular mass of 34 200 Da. The human *APOE* gene consists of at least three alleles ($\varepsilon 2$, $\varepsilon 3$, $\varepsilon 4$) encoding three protein isoforms. The three common ApoE isoforms, $\varepsilon 2$, $\varepsilon 3$, and $\varepsilon 4$, are all products of the same gene, with three alleles at a single gene locus. These isoforms differ from one another at residues 112 and 158. ApoE $\varepsilon 3$ has Cys112 and Arg158, ApoE $\varepsilon 4$ has arginine at both positions, and ApoE $\varepsilon 2$ has cysteine. In almost all populations, the $\varepsilon 3$ allele accounts for the vast majority of the *APOE* gene pool (typically ~70–80%) and the $\varepsilon 4$ and $\varepsilon 2$ alleles account for 10–15% and 5–10% of the population, respectively.

Among these isoforms, the $\varepsilon 4$ allele of *APOE* constitutes a major susceptibility factor for the development of the familial and sporadic forms of late-onset AD. Individuals with one copy of *APOE* $\varepsilon 4$ show a higher risk compared to those without the allele, and two copies of the *APOE* $\varepsilon 4$ further increase the risk of AD. At the protein-binding level, ApoE binds β-amyloid (Aβ) peptide with high avidity, and the three isoforms differ in their binding properties, which may contribute to the isoform-specific effects of ApoE on Aβ deposition. Animal studies suggest that ApoE participates in β-amyloid deposition in an isoform-specific manner. At drug treatment level, AD patients with ApoE $\varepsilon 4$ responded poorly to treatment with tacrine compared to patients with ApoE $\varepsilon 2$ and ApoE $\varepsilon 3$.

ApoE Isoforms and Familial AD-Linked Mutations

Familial AD (FAD) is caused by mutations in several genes, including *APP*, *PSEN1*, and *PSEN2*, which encode β-amyloid protein precursor, presenilin 1 (PS1), and presenilin 2 (PS2), respectively. Mutations in *APP*, *PSEN1*, and *PSEN2* account for only a small percentage of AD patients, even among those who have early age of onset and a family history of the disease. The role of ApoE isoforms in the pathogenesis of AD is visible by their interaction with FAD mutations, as well as in Down syndrome. In those cases when FAD is associated with a mutation in APP or increased load of APP, the presence of an *APOE* $\varepsilon 4$ allele, in comparison to *APOE* $\varepsilon 3$, significantly reduces the age of onset of AD. In contrast, most mutations in PS1 and PS2, which together account for the bulk of the known FAD families, are only weakly affected by the *APOE* $\varepsilon 4$ allele. This finding cannot be explained by assuming a ceiling effect on the age of onset. It would appear that the *APOE* $\varepsilon 4$ allele affects a particular pathway that is either removed or saturated by the PS1/2 mutations. It is then most likely that ApoE influences the pathogenesis of AD by altering the pathology, although cell culture studies indicate that there are no changes in Aβ production because of co-expression of any of the three *APOE* alleles.

Neurobiological Mechanisms: ApoE Isoform Status Influences Risk of AD by a Relatively Selective Effect on Episodic Memory

The neurobiological mechanisms linking the $\varepsilon 4$ allele risk of AD are beginning to be understood. Previous histopathological studies report that the $\varepsilon 4$ allele is associated with the number of neuritic plaques and neurofibrillary tangles, suggesting that the effect of the $\varepsilon 4$ allele on disease may be mediated by an increase in the rate that AD pathology accumulates, but not all studies have found this association, and others suggest that the $\varepsilon 4$ allele is related to other mechanisms, such as neural repair or survival. Data from the Religious Orders Study, an ongoing longitudinal clinical–pathologic study of aging and AD, were used to examine the pathologic mechanisms linking the $\varepsilon 4$ allele to the development of AD. These studies suggest that *APOE* allele status influences risk of AD by a relatively selective effect on episodic memory. Other studies suggest that the presence of a single *APOE* $\varepsilon 4$ allele is associated with an increased rate of hippocampal volume loss in healthy women in their sixth decade of life, but is not related to any detectable memory changes.

Neuropathological Association and Role of *APOE* $\epsilon 4$ Allele in the Clinical Manifestation of AD

Bennett and colleagues have tested the hypothesis that the $\varepsilon 4$ allele is associated with the clinical manifestations of AD through an association with the pathologic hallmarks of disease among 128 deceased participants in the Religious Orders Study. The effect

was present when measures of neuritic plaques, diffuse plaques, and neurofibrillary tangles were analyzed separately and when measures of five different cognitive systems (episodic memory, semantic memory, working memory, perceptual speed, and visuospatial ability) were analyzed independently. The ε4 allele is, therefore, associated with the clinical manifestations of AD through an association with the pathologic hallmarks of AD, rather than some other mechanism (e.g., direct effect on neuronal survival).

The relationships underlying neuropathology also exist in normal individuals. A study of Aβ42 and Aβ40 concentration in individuals without AD revealed a significant association between the *APOE* ε4 allele and greater decline in the amount of Aβ42 in cerebrospinal fluid than in non-*APOE* ε4 individuals. This sharper decrease in Aβ42 in CSF is likely due to greater precipitation of Aβ42 as amyloid plaque in brain parenchyma.

ApoE Genotype/Age Interaction Affects Cerebral Glucose Metabolism

Positron emission tomography (PET) studies in healthy elders showed that the *APOE* ε4 allele is disruptive to the regional cerebral metabolic rate of glucose metabolism (rCMRGlu), perhaps via an interaction with the aging process. Another study assessed whether this interaction occurs in AD patients. ApoE groups were comparable for age, gender, age at onset, and disease duration. Correlations between age and rCMRGlu confirmed a negative relationship for both groups. For example, lower rCMRGlu was found within the frontal and cingulate areas for *APOE* ε4 carriers as compared with the noncarriers. Additionally, a significant ApoE/age interaction was detected in the frontal and anterior cingulate cortex, with the *APOE* ε4 carriers having a steeper regression slope with respect to the noncarriers. These results indicate that age-related regional rCMRGlu decreases within the frontal and anterior cingulate areas may be more severe in AD patients carrying the *APOE* ε4 allele.

Increased ApoE mRNA Level in AD Subjects Carrying the *APOE* ε4 Allele

In addition to functional alterations associated with the ε4 isoform, gene expression of *APOE* has been assessed in the brains of AD subjects according to *APOE* genotype. Increased ApoE mRNA was reported in AD subjects carrying the ε4 allele. ApoE mRNA level was significantly higher in the AD group than in the control group ($p < 0.05$). ApoE mRNA level in the AD group with ε4 was also significantly higher than that in the control group with ε4 ($p < 0.05$). However, this is controversial. For example, in another study, levels of ApoD, but not ApoE, were reported to increase in the CSF and hippocampus of AD patients as a function of inheritance of the APOE ε4 allele.

APOE ε4 Still May Not Be a Major Susceptibility Factor for All Racial and Ethnic Groups

Even considering all of the aforementioned evidence, the relationship of the ApoE isoform to AD risk is not necessarily clear-cut. To understand the role of the ε4 allele in different racial groups, Bennett and colleagues presented data from a geographically defined biracial population on the south side of Chicago. The effect of the ε4 allele on the risk of AD differed strongly between African-Americans and Caucasians. For example, among Caucasians the presence of the ε4 allele was associated with a 2.73-fold increase in risk, while among African-Americans there was no significant increase in risk. Other studies also report a weaker (or no) association of the ε4 allele among racial and ethnic minorities, although this remains controversial. Other genetic and environmental risk factors may be important for the development of AD among racial and ethnic minorities in particular.

The Regulatory Region of the *APOE* Gene

In addition to the differential risk related to ε2/ε3/ε4 alleles, additional risk for AD may be related to transcriptional activity of the *APOE* gene. ApoE mRNA has been shown to be significantly more abundant in AD patients than in a control group, regardless of ApoE isoform genotype. In addition, reports have been made of correlation related to the presence of promoter single-nucleotide polymorphisms (SNPs), ApoE expression levels, and risk of AD.

The gene encoding ApoE in humans and in the most common model system (mice) resides in a well-conserved cluster of genes. The human *APOE* gene is on chromosome 19, while the mouse homolog, *Apoe*, is on mouse chromosome 7 (Figure 1). The genes for ApoE of mouse and human both consist of a 5′-untranslated region (5′-UTR) divided between two exons, three coding-sequence exons, and a terminator (Figure 2). All introns in the human gene are longer than those in the mouse.

Structure of the 5′-Flanking Region of the Gene for ApoE

The proximal region of the ApoE gene promoter is highly conserved in the mouse, rat, and human; the relative position of the 'TATA box' and the two copies of the 'GC box' are identical. Such characterization of the ApoE promoter is important for understanding the mechanism of ApoE gene expression and its regulation.

Figure 1 Human and mouse chromosome regions near their respective (*APOE*, *Apoe*) genes encoding apolipoprotein E. Databases for human and mouse genomes were searched for genes in the region of each species' apolipoprotein E gene on the respective chromosomes. Homologous genes were mapped according to genetic (cM, centimorgan; 1 cM ~ 1 Mb) and physical (Mb, megabase pair) distances. Mouse maps are presented in 'reversed' orientation for clarity of comparison. (a) Genetic maps of human chromosome 19 and mouse chromosome 7. Maps are to the same centimorgan scale. (b) Physical maps of human chromosome 19 and mouse chromosome 7. Maps are to the same megabase pair scale.

Figure 2 Human (a, b) and mouse (c, d) genes that encode apolipoprotein E, and 5′-flanking region structures. (a) Map of the human *APOE* gene, including introns, exons, terminator region, and 5′-flanking region. The 5′-untranslated region is in blue, coding sequence exons are indicated in green, and the 3′-untranslated region/terminators are in red. Locations of the sites of the ε2 and ε4 alleles are indicated. (b) Map of the human *APOE* 5′-flanking region, including locations of the polymorphisms at −491, −427, and −219. (c) Map of the mouse *Apoe* gene, including introns, exons, terminator region, and 5′-flanking region. The 5′-untranslated region is in blue, coding sequence exons are indicated in green, and the 3′-untranslated region/terminators are in red. (d) Map of the mouse *Apoe* 5′-flanking region. Dashed vertical line indicates the 5′-untranslated region exon/intron border. Maps (a) and (c) are drawn on the same scale, and maps (b) and (d) are drawn on the same scale. See text for discussion of other sites. Adapted from Maloney B, Ge Y-W, Alley GM, and Lahiri DK (2007) Important differences between human and mouse APOE gene promoters with implications for Alzheimer's disease. *Journal of Neurochemistry* 103: 1237–1257.

Transcription control of the mouse *Apoe* (m-*Apoe*) gene has been studied. Promoter activity of a 729-bp 5′-flanking region, which is located 729-bp upstream from the translation initiation codon (ATG), has been thoroughly examined. The 729-bp region was cloned into the reporter chloramphenicol acetyl transferase (*CAT*) gene in a promoterless vector (pBLCAT3). Transfection studies of the m-*Apoe* promoter in rat glial C6 and neuronal PC12 cell lines suggest that the 729-bp *Apoe* region (from position −675 to +54) is functionally active in these cell types. The serial deletion analysis indicates that the 278-bp promoter region (from −224 to +54) has the highest, and the 68-bp region (from −14 to +54) the lowest, activity on the reporter gene in neuronal and astrocytic cell lines. These results indicate that the 151-bp region (from −374 to −224) has a negative regulatory effect on the reporter gene. DNA–protein interaction studies reveal that the 68-bp region binds a specific transcription factor(s) in PC12 nuclear extracts. These functional studies suggest that mouse *Apoe* gene can also be expressed in neuronal cells in addition to the astrocytic cells.

Promoter Polymorphisms of the *APOE* Gene

In addition to the highly characterized isoform ε2/ε3/ε4 polymorphisms of *APOE*, three promoter SNPs have been reported with some level of associated AD risk. These polymorphisms reside at −491 (A/T), −427 (C/T), and −219 (G/T). Of the three, −491A/T has the most agreement in the literature as representing a risk factor (as −491A) for AD independent of *APOE* ε4, although some reports only indicate that it increases the effect of the ε4 allele and it has been reported that this polymorphism has no effect in some ethnic groups. In addition, it has been suggested that −491A is associated with increases in subjective memory loss. The −491T variant has been found to correlate with improved response to the drugs atorvastatin and benzafibrate. The −427C/T polymorphism has usually

been reported to offer no significant association with AD. The −219G/T polymorphism has been shown to have no significant effect on age-related neurodegeneration, to be an independent risk factor (as −219T) for AD, or to only be a risk factor in association with *APOE* ε4. Interestingly, the −219T polymorphism has been suggested to have an association with coronary artery disease and open-angle glaucoma. The incompleteness of effect for these polymorphisms strongly indicates that environmental interaction plays an important role in any effects ApoE might have on aging and age-related pathology.

Interaction of Environmental Factor(s) with the *APOE* Gene Promoter

The *APOE* promoter region contains important transcription factor sites through which the promoter interacts with various cellular factors. There are some functionally tested DNA sites in the *APOE* promoter for possible binding of interesting transcriptional factors. Nuclear factor-kappa B (NF-κB) and activator protein-2 (AP-2) sites present within the *APOE* promoter are mainly responsible for environmental factor-mediated *APOE* gene expression. DNA sequence analysis predicts the presence of putative sites for activator protein-1 (AP-1) and AP-2, and a functional site for the NF-κB transcription factor (TF) in the human *APOE* promoter. Gel electrophoretic mobility analysis has confirmed the presence of one predominant NF-κB site within the human *APOE* promoter. The significance of the presence of these important TF sites in the promoter is evident from a finding that cytokine/Aβ-induced glial activation, NF-κB, and ApoE play critical roles in neuroinflammatory process seen in AD. Notably, some of the aforementioned *APOE* TF sites are also present in the *APP* promoter region, suggesting a common regulatory pathway for both of these important genes in the pathogenesis of AD. Thus, these sites can potentially be effective drug targets to control the expression of the *APOE* gene.

In addition to acute environmental–gene promoter interactions, the possibility may exist that *APOE* gene expression may be subject to alteration in a LEARn (latent early-life associated regulation) fashion. LEARn begins by transient exposure of an organism to a stimulus such as lead (Pb), which alters DNA methylation and/or oxidation patterns. However, unlike conventional Pb-toxicity, there is no acute effect of the environmental exposure. Instead, the potential of gene expression is latently altered, only to be triggered later in life by a second event, such as the widespread changes in levels of transcription and inflammatory factors seen in the transition from maturity to old age. Mechanistically, a gene's primary DNA sequence would not be altered either by the original stimulus nor by the later trigger. Instead, methylation (or oxidation) would produce a latent 'somatic epitype' that would ultimately determine gene expression levels. The LEARn model provides a mechanism for explanation of the difficulty in tracking environment–gene interactions.

Interaction of the Aβ Peptide with the *APOE* Promoter

Treating cultured cells with the Aβ peptide increased *APOE* promoter activity in a dose-dependent manner. Interestingly, Aβ-mediated *APOE* promoter activity is regulated by the NF-κB site, as evident from other functional studies, and this interaction can be altered by salicylate. Thus, the NF-κB site could potentially be a therapeutic target to control the increased *APOE* promoter activity seen in AD (Figure 3).

Effects of Statins on *APOE* Gene Expression: Role in Regulating Inflammation and Cell Proliferation/Differentiation

The effects of statins have been tested on the activation of transcription factors, which are known to regulate inflammation and cell proliferation/differentiation. Simvastatin, atorvastatin, and lovastatin inhibited the binding of nuclear proteins to both the NF-κB and AP-1 DNA consensus oligonucleotides in human endothelial and vascular smooth muscle cells. Hydroxymethyl glutaryl coenzyme A (HMG-CoA) reductase inhibitors upregulate the inhibitory IκB-α protein levels in endothelial cells and decrease c-Jun mRNA expression in smooth muscle cells. Thus, HMG-CoA reductase inhibitors downregulate the activation of transcription factors NF-κB, AP-1, and hypoxia-inducible factor-1α. These results corroborate the concept that statins have anti-inflammatory and antiproliferative effects that are relevant in the treatment of atherosclerotic diseases. Current studies are directed to examine the role of those transcriptional factors' sites within the *APOE* promoter that would be affected by the HMG-CoA reductase inhibitors, which otherwise regulate inflammatory transcription factors that are involved in age-related disorders such as AD.

Interaction of ApoE with Other Risk Factors: Oxidative Stress, Inflammation, and Cholesterol Transport

Besides genetic etiological effects on AD, ApoE interacts with other risk factors, such as oxidative and inflammatory processes, nutrition, and environment. ApoE has been shown to possess anti-inflammatory

Figure 3 Schematic of interactions of the apolipoprotein E (ApoE)-encoding *APOE* gene with β-amyloid (Aβ) and with environmentally driven risk factors that lead to Alzheimer's disease pathogenesis. The *APOE* regulatory region contains binding sites for several transcription factors, such as nuclear factor-kappa B (NF-κB), and inflammatory factors, such as interleukins (IL-6 RE; interleukin-6 response element), which modulate expression of the *APOE* gene. In addition, promoter single-nucleotide polymorphisms influence ApoE levels and risk for age-related neurodegenerative disorders such as Alzheimer's disease. Modulation of this regulatory region alters *APOE* transcription levels, thereby changing ApoE protein synthesis. ApoE acts as a cholesterol transporter protein and carries cholesterol into the brain. Cholesterol modulates β-amyloid protein precursor (APP) processing, as it increases the activity of one of the key secretase enzymes, β-secretase, which results in an increased Aβ production. Aβ plays several roles in the neuropathology: Aβ transported into the cell contributes to reactive oxidative species (ROS), inducing cytokine response. Oligomeric Aβ causes neurodegeneration, and excessive Aβ results in amyloid deposits, which also contain cholesterol and ApoE. Furthermore, Aβ activates NF-κB, which in turn goes to the nucleus and activates the *APOE* gene. In addition to this pathway, the *APOE* ε2 allele has a positive effect on memory and protective effect against Alzheimer's disease. However, allele ε4 may have a role in neurotoxicity and promotes fibrillogenesis, as deduced from cell culture and animal studies. All of these events lead to neurodegeneration and accelerate Aβ deposition. Thus, a vicious loop of interacting Aβ, *APOE*, cholesterol, and APP forms a cascade of events, culminating in Alzheimer's disease pathogenesis. From Lahiri DK, Sambamurti K, and Bennett DA (2004) Apolipoprotein gene and its interaction with the environmentally driven risk factors: Molecular, genetic and epidomiological studies with Alzheimer's disease. *Neurobiology of Aging* 25: 651–660.

properties in a variety of models. During normal aging, the brain undergoes several alterations, including reduced neuronal functioning and alterations in glia homeostasis. An increase in inflammatory signaling has also been reported in some studies of the aging brain, with inflammation potentially mediating age-related changes in the brain. Age-related alterations in ApoE expression have been shown to correlate with age-related changes in the cytokine interleukin-1β (IL-1β) in the brain of aging rats. In another study, ApoE expression was not altered during normal brain aging, but a relationship may exist between ApoE and IL-1β transcription in the cerebral cortex.

The role of cholesterol and oxidative stress is important in the pathogenesis of AD. Our current understanding of the role of oxidative stress in AD has resulted in the potentially beneficial use of vitamin E or selegiline, in delaying the clinical progression of functional loss and the time of nursing home placement. Cerebral oxidative damage is a feature of aging and increases in neurodegenerative diseases such as AD. In aged male and female mice, it has been shown that lack of ApoE is associated with

oxidative damage in the brain, with results more pronounced for male mice, especially those fed a tocopherol-deficient diet, and that supplementation with tocopherol is not effective in reversing arachidonic acid oxidation in APOE(−/−) mice.

Summary

Apolipoprotein E is encoded by a gene located on the long arm of human chromosome 19 (19q13). The protein is a vital part of cholesterol transport and functions in neurite outgrowth. ApoE mRNA and protein are found predominantly in astrocytes within the CNS. ApoE appears in three isoforms, ε2/ε3/ε4. The *APOE* ε4 allele is associated with the development of late-onset familial AD as well as late-onset sporadic AD. *APOE* ε4 has a gene dose effect on the risk and age of onset of AD. At the gene expression level, there is a report of a high expression of *APOE* mRNA in the brains with sporadic AD. Two promoter polymorphisms, −491A/T and −219G/C, have been repeatedly shown to influence AD risk. At the protein level, ApoE has been found to co-localize with one of the typical neuropathological lesions of AD, specifically the extracellular amyloid deposits.

Herein we have reviewed *APOE* as a risk factor for AD (as the most common form of aging-related neurodegeneration), both from the standpoint of the ε4 allele and potentially influential promoter polymorphisms, in general populations, among different racial and ethnic groups. The effect of the ε4 allele on annual decline in episodic memory is significantly stronger than is its effect on decline in other cognitive systems and at baseline, but there is an equal and opposite effect of the ε2 allele. Thus, the *APOE* allele status may influence risk of AD by a relatively selective effect on episodic memory. In addition, allele status alters cerebral glucose metabolism and influences age-related hippocampal volume loss.

APOE operates in age-related neurodegeneration, such as in AD, in a complex set of feedback loops that are influenced by both intrinsic and environmental factors (Figure 3). Briefly, the *APOE* gene regulatory region is a target for transcription factors such as NF-κB and inflammatory factors such as interleukins. Single-nucleotide polymorphisms in the promoter influence ApoE levels. Modulation of this regulatory region by differences in transcription factor/cytokine binding would alter *APOE* transcription levels, changing ApoE protein synthesis levels. Different responses to the same levels of transcription factors according to promoter polymorphism would also alter *APOE* mRNA levels. ApoE acts as a cholesterol transporter protein and carries cholesterol into the brain. Cholesterol modulates APP processing, since it increases the activity of one of the key secretase enzymes, β-secretase, which results in increased Aβ production. Aβ transported back into the cell would contribute to reactive oxidative species (ROS), inducing cytokine response. Oligomeric Aβ would cause gross neurodegeneration, and excess extra cellular Aβ accumulation results in amyloid deposits, which also contain cholesterol and ApoE. Furthermore, Aβ activates NF-κB, which in turn activates the *APOE* gene. Thus a vicious loop of interacting Aβ, *APOE*, cholesterol, and APP forms a cascade of events culminating in AD pathogenesis.

The proximal region of the *APOE* gene is highly conserved in the mouse, rat, and human; the relative positions of the 'TATA box' and the two copies of 'GC box' are identical. The human *APOE* promoter DNA contains putative sites for AP-1, AP-2, and NF-κB transcription factors. The NF-κB site interacts with Aβ, and this interaction can be blocked by salicylate. The promoter region also contains inflammatory response transcription factor sites such as IL-6 response element binding protein. Moreover, some of these transcription factor sites should provide suitable targets for drug development in treating devastating aging-related diseases such as AD.

Introduction

Over the past few years, significant advances in the study of brain genomics have been made due to the advent of DNA microarray technology, which has become the selected method for large-scale gene expression assessment. Gene microarrays provide a powerful new approach for addressing the complexity of brain function and aging-related processes, as they allow expression monitoring of thousand of genes simultaneously, permitting a more global analysis of genomic data.

The technique makes use of DNA sequences from a library of synthetic oligonucleotides; these are arrayed on a chip at a very high density. After extraction and labeling, nucleic acids from experimental samples are hybridized on the array chip and the amount of emitted fluorescence can be monitored, allowing a whole-genome expression analysis. The observations are not limited to single molecules, as the results can be integrated into biochemical pathways or classes of related genes using biostatistical tools. In fact, the significantly modified genes are automatically assigned to specific functional categories, such as molecular bioprocesses, chromosomes, cell compartments, and relevant pathways based on databased gene product functions (Figure 1).

Several recent endeavors have applied microarray technology to the study of the transcriptional modifications associated with the physiology and pathology of brain aging in both mammalian models and humans. Additionally, microarrays have been used to define the effects of mutations in the mitochondrial DNA (mtDNA) on nuclear gene expression. Mutations in the mitochondrial genome accumulate over time and mitochondria appear to play a central role in the process of brain aging. Herein we review the trends in gene regulation in the aging brain, the changes in mitochondrial mutations with age, and the direct consequences of mitochondrial mutations on the transcriptional profile of the nuclear genome.

Gene Expression Profiles of the Aging Brain

The gift of long life is counterbalanced by the price of aging. Aging is a progressive and inevitable process that involves all the organs, and mental decline is a broadly experienced status consequent to physiological brain aging. The same changes experienced by brain cells during normal aging are exacerbated in vulnerable populations of neurons in neurodegenerative disorders. Neurodegenerative diseases, most frequently manifested in the form of Alzheimer's disease (AD) and Parkinson's disease (PD), affect an increasing proportion of the aging population and are considered as the pathological side effects of normal aging. Genetic, biological, and environmental factors all contribute to physiological and pathological brain aging, and thus understanding the transcriptional response in both cases might help in creating therapeutic strategies to fight pathology and in the definition of interventions to slow down physiological cognitive decline.

Several hypotheses have been proposed regarding the nature of neural death during aging, and the three main mechanisms involve oxidative stress, calcium dysregulation, and apoptosis. Oxidative stress occurs when the cellular redox homeostasis is imbalanced by an increase in pro-oxidant species, known as reactive oxygen species (ROS), without a corresponding increase in the protective antioxidant counterparts. ROS include a variety of diverse chemical species and, although partially generated by cytosolic enzyme systems such as NADPH oxidase or cytosolic reactions as dopamine catabolism, a vast majority of intracellular ROS are derived from the mitochondria. Mitochondrial ROS (superoxide anion, hydrogen peroxide, and hydroxyl radicals) are generated as by-products of mitochondrial oxidative phosphorylation (OXPHOS), which provides ATP via the reaction of hydrocarbons with oxygen. The free-radical theory of aging, formulated in the mid-1950s, hypothesizes that life span is limited by the accumulation of cellular damage from reaction with endogenous oxygen radicals. This endogenous formation of oxidative species may be spontaneous or triggered by specific external stimuli and can increase as humans age, eventually leading to irreversible and deleterious cellular modifications. Indeed, once ROS are generated, they can react with DNA, proteins, and lipids, and damage them. All organs and proteins can potentially be modified by oxidative stress, but certain tissues such as neurons and muscle may be particularly sensitive, as they are highly energy dependent. Energy-dependent tissues are in fact very sensitive to any mitochondrial alterations, the mitochondrion being the main cellular powerhouse and also the cellular compartment that has the greatest exposure to oxidative insults.

The 'calcium dyshomeostasis' hypothesis of brain aging proposes that early in the aging process, Ca^{2+}

Figure 1 A summary of basic steps in microarray technology.

balance in brain cells begins to be dysregulated, influencing multiple signaling pathways modulating cellular physiology, molecular functions, and cell structures of the normal brain. The same subtle age-dependent changes in Ca^{2+} homeostasis may increase vulnerability to neurodegenerative diseases such as AD. Changes in free Ca^{2+} concentrations in various subcellular compartments act as a universal signaling system and can be modified by uptake into the endoplasmic reticulum (ER) or into mitochondria, which can function as Ca^{2+} reservoirs. Unbalanced increase of Ca^{2+} influx into neurons can also be caused by excessive activation of glutamate receptors, a process known as glutamate excitotoxicity, which may result in dendritic damage and cell death. Glutamate is the main excitatory neurotransmitter in the central nervous system (CNS) and most neurons commonly receive synaptic glutamatergic input. Several molecular and cellular changes occurring during physiological aging and disease-specific abnormalities are known to increase neural vulnerability to excitotoxicity, and glutamatergic defects are thought to underlie the development of memory loss associated with aging.

Apoptosis is the most widely studied type of programmed cell death in the CNS. It can be triggered by several upstream factors, suggesting that, even if specific gene mutations give rise to different neurodegenerative disorders, there may be a convergence of disease- and age-related pathways on the same well-known cell death cascades. Apoptosis is regulated by cysteine proteases called caspases, which trigger cell death by degrading various structural proteins. Two main pathways are responsible for the activation of the caspases that execute the apoptotic death program. The extrinsic pathway involves cell-surface signaling complexes that activate caspase 8 and downstream caspases. The intrinsic, or mitochondrial, pathway controls activation of caspase 9 by regulating the release of cytochrome *c* from mitochondria. The latter appears to be predominant in the brain and, independently from the origin of the upstream activators, mitochondria, together with the ER, regulate and modulate the entire process, playing a role in integrating cellular stress signals.

Nonetheless, whether the mechanisms of cellular death involve ROS generation, Ca^{2+} dysregulation, or activation of apoptotic factors, the study of nuclear profiling is of enormous help in understanding the common mechanisms upstream of neuronal death and the complex process of brain aging.

Trends in Animal Models

Most genomic studies of brain aging have been performed in rodent models. Aging results in a gene expression profile indicative of oxidative stress, altered Ca^{2+} regulation, apoptosis, and reduced mitochondrial function, suggesting that the three hypotheses regarding the nature of neural death may all be part of the same process, sharing mitochondrial dysfunction as a central common element. In addition, other relevant transcriptional modifications are related to inflammatory response, altered synaptic signaling, decreased protein turnover, and decreased levels of growth and trophic factors. Overall, upregulated genes can be assigned to the following categories: stress response, Ca^{2+}-related signal transduction, vesicle trafficking, myelin and lipid synthesis, inflammatory response, and glial function (Table 1).

The stress response category comprises genes involved in oxidative stress, heat shock response,

lysosomal proteases, and apoptosis. These include ROS-activated elements, such as glutathione-*S*-transferase, several heat shock factors, components of the lysosomal proteolytic system, and injury or hypoxic stress-induced elements. The stress category thus appears to play an essential role in the aging process, although most likely a secondary one consequent to cellular insults, rather than being a primary step. The putative triggers could be calcium pathway dysfunctions as well as mitochondrial modifications. In fact, upregulation of transcripts encoding Ca^{2+}-regulating pathways has been detected, including modulators of Ca^{2+}-induced release and the voltage-dependent anion channel (VDAC) that regulates Ca^{2+} flux into the mitochondria and plays a central part in apoptosis. Elevated intracellular Ca^{2+} concentration can reduce neural activity through the activation of inhibitory Ca^{2+}-dependent conductances; amplified Ca^{2+} release and influx in aged neurons may eventually lead to decreased neural responsiveness and synaptic plasticity.

Vesicle trafficking genes include those encoding SNARE (*N*-ethylmaleimide-sensitive factor attachment protein receptor) proteins that are involved in docking and fusion of synaptic vesicles to the active zone, as well as in the calcium-triggering step itself, as part of the exocytotic process at the presynaptic plasma membrane. Their increase has been proposed to be linked to the upregulation of myelin-related proteins, myelin-associated oligodendrocytic basic protein, and myelin-associated glycoprotein. The production and the secretion of myelin in oligondendrocytes may be increased in response to light-activated demyelinating processes occurring during aging. Demyelination and, most importantly, oxidative stress can then trigger a widespread neuroinflammatory response.

Neuroinflammation is mediated by microglial activation and cytokine release and can exacerbate the initial demyelination and redox status disequilibrium, creating a positive feedback. Activated transcripts included the microglia and macrophage migration factor, receptors that mediate the microglial activation pathway, inflammation markers, complement cascade genes, and major histocompatibility complex (MHC) class I antigen-presenting molecules. Both the widespread inflammatory response and the myelin production involve glial cells, and, as further confirmation, glial function genes appear to be upregulated in rodent brain aging.

Downregulated genes are mainly involved in mitochondrial function and energy metabolism, protein synthesis and turnover, synaptic plasticity, extracellular matrix (ECM) production, and neurotrophic factors. Downregulated mitochondrial transcripts include genes responsible for mitochondrial function, as well as electron transport chain genes. The overall inhibition of mitochondrial-related transcripts may be interpreted either as a primary event related to aging or, more likely, as the nuclear response to mitochondrial alterations which cause or are caused by oxidative stress. Mitochondrial dysfunction may be responsible, together with calcium dyshomeostasis, for evoking the cellular stress response; the downregulation of mitochondrial genes could then represent a nuclear attempt to shut down a process that is not working properly. The consequences would be deleterious for energy metabolism and would lead to metabolic and biosynthetic involutions. Accordingly, a decrease in protein biosynthesis and turnover is also observed.

Table 1 Global view of nuclear transcriptional changes induced by brain aging (in mammalian models and in humans) and by human mtDNA mutations

Brain aging	*mtDNA mutations*
Upregulated transcripts	Upregulated transcripts
Stress response	Stress response
Ca^{2+}-related signal transduction	Ca^{2+}-related signal transduction
Vesicle trafficking	Vesicle trafficking
Myelin and lipid synthesis	Cell cycle and cell proliferation
Inflammatory response	Glycolysis
Glial functions	
Downregulated transcripts	Downregulated transcripts
Mitochondrial function and energy metabolism	Mitochondrial function and energy metabolism
Protein biosynthesis	Protein biosynthesis
Protein turnover	Protein turnover (mtDNA deletion specific)
Synaptic plasticity	Synaptic transmission
Extracellular matrix production	Cell migration
Growth and neurotrophic factors	Oligodendrosis

Transcripts encoding the main cellular pathway responsible for cytoplasmic protein degradation, the ubiquitin–proteasome system (UPS), are in fact mainly downregulated. Interestingly, UPS inhibition is known to cause accumulation of altered or misfolded proteins in some neurodegenerative diseases (e.g., PD and AD).

Downregulated activity-dependent synaptic/neurite plasticity genes comprise genes which have been previously linked to synaptogenesis, neurite remodeling, plasticity, or memory. Reduced synaptic signaling and plasticity in neurons have been linked to disruption of memory consolidation, which is a common feature of both physiological and pathological cognitive impairment. Moreover, some of these genes are also significant components of the ECM, and their downregulation may suggest a genomically mediated ECM erosion, which has been hypothesized to be related to the demyelination process. As a further confirmation, other ECM elements are also downregulated.

Inhibition of several genes associated with either trophic or growth functions has been detected. Lack of neurotrophic factors, which are involved in neural development and rescue from excitotoxic or metabolic insults, can thus exacerbate the whole process, leading aged brain cells to death. Transcripts comprise fibroblast growth factor, glial neurotrophic factor, and factors involved in neural migration.

Similar genomic transcriptional profiles have been identified in rodent models for AD, as multiple studies have demonstrated increased expression of inflammation-associated genes, apoptosis-related transcripts, and altered mitochondrial energy metabolism genes. Thus, common central elements for physiological and pathological aging appear to be calcium homeostasis, mitochondrial dysregulation, and stress- and inflammation-mediated neural damage. So far, the main mechanism that has proved effective in retarding the aging process in rodents appears to be caloric restriction (CR). CR may also extend the maximum life span of several nonmammalian models. Explanations involve decrease in ROS production, decreased body temperature associated with a hypometabolic state, hormone signaling changes, and alterations in gene expression and protein degradation. Interestingly, CR is found to selectively attenuate the age-associated induction of genes encoding for inflammatory and stress responses.

Trends in Humans

The patterns of changes in gene expression observed in microarray experiments performed on aged human neurons have mainly reproduced the ones identified in rodents, helping to define a potential fingerprint of brain aging. The human transcriptional profiles are characterized by the induction of genes mediating stress response and repair functions, inflammatory and immune responses, myelination, and lipid metabolism. Transcripts reduced with aging include genes involved in signal transduction, synaptic function and plasticity, learning and memory processes, calcium homeostasis, protein turnover, and mitochondrial functions (Table 1).

Genomic studies of human pathological aging mainly have focused on AD. Two basic approaches are used: the comparison of AD-affected and AD-resistant brain tissues from the same individuals or the comparison of AD-affected brain structures of AD patients and age-matched controls. Although transcriptional changes of important elements of AD neuropathology have been identified, alterations shared with normal aging are also observed. Common trends are represented by the activation of apoptotic and neuroinflammatory signaling, stress response, and lipid metabolism, and the inhibition of the gene categories involved in synaptic plasticity and neurotrophic factors.

Taken together, common features of brain aging appear to be the repression of genes implicated in mitochondrial oxidative respiration, the decline in physiological neural activities, and inflammatory and glial reactions. In order to establish a cascade of events, some authors hypothesize that the primary dysfunctions occurring in aged neurons may be either calcium or mitochondrial dysfunctions, leading to cellular stress and genome damage, which in turn may compromise biosynthetic and metabolic pathways as well as systems that subserve synaptic functions and neural survival. Eventually, neural alterations might translate into widespread reactions involving glial responses, inflammation, and demyelination.

Mitochondrial Mutations and Aging

Mitochondria, in addition to their well-known role in respiration and OXPHOS, are important sites for diverse cellular functions such as fatty acid oxidation and heme, urea, amino acid, and phospholipid biosyntheses. However, as explained previously, their relevance for the aging process consists in the central role they play in ROS generation, Ca^{2+} signaling, and apoptosis.

Mitochondria, unlike other cellular compartments, possess an individual genome. mtDNA is a small 16.6 kb double-stranded circular DNA that encodes 13 respiratory chain polypeptides and 24 nucleic acids that are needed for intramitochondrial protein synthesis. mtDNA genes cannot be translated by use of the universal genetic code, hence the need for

mtDNA to encode its own ribosomal RNA and transfer RNA genes. Replication is independent of the cell cycle and can occur even in nondividing cells. The rest of the respiratory chain elements and mitochondrial proteins (approximately 900 gene products) are all encoded by the nuclear genome. Nuclear DNA is also relevant for it maintenance, as it encodes the only DNA polymerase known to be targeted to mitochondria: DNA polymerase-γ (POLG). POLG is responsible for all aspects of mtDNA synthesis, replication, and repair of mtDNA damage. It corrects mistakes made during replication by copying and proofreading the genome and it can participate in the resynthesis of DNA during the DNA repair processes. Overall, the cross-talk between nuclear and mitochondrial genomes plays an essential function in regulating mitochondrial activities.

mtDNA damage is a very likely event, given the proximity of mitochondria to an environment rich with reactive species, the lack of genomic introns and protective histones, and the presence of a single DNA polymerase. Consequently, mtDNA accumulates mutations more than 10 times faster than does the nuclear genome. Because multiple copies of mtDNA reside within each mitochondrion, and several hundred mitochondria are present within each cell, when a mutation occurs, the result is a dual population of mtDNAs – mutant and wild-type – coexisting within the same cell, a phenomenon called heteroplasmy. Moreover, mtDNA randomly segregates during mitosis, leading to different levels of heteroplasmy in different tissues. Eventually, when the amount of mutated mtDNA in a particular tissue reaches a threshold, pathological manifestations can become evident.

In the general population, mitochondrial genes in several nonreproductive (somatic) tissues accumulate mutations over time, and this event has been proposed to underlie the deleterious cellular modifications associated with aging. Somatic mtDNA mutations, in fact, may lead to energy-generation defects, increased number of harmful free radicals, or calcium dyshomeostasis, resulting in lowered cell and tissue functions characteristic of advanced age. Point mutations (single base-pair changes), deletions, and wider rearrangements of mtDNA can all occur and increase as humans age. These mutations are unevenly distributed and can accumulate clonally in certain areas, causing a mosaic pattern of respiratory chain deficiencies in tissues such as skeletal muscle, heart, and brain. A frequently observed mutation is a deletion of mtDNA of about 5 kb in length, the so-called common deletion, which preferentially occurs at much higher levels in nervous and muscle tissues. Deletions, accumulated exponentially with age, reach much lower concentrations in most tissues of healthy individuals than in patients affected by mitochondrial disorders such as Kearns–Sayre syndrome (KSS) or chronic progressive external opthalmoplegia (CPEO). However, deletions levels may come close to 5% in muscle tissue and to 50% in substantia nigra. These deletions occur as spontaneous errors in individual cells as a consequence of age, and rise in concentration over time, with each cell containing a different predominant deletion species. Age-dependent mtDNA deletions have also been linked with respiratory chain defects in muscle and substantia nigra.

More recently, it has been demonstrated that a defective POLG is correlated with an increased level of mtDNA mutations, comprising deletions and point mutations. Eliminating the proofreading activity, POLG becomes error prone, giving rise to increased somatic mtDNA mutations. Accumulation of mutations is associated with reduced life span and premature onset of aging-related phenotypes in mice models carrying defective POLG, demonstrating a causative link between mitochondrial mutations and aging in mammals. In POLG mutant mice, the increase in mutations in the mitochondrial genome is not associated with oxidative stress, but has been correlated with the induction of apoptotic markers. Accelerated development of aging through mtDNA mutations may thus occur even without redox imbalances. In the apoptotic pathway, mitochondrial dysfunction can lead to mitochondrial outer membrane permeabilization and subsequent release of cytochrome *c* in the cytoplasm, which in turn activates the key effector, protease caspase 3. However, the hypothesis of a contribution of oxidative DNA damage to aging is supported by other studies in humans and mice. In fact, the event leading to an error-prone POLG might be secondary to protein damage caused by ROS. However, the disruption of physiological mitochondrial activities appears to be a major element in the chain of events leading to aging.

Interestingly, CR, the only nutritional intervention that retards aging in animal models, has been demonstrated to reduce the mitochondrial-mediated apoptosis pathway and to delay the accumulation of mtDNA mutations in rodents. Indeed, CR reduces fiber loss and mitochondrial abnormalities in aged muscle and attenuates the increase in cytosolic cytochrome *c* and caspase 2 activity with age. As a therapeutic strategy, the possible application of CR to the human population would face ethical and practical problems, but the study of the specific mechanisms responsible for the antiaging influences of CR could lead to the development of pharmacological agents. Moreover, the demonstration that CR increases life span by decreasing the accumulation of mtDNA

mutations and reducing mitochondrial apoptosis strengthens the concept that losses of mtDNA integrity and mitochondrial function are central factors in brain aging.

Genomic Effects of Mitochondrial Mutations

Mutations in gene products expressed in the mitochondrion cause a nuclear transcriptional response that leads to neurological disease, such as Leber's hereditary optic neuropathy (LHON), neurogenic ataxia and retinitis pigmentosa (NARP), mitochondrial myopathy/encephalopathy/lactacidosis/stroke (MELAS), myoclonic epilepsy with ragged red fibers (MERRF), KSS, and CPEO. As indicated previously, the same mutations may play a causative role in the aging process as well. In order to assess mitochondrial disease nuclear genomic profiles, microarray analyses have been performed in different cell types. The results have demonstrated that a similar transcriptional profile is shared among different mitochondrial diseases, as if each mitochondrial disease and mitochondrial mutation could generate a common nuclear response (Table 1).

Upregulated transcripts encode for genes in the categories of stress response, calcium signaling regulation, cell cycle and cell proliferation, vesicle-mediated transport, and glycolysis. In the stress response category, ER- and unfolded protein response (UPR)-related transcripts are detected. This suggests that mitochondrial inhibition might be sufficient for activation of the UPR, which occurs when ER function is perturbed. Apoptosis is known to be stimulated in the presence of prolonged ER stress. Thus, mitochondrial mutations or other factors inducing a cellular stress response may eventually give rise to the mitochondrial apoptotic pathway. UPR induction may occur consequently to ER stress, which can be generated as a result of mitochondrial mutations, either by increased ROS production or by Ca^{2+} signaling perturbations caused by mitochondrial bioenergetic defects. Upregulation of transcripts related to Ca^{2+} modulation is in fact detected, including VDAC, which is thought to reside at the mitochondrial–ER interface and to control Ca^{2+} transients. Moreover, it has been shown that depletion of mitochondrial membrane potential induces both the UPR genes and cell cycle genes. Accordingly, cell cycle and cell proliferation genes are induced. As observed for the brain aging genomic profiles, vesicle trafficking genes, protein transport genes, and ER-to-Golgi transport genes appear to be induced also as a consequence of mitochondrial mutations. However, the reason for this activation is still unclear. Glycolysis transcripts, such as aldolase C, are also upregulated, and their increase may be interpreted as the nuclear attempt to restore energetic metabolism functions.

Functional clusters inhibited by mitochondrial diseases include mitochondrial ATP synthesis, protein biosynthesis, synaptic transmission and vesicular secretion, cell migration, and oligodendrogenesis. Transcripts coding for mitochondrial proteins and specifically for ATP synthesis are downregulated. The data suggest that the nucleus senses the irreversible depletion of mtDNA-encoded mitochondrial subunits and transfer RNAs, and responds by downregulating the interacting subunits that would normally form a functional complex. The downregulation of nuclear-encoded mitochondrial ribosomal subunits and OXPHOS transcripts thus appears to reinforce the mitochondrial defect initiated by the mutations. As observed in aged brain transcriptomes, deleterious modifications of energy metabolism may lead to metabolic and biosynthetic involutions, as the functional category of protein biosynthesis appears to be inhibited. Moreover, members of the vesicular secretion pathway, or proteins that are transported by the vesicular secretion pathway, are also decreased. In addition to their function in vesicular secretion, some gene products of this category have also been shown to be involved in cellular migration, as cellular migration is dependent upon the process of vesicular secretion, both for secretion of cell migratory signals into the ECM as well as for the interpretation of them. Additionally, UPR and ER stress induction are known to inhibit protein synthesis and vesicular secretion. Oligodendrocyte-specific transcripts are found downregulated in mitochondrial diseases. Oligodendrocytes are especially dependent on lipid synthesis, cell-to-cell contact, synaptogenesis, and migration. In addition, the dihydroceramide desaturase transcript (DEGS1), which produces ceramide, the precursor of sphingomyelin, a major component of the myelin sheath, is also inhibited. These findings suggest that demyelination could be an important pathophysiologic feature of mitochondrial mutations, especially because myelin is transported by the vesicular secretion pathway.

Overall, microarray data show that there is a significantly shared transcriptomal imprint of mitochondrial mutations, which implicates specific pathophysiological pathways. The data support the hypothesis that mitochondrial mutations may preferentially causes ER stress, which in turn triggers the UPR and decreases vesicular secretion, resulting in dysfunctions of secreted proteins involved in synaptogenesis, neural cell migration, and oligodendrocyte function. Interestingly, most of these transcriptional modifications are similar to the ones relative to brain aging, as

if mtDNA mutations play a primary causative event in the aging process.

Recently published microarray data from our laboratory, conducted on several cell types harboring mtDNA deletions, show a prominent inhibition of transcripts encoding ubiquitin-mediated proteasome activity. Thus, the downregulation of the ubiquitin–proteasomal system appears to be a unique consequence of mtDNA deletions. As already described, mtDNA deletions are the most common type of mitochondrial mutations known to accumulate exponentially during aging and to preferentially occur at higher levels within the CNS, and in the substantia nigra in particular. Thus, the genomic signal of UPS inhibition characteristic of brain aging might be secondary to an increase in mtDNA deletions, and this may even be more dramatic for neurodegenerative diseases with UPS defects, such as PD, which is characterized by specific death of dopaminergic neurons within the substantia nigra.

Conclusion

The field of aging research has been completely transformed in the past decade. Genomic profiles associated with brain aging became available due to the advent of microarray technology, and it is now widely accepted that the aging process is subject to regulation, like most biological processes. Mitochondrial dysfunctions were already known to play a relevant role because of the centrality of the organelle in apoptosis, Ca^{2+} regulation, and oxidative stress, and because mtDNA mutations increase with age. In addition, the nuclear transcriptional profiles consequent to mtDNA mutations are showing multiple similarities with the ones relative to brain aging. Similar trends in activation and inhibition of functional categories can be observed. Overall, it is becoming more evident that mutations in the mitochondrial genome in aged neurons play a causative role rather than merely being correlative, and the concepts connected to the mitochondrial theory of aging are thus undergoing change.

Genomics of Brain Aging: Twin Studies

The Twin Method

The study of adult twin siblings offers a distinctive perspective on brain aging. Monozygotic (MZ; identical) twins share 100% of their genes in common, while dizygotic (DZ; fraternal) twins share 50% of their segregating genes in common. This fortunate experiment of nature affords multiple avenues to consider the etiology of brain aging. For example, comparing the relative similarity of MZ twins to DZ twins allows one to consider the extent of genetic and environmental influences on individual variation in cognitive performance or dementia status. If MZ twins are more similar than are DZ twins in recall memory performance, for example, then genetic influences are implicated. For this same trait, if DZ twins are as similar to each other as are MZ twins, then shared environmental effects, such as family environments and school environments, are implied. To the extent that MZ twins are dissimilar (e.g., a correlation less than 1.0), then nonshared environmental influences are implied.

Quantitative Traits

For quantitative traits, such as recall memory performance scores, covariances between twin pair scores are calculated for MZ pairs (C_{mz}) and for DZ pairs (C_{dz}). Next, a formal biometric model is fit to the covariances. The biometrical model quantifies understanding of all possible, though anonymous, genetic and environmental causes and shows how these factors contribute to sibling similarity. For example, the biometrical model could state that individual differences in recall memory performance (V_{mem}) are a function of genetic factors that act additively (V_a), plus rearing environment factors (V_r), plus unique person-specific (nonshared) experiences (V_e):

$$V_{mem} = V_a + V_r + V_e \quad [1]$$

Next, the model specifies that two related individuals have similar recall memory scores due to the amount of genes shared, and the environment shared. For MZ twins reared together, their recall memory scores are similar, or co-vary, because the twins are genetically identical and they share a rearing environment:

$$C_{mz} = V_a + V_r \quad [2]$$

For DZ twins reared together, their recall memory scores are similar because the twins share half of their segregating genes in common and share a rearing environment:

$$C_{dz} = 1/2V_a + V_r \quad [3]$$

Heritability is often reported as a summary statistic and is a numerical ratio of genetic factors (V_a) over the total amount of individual differences in recall memory (V_{mem}). Thus, heritability (h) indicates the proportion of individual differences in recall memory scores that is due to genetic differences:

$$h^2 = V_a/V_{mem} \quad [4]$$

Environmentality estimates are computed in similar fashion (e.g., shared environmentality is the ratio of V_r/V_{mem}). In longitudinal studies, there is increasing emphasis on unscaled genetic and environmental variance (i.e., V_a, V_r, V_e). For example, one can better judge whether both genetic and environmental influences are increasing or decreasing with age, a process that otherwise would be masked with ratio-based heritability and environmentality statistics. This knowledge is important in theorizing about potential gene action, specific environmental factors to consider, or longevity-related mechanisms whereby individuals with particular genotypes may die at earlier (or later) ages.

Disease Traits

Disease traits are typically measured in terms of absence or presence (i.e., dichotomously), or otherwise as ordinal categories. Concordance rates are commonly reported for dichotomous traits and are compared between MZ and DZ twin pairs. Probandwise concordance is the simple proportion of co-twins of affected proband twins that exhibit the disease trait (e.g., Alzheimer's disease (AD)). In much the same way as for quantitative measures of pair similarity, the extent of differences between MZ and DZ concordance rates gives an indication of genetic influence. Furthermore, the extent to which the MZ concordance rate is less than 100% suggests the degree to which nonshared environmental influences, including random factors, are important.

Other measures of pair similarity may be reported for dichotomous or ordinal categorical traits, including tetrachoric and polychoric correlations, respectively. Herein, the assumptions are that there is an underlying continuum of liability or risk of the disease and that the observed proportion of those with the disease constitutes a threshold point on the normal curve where the disorder is manifested.

The interpretation of the correlations computed for twin pairs is that they reflect the magnitude of pair similarity for the underlying disease liability continuum. Prevalence rates increase concordance rates even when the underlying pair similarity for the disease liability is identical. Thus, tetrachoric correlations are preferred over concordance rates when the prevalence rates of the disease differ between groups included in the analysis, as can be the case for males versus females (e.g., AD). The biometrical model described in eqns [1]–[3] is applied to the tetrachoric or polychoric correlations in similar fashion.

Assumptions of the Twin Method

Analytical requirements include the assumption of equal environments for twins-reared-together, as well as no assortative mating. The equal environments assumption (EEA) states that the shared environment (e.g., family environment, school environment) contributes equally to a trait in both MZ and DZ pairs. The vast majority of analyses which have tested for EEA violation across multiple psychological and psychiatric traits have indicated little support for EEA violation, thus providing sufficient confidence in the findings from studies of twins-reared-together, though it must be noted that some controversy remains over the adequacy of tests for violations of the EEA.

A second assumption is the absence of assortative mating – that is, spouses or mates do not select one another on the basis of the trait in question. There is ample evidence that spouses are moderately similar in terms of cognitive abilities, extant from the time of marriage. For aging-related cognitive traits (i.e., cognitive aging, AD), there are few data reported on spouse similarity. For now, it appears that the similarity between spouses for dementia is no greater than the similarity between any two people of the same age and sex.

Co-Twin Control

In studies of discordant twins, the co-twin control method compares affected twins to their unaffected partners on a host of environmental factors. This design is advantageous to comparable case-control designs, as matching the discordant twins to their co-twin accounts for any confounding genetic of familial factors that might bear upon the disease trait. Indeed, discordant MZ twin pairs who share 100% of their genes in common are most valuable for full control of genetic and familial factors.

Candidate Genes

Twin siblings who differ in terms of their recall memory scores, for example, and who differ in genotype at a particular gene locus (e.g., *APOE* ε3/ε4 vs. *APOE* ε3/ε3), give potential information about the association of the candidate gene with recall memory performance. True gene effects contribute to within-twin-pair differences, in the case of DZ twins, as well as to between-twin-pair differences for both MZ and DZ twins. Thus, formal tests of association in twins compare whether, according to genotype, within-pair differences and between-pair differences in trait scores are of the same magnitude. Twin designs have a distinct advantage over standard case-control designs, in which genetic association may be spurious if cases and controls originate from separate populations with differing gene frequencies (i.e., population stratification).

Cognitive Aging and Dementia via Twin Models

Twin Studies

Several research programs include adult twins as a focus in studies of cognitive abilities, most situated in the US (e.g., MTSADA, Minnesota Twin Study of Adult Development and Aging; NHLBI, National Heart, Lung, and Blood Institute Twin Study; New York Twin Study) or Scandinavia (LSADT, Longitudinal Study of Aging Danish Twins; Norwegian Twin Register; OCTO-Twin, Origins of Variance in the Oldest Old; SATSA, Swedish Adoption/Twin Study of Aging; the Gender Study of Opposite-Sex Twins), though others are located in Germany (German Observational Study of Adult Twins), Italy (Italian Twin Registry), Japan (Osaka/Kinki University Twin Study; OUATR, Osaka University Aged Twin Registry), and The Netherlands (Netherlands Twin Register). Among these research programs, the longitudinal studies, LSADT, NHLBI, OCTO-Twin, and SATSA have provided much of our knowledge about the etiology of cognitive decline. Summaries of findings from these studies are presented in the following sections.

Twin studies of cognitive impairment and dementia are fewer in number than are those addressing cognitive aging, and include two large-scale programs in the USA (NAS-NRC Registry, National Academy of Sciences – National Research Council Registry of World War II veteran twins; NHLBI), and several in Scandinavia (LSADT; Norwegian Twin Register; HARMONY, Study of Dementia in Swedish Twins).

Contributions of Genes and Environments

General cognitive abilities Cross-sectional findings of adult twins indicate a strong heritability for general cognitive ability, or *g*, with a median value of 0.69 (see Figure 1). Therefore, 69% of the individual

Figure 1 Heritability estimates of cognitive abilities; *g* represents general cognitive ability. Note: Tops of solid colored bars indicate median heritability estimates from all adult twins studies that included older adult twins. Lower ends of 'error bars' indicate median old-old estimates and upper ends indicate young-old median.

differences in general cognitive ability results from genetic differences. Furthermore, the described studies find no evidence for shared environmental factors (e.g., rearing environment) affecting general cognitive abilities in adults, thus the remaining proportion of individual difference, 0.31, or 31%, is due to person-specific or nonshared environmental influences. Studies that report separate estimates for young-old adults versus old-old adults consistently suggest a waning of heritable influences for old-old adults, and concomitantly an increase in nonshared environmentality influences. The median heritability estimate for young-old twins is 0.69 versus 0.62 in the old-old (see error bars in Figure 1). Swedish twin studies, in particular SATSA and OCTO-Twin, suggest even more marked difference in heritability: as high as 0.80 in young-old twins and 0.62 in old-old twins. Thus, cross-sectional findings imply waning genetic influences in old-old age.

Specific cognitive abilities Specific ability domains, such as verbal, spatial, memory, and perceptual speed abilities, show varying patterns of the extent of genetic influences. The median heritability ranges from 0.50 for memory to 0.66 for verbal abilities (see Figure 1). Virtually all cross-sectional studies suggest that the remaining variation is largely due to nonshared environmental influences, with few hints of shared environmental effects on select cognitive measures within a domain. Furthermore, no convincing evidence for sex differences in heritability or for sex-limited genetic or environmental factors has been presented to date.

The median estimate of 0.66 for verbal ability across all studies is flanked by a median heritability of 0.78 in the young-old and a heritability of 0.46 in the old-old, again suggesting a similar pattern of waning genetic influences in old-old age. The most disparate pattern between young-old and old-old heritability estimates is observed for spatial ability (median of 0.72 in young-old and 0.32 in old-old), and the least is observed for perceptual speed (median of 0.66 in young-old and 0.62 in old-old). The estimates for the memory domain indicate a median heritability of 0.50 across all studies, and a median heritability of 0.40 in old-old versus 0.50 in young-old adult twins.

The memory domain is made up of multiple distinctive processes, including working memory, semantic memory, episodic memory, and long-term memory. Twin studies suggest higher heritability estimates for working memory measures than for episodic memory measures. Furthermore, the SATSA study indicates a lower heritability for working memory measures in young-old versus old-old (0.36 vs. 0.63) but a higher heritability for episodic memory measures in young-old versus old-old (0.50 vs. 0.33), as has been noted for the other cognitive domains.

Across domain, the differences in heritability and environmentality estimates among young-old and old-old suggest that new environmental factors may emerge in old-old adults, or perhaps that cohort differences are important. Longitudinal studies of twins best address these possible explanations and most directly assess the heritability of cognitive decline.

Cognitive change Longitudinal studies of twins have added to our understanding of the etiology of cognitive abilities and particularly of cognitive decline with age. Figure 2(a) illustrates the nature of the data analyzed in longitudinal studies of twins. Twins have their own individual cognitive test score trajectory that can be aligned to age of measurement. Furthermore, the trajectories within and between pairs are examined to establish the extent of environmental and genetic influences. The illustrative trajectories in Figure 2(a) suggest that cognitive performance (e.g., episodic memory ability) declines with age for all four twins. Furthermore, the extent of decline differs across individuals and within pairs, particularly for the DZ twin pair versus the MZ pair. Analyses of longitudinal twin data consist of fitting characteristic curves (e.g., linear, quadratic) to individual cognitive data and comparing twin similarity for curve parameters. By and large, the curves of MZ twin pairs are more similar than are those of DZ twin pairs, but

Figure 2 Application of longitudinal twin models to longitudinal cognitive data: (a) illustrative data for monozygotic (MZ) and dizygotic (DZ) pairs of twins, ages 70–86 years; (b) actual results from the Swedish Adoption/Twin Study of Aging for general cognitive ability, *g*, for twins aged 50–80 years. V_a represents additive genetic variance contributing to systematic longitudinal growth; V_e represents person-specific (nonshared) environmental variance contributing to systematic longitudinal growth; V_u represents occasion-specific variance (nongrowth-related variance). (b) Data from Reynolds CA, Finkel D, McArdle JJ, Gatz M, Berg S, and Pedersen NL (2005) Quantitative genetic analysis of latent growth curve models of cognitive abilities in adulthood. *Developmental Psychology* 41: 3–16; and adapted from Reynolds CA (in press) Genetic and environmental influences on cognitive change. In: Hofer SM and Alwin D (eds.) *The Handbook of Coginitive Aging. Interdisciplinary Perspective*. London: SAGE, with permission.

pairs become less similar to one another with age, particularly after age 65 years. Genetic factors influence average cognitive performance levels, as well as the shape of curve trajectories, though to a lesser degree. Furthermore, the course of genetic and environmental influences with age is consistent with cross-sectional studies, with the exception of memory; that is, there are waning genetic influences after age 65 years and increasing nonshared environmental influences. Figure 2(b) shows findings from the SATSA study for general cognitive ability, *g*, where only additive genetic factors (V_a) and nonshared environmental factors (V_e) contribute to individual differences in average performance and change. Genetic factors contribute the most to individual differences in *g* with age, but a decreasing trend is evident after age 65 years, when nonshared environmental factors assume greater importance. Thus, unique person-specific environmental factors may become amplified in late adulthood, or, alternatively, new environmental factors emerge. Likewise, the increase in nonshared environmental effects may suggest the possibility of gene–environment (G × E) interactions, as G × E effects become part of the nonshared environment estimate if present but not modeled directly.

The pattern of increasing unique person-specific environmental factors and decreasing role for genetic factors has been observed nearly uniformly across cognitive domains, with the exception of cognitive measures that tap memory. For example, for both working memory and episodic memory tasks, both genetic and unique person-specific environmental factors increase in importance with age, suggesting the amplification or emergence of new genetic and environmental factors in late adulthood. Thus, the search for measured genes and measured environments for cognitive change is of interest.

Endophenotypes of cognitive aging Locating relevant and heritable intermediary neural traits (i.e., endophenotypes) which relate to cognitive aging is important to understanding mechanisms underlying cognitive change. Studies of adult twins suggest that processing speed, brain volume, and electroencephalogram (EEG) measures may be reasonable endophenotypes in the search for measured genes, given their significant though typically modest to moderate relationships with measures of intellectual ability. Recently, regional brain volume metrics have been associated with cognitive performance in Dutch twins, as well as in aging male twins from the NHLBI study, in which a significant percentage of the relationship between lateral ventricular volumes and executive functioning performance was due to common genetic influences; other lobar brain volume–cognition relationships were associated through shared and nonshared environmental pathways. Furthermore, higher white-matter hyperintensities (WMHs) predict greater rates of decline in perceptual speed performance, and this association may be due largely to common genetic effects influencing both cognitive function and WMH.

Cognitive functioning The heritability for mental status is 0.49 across studies. However, mental status performance as assessed with telephone screening

methods tends to yield lower heritability estimates than when assessed with in-person instruments (e.g., Mini-Mental Status Exam), which may in part reflect selection effects on health for those well enough to participate in person or by telephone. Furthermore, compared to cognitive performance measures or risk of AD, heritability of cognitive dysfunction is typically lower and may be the result of the diverse range of factors that lead to cognitive impairment, including health conditions and poor lifestyle habits, some of which show little evidence of genetic influences, such as cardiovascular disease.

Dementia Late-onset AD is due to multiple factors and is highly heritable, with MZ twins showing consistently higher concordance (and tetrachoric correlations) compared to DZ twins. Figure 3 shows the median heritability for AD of 0.52 across all studies to date, with minimum and maximum values indicated by the error bars. The HARMONY study, at present the biggest population-based twin study of AD, estimates heritability to be as large as 79% for prevalent AD, while nonshared environmental effects account for the remaining variation in risk. Heritability of AD appears to be of similar magnitude for males and females. Vascular dementia, on the other hand, appears to be influenced completely by shared and nonshared environmental factors, given essentially equal concordance rates for MZ and DZ twins. Late-onset Parkinson's disease (PD), of which dementia sometimes features, appears to be mediated primarily by environmental factors, with nearly identical but low concordance rates in MZ and DZ twin pairs.

Figure 3 Heritability estimates of cognitive functioning and Alzheimer's disease (AD). Note: Tops of solid colored bars indicate median heritability estimates from all adult twins studies. Lower ends of 'error bars' indicate lowest estimate and upper ends indicate highest estimate.

Measured Genes

Twin sibling designs are valuable to address the presence of true gene-trait association. However, such studies have not been used to examine candidate association with cognitive aging traits with much frequency, or the pair aspect of the twins has not been used to full advantage. However, reports from twin studies are beginning to appear.

Cognitive aging and decline The *APOE* gene coding for the cholesterol transporter apolipoprotein E is considered a major genetic risk factor for late-onset AD. The weight of evidence for *APOE* and cognitive change in nondemented adults has been less consistently observed, in comparison. Twin association studies suggest an effect on memory-related tasks: the *APOE* $\varepsilon 4$ polymorphism has been associated with poorer recall memory, poorer working memory performance, and a steeper rate of change in working memory over age.

Apart from *APOE*, additional reports using twin models of association with cognitive aging or related traits are beginning to appear in the literature. For example, a recent SATSA study of twins suggests an association of the −1438 G/A [dbSNP: rs6311] variant of the *HTR2A* gene that codes for 5-hydroxytryptamine 2A (5-HT_{2A}; serotonin) receptors with differences in memory decline over time in late adulthood. Those with the common allele (G) exhibited higher performance on an episodic figure recognition task over time than did those with the rarer allele (A). These results extend a prior case-control study and are consistent with molecular and imaging studies that indicate decreases in serotonin 2A receptors with age in hippocampus and prefrontal cortex regions. Additional promising gene candidates have been reported in association studies for general intelligence in child and adult twins, including cholinergic muscarinic receptor 2 (*CHRM2*) gene polymorphisms. Finally, there are candidates for cognitive aging and decline that ought to be considered from a twin perspective, including the catechol *O*-methyltransferase (*COMT*) gene, which has been associated with performance and/or change in executive functioning and spatial performance in older adults.

Cognitive functioning *APOE* $\varepsilon 4$ status is related to an increased risk of mild cognitive impairment (MCI) according to analyses of twins as individuals from the

NHLBI study. Aging Danish DZ twins from the LSADT study were examined for four polymorphisms in the Werner syndrome *WRN* gene. In an analysis of all twins, without consideration of pair status, a positive association was found between the *Wrn-i1* gene variant located in a noncoding region of the *WRN* gene and cognitive functioning, a composite measure consisting of word fluency, word learning, and span memory performance, as well as self-rated health. Among DZ pairs who differed in genotype for the *WRN* gene variant, findings for the cognitive composite were consistent with the overall findings, but too few pairs led to lack of significance. Overall, the findings implicate *WRN* in cognitive functioning and health, and a further search of variants in regulatory regions is warranted.

Dementia *APOE* ε4 status predicts concordance for AD among twin pairs, as well as increased risk of AD among first-degree relatives. Several additional gene association studies have included twins in analyses of AD risk but have not considered AD risk association from a twin perspective *per se* to confirm associations. Beyond *APOE*, the most well-known and replicated genetic risk factors for late-onset AD, genes for insulin-degrading enzyme *(IDE)* and ATP-binding cassette A1 transporter (*ABCA1*), have been associated with increased AD risk or with earlier age of onset. Thus, a broader role of cholesterol metabolism on AD risk may be implied (e.g., *APOE*, *ABCA1*). Replication via within- and between-twin pair comparison is needed to confirm these and other associations suggested in the epidemiological literature.

Measured Environmental Factors

Both positive and negative aspects of the environment appear to play an increasingly vital part in cognitive aging and risk of dementia. Epidemiological research points to low education, poor early-life socioeconomic factors, and head injury as risk factors, while protective factors may include physical and cognitive activity, antioxidant vitamin supplements, and nonsteroidal anti-inflammatory drugs (NSAIDs). Twin studies of measured environmental influences on cognitive aging or dementia have been conducted generally using two methods: by addressing the etiology of associations between complex traits to determine if their common variance is due to genetic or environmental pathways (e.g., education and cognitive functioning), or by comparing MZ twins discordant for AD or cognitive decline, for example, and examining differences in potential risk or protective variables (e.g., NSAID use).

Cognitive aging and decline Low education is a risk for compromised mental functioning. Theories have weighed in with biological (e.g., genetic factors influence both educational attainment and intelligence) or environmental explanations (e.g., cognitive reserve, or 'use-it-or-lose-it'). Twin studies suggest that education, cognitive ability level, and mental status performance are primarily associated due to genetic influences in common to all three, supportive of biological theories. However, as is discussed later, some weight should be accorded to environmental explanations, given the predictive value of pair differences in education and dementia risk in discordant twins.

Lobar brain-volume relationships with cognitive performance appear to be associated through environmental pathways in an analysis conducted on data from elderly male twins participating in the NHLBI twin study. Additional analyses further suggest that lower total brain volume is associated with a greater rate of decline in memory performance, perhaps influenced by common environmental factors.

Dementia Recent co-twin control studies of dementia-discordant twin pairs in the HARMONY study suggest that environmental factors may mediate dementia or AD risk, including occupational complexity, physical exercise, participation in leisure activities decades earlier, and tooth loss prior to age 35. Unaffected twins had a greater lifetime occupational complexity score, greater involvement in leisure activities 20 years prior to assessment, and were less likely to report tooth loss prior to age 35 years than was their AD affected twin partner. The reported tooth loss in earlier adulthood may reflect inflammation processes that result from poor health or nutrition factors earlier in life. Additional reports from the NAS–NRC Twin Registry and OCTO-Twin studies suggest that use of anti-inflammatory medications (NSAIDs, aspirin) may reduce risk of AD, replicating prior epidemiological studies.

In addition, co-twin-control reports from HARMONY indicate significant environmental factors important to diseases other than AD, or that are nonspecific to dementia type. Deficient physical exercise was more often observed for dementia-affected twins than for their co-twins, exclusive of AD. Risk of dementia of any type was increased in the case of lower educational attainment, and was evident to greater degree in dementia-affected twins than in their co-twins. The findings for education are supportive of environmental explanations, such as the cognitive reserve hypothesis, which posits that higher educational attainment may afford protection via greater synaptic density or cognitive compensation, despite neuropathologies, and thereby lower risk of, or delay clinically, meaningful cognitive impairments. Indeed, a host of potential neuroprotective or compensatory

factors may coalesce in twins with higher education. In education-discordant twins, the twin with higher education reported greater participation in leisure activities and higher occupational status, for example.

The evidence from co-twin-control studies indicates intriguing possibilities that particular environmental factors may modify dementia or AD risk, though some factors appear to confer advantages or disadvantages in early or mid-adulthood, a time when individuals may not reflect on their future health.

Gene–Environment Interplay

Environmentally mediated risk factors, as described earlier, may influence cognitive decline or risk of AD, and recent epidemiological literature suggests often this is dependent on genotype. For example, mid-adulthood hypertension or the occurrence of stroke or head injury, when coupled with *APOE* ε4 carrier status, may lead to poorer cognitive performance or poorer cognitive recuperation, respectively. Viewing gene–environment interplay from a twin perspective could replicate and build upon existing epidemiologic research, but this is not often done, or the twin aspect is ignored. One twin approach to establish $G \times E$, while controlling for genetic similarity, is to compare MZ twins (e.g., on measures of cognitive decline), stratified by genotype, to examine whether pair differences are smaller or greater for pairs with particular genotypes. This approach would indicate whether individuals with certain genotypes are more or less 'sensitive' or responsive to environmental factors. The advantage of the twin $G \times E$ model is that background genetic and familial factors would be controlled.

Conclusion

Twin studies provide a unique window on the etiology of brain aging. Identical twins are more similar or concordant than are fraternal twins for cognitive aging, cognitive dysfunction, and certain forms of dementia (i.e., AD). Other dementia- and aging-related traits show little evidence of genetic influences, including vascular dementia and PD, in which identical and fraternal twins are equally similar. Longitudinal twins studies of cognitive aging indicate that genetic influences decrease with age while person-specific environmental influences increase in importance. Co-twin-control studies suggest that individuals may be able to modify their risk of AD or dementia through environmental means, but that this may require effort even before midlife, before individuals may be cognizant of dementia risk. Epidemiological studies hint that the degree to which risk may be modifiable could be dependent on genotype. Twin approaches to gene–environment interplay should confirm and build upon epidemiological findings, given the strength of the twin design.

GFL Neurotrophic Factors: Physiology and Pharmacology

M Saarma, University of Helsinki, Helsinki, Finland

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Growth factors are secretory proteins that bind to their cognate receptors at the plasma membrane of the cells and activate receptors that in turn trigger the activation of cellular biochemical signaling processes and lead to the cell proliferation, differentiation, migration, morphological changes, or induce the death of cells. Currently, about 100 growth factors that affect neurons have been described, but only those that mainly regulate the development and physiology of neurons are called neurotrophic factors. Neurotrophic factors are growth factors that regulate the number of neurons in a given population, neurite branching and synaptogenesis, adult synaptic plasticity, and maturation of neuronal phenotype. Neurotrophic factors include, for example, neurotrophins (NGF, BDNF, NT-3, NT-4), neurokines (CNTF, LIF, IL-6, CT-1, etc.), and glial cell line-derived neurotrophic factor (GDNF) family ligands (GFLs).

GFLs: Structure, Secretion, and Processing

GDNF and the related factors artemin (ARTN), neurturin (NRTN), and persephin (PSPN) form the GDNF family of neurotrophic factors (Figure 1(a)). GFLs are synthesized by the cells as preproGFL proteins that are in the endoplasmic reticulum (ER) processed to proGFLs and secreted into the extracelluar space as mature GFLs or as proGFLs. The 211 amino-acid-long preproGDNF protein is finally processed into 134 amino acid mature GDNF monomer (Figure 1(b)) that is inactive and must homodimerize to generate a biologically active factor. All GFLs have seven conserved cysteines with similar relative spacing. Six of these cysteines are involved in the intramolecular S–S bonding whereas the seventh cysteine forms an intermolecular S–S bond stabilizing the homodimers of GFLs. Based on the conserved location of the seven cysteines, GFLs form a distant subfamily in the large transforming growth factor-beta (TGF-β) superfamily of growth factors. Orthologs of all four GFLs are found in all mammals, and also in teleost fishes. Interestingly, chicken genome lacks PSPN gene, but has a functional PSPN coreceptor GDNF family receptor α4 (GFRα4). Clawed frog *Xenopus tropicalis* genome surprisingly lacks the ortholog of NRTN. Even more surprisingly insects have a receptor tyrosine kinase (RTK) rearranged during transfection (RET), a putative GFL coreceptor homolog but no obvious GFL homologs. The atomic structure of the major part of GDNF has been determined and GDNF together with all other TGF-β superfamily growth factors, including all GFLs, belong to the cystine-knot family of proteins. The main structural elements of the GDNF molecule are helical regions and two fingers. Fingers 1 and 2 are involved in the binding of GDNF to its receptor GFRα1 (Figure 1(c)). In the GDNF structure the first 38 residues are disordered. Sequence analysis and experimental data indicate that this region binds heparin stabilizing the structure of GDNF and mediating GFL interactions with extracellular matrix (ECM). Recently, two laboratories have solved the crystal structure of ARTN. Although the overall fold of the ARTN covalent homodimer is similar to GDNF, the shape and the flexibility of elongated homodimer differs. ARTN also differs from GDNF in its overall charge and electrostatic distribution. Arginines in ARTN at positions 48, 49, and 51, as well as its amino terminus play a role in heparin binding. Although the three-dimensional (3-D) structures of NRTN and PSPN are not known, it is likely that their general spatial structure is very similar to GDNF and ARTN (Figure 1(c)). There are also heparin-binding regions in NRTN, but not in PSPN.

The detailed mechanism of the secretion, processing, and activation of GFLs is poorly studied. Several cells and tissues can also secrete proGDNF in addition to mature GDNF (Figure 1(b)), suggesting that processing of proGDNF (and possibly all GFLs) can occur also in the ECM. Whether proGFLs can bind GFL receptors and trigger cellular signaling is currently not known.

GFL Receptors

GFL receptor system is unique in several ways. First, GFLs can signal through three different receptor systems. Second, all three signaling receptors, RET, neural cell adhesion molecule (NCAM), and syndecans, are shared by four ligands, with the exception of PSPN that is not binding to syndecans. Third, the main GFL signaling receptor is the RTK RET, which is the only known RTK that does not bind the ligands directly but via coreceptors of GFRα family. Finally, RET activity is strictly regulated by Ca^{2+} ions, and in the intracellular part of RET in addition to tyrosine residues serines are also phosphorylated.

The RET gene was identified in 1985 as a novel oncogene. Normal RET is the transmembrane RTK.

Figure 1 (a) Schematic structure of GFL showing the relative lengths (and number of amino acids) of the mature GDNF (blue), NRTN (pink), ARTN (brown), and PSPN (yellow) molecules and their pre-(brown) and pro-(light green) domains, as well as relative positions of the seven conserved cysteine residues (black vertical lines). GDNF has two putative N-glycosylation sites (N). (b) The preregion of GFLs is cleaved off inside the cells during secretion. Cells can secrete mature GDNF and proGDNF, indicating that the processing of proGDNF can also occur in the ECM. (c) The 3-D structure of dimeric GDNF shows that it belongs to the cystine-knot family of proteins. The main structural elements of the GDNF molecule are helical regions and fingers 1 and 2 that are involved in its binding to GFRα1 coreceptor. The 3-D structure of ARTN is similar to that of GDNF. The 3-D structures of NRTN and PSPN are not known, but the modeling of NRTN shows that its spatial structure is very similar to GDNF. The binding of heparan sulfate to GDNF is shown (left). NRTN can also bind heparan sulfate. Putative binding site is shown (green).

In human cancer, especially in papillary thyroid carcinoma, the RET tyrosine kinase domain is fused with N-terminal regions of the variety of unrelated genes. In addition to these somatic rearrangements germ line mutations in RET are responsible for two inherited disorders: activating mutations cause multiple endocrine neoplasia 2 (MEN2) and inactivating mutations Hirschsprung's disease (HSCR) or congenital central hypoventilation syndrome. The alternative splicing of the human RET gene gives rise to at least three splice isoforms. The larger of these encodes a protein of 1114 amino acids that contains 51 amino acids at the C-terminus (RET51) that are replaced by nine amino acids in the RET9 isoforms. RET51 has two additional tyrosines: Tyr1090 and 1096. Orthologs of RET have been identified in higher and lower vertebrates, as well as in *Drosophila* (D-RET). The tyrosine kinase domain of D-RET is conserved as it is functional *in vitro* and activates similar intracellular signaling pathways as mammalian RET. The extracellular domain of D-RET is less conserved and fails to interact with mammalian GDNF/GFRα1 complex. Interestingly, the *Drosophila* genome does not encode putative GFLs, but has a GFRα-like gene, called munin.

RET is the only RTK among the receptors of TGF-β superfamily factors, all others being the receptor serine–threonine kinases. Although RET is similar to other RTKs, it also has several special features. First, the extracellular domain of RET consists of four cadherin-like domains (CLD1–4) and a single cysteine-rich domain (CRD). RET binds one molecule of Ca^{2+} that is required for its correct folding and function as the GFL receptor. Second, RET is the only

Figure 2 GDNF-family ligands and receptor interactions. Homodimeric GFLs activate RET RTK by first binding to their cognate GFRα coreceptors. GDNF binds preferentially to GFRα1, NRTN to GFRα2, ARTN to GFRα3, and PSPN to GFRα4. Solid arrows indicate the preferred functional ligand–coreceptor interactions, whereas dotted arrows indicate putative cross-talk. GFRα proteins are attached to the plasma membrane through a GPI-anchor and consist of three (GFRα4 has only two) globular cysteine-rich domains joined together by adapter sequences. The extracellular domain of RET, that consists of CLD1–4 and one CRD interacts with all four GFL–GFRα complexes. Binding of Ca^{2+} ions to one CLD of RET is required for its activation by GFLs. RET intracellular part contains tyrosine kinase domain and tyrosine residues that become phosphorylated upon RET activation.

RTK that does not directly bind the ligands, that is, GFLs (Figure 2). Instead, RET is activated by binding to a complex formed by a GFL bound to its cognate glycosylphosphatidylinositol (GPI)-anchored coreceptor GFRα. Thus, GFLs interact with RET, but only in the presence of specific GFRα coreceptors. Four different GFL-GFRα pairs exist in mammals: GDNF-GFRα1, NRTN-GFRα2, ARTN-GFRα3, and PSPN-GFRα4 (Figure 2). With significantly lower-affinity GDNF can interact with GFRα2 and GFRα3, and NRTN and ARTN with GFRα1, but the physiological significance of these interactions is unclear. The GFL and GFRα homodimeric complex brings two RET molecules together, triggering transphosphorylation of specific tyrosine residues in their tyrosine kinase domains and activating intracellular signaling (Figure 3).

GFRα Coreceptors

The GFL binding specificity to RET is determined by GFRα proteins that have unique binding affinities for each GFL. GFRαs are cysteine-rich GPI-anchored proteins. Mammalian GFRα1–3 and most of the vertebrate GFRα consist of three CRDs, whereas mammalian PSPN receptor GFRα4 lacks CRD1 and thus has only two CRDs (Figure 2). The structure of GFRα1 domain 3 revealed a novel protein fold: an all-α five-helix bundle stabilized by five disulfide bridges. The model for domain 2 was constructed, using its homology to domain 3. Recently, the crystal structure of ARTN in the complex with domains 2 and 3 of the GFRα3 was reported. These data reveal crucial amino acids in domain 2 of the GFRα3 receptor involved in ARTN binding and indicate that domains 2 and 3 define the potential RET binding site. Structural data on the ARTN-GFRα3 complex, on GFRα1 domain 3, and the conserved location of cysteine residues in GFRα1–4 CRDs predict a very similar general structural fold for all GFRαs. Phylogenetic analysis indicates that all vertebrate classes from teleost fishes to mammals have orthologs for all four GFRα receptors.

For several neuronal populations the full biological activity of GDNF is exerted only in the presence of TGF-β. It appears that TGF-β is required for the action of GDNF via GFRα1, but not for the action of NRTN, as TGF-β is increasing the surface location of GFRα1 but not of GFRα2.

Figure 3 GDNF interacts with coreceptor GFRα1 and activates RET. (a) Biologically active GDNF is a homodimer. In the absence of GDNF, GFRα1 and RET interaction is very weak. (b) A dimer of GDNF binds to the second CRD of GFRα1. (c) GDNF brings together two molecules of GFRα1. (d) GDNF-GFRα1 complex induces dimerization of two molecules of RET leading to transphosphorylation and activation of their tyrosine kinase domains.

Two proteins that are structurally similar to GFRα proteins – GAS1 and GFRAL – are described, but their relatedness to the GFL system is not yet clear.

NCAM

NCAM plays an important role in neural development as the homophilic cell adhesion molecule. $P140^{NCAM}$ can also function as the alternative signaling receptor for all four GDNF family ligands. GFLs can directly bind to NCAM with low affinity, but do not trigger intracellular signaling. In the presence of cognate GFRα coreceptors GFLs can bind to $p140^{NCAM}$ with higher affinity and activate Src-like kinase Fyn and focal adhesion kinase FAK (Figure 4(a)). GFRα1 interaction with NCAM even in the absence of GDNF can inhibit NCAM-mediated cell adhesion. Thus GDNF–GFRα1–NCAM and GFRα1–NCAM interactions may have different biological readouts and physiological consequences. Current experiments indicate that GDNF by binding to GFRα1 and activating NCAM stimulates Schwann cell migration, hippocampal neurite outgrowth, and development of olfactory neurons in RET-independent manner. Further experiments are needed to unravel the *in vivo* roles of GDNF–GFRα1–NCAM and GFRα1–NCAM signaling and possible cross-talk of RET and NCAM in GFL signaling.

Syndecans

Although the vast majority of GFL signaling utilizes GFRα/RET or GFRα/NCAM receptor systems, novel data indicate that additional GFL receptors exist. GDNF was originally purified by heparin-affinity chromatography, and later its interaction with heparan sulfates was documented. Recent experimental data indicate that heparan sulfates are required for GDNF signaling via GFRα1 and RET. GDNF, ARTN, and NRTN, but not PSPN, can with high affinity bind to heparan sulfate proteoglycan (HSPG) syndecans (Figure 4(b)). Syndecans that bind GDNF can function as coreceptors and deliver GDNF to GFRα1/RET complex or activate directly Src signaling pathway triggering cell spreading and inducing neurite outgrowth of hippocampal neurons. GDNF interaction with syndecan also stimulates the migration of cortical neurons. Thus, GDNF can signal in two different ways – as a soluble protein and as a matrix-bound protein. In a soluble form it binds to GFRα1 and activates intracellular signaling via RET or NCAM. When bound to ECM (both transmembrane and soluble HSPGs), GDNF triggers qualitatively different signaling that is currently poorly defined.

Signaling Pathways

The interactions of the intracellular part of RET with various signaling molecules are mainly triggered by the cognate ligands (GFLs), but in some cases also GFL-independently. GFL–GFRα homodimeric complex brings two molecules of RET together, triggering transphosphorylation of specific tyrosine residues of RET, followed by the activation of intracellular signaling cascades (Figures 3 and 5). Several cascades can be activated, which regulate cell survival, differentiation, proliferation, migration, chemotaxis, branching morphogenesis, neurite outgrowth, synaptic plasticity, etc. The mitogen activated protein (MAP) kinase pathway is involved in neurite outgrowth of the neurons. The phosphoinositide 3-kinase (PI3K)-Akt pathway is responsible for both neuronal survival and neurite outgrowth. GFL signaling also activates Src-family kinases, which elicit, for example, neurite outgrowth, neuronal survival, and kidney ureteric branching. In most cases tyrosine residues

Figure 4 RET-independent signaling by GFLs. (a) p140^{NCAM} is an alternative signaling receptor for GFLs. It interacts with a GDNF–GFRα1 dimer leading to the activation of Fyn, a Src-like kinase. It is unclear, whether GDNF triggers NCAM dimerization. NCAM has five IgG-like domains and two fibronectin-like domains. (b) HSPG syndecans carry heparan sulfate side chains that bind with high affinity GDNF, ARTN, and NRTN. Unlike GFRα1, syndecans can bind many GFL molecules simultaneously. GDNF binding to syndecans can activate Src-family kinases or modulate signaling through GFRα-RET.

Tyr905, Tyr981, Tyr1015, Tyr1062, and Tyr1096 of RET are phosphorylated and docking proteins and intracellular proteins are bound and activated through interaction with these and possibly other RET phosphotyrosines (Figure 5). Interestingly, RET activation affects different downstream targets inside and outside lipid rafts that are the dynamic assemblies of cholesterol and sphingolipids scattered within the disordered phase of the lipid bilayer. Differences in GDNF signaling through RET within and outside the rafts could lead to significantly different cellular responses.

RET is also activated by several GFL-independent pathways. First, increase in the intracellular concentration of cyclic AMP level triggers protein kinase A (PKA)-dependent Ser696 phosphorylation of RET independently of GFL that regulates the migration of enteric neural crest cells in the developing gut. Second, in the mature sympathetic neurons, RET51

Figure 5 GDNF-induced signaling pathways. The model shows the intracellular domain of RET and highlights the phosphorylated tyrosines and different intracellular RET-binding proteins and activated downstream signaling pathways. The phosphorylated tyrosine residues (Y752, Y905, Y928, Y981, Y1015, Y1062, Y1096) activate multiple signaling pathways. Serine 696 (orange) is phosphorylated GFL-independently by PKA, and Y1096 (orange) can be phosphorylated GFL-independently by NGF.

isoform becomes phosphorylated and functionally activated by nerve growth factor that signals via unrelated receptor TrkA. The physiological importance of this signaling is not yet known.

Third, there is *in vitro* evidence that RET is also a dependence receptor that triggers apoptotic cell death when not bound by the ligands. However, the *in vivo* relevance of this RET-triggered apoptosis is completely unclear.

Biology and Physiology

Mice that lack GDNF, GFRα1, or RET die soon after birth, whereas mice lacking other GFLs or GFRα coreceptors or alternative receptors NCAM or syndecans are viable and fertile. The neuronal phenotypes of the different GFLs and their receptor-knockout mice are summarized in Table 1. The strongly overlapping phenotypes of ligand and coreceptor knockouts demonstrate, under physiological conditions, a specific pairing of each GFL and corresponding GFRαs. The vast majority of cells and tissues that are affected in GFL- or GFRα-knockout mice also express RET, indicating that *in vivo* this is the main signaling receptor for GFLs. GDNF-, GFRα1-, or RET-deficient mice share a phenotype of kidney agenesis, and an absence of many parasympathetic and enteric neurons. Mice that lack NRTN or GFRα2 have similar deficits in enteric and parasympathetic innervation. Characterization of ARTN- and GFRα3-deficient mice revealed similar abnormalities in the migration and axonal projection pattern of the entire sympathetic nervous system. Ablation of GFRα4 or its ligand PSPN impairs thyroid calcitonin production in young mice. Both GDNF- and NCAM-deficient mice have impaired migration of the rostral migratory stream-derived neuronal precursors. Likewise, GDNF- and syndecan-deficient mice have an impaired migration of GABAergic cortical neurons. In some cases the ligand- and its receptor-deficient mice phenotypes differ.

Mice lacking the long RET51 isoform seem to be normal, whereas mice lacking the short RET9 isoform were similar to mice lacking all RET isoforms. Only the short isoform can rescue the phenotype of the RET-null mutation in the kidney and enteric nervous system. In another study, however, homozygous RET9 and RET51 mice were viable and show normally developed kidneys.

Knock-in mice with mutated Tyr1062 of RET had defects in the enteric nervous system similar to those

Table 1 Phenotypes of mice lacking GFLs and their receptors

Gene knockout	*RET*	*GDNF/GFRα1*	*NRTN/GFRα2*	*ARTN/GFRα3*	*PSPN/GFRα4*
Gross phenotype	P0 lethal	P0 lethal	Viable, fertile. Pseudoptosis growth retardation[b]	Viable, fertile ptosis	Viable, fertile *Gfra4*−/−
PNS					ND
Sensory: PG	Breathing defect	<40%, breathing defect Soma reduced			
DRG			Soma size reduced, loss of heat sensitivity	NS	
TG		Loss in whisker follicles			
Autonomic					
Sympathetic	SCG; migration defect	SCG; <35% in *Gdnf*−/−mice NS in *Gfra1*−/− mice	NS	SCG and other ganglia; defect in migration and axon growth	
Sympathetic cholinergic			Soma size, target innervation reduced		
Parasympathetic					
Cranial: SPG	Lack of ganglia	Lack of ganglia	NS

observed in RET-deficient mice but with only slight histological changes in the kidneys.

Dopamine neurons. GDNF and NRTN are potent survival factors for midbrain dopamine (DA) neurons and they signal through the GFRα1–RET receptor complex, which is expressed in developing and mature DA neurons. GDNF, but not NRTN, can also promote axon growth and sprouting of DA neurons. Analysis of GDNF-, NRTN-, GFRα1-, and RET-deficient mice reveals that GDNF signaling through GFRα1/RET is not required for the embryonic development of DA neurons. However, DA neurons of the substantia nigra undergo programmed cell death (PCD) during postnatal development. This is a biphasic process with an initial major peak just after birth and a second minor peak 2 weeks after birth. Intrastriatal injection of GDNF diminishes the PCD event and GDNF-neutralizing antibodies augment it. Thus, GDNF seems to serve as a physiological target-derived neurotrophic factor for DA neurons during

the first phase of PCD. This is also supported by the observation that GDNF is expressed prominently in the striatum during the first few postnatal weeks, when DA neuron target innervation is taking place. Results from mice, where RET or GFRα1 will be deleted from DA neurons, should demonstrate whether RET signaling is required for postnatal survival and maintenance of DA neurons.

Motor neurons. *In vitro*, GDNF is the most potent survival factor for motor neurons (MNs). In GDNF- and GFRα1-deficient mouse embryos, there is an increased (20–40%) loss of spinal and cranial MNs. RET-deficient mice also show significant losses in all motor neuron populations examined. Motor neuron survival is usually supported by synergistically acting trophic factors that are produced by muscle and glial cells. During development, GDNF is produced primarily by Schwann cells and by astrocytes throughout the nervous system. Muscle-specific expression of GDNF transgene or GDNF treatment *in utero* enhances survival of the MNs. In mice overexpressing GDNF under the control of an astrocyte-specific GFAP promoter, the survival of MNs in brachial, lumbar, thoracic spinal cord, and the abducens nucleus was increased. GDNF also prevented MN PCD in several cranial motor nuclei. Furthermore, GDNF could support complete and relatively long-term survival of MNs following neonatal facial-nerve axotomy. Although exogenous NRTN supports motor neuron survival, this is mostly mediated by GFRα1, as no clear loss of MNs is found in NRTN- and GFRα2-deficient mice. Continued subcutaneous injections of GDNF postnatally, or transgenic overexpression of GDNF in skeletal muscle, produce hyperinnervation of neuromuscular junctions. GDNF seems to induce this extra innervation by promoting terminal branching. Therefore, the main role of GDNF in postnatal MNs is to promote terminal axon branching and synapse formation.

Parasympathetic neurons. In the cranial region, postganglionic parasympathetic neurons are located in small ganglia: ciliary, sphenopalatine, submandibular, and otic ganglia. In GDNF-, RET-, and GFRα1-knockout mice, the otic and sphenopalatine ganglia are absent, demonstrating that GDNF signaling is critically required for the development of these parasympathetic neurons. In addition, GDNF signaling through GFRα1/RET is required for the migration and proliferation of parasympathetic neuronal precursors during early embryonic development. Postnatally, NRTN is upregulated in target tissues and parasympathetic neurons continue to express RET and GFRα2. In line with that, NRTN- or GFRα2-deficient mice have deficits in parasympathetic target innervation in many regions. Taken together, there is a shift from GDNF to NRTN signaling in developing parasympathetic neurons, where both growth factors have distinct roles.

Enteric neurons. In mice that lack RET, GDNF, or GFRα1 enteric neurons and glial cells that are derived from the vagal and sacral neural crest are missing below the stomach. GDNF promotes the migration, proliferation, survival, and differentiation of multipotent enteric precursor cells that express cognate receptors. NRTN or GFRα2 mutant mice show a significant loss of the cholinergic, substance P-containing fine myenteric nerve plexus in the small intestine, and very little loss of enteric neurons. As the release of substance P *in vitro* from the NRTN-deficient mouse colon is reduced significantly, NRTN signaling could regulate neurotransmitter release. The function of GDNF and NRTN in the adult enteric nervous system is unknown.

Sympathetic neuron development requires chemoattractant ARTN signaling through GFRα3/RET for migration and initial axon outgrowth. The role of GFLs in the postnatal sympathetic system is poorly studied.

GDNF, NRTN, and ARTN *in vitro* support subpopulations of primary sensory neurons. Although GFLs can be survival-promoting factors for some sensory neurons, their specific roles for these neurons are poorly understood.

Kidney Development and Spermatogenesis

Although GDNF is mainly known as the neurotrophic factor, it also plays a crucial role in kidney development and spermatogenesis. In mice in which GDNF, RET, or GFRα1 is knocked out, the kidneys show aplasia or severe hypodysplasia. GDNF is the major mesenchyme-derived factor that activates GFRα1/RET complex in the ureteric bud, thereby regulating ureteric budding and branching during nephrogenesis. Mutation of Tyr1015 in both RET51 and RET9 isoforms results in severe renal anomalies. In addition, loss of RET9 (Y1062)-mediated Akt/MAPK activation resulted in renal agenesis or kidney rudiments, whereas mutation of this residue in RET51 had no obvious effect on AKT/MAPK activity and renal development. However, the precise role of GDNF/RET signaling in renal branching morphogenesis and the specific responses of ureteric bud cells to GDNF remain unclear. The localized expression of GDNF in the metanephric mesenchyme, together with several types of negative regulation, is important to elicit and correctly position the initial budding event from the Wolffian duct. GDNF also promotes the continued branching of the ureteric

bud. However, it seems not to provide the positional information required to specify the pattern of ureteric bud growth and branching, as its site of synthesis can be drastically altered with minimal effects on kidney development.

In the testis, GDNF is expressed by the Sertoli cells that regulate spermatogenesis in a paracrine manner, whereas RET/GFRα1 are found in the undifferentiated spermatogonia, including spermatogenic stem cells. Mice lacking one GDNF allele show partial depletion of spermatogenic stem cells, whereas mice overexpressing GDNF show clusters of undifferentiated spermatogonia that develop seminoma-like germ line tumors in adulthood. GDNF is thus a crucial paracrine regulator of the self-renewal and differentiation of spermatogonial stem cells. Actually, GDNF is the first factor known to determine the fate of spermatogenic stem cells. GDNF signaling is therefore an attractive target for the development of male contraceptives. However, such efforts are severely shadowed by the carcinogenic consequences of deregulated RET activation. NRTN, GFRα2, and NCAM are also expressed in the developing kidney and testis, but they have no renal or testis phenotype when knocked out.

The function of GDNF and its receptors in kidney and testis should be very seriously considered when RET/GFRα1 agonists or antagonists to treat cancer or neurodegenerative diseases are developed.

Clinical Potential

GFLs have received attention as potential therapeutic agents for the treatment of certain neurological diseases, in particular the Parkinson's disease (PD). All current therapies for PD are symptomatic and do not slow down or reverse the underlying degeneration of midbrain DA neurons. GDNF has been an attractive treatment option since its discovery, because it is a naturally occurring protein that *in vivo* can protect and rescue nigrostriatal DA neurons that degenerate in PD. In various animal models of PD, GDNF can prevent the neurotoxin-induced death of DA neurons and can promote functional recovery. In the first clinical trial GDNF that was delivered into the lateral ventricles of patients with PD was without therapeutic efficacy and caused side effects, including weight loss. Later trials tested delivery of the GDNF into the site of the major DA loss in PD, namely in the caudate putamen. In a small open-label study with five patients clear positive clinical effects were found. In contrast, a more recent double-blind, placebo-controlled trial on 34 patients has shown no such effects. In this study patients with moderately advanced PD were randomly assigned intraputamenal GDNF or placebo. In addition, anti-GDNF antibodies were reported in three patients out of 34. After several failures a question arises whether there is a future for GDNF in the treatment of PD. The ability to promote endogenous repair through the use of target-derived growth factor is still very attractive. This is further supported by recent improvements in GDNF delivery in animal models of PD that include: heparin coadministration, which increases GFL spread; novel viral vectors; and engrafted- or encapsulated-GDNF-producing neuronal cells, which maintain high levels of human GDNF production. Combined with safety measures, including means to control gene expression, these new vehicles for GDNF delivery look promising for PD therapy.

GDNF is a survival factor for MNs and therefore it may have clinical importance for the treatment of amyotropic lateral sclerosis. In addition, GDNF can be useful in the treatment of various neurological traumas, as it supports the survival and axon regeneration of both MNs and sensory neurons. The combination of different GFLs might be the most efficient to promote functional regeneration of the sensory axons. Peripheral nerve injury often leads to chronic neuropathic pain. ARTN and GDNF have shown their effect in animal experiments and can be considered as drug targets for pain treatment.

In experimental models of ischemia, exogenous GDNF administered before or just after anoxia can reduce ischemic brain injury. PSPN-deficient mice show normal development and behavior, but are hypersensitive to cerebral ischemia. More recent results highlight the importance of GDNF as a new target for drug addiction. In addition to GDNF, NRTN also has promise for PD therapy and for epilepsy, and GDNF and NRTN might modulate seizure susceptibility.

Small Molecules

All known growth factors that activate RTKs bind directly to the receptor and trigger RTK dimerization. The only exception is GFLs that first bind to the ligand-specific GFRα-coreceptor that together with the ligand trigger RTK RET dimerization and activation. Unique mechanism of RET activation by GFLs also offers unique opportunities for rational drug design. Small number of GFRα receptors compared to large number of homologous RTKs predict less stringent specificity requirements for the designed drugs. Using high-throughput screening system XIB4035, a novel non-peptidyl small molecule agonist for GFRα1 was described. This compound at 12 μM concentration induced RET phosphorylation and neurite outgrowth in Neuro 2A cells. Although the *in vivo* effects of XIB4035 are still unknown, the fact that a nonpeptidyl small molecule with high affinity binds to GFRα1 and

activates RET is remarkable and very encouraging. New information on the structure of GFL receptors and their complexes with GFLs is helpful to improve the specificity and efficacy of small molecules that will be beneficial for the treatment of PD.

Summary

There are four members of the GDNF ligand family (GFLs): GDNF, NRTN, ARTN, and PSPN. These small secreted dimeric proteins, distantly related to TGF-β, promote the survival of central and peripheral neurons. GFL binds and activates the transmembrane RTK RET via specific GDNF family coreceptors α (GFRα). GDNF binds preferentially to GFRα1, NRTN to GFRα2, ARTN to GFRα3, and PSPN to GFRα4. Upon activation, RET dimerizes, transphosphorylates its tyrosine residues, and triggers activation of signaling cascades leading to survival, growth, or differentiation of cells. GDNF protects DA and MNs *in vivo*, making it a candidate for therapeutic use in several neurodegenerative diseases. Knockout mice revealed the function of GFLs and their receptors. GDNF −/− +/− mice lack enteric neurons, as in human HSCR. GDNF- and its receptor-deficient mice also lack kidneys, showing that GDNF is important in early kidney development. GDNF is also important for the regulation of stem cell differentiation in the testis. GDNF and NRTN regulate the development of enteric and parasympathetic neurons, ARTN controls the migration and initial growth of sympathetic neurons, and PSPN may protect the brain from ischemic insult and regulates calcitonin secretion.

Cerebral Ischemia

Ischemic stroke is the result of a reversible or permanent focal perfusion deficit in the territory of a brain artery. Although the early work on stroke pathophysiology focused on blood flow and metabolism, a shift has occurred toward biochemical and cellular mechanisms, and only recently have molecular and genetic aspects been added. It is becoming evident that circulatory, metabolic, cellular, and molecular mechanisms have to be considered if we are to understand, treat, and possibly prevent the consequences of focal cerebral ischemia. With this shift in focus, the contribution of nonneuronal and particularly glial cells to stroke pathophysiology is increasingly appreciated.

Recent work demonstrates that under physiological, as well as pathophysiological conditions, highly dynamic and complex glial–neuronal interactions secure brain function and survival. During the past decade, a number of molecular mechanisms by which brain cells die, or survive, after occlusion of a cerebral artery have been unraveled. In the core of ischemic lesions brain tissue undergoes necrosis, a rather passive disintegration of all cellular elements in which energy supply has been critically impeded for some time. In brain areas surrounding the densely ischemic core ('penumbra'), however, biochemical and molecular processes determine the ultimate fate of the tissue. Pathophysiological entities such as excitotoxicity, spreading depression, inflammation, and apoptosis are involved in postischemic cell death. After minor insults or in the penumbra, cellular stress can be so subtle that only certain types of neurons die with a considerable delay, whereas other neurons and nonneuronal cells survive. The fate of brain tissue after focal cerebral ischemia is thus determined by the degree and duration of ischemia and the ability of the threatened brain to mount a competent defense on the cellular level. Glial cells play important roles in the destructive, as well as protective cascades evolving in the focally ischemic or reperfused brain.

It has been demonstrated that there is a complex network of communication between brain endothelial cells, neurons, and astrocytes. This network has been termed the 'neurovascular unit,' and it is believed to play a key role in regulating cerebral blood flow and in maintaining the integrity of the blood–brain barrier (BBB). The position of the astrocyte between the neuron and the blood vessel as part of the neurovascular unit emphasizes its potential to influence and coordinate the activities of both. Glial cells are sensors of changes in the brain environment, to which they immediately react on the genomic (e.g., production of trophic factors), as well as nongenomic level (e.g., uptake of ions). Glial cells, like astrocytes, not only support and protect themselves and all the other cellular elements (including neurons) with which they are in intimate contact but also actively participate in the demise of brain tissue after ischemia.

In such a complex organ as the brain, and with such a complex stimulus as ischemia, it is very difficult to experimentally dissect protective from destructive mechanisms because they coexist in time and space. To facilitate the exploration of protective mechanisms, researchers have turned to an experimental paradigm called 'ischemic preconditioning' or 'ischemic tolerance.' The preconditioning paradigm may also help to explain why the same mechanism or mediator may be protective or destructive in cerebral ischemia: whether a signaling pathway leads to survival or cell death depends on stimulus strength and context.

Ischemic Tolerance

In many, if not all, tissues and phyla, noxious stimuli, given below the threshold of damage, are able to induce protection (tolerance) against a subsequent deleterious stimulus of the same or even another modality (cross-tolerance). Although many specific cellular and molecular elements of the protective cascade have been identified, most researchers agree that there is not one cell type or one mechanism of neuroprotection in ischemic preconditioning. Rather, a concerted action of different pathways is postulated, which affects almost all pathophysiological mechanisms of ischemic cell damage. Preconditioning reduces the deleterious inflammatory response, adapts energy metabolism, as well as enhances neuroprotective mechanisms on various other levels. Specifically, it was shown that ischemic tolerance reprograms the response to ischemia, leading to a protected state. Because of the very close interaction between neuronal and nonneuronal elements in brain physiology and pathophysiology in general, we herein examine the principal mechanisms of ischemic damage and neuroprotection and discuss what is known about the specific contribution of glial cells.

Pathophysiology of Focal Cerebral Ischemia

Early Mechanisms: Excitotoxicity and Peri-Infarct Depolarizations

Especially within the core of the ischemic territory, blood flow deficits, low ATP levels and energy stores, ionic disruption, and metabolic failure are severe. Energy depletion due to lack of substrate (oxygen and glucose) leads to the depolarization of neurons but also of astroglia, resulting in the release of glutamate into the extracellular space. At the same time, the energy-dependent reuptake of glutamate by astroglial cells is impeded, further increasing its extracellular concentration. Under excitotoxic conditions, glia is thought to be neuroprotective due to its ability to clear extracellular glutamate. However, despite protecting neurons against glutamate or *N*-methyl-D-aspartate (NMDA) toxicity, the presence of astrocytes exacerbates α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) neurotoxicity *in vitro*. As a result of receptor activation (in particular of the neuronal NMDA and AMPA receptor subtypes), intracellular calcium rises. It was shown that in the penumbra, the neurotransmitter pool of glutamate coming from astrocytic glutamine was preserved while neuronal metabolism progressively declined, implying that astrocytic glutamine contributed significantly to glutamate excitotoxicity. This is somewhat paradoxical: due to the expression of the high-affinity glutamate transporters EAAT1/GLAST and EAAT2/GLT-1, astrocytes are thought to represent the most important cells for limiting the excitotoxic potential of glutamate, and in agreement, downregulation of both produces excitotoxic neurodegeneration and exacerbates ischemic injury, whereas ischemic preconditioning was shown *in vitro* to increase cellular glutamate uptake and expression of astrocytic EAAT2/GLT-1 glutamate transporters.

In summary, astrocytes have the capacity to limit excitotoxicity by clearing glutamate, but under certain conditions they may contribute to damage by providing precursors for excitotoxin synthesis. It is believed by many researchers that the reversed uptake of glutamate by neuronal and/or astrocytic glutamate transporters is the primary cause of ischemia-induced neuronal death. Ischemic stress to the brain *in vivo* or cultured brain cells induces a biphasic increase in extracellular concentration of glutamate, the first phase of which is dependent on Ca^{2+} and caused by the release of glutamate from nerve endings, whereas the second phase is caused by reversed uptake of glutamate through neuronal and/or astrocytic glutamate transporters. This is in agreement with previous studies which suggested that the activation of neuronal NMDA receptors is essential to preconditioning-induced ischemic tolerance.

The activation of metabotropic receptors and phospholipase C and IP3 signaling mobilizes calcium from intracellular stores, further contributing to the calcium overload. The increase in the universal second messenger, calcium, overstimulates numerous intracellular pathways and enzymes. Cell membranes are degraded (e.g., via activation of cyclo-oxygenase) and free radical species are produced in high concentrations, overwhelming endogenous scavenging mechanisms, which are mainly provided by astroglial cells. Neurons, in contrast to astroglia, depend almost exclusively on mitochondrial respiration. Neuronal mitochondrial function is impaired, and particularly the appearance of the so-called mitochondrial permeability transition pore in the mitochondrial membrane leads to mitochondrial swelling, cessation of ATP production, and possibly an oxygen free radical burst. In addition, the entry of sodium and water leads to swelling (edema) and even osmotic lysis of the cells. Due to the depolarization-induced release of neuronal and glial potassium and glutamate, repetitive depolarizations propagate and the so-called peri-infarct depolarizations may occur. The depolarization-induced release of excessive amounts of glutamate from neurons is a key event in triggering downstream mechanisms of tissue damage and in regions of intermediate perfusion and remaining energy equivalents (the so-called 'penumbra'), and the glutamate buffering capacity of astrocytes may be critical in limiting damage to neurons by excitotoxicity.

Astrocytes are coupled by small pores, so-called gap junction channels. Thereby a cellular network is formed which integrates and modulates homeostasis in larger brain regions. Astrocytic gap junctions remain open during ischemic conditions, and they may link ischemic astrocytes in an evolving infarct with the surroundings. Gap junction coupling may contribute to ischemic cell death because proapoptotic substances can diffuse from dying cells to otherwise healthy cells; ATP is channeled from healthy to dying cells, critically depriving the periphery of the infarct from energy-rich phosphates; and gap junction coupling may contribute to the propagation of spreading depressions. Since peri-infarct depolarizations contribute to lesion growth, inhibition of such depolarization waves may be at least partially responsible for the neuroprotection observed after astrocytic gap junction inhibition in experimental models of stroke.

However, the results of these studies conflict with evidence for a protective role of gap junctions. Gap

junctions are responsible for the special buffering capacity of astrocytes, allowing elevated extracellular K^+ during increased neuronal activity to be dispersed. Mice lacking one allele of connexin-43, the major constituent of astrocytic gap junctions, display impaired gap junction coupling, attenuated intercellular calcium signaling, enhanced neuronal apoptosis, and increased infarct volumes after experimental stroke. Furthermore, a role for connexin-43 in mediating ischemic preconditioning has been established.

Besides their metabolic role, astrocytes are thought to play a strategic role with regard to development of brain swelling (edema) and water imbalance following cerebral ischemia. Specific channel proteins, the aquaporins (AQPs), have been identified which are abundantly expressed in astrocyte pericapillary endfoot processes and which play an important role in astrocyte swelling and cerebral edema formation. Although conflicting data exist with regard to AQP4 regulation in cerebral ischemia, downregulation of AQP4 protects against brain edema and AQP4 knockout mice display a reduced neurological deficit after cerebral ischemia.

Astrocyte swelling – which may result from water flux across AQP channels or high levels of glutamate and K^+, lactic acid, oxygen free radicals, and arachidonic acid, among others – is one of the earliest morphological changes detectable in focally ischemic brain tissue. Local cell swelling may also be responsible for further reducing tissue perfusion by vascular compression, and neuronal swelling is an early consequence of the breakdown of energy metabolism, whereas the extent of brain edema is attenuated in a model of induced tolerance.

Astrocytes are essential elements of the BBB. Astrocytes lacking glial fibrillary acidic protein (GFAP) have been shown to have defects in process formation, induction of the BBB, and volume regulation. In this context, it is interesting that GFAP null mice are highly susceptible to damage by focal cerebral ischemia. However, astrocytes can release trophic factors, which regenerate and protect the BBB: ischemic and hypoxic preconditioning induces astrocyte-derived factors such as vascular endothelial growth factor (VEGF) and adrenomedullin, which are thought to regulate BBB properties. Secretion of VEGF by activated astrocytes has been shown to be required for ischemic preconditioning.

Astroglia is the principal repository of glycogen in the brain. Studies have reported an increase in basal glycogen within the brain after hypoxic preconditioning. As intrinsic anaerobes, astrocytes may be able to transiently support anaerobic metabolism and support the structural integrity of neurons in the penumbra.

Another important aspect of the astrocytic contribution to early mechanisms of stroke pathophysiology is their role in defense against oxidants. Following cerebral ischemia and reperfusion, astrocytes are less vulnerable to reactive oxygen species (ROS) than neurons because they contain high levels of antioxidants and can initially maintain ATP levels via glycolysis. Astrocytes provide neurons with substrates for antioxidants, such as glutathione.

Moreover, metallothioneins (MTs) are expressed by astrocytes and act as scavengers of ROS, as well as of neurotoxic metals such as zinc. They are highly inducible by various stimuli including cerebral ischemia, they are neuroprotective *in vitro*, as well as *in vivo*, and they have been shown to be involved in ischemic tolerance. Thioredoxin (TRX), which scavenges ROS and regulates various intracellular molecules by modifying their redox status, is also induced in glial cells in cerebral ischemia *in vivo* and released upon exposure to H_2O_2 *in vitro*, and overexpression of TRX has been shown to attenuate focal ischemic brain damage.

Very little is known about the role of oligodendrocytes in this early phase of cerebral ischemia. Most of our knowledge is derived from work on white matter rather than gray matter, and there may be relevant differences in the pathophysiology of ischemia and the role of oligodendrocytes in both regions. Interestingly, and in contrast to previous concepts, oligodendrocytes appear to be highly vulnerable to cerebral ischemia. Early, non-Wallerian damage to oligodendrocytes seems to be mediated via AMPA receptors, which, in contrast to NMDA receptors, are abundant on oligodendrocytes. These findings may be relevant from a clinical standpoint because they could at least in part explain the failure of NMDA receptor antagonists in human stroke trials. NMDA receptor antagonists significantly reduce infarct sizes in many stroke models. However, in contrast to AMPA receptor antagonists, they do not protect oligodendrocytes. Thus, although neurons may be rescued by NMDA receptor blockade, they may remain nonfunctional due to the axonal damage resulting from oligodendrocyte death.

Inflammation

Focal cerebral ischemia is a potent inducer of inflammation. Astrocytes, microglia, as well as invading leukocytes are traditionally regarded as the key cellular elements of postischemic inflammation. However, although glial cells are the focus of this article, it should be kept in mind that endothelial cells are crucial in initiating and modulating inflammation by attracting inflammatory cells and regulating their

activity. The induction of intercellular adhesion molecule (ICAM)-1 on endothelium parallels the mobilization of CD11b/CD18 (Mac-1) on circulating leukocytes. Consequently, administration of monoclonal antibodies against CD18, CD11b, or ICAM-1 was found to significantly reduce leukocyte accumulation and stroke severity in experimental models of cerebral ischemia.

Disturbed central nervous system (CNS) homeostasis and disrupture of the BBB is associated with invading immune cells and production of a plethora of different cytokines by activated glia. As in other tissues, inflammation in the brain has two contrasting aspects: although the deleterious role of inflammation after stroke is acknowledged by most researchers, protective and particularly regenerative aspects of ischemia-induced inflammation have been suggested. Indirect evidence exists that certain types of inflammatory reactions are neuroprotective and neuroregenerative. Activated glial cells produce a host of trophic cytokines, and macrophages or T cells exposed to certain CNS antigens *ex vivo* partake in tissue repair and recovery after nerve transection and spinal cord injury. Moreover, lipopolysaccharide (LPS), the prototypic stimulus for expression of proinflammatory cytokines, can precondition the brain against subsequent ischemia.

Astrocytes appear to play a key role in brain inflammation after stroke. This is hardly surprising because astrocytes initiate and regulate immune responses through the release of numerous proinflammatory cytokines, chemokines, and components of the complement system.

Microglia and macrophages are thought to be the key effector cells of the postischemic inflammatory response. Inhibition of microglial activation by tetracylines or the deficiency of tissue plasminogen activator have been shown to protect the brain against focal cerebral ischemia in rodents. Microglia become activated within hours after focal cerebral ischemia. At this time after transient ischemia, neutrophils accumulate in the brain parenchyma and contribute to neuronal damage. With the expression of macrophage inflammatory protein-1 in microglia and monocyte chemoattractant protein-1 in astrocytes, a switch from neutrophil to macrophage chemoattraction occurs 1 or 2 days after the onset of ischemia. Although the immune function of microglia is evident, the ability of astrocytes to function as nonprofessional antigen-presenting cells in the diseased brain remains controversial. Nevertheless, astrocytes contribute to the production of proinflammatory cytokines and neuroprotective factors, such as transforming growth factor (TGF)-β and metallothionein-II, after cerebral ischemia.

In addition to the acute detrimental effects of the postischemic inflammatory response, inflammation is also linked with repair and plasticity. Activated macrophages and microglia may release neurotrophic factors, and interleukin (IL)-1β has been shown to stimulate the synthesis of nerve growth factor. Mice deficient in tumor necrosis factor (TNF) receptors had significantly larger infarcts than wild-type mice after transient ischemia and reperfusion. Moreover, TNF-α has been shown to promote the remyelination of damaged axons by promoting the proliferation of oligodendrocyte progenitors during inflammation.

IL-1β and TNF-α Under ischemic conditions, a variety of inflammatory mediators, such as IL-1, IL-6, IL-8, TNF-α, and monocyte chemoattractant protein-1 (MCP-1), are generated by diverse cell types including astrocytes. A dual role for neuronal outcome has been demonstrated for some of them. The chemokine MCP-1, for example, which is expressed in astrocytes and induced after cerebral ischemia, has been shown to cause neuronal death via direct apoptotic mechanisms through specific cell surface chemokine receptors and possibly, in the long term, neuronal survival through the induction of basic fibroblast growth factor production by astrocytes.

The two key proinflammatory cytokines in the setting of cerebral ischemia are IL-1β and TNF-α, both of which are primarily produced by activated microglia and macrophages. The biological effects of IL-1β and TNF-α are diverse and include the conversion of endothelium to a prothrombotic surface, the induction of leukocyte adhesion molecules, an increase in BBB permeability, and the activation of macrophages. Inhibition of either IL-1β or TNF-α activity by monoclonal antibodies or recombinant receptor antagonists after focal cerebral ischemia significantly reduced infarct sizes in rats. Moreover, mice expressing a dominant negative mutant of IL-1β converting enzyme developed smaller strokes.

Interleukins such as the lesion-induced interleukins of the IL-6 family are thought to exhibit a dichotomous type of action. They contribute at least partially to tissue damage, as well as induce protective mechanisms (e.g., induction of protective genes such as nerve growth factor and metallothionein). Similarly, IL-1, in contrast to the IL-1-like cytokine IL-18, mainly contributes to acute brain damage but also has been identified as a mediator of ischemic tolerance and is thought to be necessary for astroglial proliferation.

TNF-α is induced in both glial and neuronal cells after ischemic and excitotoxic brain injury. TNF-α dose dependently has neuroprotective properties despite its role as a prototypic proinflammatory

cytokine. TNF-α-mediated ischemic tolerance has been ascribed to the downstream messenger ceramide, the neuronal glutamate transporter EAAT3, and a p300-involving mechanism of selective suppression of TNF-α-induced harmful genes in preconditioned cells.

Inducible nitric oxide synthase Studies suggest that inducible nitric oxide synthase (iNOS) produced by infiltrating inflammatory cells and astrocytes also contributes to postischemic damage, possibly by the generation of toxic peroxynitrite and ROS. Pharmacological blockade of iNOS blocked the development of tolerance to focal cerebral ischemia induced by volatile anesthetics. Thus, a role for iNOS in mediating ischemic preconditioning appears likely. NO produced by iNOS also activates matrix metalloproteinase-9 (MMP-9), thereby linking MMP signaling with the well-recognized NO pathway in stroke. 'Activated' astrocytes express MMPs such as MMP-2 and MMP-9 and their inhibitors, the family of tissue inhibitors of metalloproteinases (TIMPs). The deleterious effect of MMP-9, which is tightly regulated and induced in ischemic brain tissue, is demonstrated by the protective effect of MMP-9 deficiency.

TGF-β and IL-10 The overwhelming proinflammatory signaling following ischemic brain damage is counterbalanced by the production of cytokines with homeostatic and potentially neurotrophic action, such as TGF-β1 and IL-10. TGF-β1 suppresses the translation of cytokine mRNAs and deactivates macrophages. IL-10 is secreted from peripheral blood mononuclear cells after ischemic stroke. Both TGF-β1 and IL-10 have been shown to protect rodents from ischemic injury, and it has been suggested that bacterial LPS-induced ischemic tolerance in the brain is mediated via TGF-β. It has been shown that murine heat shock protein-32 (Hsp32) mediates the anti-inflammatory effect of IL-10. Heat shock proteins are stress-induced protective genes thought to act as molecular chaperones, but numerous other functions have been described, including direct antiapoptotic effects. Whereas induction of Hsp72 has been observed mainly in neurons, astrocytes express Hsp32 (heme oxygenase-1). Induced Hsp32 protected neurons against ischemic damage *in vivo* and hypoxic preconditioning induces Hsp32 in combination with sustained astrocytic activation.

Of all the gene transcripts upregulated in the ischemic hemisphere, metallothionein-II has been identified as the most significantly induced. This small, cysteine-rich molecule is synthesized by reactive astrocytes and has been shown to exert neuroprotective effects after cerebral ischemia. Purines are released on a massive scale after ischemic cell injury, and extracellular ATP has been found to transcriptionally activate microglia and astrocytes *in vitro*. Purines may contribute to the regeneration of damaged neuronal axons by enhancing the release and activity of neurotrophic factors.

Apoptosis

Inflammation and apoptosis in cerebral ischemia appear to have a similar temporal profile. In general, apoptosis is particularly prominent in stroke areas resulting from focal ischemia of short duration (30–60 min) and in the penumbral border zone, where selective neuronal degeneration may occur. In addition, days and weeks after infarction, neurons in areas projecting to the infarct zone may also undergo apoptosis, while microglial cells in these areas become activated, as a sign of either neuronal deafferentation or neuronophagia.

Glial cells may be involved in stroke-induced apoptosis in several ways: by producing signals that induce apoptosis in neurons, by dying apoptotically triggered by the same signals and in a manner similar to neurons, by self-elimination via apoptosis, and by producing factors that protect neurons against apoptosis.

All of these processes are closely associated with inflammation. Inflammation produces toxins (e.g., oxygen free radicals) that induce mitochondrial and DNA damage as important upstream mediators of apoptosis in neurons and oligodendrocytes. In addition, apoptosis is a critical mechanism in limiting and terminating inflammation, although it is controversial whether inflammatory cells are eliminated by apoptosis. Macrophages express Bax protein, and nuclear DNA fragmentation has been found in the infarcted tissue. It is very likely that astrocytes play a major role in limiting the growth of ischemic lesions, and that antiapoptotic mechanisms are a key element of astrocyte-mediated neuroprotection after stroke. Astrocytes are a major source of growth factors which protect neurons against ischemic damage. Reactive astrocytes produce nerve growth factor, basic fibroblast growth factor, brain-derived nerve growth factor, ciliary neurotrophic factor, insulin-like growth factor-1, and TGF-β, among others.

Nerve Growth Factor, Brain-Derived Neurotrophic Factor, and Glial Cell Line-Derived Neurotrophic Factor

Neuroprotective effects of nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF) in cerebral ischemia have been demonstrated *in vitro* and *in vivo*. Although neutrophins such as NGF or

BDNF are expressed in neurons, there is *in vitro* evidence for NGF production and NGF-like activity in astrocytes. Both BNDF and NGF were shown to be induced after ischemic preconditioning, and ischemic tolerance was mimicked by the application of BDNF *in vivo*.

Glial cell line-derived neurotrophic factor (GDNF) is another potent neuroprotective factor produced by astrocytes. GDNF is regulated after cerebral ischemia, astrocytes appear to be a major source of GDNF, and GDNF has a protective effect after ischemic brain injury.

Erythropoietin

The trophic cytokine, erythropoietin (EPO), has been shown to protect neurons from ischemic damage *in vivo* and *in vitro*. EPO is induced after cerebral ischemia, as well as after hypoxic preconditioning *in vivo*. Astrocytes are the main cellular source of the glycoprotein hormone EPO in the brain and low oxygen tension stimulates EPO mRNA expression in astrocytes via hypoxia-inducible factor-1. A synergistic effect of EPO and insulin-like growth factor-1 has been shown. EPO can be viewed as the prototypical paracrine protein by which astrocytes provide protection to neurons.

Regeneration and Repair

In most stroke survivors, functional deficits are most severe in the initial phase after the event and neurological function recovers at least to some degree within days, weeks, or months. Although this improvement has been attributed to the reorganization of brain function toward brain areas that have survived the insult, it is increasingly appreciated that regeneration and repair contribute to recovery after stroke. Glial cells, particularly astrocytes and microglia, may play an important role in this process.

The neuropathological hallmark of ischemic stroke is brain infarction, which is defined as pannecrosis, the necrotic disintegration of all cellular elements. The infarct may be surrounded by a zone of neuronal degeneration, historically termed selective neuronal necrosis, which is probably mechanistically more related to apoptosis. Depending on the severity of the ischemic insult and the type of stroke, the ischemic infarct and selective neuronal degeneration develop over a period of hours to days. Tissue breakdown and phagocytosis continue, and cystic spaces filled with fluid replace the parenchyma. At the border of the lesion, which is well demarcated at that time, swollen astrocytes are abundant and astrocytes proliferate. Trophic factors induced and released by reactive astrocytes include NGF, basic fibroblast growth factor, TGF-β, platelet-derived growth factor, BDNF, ciliary neurotrophic factor, neuropilin-1, and VEGF. Moreover, reactive astrocytes exhibit elongated processes in areas surrounding the ischemic infarction, which suggests that astrocytes also respond to injury by adopting a more immature phenotype. As the developing brain is conditioned to support cell genesis, growth, and synaptogenesis, a possible return to an immature state and the release of associated growth factors may provide a local environment conductive to regeneration and neurogenesis. As discussed previously, almost all pathophysiological mechanisms appear to be 'double edged,' and this seems to also be true for astrocytes and regeneration. Within a few days after the insult, near ischemic lesions in the brain a glial scar forms around the necrotic brain tissue of the infarct. This scar is mainly generated by reactive astrocytes, and it is composed primarily of astrocytes and the extracellular matrix molecules of proteoglycans. Although there is no doubt that the glial scar can limit regeneration in the adult mammalian by inhibiting axonal sprouting, the glial scar may be important for containing the injury site and preventing its extension.

Microglia at the infarct border and microglia/macrophages in the infarct core may produce astrocyte chemoattractants, such as osteopontin, and thereby organize the formation of the astroglial scar after stroke. Microglia may also contribute to tissue reorganization by secreting MMPs (particularly MMP-2), which lead to extracellular proteolysis and may mediate parenchymal and angiogenic recovery. Reactive astrocytes upregulate adhesion molecules and produce extracellular matrix proteins, such as neural cell adhesion molecule (NCAM), laminin, tenascin, chondroitin sulfate proteoglycans, and fibronectin. Some of these products inhibit neurite outgrowth (e.g., tenascin), whereas others (e.g., NCAM) promote neurite outgrowth. Both astrocytes and microglia/macrophages produce TGF-β1 and VEGF after stroke, which are important signals for the angiogenic response. In addition, they may provide signals leading to the proliferation of oligodendrocytes which can be observed around the lesion on day 5 after focal cerebral ischemia.

From the previous discussion, it is apparent that the contributions of glial cells to stroke pathophysiology, regeneration, and repair have only recently come into focus and that our knowledge is patchy at best. It is undisputed that glial cells are major contributors to tissue damage and repair after focal cerebral ischemia. The involvement of glial cells in stroke is considered to have contrasting aspects: whereas ischemia induces the production of cytotoxins in these cells, at the same time potent defense mechanisms are

turned on. Since the transcription and translation of the effector proteins of inflammation and apoptosis are delayed, they represent interesting new therapeutic targets given that only a minority of stroke patients can be recruited immediately after symptom onset.

Whereas the previous discussion focused on the contribution of glial cells to stroke pathophysiology along the temporal evolution of damage and repair, in the following sections we synthesize and summarize our current knowledge stratified for astrocytes, microglia, and oligodendrocytes.

Astrocytes

Astrocytes are comparatively resistant to substrate deprivation and are activated very early in and around a focally ischemic brain region. Reactive astrocytes are hyperthrophic and hyperplastic, and they can be identified by their increased expression of GFAP. At the molecular level, reactive astrocytes increase the production of numerous mediators, receptors, and channels which are responsible for the altered functional state of these cells in cerebral ischemia.

Closely related to their role in inflammation, astrocytes are sources of a host of trophic factors, which affect neuronal survival in a paracrine manner. *In vitro* studies have reported that the astroglial production of growth factors and cytokines is regulated via complex autocrine and paracrine loops. Trophic support from astrocytes not only provides protection in the acute phase after cerebral ischemia but also promotes neurogenesis, angiogenesis, and regeneration in the chronic phase.

Astroglial activation is thought to be protective via destruction of pathogens, removal of debris, and promotion of tissue repair. However, beyond a certain threshold, activation might spread tissue damage. Activated astrocytes can kill neurons in co-culture, and this may occur *in vivo*. The mechanisms by which activated astrocytes kill neurons include the release of high levels of NO, peroxynitrite ($ONOO^-$), glutamate, TNF, and IL-1β. Thus, astrocytes play a key role in the induction of the inflammatory reaction to cerebral ischemia. As infarction and selective neuronal degeneration progress, astrocytes in and around the lesion (and even in remote projection areas) remain activated and even proliferate. Astrocytes are the main cellular constituent of the scar that forms around the lesion within approximately 1 week after the event. Astrocytes, particularly reactive astrocytes, have been identified as a source and potential target of endothelins, VEGF, and angiopoietin I – three factors that are prominently involved in glia-mediated vasculogenesis, neurogenesis, directed migration of neural precursors, neuritogenesis, and glial plasticity.

Microglia/Macrophages

As for astrocytes, the involvement of microglia and macrophages in ischemic injury has contrasting aspects. Resident microglia are rapidly activated around the ischemic lesion. They transform from a resting, ramified morphology into rod cell-shaped and amoeboid phenotypes. Activated microglia proliferate and migrate to the site of injury. Their response is rather stereotypic, and the transformation of resident microglia into phagocytic cells occurs in the presence of neuronal cell death. At the same time, circulating monocytes and macrophages are recruited into the ischemic brain tissue. Activated microglia and macrophages produce proinflammatory cytokines, chemoattractants, and MMPs that sustain the inflammatory response. While clearing the areas of cell death, they are a source of potentially cytotoxic substances, such as NO, ROS, proteases, and excitotoxins. Microglia and macrophages participate in the immunological reactions to cerebral ischemia by upregulating major histocompatibility and costimulatory molecules and by presenting antigens to invading lymphocytes. They also secrete factors inducing apoptosis in neurons and oligodendrocytes. On the other hand, microglia and peripheral blood mononuclear cells produce neuroprotective cytokines and trophic factors after cerebral ischemia. As has been outlined previously, they also participate actively in tissue remodeling and angiogenesis.

Oligodendrocytes

Oligodendrocytes are exquisitely sensitive to hypoxia and ischemia, possibly even more so than neurons. This may have clinical consequences since some neuroprotective strategies might fail to protect oligodendrocytes. As a consequence, neuroprotectants tested in experimental models of stroke (e.g., NMDA receptor antagonists) may have saved neurons but not the oligodendrocytes responsible for maintaining axonal function of these neurons, which may at least partially explain the failure of these substances in clinical trials. Surprisingly little is known about the role of oligodendrocytes in regeneration and repair after stroke, although it is obvious that they must be involved in maintaining myelination or helping to remyelinate axons.

Conclusions

Given the tremendous complexity of cellular and molecular interactions in health and disease in general, and in the brain in particular, it is not surprising

that most of the issues discussed in this article remain tentative, and many questions remain unanswered. We should further take into account that any medically relevant biological signaling pathway is highly complex and consists of functionally independent sets of proteins which act in a coordinated way to produce phenotypic responses.

What are the pressing issues concerning the functional roles of glial cells in cerebral ischemia? With regard to the neuroprotective roles, we need to know how the same cell type or biochemical or molecular mechanism can promote either cell death or survival. Is it possible to devise therapeutic strategies to separate beneficial from deleterious mechanisms? Can we, by pharmacological or physical means, induce beneficial mechanisms selectively? This implies that there are pathways that are purely 'prosurvival.' Apparently this is the case for the astrocytic protein erythropoietin, for which only neuroprotective, but no detrimental, actions on the CNS have been reported.

A plethora of experimental evidence suggests that astrocytes protect neurons, as well as other elements of the CNS after cerebral ischemia. Astrocytes are effective sensors of the brain microenvironment. They are capable of detecting substrate deprivation, against which they acutely and chronically activate a host of countermeasures. They modulate inflammation, participate in the clearing of cell debris, and produce trophic factors to neurons and vascular cells. Increasing evidence indicates that there are molecular parallels between neural/neuronal and vascular development and maintenance, in which astroglia might have important orchestrating functions. However, under certain conditions, activated astrocytes are perpetrators and actively contribute to the demise of brain tissue after cerebral ischemia. By the repulsion of regenerating axons, reactive astrocytes and their proteoglycan products may actively impede brain reorganization. It is likely that the same stimuli, and possibly even the same mediators and effectors, which are involved in astrocytic protection are also part of astrocyte-mediated cell death. Further research is needed to determine whether and how astrocyte protection can be therapeutically utilized after cerebral ischemia. This could be done either by boosting astrocytic neuroprotection or by delivering therapeutics that mimic astrocyte-derived neuroprotectants.

In summary, glial cells are major contributors to damage, as well as to endogenous protection and repair after stroke. The fact that the same cell types partake in damaging, as well as in protective signaling precludes simple therapeutic approaches aimed at blocking or inducing the activities of glial cells. Nevertheless, the appreciation of the high susceptibility of oligodendrocytes to AMPA-mediated cell death and the successful pilot trial on the use of erythropoietin in stroke in humans are examples of the outstanding clinical relevance of glial mechanisms in stroke. Future studies will elucidate the interplay between glia, neurons, and other nonneuronal elements in stroke in greater detail.

Glia and Synapse Formation: An Overview

N J Allen and B A Barres, Stanford University School of Medicine, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The majority of mature synapses are not just composed of a pre- and postsynaptic neuronal element, but also an astrocytic process that envelops the synapse (Figure 1). This close spatial relationship has led to the term 'tripartite synapse' to acknowledge the glial contribution. Their synaptic localization means that glial cells are ideally placed to monitor and respond to synaptic activity. Indeed, one glial cell can contact and ensheathe thousands of synapses formed between many different neurons. This morphological specialization suggests important roles for glia in synaptic development and function, which are reviewed here.

Glial Induction of Synaptogenesis

Glial cells are in the right place at the right time to play an active role in neuronal synaptogenesis. For example, there is a temporal correlation between when retinal ganglion cell (RGC) axons reach their target structure, the superior colliculus, and when they form synapses. There is a delay of 1 week between target innervation and synaptogenesis, during which time glia are generated, which suggests that neurons require glial-derived signals to enable them to form synapses. The mechanism by which glial signals act is still unclear. Are they permissive in allowing synapses to form, with the location of synapses determined by neurons, or do they instruct neurons where to form synapses?

The first demonstration of a role for glial cells in neuronal synaptogenesis was by Pfrieger and Barres in 1997. They showed that when RGCs were cultured in the presence of astrocytes they possessed significantly more synaptic activity than when cultured alone in serum-free media. This was later shown to be due to astrocytes inducing the formation of new synapses in addition to enhancing the efficacy of existing synapses. This effect was not due to astrocytes enhancing the survival of RGCs, as the same effect was seen when astrocytes were added after most of the neuronal death had occurred and RGC survival factors were present in the media. Contact between astrocytes and neurons was not required, as the same effect was seen if the astrocytes were grown in contact with the neurons or placed in a feeding layer above them, thus demonstrating that a soluble signal released from astrocytes increased the number of synapses. Interestingly, astrocytes in culture did not require a neuronal signal to stimulate secretion of synaptogenic factors – they were constitutively released. Addition of media conditioned by astrocytes was equally effective in inducing synapses as a feeding layer of astrocytes.

There are a number of lines of evidence demonstrating that the synapses induced by astrocytes are functional (Figure 2). First, electrophysiological recordings from RGCs showed an increase in the frequency and amplitude of spontaneous excitatory postsynaptic currents (sEPSCs) following exposure to astrocyte signals. Second, immunostaining for pre- and postsynaptic markers showed a sevenfold increase in co-localized pre- and postsynaptic puncta, defined as a synapse, following astrocyte addition. Third, FM dye-uptake studies showed that presynaptic vesicle recycling was enhanced by astrocytes. Fourth, electron microscopy analysis of the synapses induced between RGCs by astrocyte exposure showed them to be ultrastructurally normal, exhibiting presynaptic vesicles and an electron-dense postsynaptic density. Taken together these observations show that the synapses induced to form between neurons by glial cells are fully functional.

Glia Induce Synapses in Multiple Neuron Classes

Since this initial study, numerous researchers have demonstrated a role for glial cells in inducing synaptogenesis in multiple classes of neurons. In addition to glutamatergic RGCs, spinal motor neurons, γ-aminobutyric acid (GABA)ergic hippocampal neurons, and glycinergic neurons all show enhanced synapse formation in the presence of glial cells. Also, synaptogenic effects are not restricted to astrocytes. Oligodendrocytes and Schwann cells, whose primary function is to myelinate and ensheathe axons, have also been shown to induce neuronal synaptogenesis.

Perisynaptic Schwann cells, specialized Schwann cells that are present at the neuromuscular junction synapse, are involved in guiding nerve terminals to the muscle during development. These specialized Schwann cells have been shown to enhance synaptogenesis between cultured motor neurons from rodents and between motor neurons and target muscle in *Xenopus*. Perisynaptic Schwann cell processes make contact with the muscle first and the nerve terminal uses the processes as a guide to locate and innervate the muscle. Selective ablation of perisynaptic Schwann

Figure 1 Electron micrograph illustrating the close relationship of astrocytic processes to synapses in the hippocampus. Astrocytic profiles are illustrated (blue) in the vicinity of 11 synapses (arrows). On this section, three synapses have astrocytic profiles at their perimeters (arrowheads). Scale bar = 1 μm. Reproduced from Ventura R and Harris KM (1999) Three dimensional relationships between hippocampal synapses and antrocytes. *Journal of Neuroscience* 19(16): 6897–6906, with permission.

cells in *Xenopus* tadpoles resulted in a decrease in the number of synapses that formed, the retraction of nerve terminals that had already formed synapses, and the loss of postsynaptic acetylcholine receptors.

GABAergic hippocampal neurons undergo enhanced synaptogenesis in the presence of astrocytes, and as for RGCs, the astrocytic effect is via a soluble factor. Astrocytes induce an increase in pre- and postsynaptic clusters, increased surface levels of $GABA_A$ receptors, and increased frequency of miniature inhibitory postsynaptic currents (mIPSCs). One of the downstream effects of astrocyte signals is to regulate brain-derived neurotropic factor (BDNF) and tyrosine receptor kinase B (TrkB) signaling between neurons to enhance synaptogenesis, specifically the maturation of the postsynaptic site and insertion of $GABA_A$ receptors, but the identity of the astrocytic signal is currently unknown.

Glia Induce Synaptogenesis via Secreted Factors

Much work has focused on identifying the soluble signals secreted by astrocytes that induce formation of functional synapses. To date two signals have been identified, thrombospondin (TSP) and cholesterol, but there are likely to be many more.

TSPs are a family of large extracellular matrix proteins that can mediate both cell–cell and cell–matrix interactions. Addition of TSP to cultured RGCs increased the number of structural synapses that formed, to the same extent as that induced by astrocytes. TSP-1 and -2 are expressed in the developing brain during the peak period of synaptogenesis but decrease by adulthood. Mice in which both TSP-1 and -2 had been knocked out formed 30% fewer synapses in their brains. These observations have led to the hypothesis that immature astrocytes provide a developmental window during which synaptogenesis can occur, by producing a permissive environment via the secretion of TSP.

Interestingly, the synapses induced by TSP are postsynaptically silent – they lack the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid subtype of glutamate receptor (AMPAR) but contain extrasynaptic *N*-methyl-D-aspartate receptors (NMDARs). This suggests that a second astrocyte-derived signal is required to trigger insertion of AMPARs into the postsynaptic membrane and make the synapse fully functional.

Another astrocyte-secreted factor suggested to be involved in synaptogenesis is cholesterol bound to apolipoprotein (ApoE). Cholesterol is required for normal neuronal synaptogenesis and can be provided by glia when neuronal cholesterol is lacking. Cholesterol enhances presynaptic function and transmitter release, and contributes to dendrite development, although these effects are strongest in clonal-density cultures where neuronal cholesterol may be lacking. Indeed, it has been demonstrated that if cholesterol is depleted from neurons in culture, then surface AMPARs are reduced due to disruption of lipid rafts.

Therefore, multiple astrocyte-derived signals promote both synapse formation and function. There are many signals yet to be identified, and it remains to be seen whether different signals induce the formation of different synapse types or between different classes of neurons.

Contact-Mediated Synaptogenesis

Glia can also enhance synaptogenesis by contact-mediated signaling. It has been shown that integrin-mediated astrocyte–neuron contact was required to initiate synaptogenesis between embryonic hippocampal neurons in culture. In these experiments neurons were encircled by noncontacting astrocytes to provide trophic support, but very few synapses were formed even in the presence of soluble astrocyte factors. However, when an astrocyte was added directly to a neuron and physically contacted it, multiple synapses were formed. In contrast, direct contact by astrocytes was not needed to induce postnatal RGCs to form synapses. This raises the question of whether astrocytic contact during embryonic development can render neurons receptive to secreted factors that can induce synaptogenesis.

Figure 2 Glia induce functional synapses to form between retinal ganglion cells in culture. (a) Electrophysiological recordings from cultured retinal ganglion cells. In the absence of glia, only a low frequency of small spontaneous synaptic currents is observed, whereas in the presence of glia large spontaneous synaptic currents are frequently observed. (b) Electron micrographs of synapses between retinal ganglion cell neurons cultured in the absence of glia and presence of glia. There is no apparent difference in synaptic ultrastructure between the two conditions. Scale bar = 200 nm. (c) Glia increase the clustering of pre- and postsynaptic proteins and their co-localization. Staining of retinal ganglion cells with an antibody against the presynaptic marker synaptotagmin shows that in the absence of glia presynaptic markers are diffuse (left), whereas in the presence of glia presynaptic markers are discretely clustered (right). Staining of retinal ganglion cells with an antibody to the postsynaptic marker PSD-95 reveals that in the absence of glia there are relatively few PSD-95 puncta, whereas in the presence of glia numerous puncta are apparent. In the absence of glia there is little overlap between pre- and postsynaptic markers, whereas in the presence of glia there is a high degree of overlap. Scale bar = 50 μm. Reproduced from Ullian EM, Sapperstein SK, Christophernon KS, and Barres BA (2001) Control of synapse number by glia. *Science* 291(5504): 657–661, with permission.

Glia Influence Synapse Elimination

During development an excess of synapses are formed, but there is a reduction to the final adult number by a process of synapse elimination. It is hypothesized that elimination can be due to retraction of presynaptic terminals and axons or by degeneration of axons and subsequent phagocytosis of the debris by surrounding glial cells. It has now been suggested that glia are not just scavenging axonal debris, but are actively involved in the pruning process. In the *Drosophila* nervous system, glial cells were shown to engulf axonal varicosities prior to their degeneration. When the ability of glia to phagocytose was perturbed, axon pruning was significantly inhibited. A separate electron microscopy (EM) study showed peroxidase from labeled neurons inside neighboring glial cells in lysosomal compartments, suggesting phagocytosis. These findings are not direct evidence, but strongly suggest that glia actively contribute to pruning in *Drosophila*.

A similar process of axon removal by Schwann cells, termed axosome shedding, occurs during synapse elimination at the mammalian neuromuscular junction. This raises the possibility that glia actively contribute to synapse elimination in mammals. A combination of time-lapse imaging and serial EM showed that as axons disappeared they shed small membrane-bound particles termed axosomes, and that these axosomes appeared inside neighboring Schwann cells. It was suggested that this is a novel

means of transferring information between the cytoplasmic compartments of different cell types.

Glia Modulate Synaptic Strength

In addition to dictating the formation of synapses during development, glial cells are also actively involved in modulating the strength of mature synaptic connections. They do this by releasing factors that alter the number of neurotransmitter receptors present at synapses, and via factors that modulate the release of neurotransmitter and act as cofactors for receptor activation.

Glia, particularly microglia, release cytokines, including tumor necrosis factor-α (TNF-α), which has been shown to modulate synaptic strength via effects on the trafficking of AMPA and $GABA_A$ receptors. Addition of TNF-α to cultured hippocampal neurons increased the surface levels of AMPA receptors while simultaneously decreasing surface $GABA_A$ receptors, thus leading to an overall strengthening of the synapse, a phenomenon known as homeostatic synaptic scaling. Blockade of the actions of endogenous TNF-α led to a decrease in surface AMPA receptors. A glial source for TNF-α was shown by experiments in which TNF-α knockout (KO) glia were cultured with wild-type (WT) neurons and synaptic scaling due to activity blockade was no longer present. There were no deficits in long-term potentiation (LTP) in hippocampal slices from TNF-α KO mice, showing that glial TNF-α is involved in controlling overall synaptic strength but has no role in plasticity.

Glial Release of Transmitters and Neuromodulators

What are the effects of astrocytic transmitter release on synaptic transmission? Astrocytes have been shown to release ATP, which acts to inhibit overall neuronal excitability, and glutamate receptor agonists, which enhance overall activity levels.

Astrocytic ATP release has been implicated in heterosynaptic depression, a process whereby synapses neighboring those that have undergone LTP are depressed. ATP can exert its effects either as itself or by being converted to adenosine in the extracellular space by ectonucleotidases. In the hippocampus glial-derived adenosine has been shown to act on presynaptic A1 receptors, leading to inhibition of calcium channels, a decreased probability of vesicular release, and reduced frequency of sEPSCs. These effects were long-lasting and occurred over a large area – many synapses were inhibited. It is not clear if this inhibition was due to the diffusion of adenosine through the extracellular space or to the release of ATP from multiple regions on the astrocyte or multiple astrocytes within a network.

It has been suggested that glutamate can be released from astrocytes in an activity-dependent manner. Astrocytic glutamate has been shown to activate extrasynaptic NMDAR on neighboring neurons, which could contribute to excitation of the cell. As there is little evidence that glutamate can be accumulated in glia, it remains uncertain whether these effects are attributable to glial glutamate release or release of some other neuroactive substance.

In addition to the release of transmitters that directly activate neurotransmitter receptors, a role for astrocytes in releasing receptor co-agonists has been proposed. D-Serine, which has been suggested to be the endogenous ligand of the glycine binding site of the NMDAR, is expressed in glial cells but not neurons, and is necessary for NMDAR to be activated. There is circumstantial evidence that D-serine can be released from astrocytes in response to neuronal activity and that this release is necessary for hippocampal LTP. When astrocytes were cultured in contact with hippocampal neurons, the neurons were capable of undergoing LTP, whereas neurons grown in media conditioned by astrocytes (but without contact) were not. The addition of exogenous D-serine restored the ability of neurons grown in astrocyte-conditioned medium to undergo LTP. These data, and further studies carried out in hippocampal slices, suggest that astrocytes are actively involved in synaptic plasticity by regulating the availability of D-serine.

Glia Influence Synaptic Structure, Stability and Location

Studies on cultured neurons have shown that if synapses are induced by astrocytes and then the astrocytes are removed, these initial synaptic connections are lost. While the identity of this maintenance factor is unknown, this demonstrates that a constant astrocytic signal is needed in order to maintain synaptic connections.

Studies have shown transient physical coupling between astrocytic processes and synapses via ephrin/EphR interactions in the hippocampus. Dendritic spines express EphA4, which interacts with ephrin-A3 on astrocytic processes. Activation of EphA4 via ephrin-A3 caused a reduction in the length of dendritic spines by 30% and the collapse of 20% of spines, leading to an overall reduction in spine density. Conversely, inhibition of EphA4 caused an increase in spine length and a more disorganized pattern of spines appeared. EphA4 expression levels decrease during

development, and it is present in an inactive form in the adult brain. This raises the question of whether developmental contact between astrocytic processes and dendritic spines plays a role in the elimination and localization of synapses.

Live confocal imaging studies have produced new information about the motility of astrocytic processes at synapses. Imaging of green fluorescent protein (GFP)-labeled astrocytes in brain slices revealed that astrocytes frequently extend and retract fillipodial processes, on a timescale of minutes. Interestingly, this motility only occurred at synaptic sites, not at regions where astrocytes were contacting neuronal somata or blood vessels, and occurred in numerous brain regions. These observations add to the evidence that astrocytes are actively monitoring the synaptic environment.

In the hypothalamo-neurohypophysial system (HNS) astrocytes are capable of fully retracting from synapses, in a reversible manner, under the control of hormonal signals. When oxytocin is released it causes astrocytes to retract from neighboring neurons, which then receive more synaptic inputs. Astrocytes were previously blocking these sites and preventing neuronal innervation. In this way astrocytes can control the location and number of synaptic inputs that a neuron receives, thus influencing the overall activity and output of the neuron. This is a normal physiological process, and a similar phenomenon has been demonstrated in the cerebellum when astrocytic transmitter receptors were altered. Climbing fibers release ectopic vesicles directly onto Bergmann glia (BG) in the cerebellum. Released glutamate activates AMPA receptors on the BG; glutamate spilling over from neighboring synapses would not be at a high enough concentration to do this. BG express calcium-permeable AMPA receptors lacking the GluR2 subunit, which usually confers calcium impermeability to the channel. Expression of GluR2 in BG led to retraction of glial processes from the Purkinje cells (PCs) that they are normally in close association with and caused the PCs to be aberrantly innervated by multiple climbing fibers. Therefore, ectopic vesicular release of glutamate directly onto BG AMPA receptors signals the Bergmann glial cell in a calcium-dependent manner to remain in close apposition with the PC it is surrounding.

In the central nervous system it has been hard to interpret the effects of removal of astrocytes on synaptic function in mature animals. Experiments in which astrocytes have been ablated have had effects mainly in the cerebellum, with the loss of BG. This led to widespread death of granule neurons, presumably due to excitotoxicity from glutamate that accumulated, as the BG were no longer removing it from the extracellular space. The more global effects of astrocyte ablation on neuronal survival make it hard to infer anything about effects on synaptic function.

More subtle perturbations in astrocyte function do lead to alterations in synaptic physiology. Mice in which the astrocyte-specific intermediate filament protein glial fibrillary acidic protein (GFAP) has been deleted show altered synaptic plasticity, with enhanced levels of LTP. Deletion of GFAP will probably affect the structure of astrocytic processes and presumably their synaptic apposition, although whether this is responsible for the enhanced LTP remains to be determined.

An elegant study using the frog neuromuscular junction as a model system investigated the effects of removing synaptic glia from a mature synaptic contact. Perisynaptic Schwann cells in an intact adult frog were selectively labeled with a monoclonal antibody, exposed to complement, and lysed via the complement cascade. This approach left the presynaptic motor neuron terminal and the postsynaptic muscle cell intact, but removed their synaptic partner, the perisynaptic Schwann cell. Interestingly, this had no effect on the structure or function of the synapse until 1 week after the ablation. At this time presynaptic function decreased by half and there was a tenfold increase in the retraction of presynaptic terminals from the muscle. Therefore, glial cells play a role in stabilizing mature synaptic contacts, both in the central and peripheral nervous systems.

The studies discussed here demonstrate that glia are constantly monitoring the synaptic environment and can alter their structure and synaptic association in response to neuronal activity. This is yet another way in which they can control synaptic activity. Glial cells are ideally placed to respond to alterations in neuronal activity and to integrate information from many sources.

Conclusions

Glial cells are intimately associated with synapses at all stages of development and adult life, both in the central and peripheral nervous system. Glia induce the formation of synapses via the secretion of synaptogenic substances, and secrete additional signals that regulate both pre- and postsynaptic function. Glia contribute to the maintenance of synaptic structure and arrangement, ensuring that neurons receive the correct pattern of innervation.

Functional Hyperemia and the Astrocyte Link

More than 100 years have passed since Roy and Sherrington first appreciated that the brain possesses intrinsic factors that participate in the control of cerebral blood flow (CBF). Functional hyperemia, which is the active process of broadening vessel width in response to enhanced synaptic transmission and neuronal spiking, is a fundamental component of the entirety of CBF control, but despite its long history, there is much knowledge to be gained concerning the precise physiology responsible for the regulation of vessel diameter. Although the purpose of functional hyperemia is to augment the delivery of oxygen-rich hemoglobin and other nutrients to the working cells, while simultaneously clearing metabolic products such as CO_2, there persists an implicit assumption in the use of imaging to map brain function that changes in CBF are a simple function of neuronal activation. This has formed the basis for several imaging strategies so that specific volumes of activated brain tissue can be identified during both normal and pathological cerebral functioning. However, there is an incomplete understanding of the cellular mechanisms involved in transforming changes in neuronal activity to changes in CBF. Furthermore, there is a growing appreciation that the link between neural activity and vasomotor responses is more complicated than originally anticipated. Many factors have been identified that have direct consequences on cerebral vessel tone – including, but not limited to, prostaglandin E_2 (PGE_2), epoxyeicosatrienoic acid (EET), 20-hydroxyeicosatetraenoic acid (20-HETE), adenosine, nitric oxide (NO), and K^+. The number of cell types participating in neurovascular coupling is growing as new experimentation is performed and the cellular source of these vasoactive signaling molecules in some cases is still a matter of debate.

However, contributing to our understanding of this important physiological process, astrocytes have been examined as the missing element coupling changes in neuronal activity to alterations in the diameter of brain vessels. This article focuses on the role of astrocytes, particularly that of astrocyte endfeet Ca^{2+} signaling, in the control of brain blood vessel girth. The different experimental models and approaches used to test astrocyte involvement, the possible signaling molecules participating, and the potential mechanisms of astrocyte action are highlighted.

Astrocytes Are Ideal Regulators of Cerebral Blood Flow

Processes from individual astrocytes can form a physical bridge between numerous synapses, adjacent astrocytes – forming a glial syncytium – and the microvessels of the brain. The latter is accomplished by modified astrocytic processes termed perivascular 'endfeet.' Endfeet are enlarged astrocytic compartments that are specialized for direct interaction with vessels. It is a defining feature of the central nervous system that all cerebral arterioles in the brain are circumscribed by endfeet, suggesting a prominent role in vasculature physiology. Astrocytes also possess an equally impressive ability for cell-to-cell communication. Astrocytes can sense transmitter molecules such as glutamate, γ-aminobutyric acid (GABA), adenosine triphosphate (ATP), and norepinephrine and may respond to such signals by releasing gliotransmitters. These include ATP, adenosine via ATP breakdown, NO, PGE_2, prostacyclins, and EETs, all of which are vasoactive compounds. Furthermore, astrocytes can propagate a signal over long distances via interastrocytic Ca^{2+} waves, which rely on the release of glial-derived ATP. It is these properties that have led to the concept of the 'neurovascular unit,' in which astrocytes are well enough endowed, both anatomically and physiologically, to transmit relevant information about the extracellular environment from neurons to vessels.

The endfeet are also endowed with many features thought to be important for cerebrovasculature control. Endfeet express soluble nitric oxide synthase (NOS), noradrenergic receptors, and gap junction proteins, whereas Ca^{2+}-activated K^+ channels, aquaporin 4 water channels, and purinergic receptors are present in greater amounts here than in other astrocytic compartments. In particular, phospholipase A_2 (PLA_2) activation can lead to the downstream production of vasoactive arachidonic acid (AA), PGE_2, EET, and 20-HETE. These characteristics suggest that the endfeet are capable of producing diffusible molecules to communicate with arteriole smooth muscle cells (SMCs) and thus contribute to the physiology of blood vessel control.

Astrocytes in the Control of Cerebrovascular Diameter

Astrocytes respond to glutamate with an increase in intracellular Ca^{2+} through the activation of the mGluR subtype, and the first evidence that mGluR

activation of astrocytes is a component of neurovascular coupling was demonstrated by the Carmignoto laboratory. Activating astrocytes indirectly by disrupting membranes with patch electrodes or by applying mGluR agonists triggered the release of diffusible factors that then acted on SMCs to cause dilation of arterioles. Furthermore, an elevation of extracellular glutamate from enhanced synaptic activation evoked Ca^{2+} increases in astrocyte endfeet (via mGluR) and caused vasodilation. The dilation was reduced by blocking astrocyte Ca^{2+} signals with the cyclooxygenase (COX) inhibitor aspirin, suggesting that products from cyclooxygenase activity such as PGE_2 and/or prostacyclin were involved. The complexity of this model for functional hyperemia, in which astrocytes simply sense the level of extracellular glutamate, was soon expanded. Work by the Nelson laboratory demonstrated that in the presence of a thromboxane analog to increase vascular tone, electrical stimulation of the tissue increased endfoot Ca^{2+} and reduced spontaneous Ca^{2+} signals in SMCs, but neither of these effects were completely blocked by mGluR antagonists. These data indicate that other, nonglutamatergic inputs or transmitters are likely involved in relaying information about the state of the cellular environment to vessels through astrocytes.

The MacVicar laboratory has examined the effects of elevations in astrocyte Ca^{2+} alone, without incorporating the involvement of membrane-bound receptors, by uncaging Ca^{2+} using two-photon photolysis. This technique allowed them to increase Ca^{2+} within the discrete volume of astrocytes without provoking other cell types. Astrocytes were identified in transgenic mice that expressed enhanced green fluorescent protein driven by the glial fibrillary acidic protein promoter and these cells were loaded with the acetoxymethyl (AM) ester form of Rhod-2, the Ca^{2+}-sensitive dye. Under typical brain slice recording conditions in the hippocampus and cortex, Ca^{2+} uncaging in astrocytes induced a Ca^{2+} wave that propagated throughout the astrocyte syncytium and invaded endfeet, and the endfeet Ca^{2+} signal was immediately followed by a constriction of adjacent arterioles. Mulligan and MacVicar found a strong positive relationship between the extent of the constriction and the extent of the Ca^{2+} signal within and among the endfeet. Astrocyte-mediated vasoconstrictions were blocked by inhibiting the Ca^{2+}-dependent enzyme PLA_2 and preventing the release of the diffusible factor AA. Arteriole constrictions were found to be caused by the generation of 20-HETE within SMCs from the astrocyte-derived AA by a CYP4504a enzyme.

A study from the Newman laboratory conducted in retinal explants examined the effect of Ca^{2+} elevations within retinal glia by using UV photolysis of caged Ca^{2+} and caged IP_3. Notably, in response to Ca^{2+} uncaging, constrictions as well as dilations were observed, whereas increases in free IP_3 produced mostly dilation. Consistent with results from the MacVicar laboratory, constrictions were dependent on the generation of astrocyte AA and its conversion to 20-HETE. Dilations were also caused by astrocyte AA, but instead of its conversion to the potent constrictor molecule, AA was converted to EET by another CYP450 enzyme. These data indicate an intriguing complexity in the dialog between glial cells and arterioles with respect to the potential factors determining the polarity of the response and the different outcomes observed depending on the method of Ca^{2+} liberation within glia.

An *in vivo* study conducted by the Nedergaard laboratory described the effects of uncaging Ca^{2+} in astrocyte endfeet on vasomotor responses in arteries of the somatosensory cortex. Astrocytes were loaded with the Ca^{2+} indicator dye Rhod2-AM and caged Ca^{2+} DM-nitrophen, similar to previous strategies. Uncaging Ca^{2+} within astrocyte endfeet triggered an intracellular Ca^{2+} rise that was followed by the dilation of the adjacent penetrating arteriole. Using this protocol very few constrictions were observed. Dilations were found to be blocked by inhibitors of COX-1 but not COX-2 enzymes, suggesting that the AA conversion to PGE_2 underlies the dilation, similar to the findings of the Carmignoto laboratory (see **Figure 1** for the possible astrocyte endfoot-mediated vasoconstriction and vasodilation mechanisms).

Nitric Oxide: An Important Modulator of Astrocyte-Mediated Cerebral Vessel Control

As stated previously, the first study implicating astrocyte Ca^{2+} signals in the relaxation of vascular tone as a model for functional hyperemia was conducted by the Carmignoto laboratory. In a subset of their experiments, blood vessels were preconstricted by incubating the brain slices with L-NAME to block NOS and reduce the level of endogenous NO to ultimately enhance the vasodilations observed. This is interesting compared to the results obtained by the MacVicar laboratory, in which arterioles in untreated slices always displayed constriction when astrocytes were stimulated. Only when Mulligan and MacVicar incubated in L-NAME did they observe vasodilations in response to mGluR agonist t-ACPD.

On the basis of these dichotomous results, Metea and Newman speculated that the levels of NO dictated the type of vasomotor response. This was hypothesized to occur via regulation of the enzymatic conversion of AA to either EET or 20-HETE. Consistent with this idea, vessels that upon first test showed dilations were

Figure 1 Astrocyte endfeet control of cerebrovasculature diameter by the generation of astrocyte AA via calcium-sensitive PLA_2. Two separate endfeet making contact with an arteriole show possible constriction (left endfoot) and dilation (right endfoot) mechanisms. Reproduced from Glia, Vol. 55, No. 12, 2007, pp. 1214–1221. transformed into constrictions in the presence of the NO donor SNAP, an outcome thought to be due to the NO sensitivity of the EET producing enzyme CYP450. In the presence of the NO scavenger PTIO, the opposite was true: Vasoconstrictions were converted to vasodilations. In line with the latter experiment in which NO is limiting, blocking all forms of NOS with L-NAME produced only vasodilations when the preparation was stimulated, similar to the results of the Carmignoto and MacVicar laboratories.

An *in vivo* study conducted by the Nedergaard laboratory also examined a role for NO in astrocyte-mediated dilations by applying L-NAME to block NOS. This treatment failed to affect the degree of dilation induced when Ca^{2+} was uncaged in astrocyte endfeet. This negative result may be explained by a lower level of endogenous NO in the intact animal. However, NO donors were not tested, and it would be interesting to determine if by elevating NO levels *in vivo* the vasomotor response changes polarity from dilation to constriction when astrocytes are stimulated – as has been demonstrated in *in vitro* experiments.

The work outlined previously shows that astrocytes wield the necessary physiology to initiate both vasoconstriction and vasodilation mechanisms and that the level of NO or the degree of tonic constriction may dictate the polarity of the vasomotor response. However, there are many unknowns in the role of NO in mediating the previous processes. First, little is known about the importance of astrocyte-derived NO compared to that of neurons and endothelial cells in functional hyperemia. Second, studies testing the impact of NO on synaptic transmission have demonstrated that NO enhances the release of several neurotransmitters, including glutamate. This notion also corresponds with data collected *in vivo* showing a prominent role for enhanced NO release in function hyperemia. These demonstrations need to be reconciled both with the *in vitro* data showing that higher NO levels promote astrocyte-mediated vasoconstriction and with the *in vivo* data showing that astrocyte-mediated vasodilations do not rely on NO production.

K^+ and Vascular Control by Astrocytes

The first hypothesis to point to the glial cell as an essential controller of vascular tone was proposed by

Newman approximately 20 years ago. It was based on his observation that the endfeet of Muller cells express high levels of Kir channels, which could potentially contribute to vessel dilation by effluxing K^+ around the closely apposed vessel SMCs. However, the Newman laboratory disproved this hypothesis with two separate experiments. First, the direct depolarization of single glia that were in close proximity to a vessel did not elicit changes in vessel diameter. Second, the extent of K^+-induced vasodilations was seemingly unabated in a Kir knockout mouse compared to that of wild type.

An alternative astrocyte-mediated mechanism that takes advantage of the ubiquitous K^+ ion in the regulation of vascular tone has been proposed by the Nelson laboratory. Their work shows that a Ca^{2+} rise in astrocyte endfeet activates large-conductance Ca^{2+}-activated K^+ channels (BK channels), which upon opening allow the efflux K^+ into the extracellular space. They demonstrated that modest increases in external K^+ promote vasodilation by hyperpolarizing SMCs through an enhanced Kir conductance. This leads to decreased Ca^{2+} entry, SMC relaxation, and the consequent dilation (Figure 2). However, from the data presented, K^+ channels are not the only contributors to K^+- or activity-induced vasodilations because a fraction of the dilation response was blocked by inhibitors of cyclooxygenases, suggesting that vasoactive PGEs were also involved. Furthermore, it should be noted that the role on SMC Kir channels here likely does not conflict with Newman et al.'s data showing that there is no difference in K^+-induced dilations between wild-type and Kir knockout mice because of the difference in the Kir subtypes involved: Kir 2.0 and Kir 4.1 for SMCs and astrocyte endfeet, respectively.

Figure 2 Astrocyte endfeet control of cerebrovasculature dilation by the efflux of potassium from BK channels. Elevated extracellular potassium activates Kir channels on SMCs, which causes dilation via hyperpolarization and subsequent SMC relaxation. Reproduced from Glia, Vol. 55, No. 12, 2007, pp. 1214–1221. Norepinephrine and Astrocyte-Mediated Cerebrovascular Control

Vasomotor motor responses cannot be completely abolished by mGluR antagonists when synapses become activated, suggesting that transmitters other than glutamate can participate in neurovascular coupling. Along this line, an electron microscope examination of arterioles has revealed that the majority of noradrenergic terminals originate from the locus coeruleus that associate with vessels synapse on astrocyte endfeet rather than SMCs. Previous *in vivo* work demonstrated that activation by norepinephrine (NE) causes a decrease in CBF, an effect that may help maintain CBF at a constant rate at higher blood pressures. *In vitro* work has shown that NE triggers robust intracellular Ca^{2+} increases in astrocytes via activation of α_1 and β adrenergic receptors. Consistent with these results, experiments conducted by Mulligan and MacVicar showed that NE-mediated Ca^{2+} increases within astrocyte endfeet temporally preceded prominent vasoconstrictions. When astrocytes were loaded with BAPTA-AM to chelate rises in intracellular Ca^{2+}, vascular constrictions generated by NE were drastically reduced, suggesting that Ca^{2+} was critical for the astrocyte-mediated effect. These data add another level of complexity to neurovascular coupling by expanding the realm of vasoactive transmitter beyond that of glutamate.

Enigmatic Astrocyte Ca^{2+} Signals: Functional Significance?

From the studies described previously, it is clear that astrocytic Ca^{2+} transients, particularly those within the endfeet, have important albeit complex actions on vascular tone. Of paramount importance to all this work, however, is whether a rise in astrocyte

intracellular Ca^{2+} is indeed the signal responsible for relaying information on the metabolic state of neurons to the vasculature in order to affect vessel diameter and ultimately CBF. There are several observations concerning the very nature of astrocyte Ca^{2+} signaling that make it a worthwhile endeavor to entertain this query. Because CBF changes can occur in a graded manner to match the corresponding subtlety of ongoing synaptic communication and neuronal activation, it is expected that astrocyte Ca^{2+} will also mirror these changes if this signal is indeed the key factor in mediating functional hyperemia and other forms of neurovascular coupling. However, there are several lines of evidence that reveal a curious inconsistency with this idea. First, the Helmchen laboratory has described a novel two-photon scanning method that is capable of measuring Ca^{2+} signals at frequencies up to 10 Hz in hundreds of cells simultaneously. This technique has demonstrated that neuronal activity fails to consistently increase astrocyte Ca^{2+} with a temporal profile that follows the timing and patterning of neuronal activation. Second, Ca^{2+} increases often occur independent of neuronal activity. These spontaneous Ca^{2+} oscillations have been reported both *in vivo* and *in vitro*. Finally, the astrocyte Ca^{2+} waves thought to transduce important information toward vessels are not faithfully observed *in vivo*, suggesting that this signaling process may actually be attributable to aspects of the slice or culture condition, or that it manifests more easily in the pathophysiology of epilepsy rather than being the 'normal' method of signaling for neurovascular coupling. These discrepancies, however, may not justify the hypothetical scenario, we have just considered, that astrocyte Ca^{2+} signaling (endfeet excluded) does not constitute a mechanism utilized by the neurovascular unit. Instead, they may simply reflect our ignorance of why such timing differences arise and how the vastly different astrocyte signals preserve neural information, which we cannot currently decode. In either case, meaning versus no meaning, it is clear that more experimentation is needed to tease out the true nature of astrocyte Ca^{2+} signals in cerebrovascular control.

Because elevations in endfeet-free Ca^{2+} can trigger vasoconstriction or vasodilation, there must be different physiological conditions that permit the utilization of each astrocyte-mediated mechanism. Factors other than NO that dictate the polarity of the vasomotor response may include the vessel distance from the center of augmented neuronal activity. Work from the Dale laboratory has shown that cerebral vessels located within a brain volume undergoing an elevation in activity display, as expected, dilation, but this space is circumscribed by a surrounding brain volume in which the vessels contained therein display constriction. The result of this effect is a surround inhibition of vessel diameter, which is proposed to facilitate the enhanced CBF to the central active region that requires additional blood supply. This may constitute the physiological circumstance in which both astrocyte-mediated constrictions and dilations of cerebral vessels are utilized simultaneously directly adjacent to one another. How vasoconstriction is recruited over vasodilation as the distance from the center of the elevated activity increases is not known.

Conclusion

The work described here indicates that astrocytes are capable of eliciting changes in vessel diameter in both directions. Although there appears to be an important initiating role for glutamate through the activation of group I mGluRs that raises intraglial Ca^{2+}, other inputs and transmitters are likely involved in neurovascular coupling. An increase in intracellular free Ca^{2+} and the subsequent activation of Ca^{2+}-sensitive PLA_2 in astrocytes can trigger a surprisingly diverse array of vasoactive metabolites after the initial production of AA. Constriction occurs when AA is converted to 20-HETE, whereas dilation results from the conversion of AA to PGE_2 or EET. The enzymes governing the production of these vasoactive products are sensitive to NO, suggesting that NO levels may dictate the direction of the vessels' response. In addition, a role for Ca^{2+}-activated K^+ channels in astrocyte endfeet and the efflux of K^+ has also been suggested to relax vascular tone by hyperpolarizing SMCs via Kir channels. Astrocytes are proving to be important mediators of neurovascular coupling, but a comprehensive understanding of their role is far from complete. Novel experiments and techniques are unfurling much complexity in processes such as functional hyperemia, which historically was thought to occur by a simple correspondence to neuronal activation.

Glial Cells: Astrocytes and Oligodendrocytes during Normal Brain Aging

I Blasko and C Humpel, Innsbruck Medical University, Innsbruck, Austria
B Grubeck-Loebenstein, Institute for Biomedical Aging Research of the Austrian Academy of Sciences, Innsbruck, Austria

© 2009 Elsevier Ltd. All rights reserved.

Overview

Astrocytes are the most abundant cells in the brain, and together with oligodendrocytes, they are multifunctional housekeeping cells that allow neurons to become progressively specialized for the tasks of information processing. Astrocytes not only organize the structural architecture of the brain, but also its communication pathways and plasticity. Neurons co-cultured with astrocytes develop approximately sevenfold more synapses and display a sevenfold increase in synaptic efficacy, compared with neurons cultured in the absence of astrocytes. Astrocytes modulate synaptic strength and activity and regulate neurogenesis of the adult human brain. Oligodendrocytes are responsible for the production and maintenance of myelin, which is essential for normal brain function and signal transmission speed. A series of recent studies clearly demonstrate reciprocal paracrine interactions between astrocytes, endothelial cells, and ependymal cells and also between oligodendrocytes and neurons. In fact, astrocyte-derived signals induce neuronal differentiation of oligodendrocyte precursor cells. Coincident with these findings, it has become obvious that both cell types are substantially influenced during the aging process.

Role of Astrocytes in the Aging Process

Astrocytes in the Aging Brain

In the past decade considerable attention has been focused on understanding the role of astrocytes in aging and age-related neurodegenerative disorders. During normal aging, astrocytes display increased activation ('reactive gliosis'), with progressive increases of glial fibrillary acidic protein (GFAP) beginning before midlife (Figure 1(a)). Similar to the concept of age-related microglial dystrophy, analogous astrocytic dystrophy might be relevant in normal aging of astrocytes. Neurite outgrowth by embryonic neurons is markedly decreased when co-cultured with confluent astrocytes derived from old (24 months) versus young (3 months) animals. Overexpression of GFAP in young astrocytes models the effects of aging by reducing neurite outgrowth. These results implicate increased astrocytic GFAP expression that leads to functional defects, which may trigger neuronal dysfunction and support the development of neuronal atrophy during normal aging.

The ability of astrocytes to protect neurons or stimulate neurogenesis is compromised during aging. It is well known that activated astrocytes can produce and release cytokines, but they also produce neurotrophins such as nerve growth factor (NGF) and can enhance the survival of neurons in the brain (Figure 1(c)). There is evidence that multiple hippocampal stem cell/progenitor proliferation factors exhibit an early decline during aging, an event that seems to be linked to age-related alterations in hippocampal astrocytes. Neurogenesis in the dentate gyrus plays an important role for learning and memory and declines dramatically by middle age. Studies in rat astrocytes show that several growth factors – fibroblast growth factor-2 (FGF-2), insulin-like growth factor-1, and vascular endothelial growth factor – decline in concentration considerably by middle age but remain at steady levels between middle age and old age. Decreased concentrations of FGF-2 during aging are associated with decreased numbers of FGF-2-positive astrocytes. Quantification of GFAP and FGF-2-positive cells reveals that aging does not decrease the total number of astrocytes, but that some astrocytes express lower FGF-2 levels by middle age. Thus, dramatically decreased neurogenesis by middle age is likely linked to reduced concentrations of growth factors in the hippocampus.

Astrocytes regulate synthesis and extracellular levels of the excitatory amino acid glutamate via the glutamine cycle and strongly contribute to brain homeostasis and regeneration. Neurotrophic factors, transporter molecules, and enzymes involved in the metabolism of excitatory amino acids play a role in neuroprotection of neurons by regulating the production of potentially toxic substances (e.g., radicals). It has been found that mitochondrial membrane potentials in astrocytes isolated from old mice are more depolarized than are those from their younger counterparts and display a greater sensitivity to the oxidant hydrogen peroxide. ATP-induced Ca^{2+} responses in astrocytes isolated from old mice are consistently larger in amplitude and more frequently oscillatory than is seen in younger astrocytes, which may be attributable to lower mitochondrial Ca^{2+} sequestration. Finally, NGF-differentiated PC12

(2004) How chronic inflammation can affect the brain and support the development of Alzheimer's disease in old age: The role of microglia and astrocytes. *Aging Cell* 3(4): 169–176, with permission from Blackwell Publishing.

cells co-cultured with old astrocytes are significantly more sensitive to hydrogen peroxide treatment than are co-cultures of NGF-differentiated PC12 cells with young astrocytes.

Senescence of Astrocytes

Cellular senescence is a stress response phenomenon resulting in a permanent withdrawal from the cell cycle and the appearance of distinct morphological and functional changes. As astrocytes can be easily passaged in cell culture, replicative senescence of primary human astrocytes has been well studied. In analogy to the established '*in vitro* senescence' models of fibroblasts and endothelial cells, astrocytes isolated from postmortem brains of Alzheimer' disease patients proliferate rigorously in culture and undergo six to eight population doublings (PDs) before astrocytes stop to divide. Growth arrest can be reached after 9–10 PDs, and astrocytes are therefore referred to as 'late-passage astrocytes' after 8 PDs. The quantification of cellular GFAP content reveals that late-passage astrocytes express more GFAP in comparison to early-passage astrocytes (Figure 1(b)). In agreement with this observation, a higher GFAP content is found *in vivo* in aged rats and mice in comparison to their young littermates. Additionally, late-passage astrocytes exhibit a significantly increased expression of the senescent markers p16, p21, and cyclin D1 (Figure 1(b)). The number of PDs of gray-matter astrocytes obtained from frontal cortex is higher, compared to the number from white-matter astrocytes. Whether this increased growth rate depends on *in vivo* degenerative or inflammatory processes is not yet precisely known. In contrast to fibroblasts, but in accordance with endothelial cells, astrocytes are prone to undergo apoptosis after having reached the end of their replicative life span. Interestingly, in late-passage astrocytes, tumor necrosis factor-α and interferon-γ stimulate the production of β-amyloid, demonstrating that stimulation of β-amyloid production by inflammatory products does not decrease during aging.

Astrocytes and Age-Related Neurodegenerative Diseases

Astrocytes greatly outnumber microglia in the brain and play a more critical role in the development of age-related diseases than previously thought. Many metabolic products, depending on their aggregation and deposition status, can activate astrocytes. It is well known that astrocytes are involved in the degradation of damaging products. A disturbed balance between the production and the degradation of toxic metabolites triggers chronic inflammatory processes during aging. Chronically activated microglia and astrocytes can damage neurons via release of highly toxic products such as reactive oxygen intermediates, nitric oxide, inflammatory cytokines, proteolytic enzymes, complement factors, or excitatory amino acids (Figure (1c)). In addition, astrocytes appear to be first-line phagocytic cells of degenerating myelin in cerebral cortex, and microglia cells are not activated until degeneration of entire nerve fibers proceeds (see later).

Inflammation in the aging brain is most likely the result of accumulation of toxic metabolites or their decreased degradation. Glial products such as interleukin-1β or tumor necrosis factor-α induce the synthesis of β-amyloid binding proteins in astrocytes, microglia, or neurons. The chronic release of proinflammatory cytokines in the aging brain is likely to maintain a chronic acute-phase protein secretion favoring the formation of β-amyloid fibrils. The astrocytic synthesis of amyloid precursor protein (APP) can be stimulated by these proinflammatory cytokines through regulation of gene transcription at the promoter level. In combination, cytokines such as interleukin-1β or tumor necrosis factor-α and interferon-γ affect the metabolism of APP and stimulate the production of β-amyloid (1–40) and β-amyloid (1–42) peptides. This molecular mechanism is complex, but it seems likely that the maturation (i.e., proper glycosylation) of APP is disturbed. The chemokine monocyte chemoattractant protein-1 (MCP-1) is believed to play an important role in astrocytosis, as MCP-1 levels are increased in aging brain. It is also of interest that adult astrocytes do not respond to stimulation with β-amyloid by increasing their release of MCP-1 in the same way as young control cells do.

Astrocytosis is a typical morphological feature of the Alzheimer's disease brain and represents either proliferation of astrocytes, in an effort to replace dying neurons, or a reaction to degrade the increasing amounts of toxic β-amyloid peptides. There are clear indications that age-related changes of astrocytes may influence the development of age-related neurodegenerative disorders such as Alzheimer's disease, Huntington's disease, or Parkinson's disease. On the other hand, age-related degenerative changes can modulate astrocytes and their supportive function for neurons. Little is known about the molecular mechanisms that underlie these age-related changes in astrocytes. Alzheimer's disease may coincide with the decreased capacity of aged glial cells to degrade and/or store toxic products. It is now well understood that an early and invariant step in the pathogenesis of Alzheimer's disease is the overproduction and/or decreased degradation of β-amyloid, which leads

to the oligomerization of β-amyloid, both of which are regarded as pathogenetic hallmarks of Alzheimer's disease. In contrast to neonatal astrocytes, adult astrocytes efficiently clear exogenously added and surface-bound β-amyloid and are capable of removing β-amyloid deposited in transgenic APP overexpressing mice. In addition, in young animals, astrocytes produce low amounts of the β-amyloid-degrading enzyme neprilysin, but older animals have increased levels of both β-amyloid peptides and neprilysin.

Role of Oligodendrocytes in the Aging Process

Oligodendrocytes are highly specialized cells that support between 1 and 40 separate myelin sheaths, depending on the size of the axons with which they associate. The production and maintenance of myelin are essential for normal brain function, because myelination results in more than a tenfold increase of signal transmission speed. Faster conduction velocity facilitates information flow by allowing for precise temporal coding of high-frequency bursts of neuronal activity. The human brain, which is approximately 2% of the body weight, contains approximately 25% of the body's membrane cholesterol. Therefore, the high lipid and cholesterol content of myelin sheaths is extremely important. The total length of myelinated axons is reduced by 27–45% in old age in humans, mostly because of loss of fibers with a small diameter, which myelinate later in development.

Oligodendrocytes are the most vulnerable cells in the brain. Myelin production continues with age and this is evident when the average thickness of myelin sheaths in monkey visual cortex is compared in young and old animals. The mean number of lamellae in the sheaths in young and in old monkeys is 5.6 and 7.0, respectively. An increase in the number of myelin sheaths requires an active incorporation of newly synthesized myelin components. Incorporation and disappearance of the components are compartmentalized into two pools, rapidly and slowly exchanging, and there is evidence that through aging the metabolic turnover in rapidly exchanging myelin is slightly accelerated. Remyelination in the brain is very low due to the expression of several axonal growth-inhibiting molecules. However, astrocytes and macrophages influence remyelination and create together an environment that allows regenerative processes, by producing multiple signaling molecules. Measurement of white-matter volume demonstrates that frontal lobe white-matter volume of healthy men continues to increase into the fifth decade of life, reaching a maximum volume at the age of about 45 years, and then declining. The question of whether there is a turnover of oligodendrocytes has not yet been fully resolved, but, in contrast to neurons, there is some evidence that the number of oligodendrocytes increases.

Oligodendrocytes are markedly affected in the aging cortex, displaying enhanced dense cellular inclusions, swellings of processes, an enhanced turnover of myelin, splitting of myelin sheaths, and enhanced lysosomes and vacuoles. Furthermore, the formation of 'balloons' is found; these are round or spherical cavities and they bulge out and expand the myelin, representing degenerative alterations. The enhanced formation of sheaths with redundant myelin points to uncontrolled production of myelin during the aging process. Impairment of learning and memory is in proportion to the severity of myelin sheath degeneration. Interestingly, in experimental models of glucose applications, oligodendrocytes undergo a senescent program, displaying elongation and thickening of processes and shortening of telomeres. Aging affects several key genes that play a role in the myelin formation, most importantly the genes encoding myelin basic protein (MBP) and proteolipid protein (PLP). Constitutive levels of both of these proteins are decreased during aging. In addition, Gtx, a homeodomain transcription factor that regulates MBP and PLP, is reduced during the aging process. In this context, progesterone and progesterone derivatives counteract the age-associated abnormalities of myelin production and enhance myelin formation by regulating MBP gene expression. In fact, promyelination is enhanced twofold after injury, and interaction of macrophages and astrocytes, mediators of successful myelination, loses its precision as the brain ages. Studies have indicated that steroid hormones and their derivatives have beneficial effects on the age-related decline in maintenance of myelin integrity, and partially reverse the decline in the efficiency of myelin repair.

Oligodendrocytes are particularly susceptible to damage by toxic stimuli, including proinflammatory cytokines, nitric oxide, enhanced calcium, glutamate excitotoxicity, oxidative stress, or complement from macrophages. These degenerative events lead to changes in conduction velocity, formation of redundant myelin, and enhanced thickness of myelin sheaths. In addition, oligodendrocytes contain the highest iron content of all brain cell types, and as much as 70% of brain iron is associated with myelin. Cholesterol- and lipid-synthesizing enzymes in oligodendrocytes require iron for proper function, and age-related increases in iron levels in brain are established characteristics of aging. Since the levels of soluble β-amyloid peptides increase with age, and metals such as iron, copper, and zinc can promote β-amyloid oligomerization and

toxicity, these parameters are likely of high importance in the development of Alzheimer's disease.

The susceptibility of myelination processes over a lifetime to heterogeneous risk factors such as brain trauma, vascular disease, hypertension, nutritional deficiencies, hypercholesterolemia, and reduced hormone levels could explain the pattern of myelin breakdown in aging and age-related diseases. Age-related myelin breakdown is regionally heterogeneous, and differences in myelin properties make later-myelinating regions more susceptible to normal aging processes. Little information is available on the role of oligodendrocytes as myelin-producing cells in neurodegenerative pathologies such as Parkinson's or Alzheimer's disease. The best studied disease in regard to oligodendrocytes is multiple sclerosis, due to the severe damage to oligodendrocytes, but the majority of studies during aging have focused on Alzheimer's disease. In Alzheimer's disease, myelin breakdown is globally exacerbated, consistent with an extracellular deleterious process such as β-amyloid peptide toxicity. In addition, myelin breakdown during aging is associated with apolipoprotein E, which points to an additional role in the initiation of Alzheimer's disease.

Glial Cells: Invertebrate

J A Coles, Grenoble Institute of Neuroscience and Université Joseph Fourier, Grenoble, France

Introduction

Glia are cells that contact and invest neurons, and interact with them, but play at most an ancillary role in rapid electrical signaling. They generally share a common ectodermal origin with neurons. In general, glia surround neurons; sometimes the area of contact is increased by glial projections that fill neuronal invaginations. Present in annelids and insects, these processes are usually called trophospongia (Figure 1(b)) or, at the synapses of insect photoreceptors, capitate processes. Like vertebrate glia, invertebrate glia often contain glycogen granules and show electrical coupling. They also have a prominent cytoskeleton, usually of microtubules in arthropods and of filaments in mollusks and annelids. Large lysosomes called gliosomes (diameter, 1–4 μm) are frequent, and gliograna (diameter, 0.3 μm) are also found.

Research on glial cells has overwhelmingly concentrated on the rat (with some interest in the mouse), and the amount of research done on the several million other animal species, almost all of which are invertebrates, is tiny in comparison. However, in terms of what has been learned about major principles of glial function, studies on invertebrates have made great contributions. Invertebrate glia are most often mentioned in work on the early development of the fruit fly, *Drosophila*. This is because *Drosophila* lends itself to studies based on analysis of mutants and because precursor cells give rise to glial cells and neurons in similar numbers. The way in which genes are switched on and off to determine whether a precursor cell becomes a neuron or a glial cell and also the study of the gene products involved in neuron–glia interactions are very active fields of research. This inextricable interplay of neurons and glia in development is only briefly outlined here. Instead, the emphasis is on the physiology of neuron–glia interactions in adult invertebrates.

From the 1960s, until more powerful techniques became available for studying mammalian glia in the 1980s, a small number of invertebrate preparations with experimentally accessible glia were intensively investigated with the expectation that the results would reveal principles underlying the physiology of glia in general. The giant glial cell of the segmental ganglion of several species of leech (an Annelid), the Schwann cells of giant axons of squid and crayfish, and the 'outer pigment cell' of the retina of the honey bee drone have probably given rise to the majority of publications with this approach. Analysis of the signaling between neurons and glia necessary to the development of a nervous system is under way, particularly in insect sensory systems. However, altogether, the physiology of probably fewer than ten types of invertebrate glial cell has been studied.

Work on these model preparations has been at the origin of several general and important concepts that have been subsequently applied to mammals, and these concepts can usefully be approached through the original invertebrate work.

The Anatomical Distribution of Glial Cells in Invertebrates

Cnidaria: Nervous Systems without Glia

The phylum Cnidaria includes sea anemones, hydra, and jellyfish, all of which have nervous systems without glial cells. One or two ring nerves are found in cubozoans (box jellyfish) and hydrozoan jellyfish. In addition, the small (≈1 cm diameter) cubozoan jellyfish, notably *Tripedalia cystophora*, have elaborate visual systems with up to more than 24 eyes, each with advanced neural circuitry composed of many hundreds of neurons. Despite the absence of glia, these circuits allow rapid and complex hunting behavior.

Bilateria (Triploblastica)

Glial cells are reported in all Bilateria species that have been examined.

Nematoda The hermaphrodite form of the nematode *Caenorhabditis elegans* (Figure 2(a)) has 56 glial cells. Each of the 24 sensilla has a sheath glial cell and a socket glial cell (or two socket cells for the phasmids). In addition, six glial cells, labeled GLR cells, extend sheetlike projections that contact muscle arms in the head. These associate with 302 neurons. The glia create a large part of the architecture of each sensillum. In the case of the amphid sensillum, the socket glial cell has a long process, which follows the dendrites of 12 neurons (only one of which is shown in (Figure 1(b)). At the cuticle, it takes a doughnut shape to create a pocket open to the exterior. At the inner end of the pocket, the sheath cell takes the form of a sieve with eight channels through which pass the sensory cilia of eight of the neurons. Laser ablation of

Figure 1 (a) Transverse section through a ganglion of the ventral nerve cord of the leech *Hirudo medicinalis*. Between the inner and outer capsules are six packet glial cells (five shown), each enclosing a packet of neuronal cell bodies. Two giant neuropil glial cells (one shown) lie on the axis of the cord and send processes among the neuropil within the inner capsule. (b) More detailed scheme showing the cell bodies of two packet neurons lying within a packet glial cell. From Coggeshall RE and Fawcett DW (1964) The fine structure of the central nervous system of the leech, *Hirudo medicinalis*. *Journal of Neurophysiology* 27: 229–289.

single cells is contributing to understanding how the cells act together to form the sensillum.

Annelida In leeches such as *Hirudo medicinalis*, the ventral nerve cord has 23 ganglia, each containing the cell bodies of monopolar neurons grouped in six packets. The neuronal somata and initial axon segments of each packet lie within a packet glial cell (Figure 1). Two further giant neuropil glial cells invest the neuropil in the center of the ganglion. The axons connecting neighboring ganglia are enclosed in a glial cell sheath. There is no myelin (here or in any invertebrate); the larger axons are separated one from another by glial processes, but smaller axons are in bundles with no intervening glia.

The neuropil glial cell has a cell body more than 100 μm across and extensive processes; it is probably the largest of all glial cells. For this reason, it was chosen in the 1960s by Stephen Kuffler and colleagues for the first systematic study of glial cell physiology. They found that the ionic basis of the membrane potential depended more strongly on potassium ions than is the case for neurons. They showed that glucose (and other compounds) can diffuse freely from

Figure 2 Glia in the nematode *Caenorhabditis elegans*. (a) Schematic of an adult hermaphrodite, approximately 1 mm long, showing the outline of the pharynx. Some neuronal tracts are shown in green, and one amphid sheath glial cell is shown in red. (b) Enlarged view of the anterior region. The nerve ring (green) is a neuropil where most synaptic interactions between neurons occur. Elements of one amphid sensillum are shown: one of the 12 neuronal dendrites (green), the sheath glial cell (red), and the socket glial cell (blue). Adapted from figures in www.wormatlas.org and from Shaham S (2005) Glia–neuron interactions in nervous system function and development. *Current Topics in Developmental Biology* 69: 39–66.

outside the ganglion to the surfaces of the neurons, and they concluded that these leech glial cells do not normally supply metabolic substrate to neurons. This is certainly not universally the case, and it may be exceptional. Over subsequent decades, it has been shown that these glial cells do, in fact, do a lot of interesting things (see Figure 3(a)).

Insecta In the central nervous system of insects (ventral nerve cord and brain) there are three main classes of glia: surface (or subperineurial) glia form a sheath around the entire central nervous system (Figure 4), cortex glia provide a matrix in which are embedded neuronal cell bodies, and neuropil-associated glia send processes into the neuropil. Unlike the neuropil glia of the leech (Figure 1), the cell bodies of insect neuropil-associated glia are numerous (25–30 in each neuromere segment of *Drosophila*) and are located outside the neuropil.

In addition, several types of glia in the periphery can be defined, such as the antennal nerve glial cells of *Manduca* and the outer pigment cells of *Apis* retina (Figure 5).

Urochordata

Ascidiacea (sessile tunicates) The nervous systems of the pelagic larval forms of sea squirts (*Urochordata* and *Ascidia*) are laid out much like those of vertebrates. Nonneural cells, usually called ependymal cells, outnumber neurons. When the larvae become sessile, the brain is remodeled, becoming an order of magnitude larger. In this adult form, glial cells may be absent: the axons are unsheathed, but a few nonneural cells are present within the brain.

Thaliacea (pelagic tunicates and salps) There are no glia in the peripheral nervous system. They are not in evidence in the brain: this is covered by a two-layered epithelium, but the cells of this differ markedly from most glia in that they conduct action potentials.

Figure 3 Invertebrate neuron–glia interactions are divers and usually have parallels in vertebrates. (a) Some of the receptors, channels, and transporters found on the giant neuropil glial cell of the leech. iGlu, ionotropic (AMPA/kainate) glutamate receptor; mGlu, metabotropic glutamate receptor; nACh, nicotinic acetylcholine receptor; 5-HTR, receptor for 5-hydroxytryptamine; MMR, receptor for myomodulin, a neurotransmitter in leech. (b) Signaling from giant axon to Schwann cell in the crayfish. Propagation of action potentials along the axon causes release of *N*-acetylaspartylglutamate (NAAG). NAAG is split into *N*-acetylaspartate (NAA) and glutamate (glu) by the extracellular enzyme glutamate carboxypeptidase II (GCPII). Glutamate acts on metabotropic glutamate receptors, which activate parallel signaling pathways, including signaling through extracellular acetylcholine. (c) On glia of *Drosophila* brain, glutamate transporters of the EAAT1 class reduce oxidative stress. In addition, the glia contain a cysteine protease, cathepsin, which is normally inhibited by Cer. Approximately 3 h after conditioned learning, the establishment of long-term memory involves a decrease in Cer concentration leading to increased cathepsin activity. (a) Modified from a scheme kindly supplied by JW Deitmer. (b) Based on results in Urazaev AK, Grossfeld RM, and Lieberman EM (2005) Regulation of glutamate carboxypeptidase II hydrolysis of N-acetylaspartylglutamate (NAAG) in crayfish nervous tissue is mediated by glial glutamate and acetylcholine receptors. *Journal of Neurochemistry* 93: 605–610 and papers cited therein. (c) Based on results in Rival T, Soustelle L, Strambi C, Besson MT, Iche M, and Birman S (2004) Decreasing glutamate buffering capacity triggers oxidative stress and neuropil degeneration in the *Drosophila* brain. *Current Biology* 14: 599–605, and Comas D, Petit F, and Preat T (2004) *Drosophila* long-term memory involves regulation of cathepsin activity. *Nature* 430: 460–463.

Figure 4 A glial blood–brain barrier. The ventral nerve chord (central nervous system) of the cockroach *Periplaneta americana*. (a) The connectives running between the ganglia are avascular and contain giant axons and small axons (all unmyelinated). (b) The neural lamella provides a connective tissue sheath. Some work suggests that the main barrier to extracellular diffusion of molecules to the axons is formed by tight junctions between the perineurial sheath cells, which are sometimes classed as glial cells. However, work on *Drosophila* suggests that these cells are of mesodermal origin and also that the barrier is constituted by the underlying glial cells. Adapted from Treherne JE and Scholfield PK (1981) Mechanisms of homeostasis in the central nervous system of an insect. *Journal of Experimental Biology* 95: 61–73.

Cephalochordata

The amphioxus or lancelet, *Branchiostoma lanceolatum*, has glial cells. Thin glial lamellae containing gliofilaments enclose the rhabdom of the Joseph photoreceptor cells.

Functions of Glia in Adult Invertebrates

Glia as a Blood–Brain Barrier

The nervous systems of invertebrates are not vascularized; thus, unlike vertebrates, if they have a blood–brain barrier, it is not between capillaries and the brain parenchyma but, rather, around the various elements of the more or less distributed nervous system. The structures usually responsible for occluding extracellular clefts are tight junctions. They are found between glia in the sheaths around the central nervous system of insects and at least some mollusks (e.g., cuttlefish). Insects have a remarkable blood–brain barrier that supports large differences in the concentrations of ions and molecules. In the ventral nerve cord of the cockroach, the barrier is ascribed to tight junctions between the outer perineural sheath cells (Figure 4(b)). Some authors call these cells glia, but examination of *Drosophila* mutants suggests that they are not of ectodermal origin. The retinas of insect compound eyes also have a glial blood retina barrier, and in *Apis*, at least, this barrier separates fluids with different concentrations of amino acids and carbohydrates (Figure 5(a)).

In contrast, in ganglia of the leech (Annelida) and the snail (Gastropoda), ions and molecules with a molecular weight of up to approximately 10 kDa can diffuse readily through the extracellular clefts of the glial sheath to reach the neurons.

Glia and Homeostasis of Extracellular Ion Concentrations

Although groups of short axons not separated by any glial sheath are found in animals from jellyfish to man, activity more subtle than the transmission of action potentials benefits from a regulated ionic environment. Potassium is the ion of most concern since

Figure 5 The retina of the drone (male) honey bee: a model for studying glia–neuron exchanges. (a) Drawing of a slice of the head, caudal upwards. Much of the chitin that normally covers the caudal surface of the head has been removed to expose the retina and brain. The facetted cornea covers much of the surface of the head (here, the facets are shown too large; there are approximately 10 000 in total). Behind each facet, the cell bodies of six large photoreceptor neurons extend for 400–500 μm to the basal membrane (brown line). (b) In section, the large photoreceptor cells appear clustered in sixes, like the petals of a rosette. The outlines the glial cells can be seen clearly in the lower left. The rosettes are approximately 25 μm in diameter. (c) Stimulation of the neurons with their physiological stimulus (light) causes large movements of ions. The initial and final values are the measured mean values; the time courses are schematic. Green, K^+; red, Na^+; blue, Cl^-. The volumes of the fluid in the three compartments have been estimated as follows: photoreceptors, 0.29 liters per liter of tissue; glial cells, 0.44 liters; and extracellular space, 0.05 liters. K^+ is removed from the extracellular space both by net uptake into the glia and by spatial buffering. (d) Metabolic exchanges. Glucose is taken up only by the glia. Pyruvate formed from glucose or glycogen is converted to alanine, which is transferred to the neurons. Ammonium, liberated when alanine is reconverted to pyruvate, returns to the glia being taken up on a specific Cl^-dependent cotransporter. (a, b) Adapted from Coles JA (1989) Functions of glial cells in the retina of the honeybee drone. *Glia* 2: 1–9. (c) Data from Coles JA, Orkand RK, Yamate CL, and Tsacopoulos M (1986) Free concentrations of Na, K, and Cl in the retina of the honeybee drone: Stimulus-induced redistribution and homeostasis. *Annals of the New York Academy of Sciences* 481: 303–317, and Coles JA, Orkand RK, and Yamate CL (1989) Chloride enters glial cells and photoreceptors in response to light stimulation in the retina of the honey bee drone. *Glia* 2: 287–297. (d) Based on Tsacopoulos M, Poitry-Yamate CL, and Poitry S (1997) Ammonium and glutamate released by neurons are signals regulating the nutritive function of a glial cell. *Journal of Neuroscience* 17: 2383–2390, and Marcaggi P, Thwaites DT, Deitmer JW, and Coles JA (1999) Chloride-dependent transport of $NH4^+$ into bee retinal glial cells. *European Journal of Neuroscience* 11: 167–177.

extracellular [K^+] affects the membrane potential of neurons, and active neurons release K^+, thus tending to increase extracellular [K^+]. Extracellular [K^+] is normally quite low, with the highest reported value being 10 mM (in bee retina), so addition of modest amounts of K^+ produces considerable fractional increases in [K^+]. Homeostasis of extracellular [K^+] has been studied particularly in the retina of the honey bee drone and in the giant nerve fiber of the squid. Regulation of extracellular [H^+] (pH) by transport of H^+ or HCO_3^- has been studied in ganglia of the leech, in which the presence of a glial Na^+-HCO_3^- cotransporter was discovered.

Ion homeostasis in the retina of the bee (*Apis*) The drone (male) honey bee has a highly performing eye, which it uses in pursuing queen bees. The functional units of the retina, the ommatidia, are arranged with an almost crystalline regularity imposed by the facets of the cornea (Figures 5(a) and 5(b)). The retina is composed essentially of two populations of cells – the photoreceptor neurons and the major glial cells, which were originally called 'outer pigment cells.' The drone retina is the only nervous tissue in which measurements have been made (using ion-selective microelectrodes) of the free concentrations of the major ions, K^+, Na^+, and Cl^-, in the three compartments – neurons, glial cells, and extracellular space. Stimulation of the photoreceptor neurons with light causes considerable shifts of ions between the neurons and glia, whereas the concentrations in the extracellular clefts show only modest changes (Figure 5(c)). It was found that the glial cells clear excess extracellular K^+ in two ways. The glial cells are connected to each other by gap junctions. When the activation of the neurons is nonuniform, extracellular [K^+] rises locally, and K^+ enters the glial cells and somewhat depolarizes the functional syncytium of glial cells. This depolarization drives K^+ out of the glial cells in places where extracellular [K^+] is only slightly raised. The process is called 'spatial buffering.' In addition, glial cells of drone retina also clear extracellular K^+ by taking it up together with Cl^- and water, which leads to swelling of the glial cell. This behavior is not shared by inactive neurons, which take up very little K^+. The situation appears to be similar in mammalian brain, in which raised extracellular [K^+] causes astrocytes to swell more than do neurons.

Possible role of glial cells in homeostasis of extracellular K^+ around the giant axon of the squid The giant axon of the squid (a cephalopod) is unmyelinated but achieves a high conduction velocity by having a large diameter, which can exceed 500 μm. It is surrounded by a thin continuous sheath composed of Schwann glial cells, each approximately 2 μm thick, 20 μm wide, and 100–600 μm long. This sheath is further surrounded by connective tissue. The ion channels of both the axon and the Schwann cells are well characterized.

Two Schwann cell conductances have been described – an L-type Ca^{2+} conductance and an outwardly rectifying K^+ conductance activated by entry of Ca^{2+}. These currents are functionally almost identical to conductances found on mammalian Schwann cells. Although propagation of action potentials along the axon causes release of K^+ through the axon membrane, little increase in [K^+] in the periaxonal space is observed in healthy squid nerves. The K^+ conductances of the Schwann cells are not suited to clearing K^+. Possibly, [K^+] does not rise excessively simply because the extracellular space is large.

Glia and the Removal of Neurotransmitter

Astrocytes in vertebrates take up neurotransmitter glutamate. The neuropil glial cells of the leech (Figures 1 and 3(a)), and glial cells of *Drosophila* (Figure 3(c)), are also equipped to do this. In the retina of the honey bee drone, the neurons release glutamate and the glial cells take it up in the absence of synapses – a situation with parallels to vertebrate nerve tracts, which also release glutamate. In *Drosophila*, the absence of the transporter dEEAT1 increases oxidative stress. Photoreceptors in insects and barnacle (*Balanus*, Crustacea) use histamine as their principal neurotransmitter. In barnacle, the glial cells make little or no contribution to recycling this histamine. In contrast, in *Drosophila*, glial cells are involved in at least two ways. Formation of neurotransmitter vesicles occurs on the neuronal membrane close to glial capitate processes that invaginate the neurons. Also, the enzymes coded by the genes *ebony* and *tan*, which are involved in histamine metabolism in the glial cells, are essential to normal neurotransmission.

Glia as a Site of Glycogen Metabolism

In many insects, reserves of glycogen and lipids (principally in the glia) are depleted during starvation, and the glial trophospongia which invaginate neurons are well placed to mediate transfer of substrate to the neurons. In isolated slices of bee head, not supplied with glucose or other exogenous metabolic substrate, glial glycogen is broken down to provide metabolic substrate (alanine) which is transferred to the photoreceptor neurons (Figure 5(d)). However, the metabolism of glycogen is active and regulated in complex ways, suggesting that it is not a passive

store but has physiological roles in normally fed animals. In isolated ganglia of the leech, electrical stimulation in the absence of exogenous glucose first causes a decrease, then an increase, and then a decrease in glycogen content. Light stimulation *in vivo* of *Apis* eye increases, rather than decreases, incorporation of glucose into glycogen in the retinal glia. In isolated leech ganglia, glycogen content is decreased by 5-hydroxytryptamine, dopamine, histamine, and octopamine and increased by GABA and glycine. In the retinas of bee drones, the quantity of glycogen in the glia is sufficient to support photoreceptor function for many hours, which seems a useless weight to be carried by an animal that does not leave its well-stocked hive for more than a few tens of minutes.

Glia as Suppliers of Fuel to Neurons

Do glial cells, in addition to providing fuel from glycogen during starvation, have a role in the normal supply of metabolic fuel to the neurons? A clear answer is available only for the retina of the drone honey bee. In slices of drone retina, glucose appears to be taken up exclusively by the glia. Pyruvate, formed by glycolysis, is converted to alanine, which leaves the glia and is taken up by the photoreceptors. In the photoreceptors, alanine is reconverted to pyruvate, liberating ammonium, which passes back to the glia, being taken up on a Cl^- cotransporter specific for NH_4^+ over K^+ (Figure 4(d)).

Glia and the Maintenance of Axon Function

Local synthesis of axon proteins It is quite simple to squeeze out most of the axoplasm from a squid giant axon, or to perfuse it, and the ability to do this has contributed greatly to understanding how proteins are maintained in axons. Proteins move down axons at a rate of 1–4 mm per day and most have half-lives of less than 1 or 2 weeks. Axons can be many meters long (as in giant squid); thus, at least in axons more than a few centimeters long, proteins have to be produced locally. It is well established that when squid axons, severed from their cell bodies but still ensheathed by glial cells, are bathed in radioactive amino acids, labeled proteins appear in the axoplasm. Furthermore, when the axon is bathed in a labeled RNA precursor ([^{3}H]uridine), labeled RNA appears in the cytoplasm of the axon. Transcription machinery appears to be present within the squid axon. The only known available DNA templates are in the glial cells; thus, presumably RNA is transferred from the glial cells to the axon. The mode of this transfer is unknown and the idea is controversial. Similar conclusions have been reached for the terminals of squid photoreceptors and for the giant Mauthner neuron of goldfish.

Rapid Signaling from Neurons to Glia

Neurotransmitter-mediated effects of neuronal activity on glia have been studied particularly in the neuropil glia of the leech (Figures 1 and 3(a)), in the glia surrounding the giant axons of squid and crayfish (Figure 3(b)), and in the glia ensheathing neurons of the snail. In all these cases, bursts of neuronal activity activate a Ca^{2+}-dependent K^+ conductance, usually leading to a hyperpolarization. This may improve the clearance of K^+ from the extracellular space and the efficacy of Na^+-dependent membrane transport, such as Na^+–HCO_3^- cotransport, and glutamate uptake.

A striking feature of these glial cells is the presence of receptors for a wide variety of transmitters. Leech neuropil cells, for example, respond to glutamate, 5-hydroxytryptamine, acetylcholine, adenosine phosphates, and myomodulin (a transmitter best known in gastropods).

The glial response to an agonist can be extremely complex. In the ventral nerve cord of the crayfish, the passage of a train of impulses along the giant axons causes the axons to release *N*-acetylaspartylglutamate (NAAG), which leads, by a cascade of events, to hyperpolarization of the periaxonal glia. The main pathway requires the presence of the extracellular enzyme glutamate carboxypeptidase, which splits off glutamate from NAAG, and metabotropic glutamate receptors. Acetylcholine plays a role in the cascade: it is released by the glial cells and acts back on glial acetylcholine receptors leading to activation of K^+ channels (Figure 3(b)). All the details of the overlapping pathways have not been worked out, but the analysis has been carried further than in vertebrates, in which elements of this signaling system have been found at the rat neuromuscular junction. At least some elements of this signaling are also found between the giant axon and its Schwann cells in the squid.

Signaling between glia and neurons in *Drosophila* In the mushroom bodies of *Drosophila* brain, *cer* encodes an inhibitor of a subfamily of cysteine proteinases named cathepsins. Three hours after conditioned learning, expression of *cer* in glial cells is transiently reduced (Figure 3(c)). Interference with this pattern of expression impairs long-term memory. In mammals, prolonged activation of cysteine proteinases is associated with neuronal degeneration in

Alzheimer's disease. This is an example of how the genetic manipulations that can be done relatively quickly in *Drosophila* can give clues to the functioning of mammals.

No evidence of multiple neuron–glia signals in bee retina In marked contrast to leech giant glial cells, snail glial cells, and the periaxonal glia of squid and crayfish, no neurotransmitter signaling to the glial cells of drone retina has been reported.

Glia as Actors in the Development of the Nervous System

For analyzing the genetic and molecular mechanisms involved in the development of a nervous system, the nematode *Caenorhabditis elegans* and a few insects have proved useful models. The development is rapid, the number of cells involved is not enormous, and genetic tools are available. At various stages, glial cells can regulate the proliferation, migration, and apoptosis of neurons.

Early Development of the Nervous System

For both *Caenorhabditis* and *Drosophila*, neurons and glia are roughly equal players in early development and are derived from common precursors. A landmark discovery was the role in *Drosophila* of the gene *glial cells missing* (*gcm*), whose expression determines the glial fate of all the glia except the midline glia, a small class of neuropil-associated glia. The gene product, Gcm, is a transcription factor that directly or indirectly activates transcription of approximately 50 genes, most of which have mammalian orthologs. Some Gcm-activated genes (e.g., *repo*, *loco*, and *pnt*) determine that a precursor becomes a glial cell rather than a neuron, whereas *tramtrack* represses neuronal fate. Other Gcm-activated genes are expressed only during a certain time or only in a subset of glial cells. This means that cofactors are required that determine the maturation and diversity of the glia.

Development of Sensory Systems

Most insects have sensory systems that are highly perfected yet relatively small, and some have been selected as models for a detailed analysis of their development. This can be illustrated by work on the olfactory system of the moth *Manduca sexta*.

The olfactory system of the moth, *Manduca sexta* The main olfactory receptor neurons in insects are in the antennae, and their axons extend to the olfactory lobe of the brain. In *Manduca sexta*, the receptor neurons for different molecular attributes of odorants are spatially intermixed in the antennal epithelium, but their axons, on entering the olfactory lobe, are sorted into fascicles according to their odorant specificity and terminate in glomeruli whose number increases during maturation to reach 64 ± 1 in the adult. This system develops over approximately 18 days during the metamorphosis from larva to adult. The axons of the olfactory receptor neurons initially grow down the antenna without glia (Figure 6(a)). On arriving outside the antennal lobe, the axons encounter sorting zone glial cells and reciprocal neuron–glia interactions occur. The axons send signals to the glia, which then increase in number. Also, the glia contribute to the sorting of the axons: On contacting glia, the growth cones enlarge, explore, turn, and find like axons (Figure 6(c), stages 4–6). Glial cells of a second kind, the olfactory ensheathing cells, migrate along the axons from the receptors and, later, enwrap bundles of axons.

In the olfactory lobe, the neuronal cell bodies are clustered in its periphery, outside an initially spherical zone of neuropil (Figure 6(a)). The cell bodies of the neuropil glial cells surround this neuropil. The outer parts of the neuropil progressively separate into glomeruli, and the layer of neuropil glial cells is deformed to follow this change of shape (Figure 6(b)). The neuropil glia show reciprocal interactions with the receptor cell axons. The axons induce properties of the neuropil glia, including expression of Ca^{2+} channels. Also, the neuropil glia induce synapse formation. Some elements of the neuron–glia signaling are known. In the case of the neuropil glia, acetylcholine released by the ingrowing receptor axon terminals depolarizes the glia. This activates voltage-dependent Ca^{2+} channels, and the resulting increase in intracellular free $[Ca^{2+}]$ in some way initiates glial cell migration (Figure 6(d)).

A glial function, myelination, is responsible for major differences in the sizes and life styles of vertebrates and invertebrates Electrical signaling by changing the electrical potential across a neuronal plasma membrane consisting of a lipid bilayer is slow and energetically expensive. This is because the capacitance of the lipid bilayer is very high ($1\,\mu F\,cm^{-2}$), which means that many ions have to cross it to change the potential. In many vertebrate nerves, the effective membrane capacity of the axon membrane is reduced by a myelin sheath, produced by glial cells. This makes possible the high nerve impulse conduction velocities necessary for large animals capable of rapid and complex movements, such as dinosaurs and humans. The structure most resembling myelin in invertebrates may be the several loosely wrapped layers of

Figure 6 Glial cells contribute to the development of the olfactory system in the moth *Manduca sexta*. (a, b) The antennal lobe with the base of the antennal olfactory nerve (top left). During metamorphosis, axons from the olfactory epithelium (not shown) are sorted to appropriate odor-specific glomeruli. Probable neuron–glia interactions are numbered in (c). (1) The first axons to reach the lobe encounter central glial cells and induce them to proliferate. (2) Glia migrate into the nerve to become sorting zone glia. Axons encountering sorting zone glia form large growth cones. (3) *In vitro*, the growth cones of axons contacting neuropil glia cells become larger and more complex. (4) Glia arising in the olfactory receptor epithelium migrate along the olfactory nerve (not shown in b). (5) Receptor axons induce neuropil glial cells to extend stabilizing processes around protoglomeruli. (6) Antennal nerve glial cells enwrap bundles of receptor axons. (7) Neuropil glia define the borders of the glomeruli. (d) The signaling mechanism involved in step (5). Acetylcholine released by the axon terminal depolarizes the glial cell, and the depolarization opens voltage-gated Ca^{2+} channels, leading to an increase in intracellular $[Ca^{2+}]$. (a, b, d) Adapted from Lohr C and Deitmer JW (2006) Calcium signalling in invertebrate glial cells. *Glia* 54: 642–649. (c) Adapted from Tolbert LP, Oland LA, Tucker ES, et al. membrane that are sometimes found around axons of *Drosophila*, although *Drosophila* possesses homologs of only a few of the genes required for myelin. This wrapping is probably not useful for conducting active nerve impulses, but it would speed up passive, electrotonic conduction. The invertebrate solution to the problem of nerve conduction velocity is either to stay small (as are insects) or to make axons of very large diameter. These giant axons take up much space and their use is mainly limited to stereotyped escape reactions, as is the case in annelids and squid.

Lessons from Invertebrate Glial Cells

The conclusion from the small number of invertebrate glial cells whose functions have been studied is that in adult animals the proteins that serve as ion channels, transporters, receptors, and elements of intracellular signaling pathways have properties very similar to those of vertebrate glia. It is true that some invertebrate glia show behavior that has not been clearly described in vertebrates, such as a possible involvement of cathepsin in memory formation in *Drosophila*, or the choice of alanine, rather than lactate, as a substrate transferred from glia to neurons, as in bee retina. However, it would be premature to state that similar phenomena do not occur in vertebrates. The involvement of glial cells in the development of insect nervous systems also shows many close parallels with mammals, although many of the genes involved appear to have different functions in vertebrates. It should be borne in mind that

an invertebrate nervous system has evolved through many more life cycles than has that of *Homo sapiens*, even though the body shape of the animal may have changed little over several hundred million years.

Glial Cells: Microglia during Normal Brain Aging

M B Graeber

© 2009 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition © 2004, Elsevier B.V.

Background

Microglia were first described at the turn of the nineteenth century, independently by the neuropathologists Franz Nissl (in Munich) and William Ford Robertson (in Edinburgh). In Spain, in 1913, the Nobel prize-winning physician and histologist Ramón y Cajal described these cells as a *tercer elemento* ('third element') among central nervous system cells. However, it was Cajal's student, Pio del Rio-Hortega, who, around 1920, coined the term 'microglia' and conducted the first systematic studies on this cell type. Many of the observations of Rio-Hortega were of fundamental character and are still valid.

Morphology

After staining with Rio-Hortega's silver carbonate method, resting microglia show characteristic elongated, almost bipolar cell bodies with spinelike processes arising at a right angle and carrying short branches (Figure 1). The nucleus is large in comparison with the small perikaryon and contains heterochromatin apposed to the nuclear envelope. In electron micrographs, microglia show a dense cytoplasm, vimentin-positive intermediate filaments, a few microtubules, and prominent cisterns of granular endoplasmic reticulum, especially when activated, which run in parallel to the main axis of the cell (Figure 2). Lysosomes and Golgi complexes are also present.

Cellular Markers

After their discovery and description, there was decades-long controversy surrounding microglial identity and nature; the uncertainty about these cells, which lasted until the 1980s, can be explained by the remarkable phenotypic plasticity of microglia. Their appearance ranges from that of highly ramified cells in normal central nervous system (CNS) tissue (Figure 1) to rod cells in chronically inflamed cerebral cortex (Figure 3) to full-blown macrophages in tissue-destructive pathologies (Figure 4). The problem of defining the nature of microglia was solved when lectin and immunocytochemical markers became available, and when experimental models, including bone marrow chimeras, unequivocally demonstrated that microglia are closely related to cells of the peripheral monocyte–macrophage system. However, no marker possesses true, singular microglia specificity, and all known histological microglia markers are only microglia specific in the sense that they do not label other glia or neurons. Other macrophages that normally occur within the bony confinements of the CNS – for example, perivascular, plexus, and meningeal macrophages – typically cross-react with microglial detection methods, but many of the molecules expressed by the former are absent from microglia. Thus, the immunophenotype of microglial cells appears to be 'downregulated.' Before monoclonal antibodies became available, enzymes such as thiamine pyrophosphatase and nucleoside diphosphatase were used to identify microglial cells in tissue sections. Furthermore, the ectoenzyme 5′-nucleotidase is positive in the plasmalemma of microglia and strongly expressed in activated cells, but is not cell type specific. Nonspecific esterase, a monocytic marker, is negative.

Distribution

Resting microglia account for up to 20% of all glial cells in the CNS. Their almost uniform distribution varies rather little between brain regions, although there appear to be local differences in the expression of some molecules, such as major histocompatibility complex (MHC) class II antigens, which are present at higher levels in white matter and in the aged brain.

Origin

During vascularization of the CNS, cells related to the mononuclear phagocyte system invade the central nervous tissue and settle as resting microglia. They form the resident macrophage precursor cell pool of the brain, spinal cord, and retina. Renewal of juxtavascular (perivascular) and parenchymal microglia from the bone marrow occurs at an extremely low rate in the adult. Perivascular macrophages ('perivascular cells'), which are separated from the brain parenchyma by a basement membrane, are anatomically, immunophenotypically, and functionally distinct from microglia.

Function

The main function of microglia in the normal brain and spinal cord appears to lie in the formation of a network of highly responsive surveillance and defense cells. Accordingly, microglia serve as 'sensors of threats' (a term introduced by GW Kreutzberg) to the CNS. Microglia are potentially cytotoxic, but

healthy microglia do not attack their microenvironment except in the case of CNS infections. Thus, the metaphor of microglial 'guardians' that are armed to defend seems more appropriate than that of harmful 'killer cells.' In contrast to neuroectodermal glia, microglial cells are not electrotonically coupled via gap junctions. This may explain their very localized involvement in disease processes, which is of great diagnostic use. Antigen presentation is a likely function of microglia. Complement receptors are quickly upregulated in response to various stimuli. The mitotic activity of microglia is regulated by macrophage and granulocyte/macrophage colony-stimulating factors (M-CSFs and GM-CSFs) and the appropriate receptors. Other cytokines, such as interleukins (IL-1, IL-6, and IL-10) and transforming growth factor-β (TGF-β1), function as important signals in the control of microglial activation. Brain macrophages of microglial origin have a strong respiratory burst activity, meaning that they can produce oxygen radicals.

Figure 1 Microglia as illustrated by Pio del Rio-Hortega in 1920.

Pathology

More than a dozen names for microglia document their involvement in neuropathologies such as inflammation and vascular disease, and in removal of tissue debris after trauma, pointing to the phagocytic nature of the reactive microglial cells. Terms still in use are foam cells, gitter cells, rod cells, and fat granule cells. The term 'ameboid microglia' should be reserved to describe microglia as they appear in developing tissue. It is thought that microglial phagocytes become motile and migrate toward lesion sites, where they are loaded with tissue debris, which they then transport to the meninges or vascular system. Perivascular cuffs of fat-laden phagocytes can be seen many months and even years after acute tissue destruction. Axotomy of motor nerves leads not only to retrograde changes of the motor neurons but also to proliferation of perineuronal microglial cells. After a few days these microglia are found covering most of the surface of the regenerating motor neurons, thus displacing the synaptic terminals ('synaptic stripping'). In this situation no phagocytosis is observed. Based on observations under various pathological conditions, a concept of a graded response of microglial cells has been developed. The diagram in Figure 5 describes the stepwise activation of microglia from a resting to a phagocytic state.

Figure 2 Activated perineuronal microglia (MG) cell covering the surface of a chromatolytic facial motor neuron (N) in the rat. The MG has a dense cytoplasm and an active rough endoplasmic reticulum arranged in parallel broad cisterns. Electron-dense reaction product indicates the presence of ecto-5′-nucleotidase in the plasmalemma of the MG. Electron micrograph 1:40 000. From Kreutzberg GW (1999) Microglia. Glial Cells: T Cell Interactions

C Infante-Duarte and F Zipp, Charité – Universitätsmedizin Berlin, Berlin, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

T cells are a major subset of lymphocytes that exert a central function during the specific immune response to pathogens. Interaction of T cells and cells of the central nervous system (CNS) is part of the normally occurring host defense against CNS pathogens and is crucial for combating infectious agents and preventing persistent infection inside the nervous system. However, an uncontrolled immune response inside the CNS may lead to serious pathologies, such as autoimmunity or neurodegeneration.

T Cell-Mediated Immunity

In order to successfully fight against pathogens, the mammalian immune system has developed into two arms – (1) innate and (2) adaptive or specific immunity. Innate immunity commences immediately upon pathogen entry and represents a very fast and generic response which does not lead to immunological memory. In contrast, the cells of adaptive immunity are able to recognize antigens specifically, to expand after exposure to the same antigen, and to develop into memory cells. T lymphocytes, together with the B lymphocytes, represent the cellular compounds of the adaptive immune system (Table 1). T cells originate in the bone marrow and mature in the thymus (T stands for thymus). T lymphocytes recognize specific antigens via the T cell receptor (TCR) and, in contrast to B cells that can recognize soluble antigens, respond only to antigens when they are presented by major histocompatibility complex (MHC) molecules on antigen-presenting cells (APCs).

There are two main subpopulations of T cells – cytotoxic T cells (CD8-positive) and helper T cells (CD4-positive). Cytotoxic T cells (CTLs) recognize the antigens in the context of MHC class I molecules, expressed on nearly all nucleated cells. Class I molecules present endogenous antigens, such as viral or tumor-derived peptides, which are indicative of intracellular alterations. CTLs are thereby able to identify and destroy infected or mutated cells. On the other hand, helper T cells (Th cells) (which can in fact also be cytotoxic) recognize antigens in the context of MHC class II molecules expressed on APCs. MHC class II molecules present exogenous antigens, such as microbial peptides, which result when APCs engulf and process pathogen-derived material. After interacting with the APC, Th cells become activated and are able in turn to trigger effector cells (e.g., B cells or CTLs), causing the destruction of the pathogen. Thus, T cells orchestrate the host immune system by secreting cytokines to regulate the immune response to infection. Cytokines are soluble proteinic factors which act on different cell types. They are redundant (most cytokine functions can also be carried out by other cytokines) and pleiotropic (a cytokine exerts many different functional effects), characteristics which make it difficult to understand their functional network. Cytokines function by binding to specific cell surface receptors on their target cells. Cytokine receptors are present not only on immune but also on various nonimmune cell types, such as astrocytes and oligodendrocytes.

Th cells can be subdivided into three distinct effector subpopulations according to their cytokine profile and effector functions. Th1 lymphocytes secrete interleukin (IL)-2, interferon gamma (IFN-γ), and tumor necrosis factor-β (TNF-β), and they induce cell-mediated immune responses; Th2 lymphocytes selectively produce IL-4, IL-5, IL-10, and IL-13 and promote humoral immune responses; whereas Th17 cells secrete IL-17, IL-6, and TNF-α and induce activation and recruitment of neutrophils. Regulatory T cells (T reg, Tr1, and Th3) are also CD4-positive T cells which, together with other immune cells, are responsible for controlling activation of the immune system once an antigen has been eliminated from the body, as well as for maintaining immune homeostasis (Figure 1). These cells also need to become activated via the TCR in order to exert their suppressor function. Failure of regulatory T cells to function properly may result in chronic inflammation or even in autoimmune disease.

Heterodimeric TCR is associated with proteins of the CD3 complex and with the CD4 or CD8 coreceptors on Th cells and CTLs, respectively. Interactions between the CD4 molecule and MHC class II or the CD8 molecule and class I MHC stabilize the binding between TCR and MHC molecules, thus accomplishing the process of antigen recognition. CD3 as well as CD4 and CD8 are therefore suitable markers for identifying and quantifying all T cells (CD3-positive) or their different subtypes. The ligation of TCR and its coreceptors (CD4 and CD8) with the MHC/antigen complex is necessary but not sufficient to induce a physiologic stimulation of T cells, a process which involves at least one additional activation signal. This second signal is dependent on either soluble factors such as APC-derived cytokines or the ligation of

Table 1 Natural and specific immunity

	Mechanisms involved	*General features*
Natural or innate immunity	Skin, mucous membranes Macrophages, neutrophils, NK cells Complement IFN-α/β, IFN-γ, TNF-α	Cannot distinguish between distinct antigens Are not able to expand after exposure to the same antigen Do not lead to immunological memory
Adaptive or specific immunity	T and B lymphocytes Antibodies Lymphocyte-derived cytokines	Specific for a given antigen Their production or expansion is stimulated specifically by an antigen Lead to immunological memory

Figure 1 Phenotype development. Polarized Th cell subsets differentiated from a common Th precursor (Thp) in the periphery. Although differentiation is influenced by several factors, the most important of these are the cytokines present at the stage of TCR stimulation. Effector Th1, Th17, and Th2 cells protect against different microbial pathogens by producing cytokines able to mobilize different mechanisms of defense. On the other hand, an imbalanced Th effector response can promote different systemic and organ-specific disorders (text in red). In contrast to the effector Th cells, the factors influencing regulatory cell differentiation are not well defined.

cell surface proteins, the so-called costimulatory molecules, and it serves to initiate, maintain, and regulate the immune response. In line with this, T cells encountering antigens in the absence of adequate costimulation may remain unresponsive or anergic. Thus, costimulation has been postulated to play a critical role in determining T cell activation versus anergy. Throughout the years, several ligand–receptor pairs functioning as costimulators have been described; however, the best characterized costimulatory pathways remain the CD80/CD86 (B7)-CD28 and CD40-CD40L systems (Figure 2).

Immune Surveillance of the Central Nervous System

The CNS has often been considered as an 'immunologically privileged organ,' with limited prerequisites for mounting an immune response owing to, for example, the lack of a specialized lymphatic drainage, the absence of dendritic cells, the low expression levels of MHC class I and II, and the presence of the blood–brain barrier (BBB). The BBB is constituted by endothelial tight junctions and surrounding astrocytes which restrict the leukocyte traffic into the CNS. However, it has become evident that activated lymphocytes can cross the BBB, inspect the normal CNS in the absence of inflammation, and recognize target antigens within the CNS. This active immune surveillance of the CNS is essential to protect the brain from pathogen-induced damage. CNS infection and inflammatory disorders such as autoimmune reactivity promote the breakdown of the BBB, and under these conditions a much higher number of activated leukocytes penetrate the brain parenchyma to interact with neurons and glial cells.

Interaction of T Cells with Glial Cells

Glial cells represent the majority of cells in the nervous system (approximately 90% in some regions of

Figure 2 Scheme of the complex interactions between Th lymphocytes and APC. The presentation of antigen/MCH class II complexes to naive Th cells results in the upregulation of CD80/CD86 expression on APC and in the expression of CD40L on T cells. The ligation of this newly expressed CD40L with CD40 on APC also induces CD80 and CD86 on APC. At this point, the costimulatory signal provided by the APC is received by the T cells via the CD28/CTLA-4 receptors, which drive the T cells to enter into cell cycle, to complete T cell activation, and to produce cytokines. On the other hand, the signals originated through CD28 can also upregulate CD40L in the Th cells.

the human brain). They are nonneuronal cells that supply support and nutrition to neurons, maintain homeostasis, provide myelin sheaths, are integral parts of synapses, and participate in brain development. Here, we outline the interaction of T cells with the main glial populations in the CNS – that is, microglia, astrocytes, and oligodendrocytes.

Microglia

Microglia represent 10–20% of the glial cell population in the brain and are considered as phagocytic immune cells of the CNS. They share many features with macrophages and develop from a common myeloid precursor cell; therefore, they have been considered as potential resident APCs of the CNS. Microglia can be divided into two main populations: the parenchymal and the perivascular microglia. In contrast to the short-living macrophage-like perivascular microglia, parenchymal microglia can live for as long as the individual and express low levels of MHC class I or II in an inactive/resting state.

Microglia, and in particular perivascular microglia, may act as the professional APC population of the CNS, being involved in processing and presentation of target antigens to infiltrating T cells at the level of the BBB. Once an infection or inflammatory process is established inside the CNS, parenchymal microglia also become capable of presenting antigens. Parenchymal microglia become activated in response to many different inflammatory signals, such as IFN-γ, granulocyte–macrophage colony-stimulating factor (GMCSF), or TNF-α. Activated microglia express MHC class II and costimulatory molecules such as CD80, CD86, and CD40, and they are able of interacting with T cells in an antigen-dependent manner. This interaction directly affects the T cell effector function without inducing T cell proliferation, a mechanism which may support immune surveillance of the CNS, necessary for detecting and combating infections, and at the same time controls T cell expansion and subsequent inflammation, permitting a rapid T cell elimination.

It has been shown that activated microglia can regulate different effector Th responses, including Th1, Th2, and Th17, as well as regulatory Th responses. T cells activated by microglia are then able to produce effector cytokines, and perhaps also neurotrophic factors, which will support brain regeneration after an infection-promoted acute immune response. In response to pathogens or during inflammation (e.g., IFN-γ exposure), microglia secrete high amounts of IL-1, TNF-α, and IL-12, a cytokine that induces Th1 phenotype differentiation. This may help microglia modulating the development of a Th1 versus Th2 response necessary for the elimination of certain pathogens. At the same time, however, if the immune response is not properly controlled, this Th1-dominated response may support microbial-induced tissue damage or the development of autoimmune processes. In contrast, interactions with Th1 and Th2 cells, or interaction with T cells in the absence of CD40–CD40L ligation, induce the production of anti-inflammatory prostaglandin in microglia, a substance which may be neurotoxic but necessary for limiting T cell response. On the other hand, rat microglia activated *in vivo* by graft versus host disease do not express the costimulatory molecules CD80 and CD86, are unable to induce T cell expansion, and promote T cell apoptosis. Thus, the ability of microglia to influence T cell effector function is dependent both on their state of activation and on the state of activation and differentiation of the Th cells, indicating that T cell–microglia interaction consists of bidirectional communication in which both cell types regulate each other. As mentioned previously, the T cell-derived cytokine IFN-γ is a strong factor in promoting parenchymal microglia maturation into APC. Th1-derived IFN-γ and interaction of microglial CD40 with its ligand CD40L on T cells are known to induce IL-12 secretion by microglia even in the absence of antigenic presentation. In organotypic cultures, Th1 cells switch the expression of costimulatory molecules on microglia from CD86 to CD80, whereas Th2 cells decrease CD86 expression without affecting the expression of CD80. Furthermore, Th2 cells can modulate APC activity of microglia by

enhancing, for instance, their IL-10 production or by downregulating microglial expression of the intercellular adhesion molecule 1 (ICAM-1).

In summary, in the case of pathogenic insult, T cells patrolling the CNS can recognize antigen on antigen-presenting perivascular microglia. Inside the brain parenchyma, these reactivated antigen-specific T cells will, in turn, activate the parenchymal microglia and promote their maturation to APC, which is necessary for supporting a T cell response and eliminating pathogens. Under normal conditions, this could induce an acute but controlled inflammatory cascade, which might promote some self-resolving CNS injury. Thus, whether an infection will result in a chronic pathology or will remit after acute immune response depends on the balance of pro-versus anti-inflammatory and neurotoxic versus neurotrophic signals derived primarily from the interaction of T cells and microglia.

Astrocytes

Astrocytes represent the most abundant glial cell type. Astrocytes are responsible for maintaining homeostasis in the CNS, participate in the formation and maintenance of the BBB, function as detoxificating cells in the neuronal microenvironment, and produce a variety of neurotrophic and neuroprotective factors. Furthermore, they exert an ill-defined immune function inside the CNS. Inactive astrocytes do not express MHC class I or class II molecules. Similar to microglia, astrocytes are able to secrete IL-1, IL-6, and TNF-α in response to a diversity of stimuli and to present antigen to T cells after becoming properly activated by IFN-γ, for example. However, since reports on astrocytic immune functions are very controversial, it is under debate whether they can act as APCs at all. On the one hand, it has been shown that murine resting astrocytes constitutively express CD86 and are able to promote expansion of activated Th1 cells, whereas treatment with IFN-γ induces astrocytic expression of MHC class II and the costimulatory molecules CD80 and CD86. Thus, IFN-γ-treated astrocytes may be capable of antigen processing and presentation as well as of priming naive T cells. On the other hand, a large body of evidence indicates that astrocytes do not express costimulatory molecules and may deliver an inhibitory or tolerogenic signal to T cells, inducing anergy or apoptosis instead of proliferation. In addition, it has been postulated that activation of Th cells in the absence of costimulation could promote Th2 phenotype differentiation or activate exclusively Th2 cells, implicating astrocytes in the control/suppression of undesired inflammatory immune responses. In line with this, we have previously shown that adult astrocytes are capable of inducing T cell apoptosis via the CD95/CD95 ligand pathway. Since astrocytic endfeet contribute to the formation of the BBB, this depletion mechanism may play an important role as the brain's first line of defense against activated T cells.

Oligodendrocytes

Oligodendrocytes are glial cells specialized in the elaboration and maintenance of myelin in the CNS. Oligodendrocytes do not express MHC class I or MHC class II constitutively. Thus, under normal conditions these cells are unable to interact with T cells in an antigen-dependent manner. It has been shown that although few oligodendrocytes express MHC class I in the healthy human brain, this expression becomes upregulated during inflammation, such as in multiple sclerosis (MS). In contrast, oligodendrocytes seem not to express MHC class II molecules under any condition investigated so far, and consequently they cannot present antigens to Th lymphocytes. However, the fact that oligodendrocytes express Th2-like cytokine receptors, such as IL-4 receptor (R) and IL-10R, even under noninflammatory conditions, points to a possible communication path between both cell types. Additionally, during inflammation oligodendrocytes are able to express additional cytokine receptors, such as IL-12R or IFN-γR. This cytokine-mediated communication appears to be essential in the case of pathogenic insult affecting oligodendrocytes. In this context, it has been reported that a successful clearance of mouse hepatitis virus (JHMV strain) from rat oligodendrocytes requires expression of IFN-γR.

In addition, interactions between T cells and oligodendrocytes represent an important piece of the immune response in demyelinating pathologies such as MS. These aspects of T cell–glial cell interaction in inflammatory pathologies are described in more detail in the next section.

Interaction of T Cells with Glial Cells in Different Disorders

This section focuses on pathological T cell–glial cell interactions in acute and chronic inflammatory diseases, exemplified by human immunodeficiency virus type 1 (HIV-1)-induced encephalitis and MS, respectively, as well as in three examples of primarily noninflammatory neurodegenerative disorders: adrenoleukodystrophy (ALD), stroke, and Alzheimer's disease (AD).

Acute Inflammation

Encephalitis is an acute inflammation of the brain, commonly caused by a viral infection. In encephalitis

caused by HIV-1, microglia cells are the primary target of the infection and serve as a viral reservoir. Microglial infection leads to severe tissue damage in the CNS and ultimately to HIV-associated dementia, characterized by progressive motor disturbances, impaired memory and cognitive function, as well as behavioral abnormalities.

It is assumed that HIV enters the CNS very early after peripheral infection of circulating T cells and monocytes, probably as a passenger inside the infected cells. In the CNS, the most infected cells are the perivascular microglia, perhaps because they become replenished by infected circulating monocytes. The role of infected CD4-positive T cells inside the brain is unclear, and the question of whether parenchymal microglia become infected is still open. A hallmark of HIV encephalitis is the formation of multinucleated giant cells resulting from the fusion of infected and uninfected microglia/macrophages. The first stage of CNS infection with HIV appears to be characterized by a potent T cell response against the virus. The presence of large perivascular infiltration of CTLs, and the fact that during infection activated microglia produce lymphoattractant chemokines such as CCL3, indicates that at this stage a microglia–T cell interaction takes place. This strong immune response seems to be involved in HIV-induced neurodegeneration in a bystander way; that is, neurons are most likely damaged as a consequence of uncontrolled inflammatory processes. HIV-infected microglia express high amounts of chemokines and proinflammatory cytokines (mainly IL-1β and TNF-α), which may induce activation of other uninfected cells, alter the permeability of the BBB, and promote the migration of HIV-specific activated T cells into the brain. These cells may contribute to the amplification of the immune response and to HIV-induced neurotoxicity. The latter is mediated mainly by neurotoxic factors such as TNF-α, TNF-related apoptosis-inducing ligand (TRAIL), arachidonic acid, nitric oxide (NO), or quinolinic acid (probably generated by HIV-induced indoleamine 2,3-dioxygenase, which is produced by microglia and astrocytes). On the other hand, as demonstrated for other neurodegenerative diseases, it has been shown that the interaction between lymphocytes and microglia/macrophages is essential for promoting tissue repair after virus clearance. Even factors such as TNF-α, which are known to be potent neurotoxins, can also manifest neurotrophic effects under certain neuroinflammatory conditions. Thus, the degree of neurotoxicity or neuroprotection depends on the balanced interaction between cells of adaptive and innate immunity.

Chronic Inflammation

By definition, chronic inflammation is an inflammatory response of prolonged, even indefinite, duration which inevitably causes tissue damage and is provoked by persistence of the causative stimulus in the tissue. The classic example is MS, considered an autoimmune disease in which the immune response is presumably directed toward myelin-related autoantigen peptides. Myelin-specific Th cells are believed to orchestrate an immune reaction leading to damage to myelin and oligodendrocytes and thus severe disability in young adults. Studies of MS and its animal model, experimental autoimmune encephalomyelitis (EAE), have demonstrated that in addition to myelin and oligodendrocyte damage, axonal injury and loss of parental cell bodies are involved in disease severity. MS and EAE have been associated with an aberrant Th1- and also with Th17-dominated response to autoantigens. Conversely, several anti-inflammatory cytokines produced by Th2 or regulatory T lymphocytes, such as IL-4, IL-10, and IL-13, contribute to controlling pathogenic T cell response. As the professional APCs of the CNS, microglia are considered to be directly involved in antigen presentation to pathogenic T cells. Interestingly, in early MS lesions the expression of CD80 is increased, suggesting that CD80 upregulation is somehow involved in pathogenic T cell–microglia interaction. Myelin-specific Th1 cells induced the microglia expression of MHC class II, CD40, CD80, and CD86, as well as the expression of IL-12, a cytokine that increases IFN-γ secretion in Th cells. In inflammatory MS lesions, microglia express ICAM-1, CD40, CD80, and CD86, suggesting that these cells are matured to full APCs (perhaps stimulated by myelin-specific Th1 cells) and become able to reactivate newly infiltrated antigen-specific Th cells. This would represent an inflammatory loop, in which both cell types are likely involved in tissue damage during MS. However, microglia appear to be not only involved in tissue injury through the secretion of neurotoxic factors but also involved in modulating the pathogenic immune response, controlling CNS inflammation, and inducing neuroregeneration. The same phenomenon appears to occur in the contribution of T cells to immune pathogenesis. T cells are clearly involved in disease pathogenesis; however, it has been demonstrated that myelin-reactive T cells produce neurotrophic factors and support neuronal survival. This protective effect seems to rely in part on microglia. To what degree microglia–T cell interaction can be pathogenic or protective is a result of the cross-regulatory interactions between both cell types. This becomes

Figure 3 Possible interactions of T cells with glial cells in chronic CNS inflammation. Activated Th cells, such as myelin-specific Th1 cells, are reactivated inside the CNS by antigen-presenting perivascular microglia. Th1-derived IFN-γ activates parenchymal microglia expressing MHC class II, CD40, CD80, and CD86, as well as IL-12, a proinflammatory cytokine that further increases IFN-γ secretion by Th cells. Mature microglia are then able to reactivate newly infiltrated antigen-specific Th cells. Microglia-derived TNF-α and NO, and also Th-derived TNF-α or TRAIL can damage oligodendrocytes and interfere with myelin production. IFN-γ may also influence oligodendrocytes and astrocytes. Activated oligodendrocytes express MHC class I and can be attacked by antigen-specific CTL, which in turn is also stimulated by Th1-derived IFN-γ. Furthermore, the microglia-derived cytokines IL-1, IL-6, and TNF-α induce astrogliosis. In this inflammatory scenario, astrocytes may mature to APC and become capable of presenting antigen and of activating further myelin-specific T cells.

evident when considering that genetic susceptibility to MS has been associated with certain MHC class II molecules – that is, with particular interactions between APCs and T cells.

Not only microglia but also astrocytes have been considered a key cell type in initiating the autoimmune response. As previously mentioned, IFN-γ induces astrocytic expression of costimulatory and adhesion molecules. Some investigators also postulate that astrocytes of MS plaques express MHC class II molecules, although these data are conflicting and have not been confirmed by other authors. Furthermore, various studies failed to detect costimulatory molecules on astrocytes in MS plaques. Thus, the contribution of astrocytes to MS pathogenesis is still a subject of debate. Moreover, evidence indicates that astrocytes may instead be involved in neuroprotection and downregulation of the autoreactive T cell response. Astrocytic production of nerve growth factor (NGF) is increased during CNS inflammation, and Th cells significantly increase production of NGF in an antigen-dependent manner. Furthermore, astrocytes can suppress myelin-specific Th1 and Th2 cell activation, proliferation, and effector function, contributing perhaps to the immune privilege of the CNS. On the other hand, Th cells also modulate astrocytic function. Findings show that myelin-specific T cells inhibit glutamate uptake in astrocytes, which may contribute indirectly to glutamate-mediated axonal injury.

Oligodendrocytes are thought to represent the initial cellular target of the autoimmune attack during MS. Interactions of T cells with oligodendrocytes, via cell–cell contact and/or soluble factors, appear to be involved in oligodendrocyte injury but also in induction of remyelination during demyelinating pathology. The fact that oligodendrocytes upregulate MHC class I expression under inflammatory conditions supports the assumption that CTLs may be involved in myelin destruction during MS. Furthermore, in active MS lesions oligodendrocytes express not only Th2-like cytokine receptors but also receptors for IL-12, IL-18, and IFN-γ, indicating that they can respond to inflammatory cytokines produced by activated microglia as well as by Th1 lymphocytes (Figure 3).

Primarily Noninflammatory Disorders

Whereas neurodegenerative diseases are disorders of the CNS characterized by the gradual and progressive loss of neural tissue or nerve cells, stroke represents

an acute injury of the CNS. In the pathology of these diseases, the role of inflammation is only just beginning to be understood. Limited immune response in the CNS ('immune privilege') may permit the initiation of neurodegeneration, for example, upon aging. Moreover, breakdown of the immune privilege during disease course presumably contributes to severity. Whereas microglia seem to become activated in most cases of neurodegeneration, the contribution of T cell populations appears to vary between different disorders. In ALD, for instance, a T cell-mediated inflammatory process seems to determine clinical outcome. By contrast, in AD the role of T cells is apparently marginal, and inflammation may be caused mostly by cells of the innate immune system.

ALD is a rapidly progressive X-linked inherited recessive disorder characterized by the accumulation of saturated very long-chain fatty acids predominantly in the white matter of the brain and the adrenal glands. The disease leads to MS-like symptoms, but in a very rapid course, and is usually lethal in childhood. The cerebral lesions show massive breakdown of myelin and a perivascular lymphocyte infiltrate of mainly CD4-positive and CD8-positive T cells. Hematopoietic stem cell transplantation, whose effectiveness is most likely based on immunosuppression and then reconstitution of the immune system, is one of the current therapies in patients in the early stage of the cerebral inflammatory phenotype. The beneficial effect of this therapy indicates that immune cells, such as T cells present in the lesions, might be involved in disease pathogenesis. Although CD8-positive T cells are believed to be involved in oligodendrocyte cytolysis, it is still unclear what role is played by CD4-positive T cells. Neither the phenotype nor the specificity of these T cells has been defined, and it remains an open question whether these cells are able to interact with activated microglia in an antigen-dependent manner.

Stroke is one of the major causes of mortality worldwide, occurring when the blood flow to a part of the brain is suddenly blocked by occlusion and reduced delivery of oxygen causes the death of brain cells. Depending on the part of the brain that is affected, stroke can result in different clinical manifestations, such as weakness or paralysis of the arms, legs, and/or facial muscles and loss of vision or speech. The immune system apparently exacerbates the injury caused by the infarction since microglia become activated, express MHC molecules, and produce proinflammatory cytokines such as TNF-α and IL-1β. Activated microglia can recruit inflammatory leukocytes into the brain and might be able to present antigens and further activate CNS-specific inflammatory T cells, initializing an inflammatory cascade and leading to postischemic tissue destruction. This role of inflammation in stroke-related tissue destruction is supported by the fact that blockade of IL-1 or the death ligand TRAIL reduces brain damage in ischemia and by the beneficial effect of myelin-specific IL-10-producing Th cells in reducing stroke size.

AD is the most common neurodegenerative disorder, affecting approximately 13 million people worldwide and representing the major cause of dementia. Neurodegeneration in AD affects primarily hippocampal and neocortical brain regions, resulting in a progressive loss of cognitive and memory functions, finally leading to dementia. The neurodegenerative process is associated with deposits of β-amyloid (Aβ) in the brain as a consequence of a metabolic dysregulation of the Aβ precursor protein (βAPP). Cleavage of βAPP by the β and γ secretases releases both Aβ1–40 and Aβ1–42 peptide. The ratio between the two forms, as well as their capacity to precipitate, is determined by genetic factors such as gene mutations in the APP and presenilin genes or the presence of the ApoE4 allele. The fibrillar plaques formed by Aβ deposits are associated with dystrophic neurites as well as activated microglia (expressing high levels of MHC class II molecules) and astrocytes. Aβ-treated microglia express increased levels of proinflammatory cytokines and chemokines, including IL-1β, TNF-α, IL-12, IL-8, and CCL3; might be able to process and present peptides; and are capable of chemoattracting and activating Aβ-specific T cells. Nevertheless, apparently only few activated T cells are found in AD brains, and it is controversial whether and how these cells may contribute to disease pathogenesis. Although AD development seems to be independent of T cell-mediated inflammation, a large body of evidence indicates that disease development can be modulated by inducing an appropriated systemic T cell response to Aβ42 by vaccination. In an animal model, an Aβ42 vaccine prevented peptide deposits, induced clearance of the plaques, and improved cognitive deficits. This beneficial effect was triggered by antibody-mediated microglia activation. However, a placebo-controlled clinical trial designed to test the vaccine Aβ42 in patients had to be interrupted when aseptic meningoencephalitis was identified in 6% ($n = 18$) of the vaccinated patients. There is evidence that this severe adverse reaction was probably mediated by T cell-dominated immune reaction to Aβ and the consequent IFN-γ-induced activation of microglia. Despite the disappointing results of the clinical trial, this therapeutic strategy remains under intense investigation. Researchers are convinced

that the key question in AD vaccination is to find the mode of modulating the immune response to Aβ in a way that results in both suppression of Th1-dominated immunity and increment of Th2- and antibody-mediated response.

Perspectives

Although major advances in the understanding of immune cell interactions have occurred in the past few years, particularly regarding T cells and glial cells, we still have to contend with many conflicting and, in part, controversial data. Most of these data have resulted from the *ex vivo* evaluation of CNS tissue or have been obtained using *in vitro* models, and these methods may not reliably reflect the cell interactions taking place under *in vivo* conditions. This problem may be solved by molecular imaging, a newly emerging, methodology that combines tools from both molecular and cell biology for the purpose of imaging biological processes in living organisms. The field of molecular imaging encompasses sophisticated technologies, such as magnetic resonance imaging, positron emission tomography, single-photon emission computed tomography, two-photon microscopy, and bioluminescence or fluorescence. The further development and use of these novel methods will doubtless shed new light on molecular and cellular interactions in health and disease – knowledge that is indispensable for improved monitoring of disease, accurate diagnosis, and the development of novel therapeutic strategies.

Glial Energy Metabolism: A NMR Spectroscopy Perspective

R Gruetter, Ecole Polytechnique Fédérale de Lausanne, University of Lausanne, Lausanne-Geneva, Switzerland

© 2009 Elsevier Ltd. All rights reserved.

Introduction

During increased electrical brain activity, blood flow increases, tissue deoxyhemoglobin content decreases, glucose metabolism increases, and possibly oxygen metabolism increases. These changes in metabolism and the hemodynamic consequences are measured with contemporary brain imaging methods. However, the measurement of brain activity, be it through the hemodynamic correlates of increased electrical activity, increased oxygen consumption, or deoxyglucose uptake, is unable to depict the fundamentals of brain activity at the neuroglial level *in vivo*. The major mechanism of deactivation of the major excitatory neurotransmitter, glutamate, is glial uptake and conversion to electrophysiologically inactive glutamine, which is then transported back to the neuron to replenish the neurotransmitter pool of glutamate, completing the glutamate–glutamine cycle. It is the purpose of this article to summarize perspectives on *in vivo* metabolism in the glial compartment, relative to that in the neuronal compartment, that have been gained using an emerging method, namely nuclear magnetic resonance (NMR) spectroscopy. Most measurements are performed at metabolic steady state, defined as a condition of metabolic fluxes being constant.

NMR Spectroscopy of Brain Energy Metabolism: A Brief Primer

NMR spectroscopy of brain energy metabolism has focused chiefly on the signals from three NMR-active nuclei – the ubiquitously used ^{1}H, as well as ^{31}P and ^{13}C. Of the three, ^{1}H and ^{31}P are 100% naturally abundant, whereas ^{13}C is only 1.1% abundant in nature. Techniques to establish the quantitative measurement of energy metabolism depend critically on the specific signal measured from a given nucleus. In the following discussions, the current state-of-the-art measurements are given, without elaborating on methodological considerations in detail.

Proton NMR Spectroscopy

With suppression of the intense signal of water, which is used for magnetic resonance imaging (MRI), and elimination of the extracerebral fat signal by adequate localization, a multitude of resonances can be observed in the *in vivo* ^{1}H NMR spectrum; these are attributed to date to more than 20 compounds that can be quantitated with typical precision of ~10%, amounting to a neurochemical profile (Figure 1). Quantification is typically achieved by referencing the metabolite signal to an internal reference signal of known concentration, such as water. Metabolic rates are typically either inferred from measured metabolite concentrations or from their changes with time.

Phosphorus NMR Spectroscopy

The *in vivo* signal of the ^{31}P nucleus contains signals from the three phosphates of ATP – signals from inorganic phosphate and phosphocreatine, as well as signals attributed to phosphomonoester compounds, such as phosphoethanolamine and phosphocholine, and signals attributed to phosphodiesters, such as glycerophosphocholine and ethanolamine. The signals of ADP and UDP-glucose are in principle observable but are typically too low to be detected. The chemical shift of inorganic phosphate reveals intracellular pH, and by manipulating the magnetization of inorganic phosphate, phosphocreatine, or the γ-phosphate of ATP through magnetization transfer, the rates of the reactions of creatine kinase or ATPase can be assessed. Quantification is typically achieved by referencing relative to a brain ATP concentration of 3 mM.

Carbon-13 NMR Spectroscopy

The sensitivity of ^{13}C NMR spectroscopy can be improved by administering ^{13}C-labeled precursors, such as glucose, lactate, β-hydroxybutyrate, or acetate. Further sensitivity improvements are possible by indirectly detecting the ^{13}C label through vicinal ^{1}H nuclei. As in radiotracer methods, such as positron emission tomography (PET), the measurement of label incorporation into metabolic products allows the determination of metabolic rates using similar mathematical approaches. Energy metabolism has been assessed from the measurement of brain glucose, glycogen, lactate, glutamate, glutamine, and aspartate (Figure 2). Quantification is typically achieved by performing an external reference measurement.

Glycolysis

Glucose Transport

The brain relies on a continuous import of glucose from the blood across the blood–brain barrier. Glucose transport rates into the brain are thus indicative of the maximal sustainable rate of glucose consumption,

Figure 1 A neurochemical profile can be derived from the proton nuclear magnetic resonance spectrum of the brain (TE = 2.7 ms, 9.4 T). Shown are 21 compounds that can be measured *in vivo*, grouped according to their major significance. In addition, when present, acetate and β-hydroxybutyrate can also be measured.

Figure 2 (a) Localized ^{13}C nuclear magnetic resonance spectroscopy of the C1 of glucose and glycogen in rat brain (9.4 T). (b) Localized ^{13}C nuclear magnetic resonance spectroscopy of the human brain (4 T). Spectra in both panels are shown after [1–^{13}C]glucose administration. Label incorporation is observed in the predominantly neuronal glutamate and aspartate and the predominantly glial glutamine, in multiple positions due to label scrambling in the tricarboxcylic acid cycle, and exchange with cytosolic amino acids due to, for example, the action of the malate–aspartate shuttle.

CMR_{glc}. Knowledge of the size of the brain glucose pool is important for the derivation of absolute metabolic fluxes and quantitative positron emission tomography studies. Steady-state glucose transport kinetics can be derived from the relationship between brain and plasma glucose. The former can be directly measured using NMR spectroscopy.

Brain glucose is distributed in the entire aqueous phase of the brain The volume in the brain into which glucose diffuses (i.e., the physical distribution volume, V_d) is critical in the derivation of glucose transport kinetics. The diffusion behavior of glucose, measured by diffusion-weighted NMR spectroscopy, reflects that ~80% of the glucose in brain tissue is intracellular, consistent with a high physical distribution volume for glucose, $V_d = 80\%$, which is approximately equal to the brain's water phase. Intracellular and extracellular glucose concentrations are approximately equal, suggesting that transport of glucose across the cell membranes is fast compared to the glucose consumption rate. Conversely, the limiting step for glucose entry into the brain is at the blood–brain barrier (BBB), comprising the endothelial cells.

Glucose content reflects the balance between transport and consumption The steady-state brain glucose concentration is a sensitive indicator of the ability of the BBB to transport glucose relative to the rate of glucose consumption, T_{max}/CMR_{glc}. The observed linear relationship between plasma and brain glucose is consistent with the need to take into account the reversibility of the transport process (Figure 3). The apparent K_m of glucose transport, K_t, is of the order of 5 mM. Decreased electrical activity and thus decreased energy metabolism result in increased brain glucose concentrations; yet a sizable concentration gradient is maintained at isoelectricity, implicating considerable net glucose uptake and thus substantial energy metabolism not related to signaling (Figure 4(a)). Increases in luminal glucose transporter (GLUT-1) result in an increase in the maximal transport capacity of the BBB, the consequence of which is an accordingly increased brain glucose content, suggesting that the luminal membrane is the major rate-determining step for glucose entry into the brain (Figure 4(b)).

Brain glucose becomes rate limiting for metabolism when its concentration approaches that of the K_m of the first step in its metabolism, which in the brain is

$$T_{in} = T_{out} + CMR_{glc}$$

$$T_{in} = T_{max} \frac{G_{plasma}}{(K_t + G_{brain}/V_d) + G_{plasma}} \qquad T_{out} = T_{max} \frac{G_{brain}}{(K_t + G_{plasma})V_d + G_{brain}}$$

Figure 3 Schematic of glucose (G) transport across the blood–brain barrier, depicting the steady-state situation and showing the reversible Michaelis–Menten kinetic expression for transport (CMR_{glc}, maximal sustainable rate of glucose consumption). Standard Michaelis–Menten kinetics neglect the effect of product concentration on reaction velocity (V), and expressions for the transport rates (T_{in} and T_{out}) are derived by assuming zero product concentration (i.e., by setting $G_{brain} = 0$ for T_{in} and $G_{plasma} = 0$ for T_{out}).

Figure 4 (a) Effect of reduced brain activity on brain glucose concentration in the rat brain. Reduction of electrical activity increases brain glucose content substantially, but a considerable gradient across the blood–brain barrier is maintained (the dashed line indicates the G_{brain}:G_{plasma} relationship in the absence of a gradient). (b) Effect of 50% increased blood–brain barrier glucose transporter GLUT-1 on brain glucose content. GLUT-1 was increased by inducing chronic hypoglycemia, which led to a substantial increase in brain glucose content at a constant brain glucose consumption rate.

Figure 5 Glucose transport can become rate limiting for metabolism, but this is a gradually increasing deficit. The graph shows the unidirectional glucose influx rate, T_{in}, relative to the glucose consumption rate, CMR_{glc}. In this example glucose influx matches the consumption at $G_{plasma} \sim 2$ mM. As a result, even at substantial hypoglycemia (e.g., $G_{plasma} = 1.5$ mM), the glucose supply (i.e., T_{in}) accounts for ~85% of total glucose requirements.

mostly phosphorylation by hexokinase. Since the K_m of brain hexokinase is very low (~50 μM), brain glucose concentrations that are close to zero indicate metabolism that is limited by the glucose available to the brain cell (transport-limited metabolism). The substantial brain glucose content at euglycemia indicates that brain glucose transport is not rate limiting for metabolism under normal circumstances; the maximal sustainable rate of glucose consumption is approximately two to three times above the basal rate of glucose metabolism. Glucose consumption can, however, transiently exceed the maximum unidirectional transport into the brain, which may occur in conditions of extreme metabolic activation, such as during seizures. While plasma glucose drops, the brain traverses from excess glucose supply to a condition in which transport across the BBB supplies just enough glucose for metabolism, and eventually to a gradually increasing deficit in glucose supply (Figure 5).

During hypoglycemia, glucose metabolism tends to decrease and cerebral blood flow (CBF) increases when the brain glucose concentration approaches the K_m of hexokinase. The mechanism of such blood flow regulation is different from the neurovascular coupling in physiological activation, whereby glucose metabolism and CBF increase concomitantly.

Glial Glycogen – The Only Energy Reserve in Brain

Glycogen, ascribed to the glial compartment, is present in concentrations that exceed those of euglycemic brain glucose by severalfold. It thus comprises by far the most concentrated endogenous storage of glucose equivalents in the central nervous system (CNS), and the presence of glycogen stores is essential for brain function. Similar to glucose, brain glycogen is rapidly eliminated postmortem; therefore, its direct biochemical measurement is difficult. Localized ^{13}C NMR spectroscopy has the unique capability of following brain glycogen metabolism longitudinally, allowing measurement of the rate of change of metabolic rates and concentration changes of glycogen.

Brain glucose can regulate glycogen metabolism Glycogen metabolism in brain accounts for only a few percent of total glucose metabolism under resting conditions. In contrast to transport and metabolism of bulk brain glucose, glycogen metabolism is strongly insulin dependent and to a lesser degree its content

depends on the plasma glucose concentration. In deep anesthesia and hyperglycemia – conditions which are associated with increased brain glucose content – brain glycogen levels rise well above the normal concentration. Together with the apparent stability of glycogen in the nonstimulated brain at euglycemia or hyperglycemia, these data suggest that brain glucose plays an important regulatory role in cerebral glycogenolysis.

When the intracellular glucose concentration approaches the K_m of hexokinase, glycogen phosphorylase is activated and glycogen synthase is deactivated, resulting in net glycogenolysis to glucose-6-phosphate (and some free glucose, due to cleavage of the 1–6 bonds in glycogen by the debranching enzyme). Glucose-6-phosphate is eventually metabolized to pyruvate, which can either enter the tricarboxcylic acid (TCA) cycle or be converted by lactate dehydrogenase to lactate. Glial lactate can be exported via the action of monocarboxylate transporters at the glial and neuronal cell membranes.

Glycogen stores are neuroprotective By providing lactate to the extracellular fluid, astrocytes can sustain neuronal energy metabolism of neighboring neurons in conditions of fuel deprivation, such as hypoglycemia. During glycogenolysis, two ATPs per glucosyl unit are generated in glycolysis, which can provide energy to support uptake of synaptic glutamate and conversion into electrophysiologically inactive glutamine. Astrocytes thus can remove excitotoxic glutamate from the synaptic cleft in energy-deprived situations, which may be one mechanism by which glial glycogen exerts its neuroprotective effect (Figure 6).

Following glycogen depletion, be it induced by neurotransmitters, by hypoglycemia, by hypoxia, or by sleep deprivation, brain glycogen increases above the basal level and beyond in the presence of ample insulin and glucose, resulting in 'supercompensation' similar to that observed for glycogen in noncerebral tissues. Increased astrocytic glycogen levels reduce neuronal damage following subsequent fuel deprivation. Brain glycogen metabolism may be a factor involved in the mechanism of the hypoglycemia unawareness syndrome observed clinically in patients with insulin-treated diabetes, probably through the enhanced neuroprotective effect of increased brain glycogen.

Glycogen is an important energy reserve Glycogen serves as an energy reservoir of glucose equivalents.

Figure 6 Schematic showing the neuroprotective role of glial glycogen and its ability to nourish neighboring neurons with substrates, such as lactate (Lac). In glucoprivation, such as hypoglycemia, glucose phosphorylation impaired, leading to insufficient glucose-6-phosphate (Glc-6-P) generation, deactivated glycogen synthase (red stars), and activated glycogen phosphorylase. The ensuing glycogen breakdown, through its metabolic pathways (solid thick lines), ultimately produces fuel for neighboring neurons. Glial glycogen is probably also neuroprotective through its ability to minimize excitotoxicity by providing energy for removal of glutamate from the synaptic cleft in fuel-deprived conditions.

For example, during aglycemia, when the supply of glucose to the brain cells is completely abolished, glycogen would sustain total glucose metabolism for about 20 min. However, aglycemia is difficult to achieve in the living brain, and the reduction of plasma glucose in reality is gradual in time, resulting in a gradually increasing glucose supply deficit (Figure 5). For example, in order to cover a partial supply deficit of the metabolic rate of glucose of 0.05 μmol g^{-1} min^{-1} in the awake human brain (corresponding to a deficit of 14% of a basal metabolic rate of 0.35 μmol glucose g^{-1} min^{-1}), the cerebral content of glycogen of 3.5 μmol glucosyl units g^{-1} can account for this fuel deficit for more than 1 h. The rate of brain glycogen degradation during hypoglycemia accounts for the majority of the glucose supply deficit during the hypoglycemic period, and following extended periods of moderate hypoglycemia, substantial glycogen reserves remain. The time estimated for complete glycogen depletion is 4 h, which corresponds to the time period that clinically results in residual neurological symptoms after an episode of hypoglycemia.

In chronic hypoglycemia, brain glucose content is elevated (Figure 4(b)), resulting in ambient intracellular glucose content that appears normal, despite the prevalent hypoglycemia. In this condition, consistent with the upregulation of brain glucose content, astrocytic 45 kDa GLUT-1 and neuronal GLUT-3 are unaltered, as are brain glycogen concentrations.

Glycogen is an important store of glucose equivalents in the brain, having a significant neuroprotective effect; glycogen metabolism is affected not only by tissue glucose levels and plasma insulin, but also by other hormones, neurotransmitters, and second messengers.

Lactate Metabolism – An Integral Part of Normal Brain Function

Brain lactate is present at near 1 μmol g^{-1} concentration under normoxic conditions *in vivo*, and is continuously synthesized and broken down. Glucose and glycogen are the major metabolic precursors for lactate, which can be exported and serve as fuel for other cells. A small lactate efflux from the brain is observed normally. Rapid but small increases in brain lactate are observed in focal activation, consistent with a transient uncoupling of oxygen and glucose metabolism. Similar to that for glucose, lactate diffusion behavior is restricted, indicating that most tissue lactate is intracellular. Lactate is almost evenly distributed in the brain's aqueous phase, owing to the large transport capacity of the abundant monocarboxylate transporters at the neuronal and glial cell membranes.

Tricarboxylic Acid Cycles

Glutamate Turnover – How Oxygen Metabolism Is Measured by NMR Spectroscopy

When using a substrate labeled at a suitable position, be it glucose or other suitable substrates, the measurement of oxygen metabolism by NMR spectroscopy can be accomplished by measuring the rate of labeling of glutamate. For simplicity we consider glucose labeled at the 1 and 6 positions, which labels the C3 of pyruvate and ultimately the C2 of acetyl-CoA, which condenses with oxaloacetate to form citrate. In the course of the metabolic reactions of the TCA cycle, which occur at a rate denominated as V_{TCA}, label arrives at the C4 of 2-oxoglutarate. Oxoglutarate is exchanged with glutamate through transamination and thus readily labels mitochondrial glutamate. However, in the brain *in vivo*, most of the tissue glutamate is of cytosolic origin, given the small volume fraction occupied by mitochondria. Therefore, when label incorporation into glutamate is observed, it reflects a signal ascribed mainly to the cytosol (Figure 7(a)). The label scrambling, however, occurs in the mitochondria. Carbon-13 label is transferred to the cytosolic glutamate by label exchange across the inner mitochondrial membrane. Processes such as the malate–aspartate shuttle (Figure 7(b)), which transfer reducing equivalents from the cytosol to the mitochondrion, play a key role in label exchange across the mitochondrial membrane. Therefore, the rate of labeling of glutamate is both a function of the TCA cycle rate (V_{TCA}) as well as of isotope exchange across the inner mitochondrial membrane (V_x).

When considering the further fate of label in the C4 of glutamate (and conversely the C4 of 2-oxoglutarate), the investigational power of NMR spectroscopy can be demonstrated. The label at C4 of 2-oxoglutarate proceeds along the TCA cycle to scramble equally between the C2 and C3 of succinate (a symmetric molecule), which ultimately leads to a symmetric labeling of the C2 and C3 of 2-oxoglutarate and thus by the same exchange mechanism (V_x in Figure 7(a)) the C2 and C3 of glutamate. Hence, as a result of metabolic reactions ascribed to the TCA cycle, label from a singly labeled acetyl-CoA molecule results in labeling of glutamate in three positions in two turns of the TCA cycle. Whereas the labeling of the C4 of glutamate takes up a simple analytical form of an exponential function, the rate of which is the geometric average of V_{TCA} and V_x divided by the glutamate pool size, the labeling of the C2 and C3 of glutamate is more complex. Briefly, at the C3 position, glutamate receives label not only from acetyl-CoA, but since some of the label escapes the oxoglutarate pool into glutamate (with a probability determined by the relative rate of V_{TCA} and V_x), its C4 position increasingly serves as

Figure 7 The flow of label from glucose to glutamate: (a) illustration of the flow of label from acetyl-CoA to glutamate; (b) the metabolic reactions involved in the malate–aspartate shuttle. The malate–aspartate (Asp) shuttle allows the cell to combust glucose oxidatively, by transferring the reducing equivalent generated per pyruvate (Pyr) molecule oxidized to the mitochondrion. This shuttle is critical in permitting respiring neural cells to metabolize glucose. When pyruvate is the sole fuel for the tricarboxcylic acid (TCA) cycle, the TCA cycle rate $V_{TCA} = V_{PDH}$ (PDH, pyruvate dehydrogenase; V_x, isotope exchange across the inner mitochondrial membrane; OG, oxoglutarate; OAA, oxaloacetic acid).

label substrate for the C3. Since the rate of labeling of Glu_4 is delayed compared to that of acetyl-CoA, due to the time required to completely label the glutamate pool, the labeling of Glu_3 is an increasingly concave function when increasing transmitochondrial exchange rate V_x, which thus can be assessed, allowing important insights into the regulation of oxidative metabolism and mitochondrial integrity *in vivo*. The labeling of glutamate by itself does not permit to study compartmentalization between astrocytes and neurons, however, as glutamate is ubiquitously present in many cells, including astrocytes.

The Glutamate–Glutamine Cycle

Glial-specific tracers Acetate and glucose do not share the same product-precursor relationship.

Today it is well established that acetate is selectively taken up by astrocytes, and hence labeled acetate can be used to 'trace' glial metabolism, whether it is by using radiotracers, as in ^{14}C autoradiography or ^{11}C (using PET), or by using [^{13}C]acetate in conjunction with NMR spectroscopy. The advantage of using acetate as a tracer lies in its exclusive uptake into the astrocytes, and thus from the turnover of glutamate, astrocytic TCA cycle flux can be assessed.

Labeled acetate will thus label glial glutamate much in the same manner as discussed previously; however, the action of glutamine synthetase and the diffusion of glutamine from the astrocyte into the presynaptic terminal result in label being scrambled from glutamine to neuronal glutamate, where it is being diluted with unlabeled carbon derived from the neuronal TCA cycle; this leads to a lower isotopic enrichment of tissue glutamate, compared to tissue glutamine (resulting in an anomalous product-precursor relationship). In general, glutamate and glutamine are not labeled to an equal extent, reflecting the substantial activity of the glial TCA cycle (see later).

When electrical activity ceases (isoelectricity) the glutamate–glutamine cycle activity is close to zero, but substantial energy is still expended, powering ion gradients, among others. This results in a substantial glucose concentration gradient at isoelectricity and active oxygen consumption (Figure 4(a)). With increasing electrical activity, the rate of glutamine synthesis increases but the glutamate–glutamine cycle does not operate stoichiometrically.

Glutamine Synthetase and Pyruvate Carboxylase

The synthesis of glutamine is catalyzed by glutamine synthetase (EC 6.3.1.2), which is attributed to the glial compartment (Figure 8). Hence the *in vivo* observation of glutamine labeling by ^{13}C NMR is a direct manifestation of glial metabolism. In principle, the simultaneous observation of labeling of glutamate, mainly ascribed to the neuronal compartment, and glutamine, a glial reaction, would thus follow the path of acetyl-CoA → glutamate → glutamine → glutamate, and thus would represent a direct manifestation of the glutamate–glutamine cycle, which is the dominant mechanism of glutamate neurotransmission. However, additional labeling of glutamine occurs via the glial TCA cycle, as astrocytes contain mitochondria and thus the necessary enzymatic predisposition for oxidative generation of energy (e.g., a high cytochrome oxidase content).

The presence of significant glial oxidative metabolism results in incorporation into glutamine label that does not match that of glutamate. Reactions associated with CO_2 fixation, such as the major anaplerotic enzyme, pyruvate carboxylase (EC 6.4.1.1), have been localized to astrocytes. *De novo* synthesis of

Figure 8 Schematic depiction of the metabolic relationship between neurons and glia. The compounds in red are those measured by nuclear magnetic resonance spectroscopy *in vivo*. Deactivation of neurotransmitter glutamate is primarily by uptake into the glia and conversion to glutamine, which at least in part diffuses back into the presynaptic terminal, to be converted to glutamate by phosphate-activated glutaminase, completing the glutamate–glutamine cycle (thick arrows; TCA, tricarboxcylic acid).

amino acids is thus a unique capability of the glial compartment, given that transamination which occurs in both astrocytes and neurons by itself cannot provide a net increase in tissue TCA cycle intermediate and hence amino acid concentration. In the reaction catalyzed by pyruvate carboxylase, pyruvate is combined with CO_2 to form oxaloacetate (OAA). As previously, we consider glucose labeled at the 1 and 6 positions as the precursor molecule, which results in label incorporation in the C3 of oxaloacetate from the C3 of pyruvate, which in turn labels the C2 of oxoglutarate, and thus the C2 of glutamate. As a result, the C2 of glutamate is labeled to a larger extent than is the C3. By comparing the labeling of glutamate in C2 and C3, the quantitative presence of anaplerotic reactions can be estimated *in vivo* by NMR, although some equilibrating flux back to fumarate may obscure the true extent of CO_2 fixation present. Anaplerotic reactions are a substantial metabolic activity in the brain, amounting to approximately one-third of glutamine synthesis, and are linked to brain activity. Anaplerotic reactions are decreased in metabolically depressed states, resulting in reduced glutamine synthesis and lowered brain glutamate and glutamine concentrations in hibernation, for example. Net synthesis of glutamine from glucose produces approximately ten ATPs per glutamine molecule, from the generation of several NADH molecules in the process, and thus is energetically favorable.

Summary

At rest, most of the energy requirements in the brain are matched by oxidative metabolism of glucose. Oxygen metabolism is uniquely compartmentalized between neurons and glia, the latter comprising about 25% of the energy metabolism. The consumption of acetate and fixation of CO_2 in glutamine are oxygen-dependent glial reactions. At least two-thirds of the ATP generated in astrocytes is by oxidative processes. Astrocytes thus can, in a unique way, buffer metabolic demand of the tripartite synapse. Glia exhibit a large capacity to phosphorylate glucose and can store it in the form of glycogen, the glucose equivalents of which can be exported in the form of lactate to neurons, providing neuroprotection. Astrocytes have a substantial anaplerotic activity, as *de novo* synthesis of glutamine by itself is an energetically favorable process. Glia therefore adapt the fuel demands to the specific requirements encountered in activation, hypoglycemia, and deactivation, nurturing surrounding neurons with substrates, while at the same time eliminating neurotransmitter glutamate from the synaptic cleft.

Introduction

In the late nineteenth century, neuroanatomists described the morphological features of glial cells and their cytoarchitectural relationships with other elements of the central nervous system. Among glial cells, astrocytes are the most numerous and exhibit a number of striking characteristics. First, they occupy a strategic position, being usually located between blood vessels and neurons. Second, they possess specialized processes called end-feet, and these processes come into close contact with blood vessels, covering a large part of their surface. Third, they also ensheathe numerous synapses. Altogether, these characteristics suggested to those early neuroanatomists, and among them Camillo Golgi, that astrocytes could play a critical role in the allocation of metabolic substrates to neurons. This view was nicely formulated by Andriezen in 1893:

> The development of a felted sheath of neuroglia fibers in the ground-substance immediately surrounding the blood vessels of the Brain seems therefore ... to allow the free passage of lymph and metabolic products which enter into the fluid and general metabolism of the nerve cells.

It is only recently, however, that such a theory experienced a revival through a series of experimental demonstrations that benefited from the advances made in the isolation of specific brain cell types and their use *in vitro* to study their metabolic characteristics. The current understanding of brain energy metabolism is still incomplete, but in recent years insights have been gained into a number of aspects related to glial energy metabolism.

Aerobic Glycolysis: A Versatile Metabolic Feature of Astrocytes to Cope with the Burden of Glutamate Recycling

Several studies have demonstrated the large glycolytic capacity of astrocytes that is accompanied by a sizable production and release of lactate despite the sufficient amount of oxygen present and active oxidative phosphorylation. Not only is their basal glycolytic rate elevated, but astrocytes also possess a large glycolytic reserve that can be mobilized under various conditions. This is the case under hypoxia or if oxidative phosphorylation is inhibited. But more important, this reserve can be used in specific physiological situations. Thus, it has been shown that enhanced sodium entry within an astrocyte, causing an elevation of intracellular sodium concentration, will lead to an increased glycolytic rate. Such a situation occurs notably when astrocytes are exposed to the excitatory neurotransmitter glutamate. Glutamate transport occurs in astrocytes via two glutamate transporters, glutamate aspartate transporter (GLAST) and glutamate transporter 1 (GLT1). Both depend on the Na^+ gradient and carry glutamate, together with three Na^+ ions, inside the cell. The increase in intracellular Na^+ concentration that accompanies glutamate transport will activate Na^+/K^+ adenosine triphosphatase (ATPase), and as a consequence of adenosine triphosphate (ATP) consumption, an activation of glucose utilization will take place, together with enhanced lactate production (Figure 1). Such an activation of aerobic glycolysis in astrocytes appears to be facilitated by a few molecular characteristics. First, it has been shown that astrocytes have a large part of their pyruvate dehydrogenase enzyme present in a phosphorylated and thus inactive form. This characteristic may limit the entry of pyruvate into the tricarboxylic acid (TCA) cycle (Figure 2). Second, astrocytes appear to have very reduced levels of an essential component of the malate–aspartate shuttle called ARALAR 1. As a consequence, the transfer of reducing equivalents from the cytosol to the inner mitochondria is reduced, and cytosolic nicotinamide adenine dinucleotide (NAD^+) regeneration is limited. To maintain a high glycolytic rate as observed in astrocytes, which requires a rapid regeneration of NAD^+ levels, the solution is to convert pyruvate to lactate via the lactate dehydrogenase enzyme. To facilitate this task, astrocytes prominently express the lactate dehydrogenase M isoform that is not inhibited by pyruvate and sustains high enzymatic rates. Moreover, astrocytes were found to express the monocarboxylate transporter (MCT) isoforms MCT1 and MCT4 that are particularly suited for lactate export from glycolytic tissues because of high K_m values.

An important question is whether such a metabolic response of astrocytes can be triggered by other neuroactive substances. The main inhibitory neurotransmitter, γ-aminobutyric acid (GABA), is an interesting case since it is also transported by a Na^+-dependent mechanism in astrocytes and it is the most important neurotransmitter after glutamate. However, it was

Figure 1 Schematic representation of the mechanism for glutamate-induced glycolysis in astrocytes during physiological activation. EAAT, excitatory amino acid transporter. Modified from Pellerin L and Magistretti PJ (1994) Glutamate uptake into astrocytes stimulates aerobic glycolysis: A mechanism coupling neuronal activity to glucose utilization. *Proceedings of the National Academy of Sciences of the United States of America* 91: 1065–10629.

shown that GABA does not cause a similar enhancement of aerobic glycolysis in astrocytes. The explanation resides in a rapid reduction in GABA transport with increasing intracellular Na^+ concentration before it reaches the threshold to activate glycolysis, a phenomenon not observed with glutamate transport. Several other neurotransmitters and neuromodulators have been tested, but all failed to activate glycolysis except noradrenaline. However, the mechanism by which noradrenaline stimulates glycolysis in astrocytes is different from that of glutamate but remains unclear. Another intriguing issue is whether the effect of glutamate is linked only to its uptake via glutamate transporters or whether activation of glutamate receptors (GluRs) can also participate in the metabolic effect. Indeed, astrocytes express both ionotropic and metabotropic glutamate receptors. Among ionotropic receptors, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainate receptors are abundantly expressed, and all four subunit isoforms (GluR1–4) have been detected in astrocytes. Although activation of AMPA/kainate receptors with the specific agonist AMPA leads to a transient increase in intracellular Na^+ concentration, this is not sufficient to cause an activation of aerobic glycolysis. In this case, rapid desensitization of the receptors prevents the Na^+ influx from activating metabolism. Kainate causes a more important intracellular Na^+ change and a small but significant stimulation of aerobic glycolysis. This effect could be explained by the fact that kainate, in contrast to

Figure 2 Metabolic pathways of glucose. LDH, lactate dehydrogenase; NADP, oxidized nicotinamide adenine dinucleotide phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate; TCA, tricarboxylic acid cycle.

AMPA, leads to only a partial desensitization of AMPA/kainate receptors. One particularity of AMPA/kainate receptors is that they contain allosteric sites allowing certain agents to modulate their degree of desensitization/deactivation. In recent years, a series of compounds have been developed on the basis of their ability to prevent desensitization/deactivation of AMPA/kainate receptors. It is quite interesting that they were shown to exhibit neuroprotective and cognitive enhancement effects in various models showing impaired cognitive functions. Although the main explanation proposed for these effects is related to their action on neuronal AMPA/kainate receptors, it has also been suggested that a potentiation of glutamate-induced aerobic glycolysis in astrocytes occurs and participates in the beneficial effects of these drugs. Thus, enhancing the glycolytic response of astrocytes might represent a valuable therapeutic target for the future.

A new dimension of the role of enhanced aerobic glycolysis in astrocytes was revealed recently. It has been known for a while that astrocytes communicate with each other through Ca^{2+} waves that propagate in a regenerative manner along the astrocytic network. The specific role of these traveling Ca^{2+} waves is still not entirely clear. But in parallel with Ca^{2+}, Na^{+} waves have been described. These Na^{+} waves arise from glutamate released by one astrocyte on elevation of intracellular Ca^{2+} and taken up by its neighbors. As a consequence of this Na^{+} influx, a metabolic wave of enhanced aerobic glycolysis will ensue among the astrocytic network. It is purported that such a mechanism could be used to coordinate metabolism and provide adequate energy substrate supply to activated neuronal ensembles, irrespective of their neurotransmitter phenotypes. If confirmed *in vivo*, such a phenomenon would have important implications not only for an understanding of neuroenergetics but also for the analysis of images obtained with brain imaging techniques that rely on metabolic signals.

Glycogen: Helping to Face Increased Energy Demands

Glycogen has been viewed traditionally as an energy reserve maintained to face periods of low energy supply. This notion has been inherited from studies in peripheral organs such as the liver and muscle. However, the amount of glycogen contained in the brain is relatively small: approximately 10 times less than in muscle and 100 times less than in liver. Moreover, under physiological conditions, energy supply to the brain is maintained within narrow limits such that the idea of maintaining an emergency reserve for pathological situations appears unlikely. Rather, a series of observations argues in favor of a role for glycogen as an energy buffer rather than an energy reserve in the central nervous system.

Glycogen turnover was shown to be enhanced *in vivo* under sustained stimulation. In contrast, glycogen was found to accumulate in the brain under anesthesia. These observations suggest that glycogen utilization is tightly linked to neuronal activity. It is interesting that at the cellular level, glycogen is found almost exclusively in astrocytes. Since it is purported that the vast majority of energy expenditures are the consequence of neuronal activity, it may seem paradoxical that the sole energy reserve is located in a nonneuronal cell type. However, several lines of evidence indicate that astrocytes respond to neuronal signals and mobilize their glycogen stores to release a metabolite for use by neurons as an energy substrate. It has been shown that the brain, and in particular astrocytes, do not possess glucose-6-phosphatase and thus cannot release glucose as a product of glycogenolysis. Rather, it has been demonstrated that lactate constitutes the main substrate formed from glycosyl residues arising from glycogenolysis and released by astrocytes. Among the various neuroactive substances shown to induce glycogenolysis are the neurotransmitters noradrenaline and serotonin, the neuropeptide vasoactive intestinal peptide (VIP), and the neuromodulators adenosine and ATP. It has also been shown that elevated K^{+}occurring as a consequence of neuronal activity can efficiently cause glycogenolysis in astrocytes. In addition to glycogenolysis, several of these neuroactive substances promote a delayed but massive resynthesis of glycogen in astrocytes that takes place over several hours. Such resynthesis is critically dependent on the expression of a key protein called protein targeting to glycogen. This protein serves as a scaffold that binds not only glycogen but also all the enzymes involved in the regulation of glycogen synthesis and degradation. It is also massively induced in astrocytes following treatment with noradrenaline or VIP (Figure 3). Although its purpose is still a matter of debate, this mechanism might be essential to replenish glycogen stores and thus ensure adequate levels in order to face subsequent periods of high activity. In the optic nerve, glial glycogen has been shown to play a critical role in maintaining neuronal activity, in particular by providing lactate to meet the energetic demands of the axon.

The Pentose Phosphate Pathway: Energy Fluxes and Neuroprotection

ATP is not the only form of metabolic energy, as reducing power is needed in addition to ATP to energize

Figure 3 Regulation of glycogen metabolism by noradrenaline. Similar regulatory mechanisms are activated by vasoactive intestinal peptide and by adenosine. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; GS, glutamine synthase; mRNA, messenger RNA; NA, nicotinamide adenine; Prot, protein; PTG, protein targeting to glycogen.

several important cellular processes. This reducing power is provided by the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH). The processing of glucose through the pentose phosphate pathway produces NADPH (Figure 2).

A critical cellular process for which NADPH is needed is the scavenging of reactive oxygen species (ROS). The superoxide radical anion (O_2^-) hydrogen peroxide (H_2O_2), and the hydroxy radical (HO.) are three ROS generated by the transfer of single electrons to molecular oxygen as by-products of several physiological cellular processes. A considerable contribution to the generation of ROS is the oxidative metabolism of glucose taking place in the mitochondrial electron transfer chain associated with oxidative phosphorylation see below). Other ROS-generating reactions include the activities of monoamine oxidase, tyrosine hydroxylase, nitric oxide synthase, and the eicosanoid-forming enzymes lipoxygenases and cyclooxygenases. Reactive oxygen species are highly damaging to cells because they can cause DNA disruption and mutations, as well as activation of enzymatic cascades, including proteases and lipases, that can eventually lead to cell death. The coordinated activity of NADPH and glutathione is essential in protecting cells against ROS-mediated damage, or oxidative stress. Scavenging of ROS is ensured by the sequential action of superoxide dismutase (SOD) and glutathione peroxidase. Thus, two superoxide anions are converted by SOD into H_2O_2, still an ROS. Glutathione peroxidase converts H_2O_2 into H_2O and O_2 at the expense of reduced glutathione, which is regenerated by glutathione reductase in the presence of NADPH.

Scavenging of ROS provides another example of metabolic cooperation between neurons and astrocytes. Glutathione is a tripeptide (γ-L-glutamyl-L-cysteinylglycine (GSH)) synthesized through the concerted action of two enzymes, γ-GluCys synthase, which combines glutamate and cysteine to yield the dipeptide γ-Glu Cys, and glutathione synthase, which adds a glycine to the dipeptide to yield GSH.

The glutathione content and reducing potential are considerably higher in astrocytes than in neurons; this fact, combined with the much higher oxidative activity of neurons than of astrocytes, makes neurons more vulnerable to oxidative stress as well as highly dependent on astrocytes for protection. Indeed, a cooperativity between astrocytes and neurons appears to exist for glutathione metabolism; astrocytes release GSH, which is cleaved by the ectoenzyme γ-glutamyltransferase, releasing CysGly. The dipeptide is transported into neurons (note that neurons cannot take up GSH), providing two precursors for GSH synthesis. Glutamate, the third precursor of GSH, is also provided by astrocytes to neurons in the form of glutamine, from which glutamate is produced through the action of glutaminase.

This astrocyte–neuron metabolic cooperation aimed at controlling the damaging effect of ROS generated by cellular activities may be critical for neuroprotection. Indeed, neurons, being highly oxidative cells

dependent on astrocytes for scavenging ROS, are at high risk for neurodegeneration. Indeed, dysfunction of such neuroprotective mechanisms has been described in certain neurodegenerative diseases, such as a familial form of amyotrophic lateral sclerosis, due to an SOD mutation. Evidence for a decrease in GSH content in the substantia nigra has also been described in Parkinson's disease.

The TCA Cycle, Glutamate Metabolism, and Anaplerosis

The main metabolic pathway for ATP production is the TCA cycle. While this pathway is active in both neurons and astrocytes, neurons, being richer than astrocytes in mitochondria where the TCA cycle occurs, are overall more oxidative than astrocytes. In addition to its central role in ATP production through its coupling to oxidative phosphorylation, the TCA cycle contributes to another critical aspect of astrocyte–neuron metabolic cooperation, related to glutamate metabolism.

Synaptically released glutamate is removed rapidly from the extracellular space by a transporter-mediated reuptake system that is particularly efficient in astrocytes. This mechanism contributes in a crucial manner to the fidelity of glutamate-mediated neurotransmission. Indeed, glutamate levels in the extracellular space are low ($<3\ \mu mol^{-1}$), allowing for optimal glutamate-mediated signaling after depolarization while preventing overactivation of glutamate receptors, which could eventually result in excitotoxic neuronal damage.

What is the metabolic fate of glutamate taken up by astrocytes? Glutamate cannot be stored like carbohydrates or lipids. In astrocytes, one pathway involves the TCA cycle, namely, the transfer of the α-amino group of glutamate to oxaloacetate to yield α-ketoglutarate (α-KG) and aspartate in a reaction catalyzed by aspartate amino transferase (AAT). The α-KG generated is an intermediate of the TCA cycle and is therefore oxidized further. Another transamination reaction catalyzed by alanine amino transferase (ALAT) transfers the α-amino group of glutamate to pyruvate, resulting in the formation of alanine and α-KG.

Two other pathways exist in astrocytes to metabolize glutamate. First, glutamate can be converted directly to α-KG through an NAD-requiring oxidative deamination catalyzed by glutamate dehydrogenase (GDH). Glutamate, by entering the TCA cycle indirectly (through AAT or ALAT) or directly (through GDH), is an energy substrate for astrocytes. Second, the quantitatively predominant metabolic pathway of glutamate in astrocytes is its amidation to glutamine, an ATP-requiring reaction in which an ammonium ion is fixed on glutamate. This reaction is catalyzed by glutamine synthase, an enzyme almost exclusively localized in astrocytes, and provides an efficient means of disposing not only of glutamate but also of ammonium (Figure 1). Glutamine is released by astrocytes and is taken up by neurons, where it is hydrolyzed back to glutamate by the phosphate-dependent mitochondrial enzyme glutaminase. This metabolic pathway, often referred to as the glutamate–glutamine shuttle, is a clear example of cooperation between astrocytes and neurons. It allows the removal of potentially toxic excess glutamate from the extracellular space while returning to the neuron a synaptically inert (glutamine does not affect neurotransmission) precursor with which to regenerate the neuronal pool of glutamate.

However, not all glutamate is regenerated through the glutamate–glutamine shuttle because some of the glutamate released by neurons enters at the α-KG level, the TCA cycle in astrocytes; therefore, *de novo* synthesis is required to maintain the neuronal glutamate pool. Glutamate can be synthesized through NADPH-dependent reductive amination of α-KG catalyzed by GDH (note here another role of NADPH, in addition to ROS scavenging, in cooperation with glutathione). For this pathway leading to the synthesis of glutamate, glucose provides the carbon backbone as α-KG does through the TCA cycle, while plasma leucine, taken up by astrocytic end-feet, provides the nitrogen required for net glutamate synthesis from α-KG. Because this reaction, catalyzed by leucine transaminase, takes place in astrocytes to replenish the neuronal glutamate pool, the astrocytes export glutamate as glutamine.

As can be appreciated, because α-KG is used for glutamate synthesis, metabolic intermediates downstream of α-KG must be available to maintain a sustained flux through the TCA cycle in astrocytes. This need is met by the activity of the enzyme pyruvate carboxylase, which fixes CO_2 on pyruvate to generate oxaloacetate, which, by condensing with acetyl-CoA, maintains the flux through the TCA cycle. The carboxylation of pyruvate to oxaloacetate is referred to as an anaplerotic (Greek for 'fill up') reaction. It is interesting that like glutamine synthase, pyruvate carboxylase is selectively localized in astrocytes. The fact that these two enzymes are localized in astrocytes in conjunction with the existence of a glutamate–glutamine shuttle stresses that astrocytes are essential for maintaining the neuronal glutamate pool used for neurotransmission.

The Astrocyte–Neuron Metabolic Unit

In conclusion, the axon terminals at glutamatergic synapses, which represent more than 80% of all

synapses in the cerebral cortex, and the astrocytic processes that surround them should be viewed as a metabolic unit in which the neuron furnishes the activation signal (glutamate) to the astrocyte, and the astrocyte provides, not only the precursors needed to maintain the neurotransmitter pool (glutamine), but also the energy substrate (lactate) and a neuroprotective agent (glutathione) to scavenge ROS formed by the active oxidative phosphorylation of neurons. Thus the efficacy of the predominant excitatory synapse in the brain, the glutamatergic synapse, cannot be maintained without a close astrocyte–neuron interaction.

Glial Glutamate and GABA Metabolism

Termination of Excitatory and Inhibitory Neurotransmission

The two amino acids glutamate and γ-aminobutyric acid (GABA), acting as an excitatory and inhibitory neurotransmitter, respectively, probably account for 80–90% of all neurotransmission signaling in the central nervous system (CNS). In the case of glutamate, termination of the transmission process is to a very large extent based on uptake of glutamate into astrocytes completely ensheathing the synapses. In GABAergic neurotransmission, on the other hand, astrocytic uptake of GABA seems less pronounced, and the majority of released GABA appears to be transported back into the presynaptic GABAergic nerve endings for recycling as a neurotransmitter. The fraction of released GABA which is taken up into surrounding astrocytes undergoes oxidative metabolism, as is delineated later. The balance between neuronal and glial GABA uptake is likely to play a fundamental role for the optimal function of inhibitory neurotransmission.

Glutamate Metabolism

Glutamate is taken up into astrocytes by the two transporters GLAST (EAAT1) and GLT-1 (EAAT2), which are abundantly expressed in astrocytic membranes, accounting for at least 10% of all membrane-associated proteins. This provides astrocytes with an enormous capacity for glutamate transport, a feature of great importance for maintaining a low extracellular glu tamate concentration, thereby preventing excitotoxic neuronal damage and cell death. As shown schematically in Figure 1, a complex set of enzymatically catalyzed reactions is responsible for glutamate metabolism in astrocytes. The major metabolic pathways are those catalyzed by the enzyme glutamate dehydrogenase (GDH) and aminotransferases such as aspartate aminotransferase (AAT), alanine aminotransferase (ALAT), and branched chain amino acid transaminase (BCAT), to mention the most important ones. Additionally, glutamate can be amidated in an ATP-requiring process catalyzed by glutamine synthetase (GS), an enzyme which is exclusively expressed in glial cells. This latter reaction produces glutamine which will be released from the astrocytes utilizing the glutamine transporters of system N and L. The former reactions lead to production of α-ketoglutarate which will enter the tricarboxylic acid (TCA) cycle for further metabolism, resulting in oxidation of the carbon skeleton, a process ultimately requiring pyruvate recycling to occur. Whether or not glutamate undergoes amidation (GS reaction) or oxidation (GDH/aminotransferases plus TCA cycle) is of fundamental importance for the maintenance of glutamatergic neurotransmission. Formation of glutamine and its subsequent release constitute the basis for the operation of the glutamate–glutamine cycle (Figure 2). If, however, the carbon skeleton of glutamate enters the TCA cycle, it is prevented from being part of the glutamate–glutamine cycle and glutamate is lost from the transmitter pool. Astrocytes are equipped with an alternative enzymatic machinery to compensate for this. Pyruvate formed from glucose in the glycolytic pathway can undergo carboxylation in an energy (ATP)-requiring process catalyzed by pyruvate carboxylase (PC), another astrocyte-specific enzyme. This may allow a net synthesis of either citrate or glutamine, of which particularly the latter can be used as precursor for glutamate in glutamatergic neurons. Citrate is also released from astrocytes, but the functional importance of this process is presently only poorly understood.

GABA Metabolism

The only GABA-metabolizing enzyme is GABA-aminotransferase (GABA-transaminase, GABA-T), which is expressed in all cells of the CNS as well as peripherally. It catalyzes the conversion of GABA to succinic semialdehyde (SSA) concomitantly with conversion of α-ketoglutarate to glutamate (Figures 3(a) and 3(b)). Subsequently, SSA is oxidized to succinate by the enzyme SSA-dehydrogenase (SSADH), which as a consequence prevents the otherwise freely reversible aminotransferase reaction from producing GABA due to a very low SSA concentration. Both GABA-T and SSADH are mitochondrial enzymes. The two metabolic schemes in Figures 3(a) and 3(b) illustrate that α-ketoglutarate, which is required as a co-substrate for GABA in the GABA-T reaction, may originate from the TCA cycle by two different series of reactions. It may be the result of conversion of succinate to oxaloacetate and further generation of α-ketoglutarate after condensation with acetyl CoA produced from glucose via pyruvate formed

Figure 1 A schematic representation of glutamate (Glu) metabolism in astrocytes. Glu is taken up by high-affinity Glu carriers, that is, GLAST and GLT-1, and subsequently converted into either glutamine (Gln) by the operation of glutamine synthetase (GS) or α-ketoglutarate (α-KG) by glutamate dehydrogenase (GDH) or an aminotransferase. The latter reaction simultaneously converts a keto acid to the corresponding amino acid. α-KG may subsequently accelerate oxidation of acetyl CoA units in the tricarboxylic (TCA) cycle, producing energy. Gln is released from the astrocyte.

Figure 2 The GABA-glutamate (Glu)/glutamine (Gln) cycle depicts a metabolic interaction between astrocytes and glutamatergic or GABAergic neurons for maintenance of Glu and GABA homeostasis during neurotransmission. Glu and GABA are both synthesized from Gln by the concerted action of phosphate-activated glutaminase (PAG) and glutamate decarboxylase (GAD). Glu and GABA are released from the glutamatergic and GABAergic neurons, respectively, and subsequent to synaptic action, they are both partly taken up by surrounding astrocytes. GABA is degraded to succinate, a tricarboxylic (TCA) cycle intermediate, by the combined action of GABA-transaminase (GABA-T) and succinate semialdehyde dehydrogenase (SSADH). Succinate may after one turn in the TCA cycle serve as precursor for Glu and subsequently for Gln via glutamine synthetase (GS). Glu is either directly converted into Gln or metabolized in the TCA cycle. Gln is released from the astrocytes and taken up by the neuron completing the cycle.

by the glycolytic pathway (Figure 3(a)). This series of reactions allows glutamate produced from α-ketoglutarate in the GABA-T reaction to be amidated to glutamine by GS and thereby provides the means to generate glutamine from GABA. This allows release of glutamine for uptake into, for example, GABAergic neurons constituting the glu-GABA-glutamine cycle, which is an extension of the glutamate/glutamine cycle (Figure 2).

An alternative series of reactions is shown in Figure 3(b). Regeneration of α-ketoglutarate from glutamate in the GABA-T reaction takes place in an aminotransferase reaction catalyzed by alanine aminotransferase using pyruvate generated from glucose in the glycolytic pathway. This results in a net production of alanine. It should be noted that this alternative set of reactions does not lead to production of glutamine, excluding the operation of the GABA–glutamate–glutamine cycle. It should be noted that while the series of reactions shown in Figure 3(a) leads to production of glutamine without the need for anaplerosis involving pyruvate carboxylase, no glutamine production is associated with the reactions outlined in Figure 3(b). This means that in order to fulfill the requirement for glutamine production in and release from the astroglial compartment, anaplerosis must take place. These considerations are important in the light of the fact that glutamine is the

Figure 3 A schematic representation of GABA metabolism suggesting possible coupling to either glutamine (Gln) or alanine (Ala) synthesis in astrocytes. GABA is taken up by high-affinity GABA carriers, that is, GAT1–4, and subsequently degraded to succinate (Suc) via succinate semialdehyde (SSA) catalyzed by the combined operation of GABA-transaminase (GABA-T) and succinate semialdehyde dehydrogenase (SSADH). (a) The action of GABA-T simultaneously converts α-ketoglutarate (α-KG) to glutamate (Glu) being the precursor of releasable Gln via glutamine synthetase (GS). Suc may be precursor of this Gln, since α-KG can be formed from Suc via the tricarboxylic (TCA) cycle and condensation of one molecule of acetyl CoA possibly generated from glucose. (b) Glu formed in the GABA-T reaction may alternatively be reconverted into α-KG by the functioning of alanine aminotransferase (ALAT) concurrently forming Ala from pyruvate (Pyr), the latter being formed from glucose. This series of reactions thus leads to net synthesis of Suc, a TCA cycle constituent.

most important precursor for GABA synthesis in GABAergic neurons.

Pharmacology of GABA Metabolism

Contrary to glutamate metabolism, the GABA metabolic pathway constitutes an important pharmacological target. Inhibition of GABA degradation is theoretically an interesting way to elevate GABA levels. However, due to the fact that both the GABA-synthesizing enzyme glutamate decarboxylase (GAD) and the catabolic enzyme GABA-T utilize pyridoxal phosphate as a coenzyme, it is difficult to affect only one of the enzymes since carbonyl trapping agents will affect both enzymes. This problem was solved using γ-vinyl GABA, which is a catalytic substrate-directed suicide inhibitor specific for GABA-T. This compound was developed into a clinically active antiepileptic drug by the name vigabatrin. It was later discovered that it not only is specific for GABA-T but also affects particularly the neuronal (neurotransmitter) pool of GABA due to the presence of a vigabatrin transporter preferentially expressed in neurons.

Introduction

At glutamatergic synapses, excitatory amino acid (EAA) transporters are involved in the removal of the neurotransmitter glutamate (Glu) from the synaptic cleft to stop intercellular signaling following the release of the neurotransmitter and action on receptors (Figure 1). EAAs are major brain neurotransmitters. They are primarily involved in the so-called excitatory 'fast signaling,' which supports rapid transfer of excitatory information in neuronal networks. Glu is the main EAA. It is generally accepted to be present in approximately 30–40% of total brain synapses and probably much more in selected cortical and hippocampal areas involved in cognitive processes. One of the most interesting properties of the EAA synapse, however, is its contribution to neuronal plasticity through cellular mechanisms known as long-term potentiation and long-term depression processes, which are generally accepted to represent basic mechanisms for learning and memory. Indeed, numerous reports have shown specific impairments of learning and memory when synaptic transmission involving the NMDA receptor subtypes is altered *in vivo*.

In addition to the key contribution to the transfer of excitatory information in the brain, EAAs and especially Glu exhibit the unique property of representing a very potent endogenous neurotoxin. Pharmacological stimulation of EAA receptors using various Glu agonists has been shown both *in vitro* and *in vivo* to induce neuronal death, suggesting that an overconcentration of EAAs in the synaptic space is deleterious for the cells due to an excess of excitation. This process is called excitotoxicity. However, excitotoxicity is not the only mechanism that induces neuronal death; the depolarizing action of Glu is concomitant with a massive increase in Na^+ in the cell, which can lead to cell death through swelling of the cell in the case of overstimulation of the EAA receptors. Therefore, although such a consideration of neuropathology can be viewed as highly reductionistic, dysfunctions of brain neurotransmission involving EAAs have been reported in select brain diseases with neuronal death and their putative contribution to many others is often proposed. However, what is the basic nature of the mechanisms involved in the clearance of EAAs at the synapse? What is the role of the transporters? What could be their real contribution to neurodegenerative diseases?

The EAA Transporter Family as Key Membrane Proteins

Five members of the Glu transporter family have been characterized. The human subtypes are designed EAAT1–EAAT5. EAAT1, -2, and -3 are the human homologs, respectively, of GLAST, GLT-1, and EAAC1, the three main Glu transporters in the rat brain cloned in 1992. GLT-1 was initially purified as a 73 kDa glycoprotein and GLAST as a 66 kDa protein. When comparing the different Glu transporters, the identity of amino acid sequence is in the range of 44–55%. *Drosophila* EAAT homologs dEAAT1 and dEAAT2 have also been identified in the central nervous system. However, only dEAAT1 can transport Glu since dEAAT2 was characterized as an aspartate/taurine transporter.

EAAT1/GLAST and EAAT2/GLT-1 are primarily astrocytic, although some authors have suggested a limited neuronal expression of EAAT2/GLT-1. Conversely, EAAT3/EAAC1 and EAAT4 and -5 are considered to be neuronal transporters. However, EAAT3/EAAC1 expression was proposed to occur in some astrocytes and even oligodendrocytes, but such glial expression is considered as exceptional and limited.

Genetic approaches have been used following biochemical characterization of the transporters. Five different genes related to the solute carrier family 1 (SLC1) genes have been identified in humans. For example, the human EAAT2 gene is localized on chromosome 11p13–12 and consists of approximately 100 kb of DNA. The gene contains 11 exons. At least three different splice variants of the EAAT2/GLT-1 protein are issued from the reading of the sequence as the result of alternative splicing. In this respect, it has been shown that in an animal model of amyotrophic lateral sclerosis (ALS) exhibiting a mutation in the superoxide dismutase 1 (SOD1) gene associated with some forms of the human disease, the expression of five different splice variants of EAAT2/GLT-1 is affected.

Regarding the neuronal transporters, very little is known about EAAT4 and -5. The contribution of EAAT3/EAAC1 to glutamatergic transmission is still under investigation. Briefly, its postsynaptic localization and early expression in the fetus suggest a contribution to brain development. Because of its apparent capacity to also contribute to neuronal uptake of

Figure 1 Main features of a brain synapse using excitatory amino acids as neurotransmitter. The neurotransmitter glutamate (Glu) is released from nerve terminals by an active process. In the synaptic space, Glu acts on receptors of both ionotropic (iGluR) and metabotropic (mGluR) subtypes. The termination of Glu action is assumed by quick removal from synaptic space either by the neuronal EAAT3/EAAC1 transporter, primarily located on the postsynaptic membrane, or by astrocytic EAAT1/GLAST and EAAT2/GLT-1 transporters. The question of the presence of a presynaptic Glu transporter is still a matter of debate. The diagram also shows the ion dependence of Glu transport into cells through transporter systems and the destination of Glu in the astrocytes. Glu is first subjected to transformation into glutamine, which acts as a Glu precursor when transported into the neuron (referred as the Glu–glutamine cycle). Glu is also transformed into glutathione, which constitutes one of the main antioxidative defenses of astrocytes. In fact, glutathione is even more dependent on Glu since Glu is also involved in the uptake of cystine through the transporter Xc-, which also acts as a precursor for glutathione. Newly synthesized Glu from glucose also contributes to neurotransmitter biosynthesis. The electrochemical gradient is maintained by Na^+/K^+ ATPase.

cysteine, which acts as a key substrate for the synthesis of glutathione, such a transporter may contribute to neuroprotective mechanisms against oxidative stress. Interestingly, numerous regulatory mechanisms involving both extracellular signals and intracellular signaling cascades have been evidenced, thus suggesting that the fine tuning of EAA neuronal uptake is a highly regulated process, which influences glutamatergic excitatory transmission.

EAA Transport Shows Selective Ion Dependence

One of the main characteristics of the transport involving members of the SLC1 gene family is the dependence of the transport of extracellular sodium concentration. The electrogenicity of the transport of Glu was first demonstrated approximately 30 years ago using brain synaptosomes, although in such a preparation the contribution of each selective ion was not easy to establish. Data from studies using cell expression of the cloned transporters and patch clamp analysis have identified the precise stoichiometry of the transport. For each Glu molecule transported into the cell, the transport involves two or three sodium ions (Na^+) and one hydrogen (H^+) ion entering the cell together with the molecule of Glu, in exchange for one potassium (K^+) ion. A sodium-activated chloride (Cl^-) conductance is also mediated through EAATs, but such a conductance is

not thermodynamically linked to Glu translocation into the cell. Site-directed mutagenesis has been used to identify amino acid residues related to ion transports associated with EAA translocation, verifying that Cl^- movement is not necessary for EAA transport.

Consequently, it appears that the transport of EAAs into the cells is driven by the electrochemical gradient existing through the membrane. Such a transport is highly efficient to concentrate the neurotransmitter into the cell. The transport is electrogenic, generating a net depolarization of the membrane, which can be measured by using electrophysiological recordings. Detailed analysis of currents produced by the transport has led to the proposal of hypothetic kinetic models which describe the different steps of Glu transport assuming that EAATs behave like sequential exchangers. Differences may be related to variations in the cycle and efficacy in the transport regarding the heterogeneity of the transporters. In this respect, although there are some differences, Glu transport appears to be rather slow since one complete transport cycle is believed to range from 60 to 80 ms.

Molecular Structure and Presumed Topology of EAATs

After purification of the first EAATs was achieved, sodium dodecyl sulfate–polyacrylamide gel electrophoresis demonstrated that these proteins have a tendency to form oligomers. In contrast to the pentameric structure proposed for EAAT3/EAAC1, the glial transporter contributing to the maturation of the pore was proposed to involve a trimeric structure. Such a proposal was verified by the crystallization of bacterial homologs of the SLC1 Glu transporters. The Glu transporters in eukaryotic cells are in fact members of a more general membrane transport protein family also involving prokaryotic transporters. Both types of proteins share a high degree of amino acid homology, similar substrate transport ionic specificity, and close transmembrane topology. The crystallized transporter from *Pyrococcus horikoshii* (Glt_{Ph}) shows a 37% sequence identity with the human EAAT2/GLT-1. In agreement with the previously proposed multimeric structure, which emphasized that trimers and dimers predominate, in the presence of Glu the Glt_{Ph} transporter appears to consist of three functional units, also in agreement with previous results obtained from the purification of Glu transporters from *Bacillus caldotenax* and *Bacillus stearothermophilus*.

The high-resolution topology of each subunit, however, remains to be clarified. Although two main models have been proposed based on studies using site-directed-mutagenesis, the controversy persists. The latest developments suggest that the protein, which exhibits intracellular localization of N- and C-terminals, consists of six transmembrane (TM) domains thought to be organized as α-helices, followed by two reentrant loops corresponding to hairpin loops in the proximity of the C-terminal part of the protein (Figure 2). Regarding GLT-1 topology, several amino acid residues have been shown to be critical for Glu transport, for example, at the levels of the two hairpin loops. The protein can be glycosylated in the large extracellular hydrophilic loops between TM3 and TM4 (two sites) and shows putative consensus phosphorylation sites in its intracellular part, suggesting the possibility of posttraductional regulation of activity. Furthermore, because of interactions between the transporters and proteins located in the immediate vicinity, there is a strong possibility that such partners contribute to intracellular trafficking to and from the plasma membrane. Regarding EAAT2/GLT-1, the transporter was shown, for example, to interact at its N-terminal ending with a protein of the LIM family Ajuba, which may be involved in regulation of intracellular signaling cascades or acting on the cytoskeleton. Similarly, the C-terminal part of the EAAT1/GLAST protein may be preferentially linked to the protein septine 2, a member of the GTPase family, and such an interaction may be involved in the intracellular trafficking of the transporter and, specifically, its presence at the membrane. Finally, because depletion of membrane cholesterol by methyl-β-cyclodextrin induced primarily marked reduction of glial Glu uptake in primary cortical cultures, it has been proposed that the Glu transporters, including EAAT3/EAAC1 but especially EAAT2/GLT-1, are associated with cholesterol-enriched lipid raft microdomains, and that such a localization is important for function.

Glial EAATs Are a Target for Drugs: Toward a New Molecular Pharmacology?

Because of high structural homology, it is difficult to selectively act on the different transporter subtypes. The initial generation of compounds that inhibit EAA transport of Glu focused on competitive substrates such as pyrrolidine decarboxylate (PDC) derivatives, which induce an efflux of endogenous Glu due to heteroexchange. Further development of nontransportable compounds, such as DL-TBOA or dihydrokainic acid (DHK), contributed to a more precise identification of transporter properties. DHK is one of the most interesting compounds because of its rather selective binding to EAAT2/GLT-1 but not to EAAT1/GLAST or EAAT3/EAAC1. However, it has the major drawback of also binding to the kainic acid EAA receptor subtype. Conversely, the serine derivative serine-O-sulfate was proposed to inhibit preferentially

EAAT1/ GLAST and EAAT3/EAAC1, and L-β-benzylaspartate was shown to act as a preferential inhibitor of EAAT3/EAAC1 compared to glial transporters.

The Brain Regional Distribution of EAATs Is Uneven and Their Expression Is Developmentally Regulated

In addition to brain expression, mRNA encoding EAAT1/GLAST and, more frequently, EAAT2/GLT-1, has been detected in the heart, kidney, pancreas, bone cells, and mammary glands. However, the functional role of such tissue expression is not completely understood. In the brain, since the demonstration that most Glu uptake activity is attributable to the glial transporters, the key role of astrocytes in EAA transport has been emphasized because EAAT1/GLAST and EAAT2/GLT-1 proteins are selectively expressed by these glial cell subtypes in the adult. Some ependymal cells and neurons in the retina, however, have also been shown to express these transporters. Thus, the debate is still open regarding especially EAAT2/GLT-1 since mRNA cellular localization has been described to occur not only in astrocytes but also in neurons from the adult brain in hippocampus and cortical areas. Moreover, transient EAAT2/GLT-1 expression has been reported in Purkinje cells or in neurons in the spinal cord during development. This is apparently not the case in rat cortical primary neuronal cultures: Astrocytes selectively express EAAT1/GLAST and EAAT2/GLT-1, whereas EAAT3/EAAC1 is expressed in the neurons (Figure 3). Finally, a truncated variant of the EAAT2/GLT-1 protein cloned from mouse liver (GLT-1v) is possibly expressed in astrocytes and certain neurons. However, the level of such neuronal expression of EAAT2/GLT-1 is low, and there is a consensus that EAAT2/GLT-1 expression is generally restricted to astrocytes in the adult brain.

The regional brain distribution of EAAT glial transporters is uneven, in contrast to that for EAAT3/EAAC1. In the rat brain, EAAT1/GLAST is primarily expressed in the cerebellum. The olfactory bulb, hippocampus, and striatal and cortical areas also express the transporter. Moreover, the distribution of the transporter is not restricted to brain areas; the EAAT1/GLAST is also present in the inner ear, for example. EAAT1/GLAST expression is restricted to

Figure 3 Cell selectivity and developmental profile of the expression of different EAATs in rat primary cortical cultures. Confocal double-labeling immunocytochemistry was used to study the localization of the three main EAA transporter proteins to neurons identified by neuronal neurofilament (NF) labeling or to astrocytes labeled by the glial fibrillary acidic protein (GFAP). (a–c) Data from cortical cultures on day *in vitro* (DIV) 7 treated for double labeling using GFAP or NF antibodies, which are combined on the same preparation with antibodies EAAT3/EAAC1 (a), EAAT1/GLAST (b), and EAAT2/GLT-1 (c), respectively. Data from similar experiments performed on DIV 14 (d–f) confirmed the selective neuronal expression of EAAT3/EAAC1 and astrocytic expression of EAAT1/GLAST and EAAT2/GLT-1. Interestingly, the expression of EAAT2/GLT-1 was only detected at DIV 14, in agreement with data from *in vivo* experiments showing delayed expression of the transporter. Reproduced from Guillet B, Lortet S, Masmejean F, Samuel D, Nieoullon A, and Pisano P (2002) Developmental expression and activity of high affinity glutamate transporters in rat cortical primary cultures. *Neurochemistry International* 40: 661–671, with permission from Elsevier.

astrocytes and Muller cells in the retina. Developmental analysis *in vivo* shows a progressive increase in EAAT1/GLAST expression from birth to adulthood. Conversely, in the newborn rodent EAAT2/GLT-1 brain expression is undetectable, whereas EAAT1/GLAST is present. Thus, the expression of both transporters increases dramatically with synaptogenesis during the first month after birth, which supports the proposal for the essential contribution of EAA to brain maturation. Interestingly, the expression of EAAT1/GLAST in cortical primary cultures occurs in the early stages of the cultures *in vitro* (day *in vitro* (DIV) 3), whereas EAAT2/GLT-1 expression in similar conditions occurs later (DIV 10). In such an experimental model, EAAT3/EAAC1 expression occurs as early as DIV 1. EAAT2/GLT-1 is actually the major EAAT expressed in the forebrain, especially in cortical areas, hippocampus, and striatal areas. However, the transporter is expressed at significant levels in the entire brain. EAAT2/GLT-1 is also present in the retina, where it is expressed in photoreceptor cells and in some bipolar ganglionic neurons. As mentioned previously, brain EAAT2/GLT-1 is expressed at very low levels at birth, and it progressively increases during the second week of life and reaches the adult level after approximately 1 month, in agreement with what is observed in primary cultures. The same astrocytes were shown to be able to simultaneously express EAAT1/GLAST and EAAT2/GLT-1.
