Finally, regarding the subcellular localization of the glial transporters in astrocytes, basal expression is preferentially membranar (70%). The density of the proteins is also thought to be higher in the vicinity of glutamatergic synapses. However, this changes with stimulation or pharmacological manipulation, thus showing dynamic regulation of trafficking of the transporters.

Glial EAATs Are Essential Actors of the Excitatory Synapse: Evidence for Multiple Functional Implications

Importance of Glu Transport in Maintaining Synaptic Glu Concentration within Physiological Limits

As mentioned previously, glial EAATs are major contributors to the removal of EAAs and especially Glu from the synaptic space. The relative contribution of the different transporters to Glu uptake was examined *in vivo* using specific antisense oligonucleotides administered in the rat brain to transiently block the expression of the transporter subtypes. Data showed that the extracellular concentration of Glu is highly increased in selected brain structures (hippocampus and striatum). Comparative studies found that EAAT1/GLAST and especially EAAT2/GLT-1 are the major actors of Glu uptake, contributing approximately 80% of EAA uptake in the striatum and 60% in the hippocampus, although the resulting increase in extracellular Glu could be due to cytotoxic effects related to elevated Glu and subsequent excitotoxicity.

Glu transport is believed to be primarily involved in regulating excitatory transmission. Because of the desensitization properties of EAA receptors involved in fast signaling, the rapid removal of the neurotransmitter from the synapse is an essential step of neurotransmission to ensure the functionality of intercellular communication. Interestingly, Glu uptake is thought to also play a key role in limiting the spillover of the excitatory transmitter to EAA receptors located at a distance from the releasing site. Two hypotheses have been proposed. First, limiting the spillover of Glu could contribute to limit activation of receptors of the NMDA subtype present at neighboring synapses and thus to focus excitatory transmission, which may only involve active synapses and not neighboring, so-called 'silent synapses.' Second, because extrasynaptic NMDA activity would presumably contribute to cytotoxicity and neuronal death in contrast to synaptic NMDA receptors, limiting Glu spillover through primary EAA glial uptake could be neuroprotective. In this respect, *in vivo* experiments in the rat using antisense oligonucleotides administered in the brain with miniosmotic pumps showed that the loss of the glial transporters EAAT1/GLAST and EAAT2/GLT-1 produced neurodegeneration in the striatum or hippocampus similar to that observed in excitotoxicity. The progressive motor deficit observed in the treated animals was considered to be the consequence of neuronal cytotoxicity.

However, it has to be taken into account that the lack of glial Glu uptake could have differential effects in the brain regarding regional brain differences in neuronal–astroglial relationships. For example, in the cerebellar cortex, the excitatory synapses on Purkinje cells are closely surrounded by Bergmann glia. Thus, glial processes are in a position to efficiently limit Glu extracellular synaptic diffusion and receptor influence. In contrast, this is not the case at the cortical level and in the hippocampus since very few synapses are entirely surrounded by astrocytes. Consequently, limiting Glu uptake will influence EAA transmission in these brain structures less than in the cerebellar cortex, further suggesting that following synaptic release Glu can rapidly diffuse out of the synaptic cleft and act at a distance.

Glial EAATs Provide Neurons with Glu

Glu uptake into astrocytes provides a major contribution to the so-called 'Glu–glutamine cycle' (Figure 1). Numerous data indicate that Glu released in the synaptic space is taken up by surrounding astrocytes and subsequently transformed in glutamine by glutamine synthetase. The astrocytes release glutamine into the extracellular space, and glutamine is secondarily taken up by excitatory nerve terminals. In the nerve terminals, glutamine is transformed in Glu by the enzyme glutaminase phosphate, which contributes to increase the cytosolic and vesicular pool of the neurotransmitter. Approximately 30% of total Glu entering astrocytes is subjected to oxidative processes and 70% contributes to the Glu–glutamine cycle, which indicates that biosynthesis of Glu continuously occurs in the neurons, supplying nerve terminals with sufficient neurotransmitter. Interestingly, glutamine is not selectively taken up by excitatory terminals: Inhibitory GABA-containing neurons can also take up glutamine. In the inhibitory nerve terminals, glutamine is metabolized into Glu, which represents a metabolic precursor of GABA synthesized from Glu by glutamate decarboxylase. Thus, through the contribution of glial EAATs, the Glu–glutamine cycle contributes to biosynthesis of both the excitatory neurotransmitter Glu and the inhibitory transmitter GABA.

EAA Glial Transporters as Active Contributors to Energetic and Metabolic Processes in Astrocytes and Neurons

It is worth discussing another possible major destination of Glu taken up into astrocytes through glial EAATs. Glu transformed into α-cetoglutarate can be considered as an energetic substrate for the cell. Multiple transamination and oxidative deamination processes contribute to the production of this energetic substrate from Glu. Thus, when necessary, pyruvate produced in the astrocytes can be transferred as lactate to neurons through monocarboxylate transporters and used as pyruvate again in the tricarboxylic acid cycle as an energy source for the cell. The increase in glial Glu uptake occurs concurrently with glucose uptake and consumption and an increase in lactate release, which supports the concept of a net increase in Glu biosynthesis from glucose in astrocytes and increased metabolism when Glu uptake is activated. Lactate provides the energy to the cells. Glu uptake activates the Na^+/K^+-ATPase α_2 subunit, which is specifically expressed in the astrocytes. This mechanism has been suggested to contribute to coupling excitatory neuronal transmission to an increase in astrocytic glucose metabolism. Such a mechanism emphasizes the contribution of glial EAATs to results obtained with functional brain imaging methods (functional magnetic resonance imaging or positron emission tomography). The metabolic response to sensory stimuli is reduced in transgenic mice in which the expression of EAAT1/GLAST or EAAT2/GLT-1 is suppressed or following reduced expression of EAAT1/GLAST using antisense oligonucleotides.

The Glial EAATs as Key Actors for Antioxidative Defenses in Astrocytes

The glial EAATs may contribute to antioxidative defenses in astrocytes. Glu acts as a metabolic precursor of glutathione (GSH), the major neuroprotective agent against the deleterious action of reactive oxygen species (ROS). Glu is metabolized into γ-glutamylcysteine and then into GSH by selective enzymes. Interestingly, the contribution of Glu to GSH biosynthesis is also indirect since Glu is involved in the incorporation of cystine into the astrocytes from outside through the Xc- transport system. The incorporation of cystine provides astrocytes with cysteine used to synthesize GSH. In such a transport system, incorporation of cystine is associated with an efflux of Glu. Consequently, a decreased concentration of Glu in astrocytes may significantly effect the antioxidative defenses of the cell. This occurs when the transport of EAA is pharmacologically blocked: In cell cultures, we measured a progressive and massive death of astrocytes in the presence of PDC, which was correlated with increased production of ROS and further depletion in GSH. We verified that the death of astrocytes in the presence of PDC is neither due to excitotoxicity nor due to oxidative properties of Glu because increasing extracellular Glu concentrations, for example, is protective. Moreover, *N*-acetylcysteine was also shown to exert a protective action against PDC, which further supports the hypothesis that the key contribution of Glu transport into astrocytes is to antioxidative defenses through GSH production.

Further Evidence for an Essential Contribution of Glial EAATs to Brain Homeostasis

Evidences for a functional role of glial EAATs has been obtained from mutations inducing loss of function of the transporters. Mice lacking expression of the Glu transporter EAAT2/GLT-1 showed marked neurodegeneration in the hippocampus and spontaneous seizures. These mice generally died within 6 weeks after birth, further suggesting that such a glial transporter has a key role in controlling excitatory synaptic activity and EAA-induced cytotoxicity. The phenotype resulting from mutation of EAAT1/GLAST showed impaired

motor coordination and increased susceptibility to cerebellar injury, illustrating the importance of the transporter in cerebellar physiology, at least in mice. These experiments emphasize the major contribution to brain functioning of EAAT2/GLT-1 compared to EAAT1/GLAST or EAAT3/EAAC1. Furthermore, in the SOD1 mutant mouse developed as an animal model of some forms of ALS, in which different splice variants of EAAT2/GLT-1 are affected, histological analysis showed alterations in astrocytes concomitant with progressive hind limb paralysis and animal death.

Does Inversion of Glu Uptake Represent a Physiological Process Contributing to Regulation of Excitatory Transmission?

Since not only neurons but also astrocytes exhibit vesicles that contain neurotransmitter and can apparently contribute to exocytosis, the previous observations raise the question of the possible contribution to physiological processes of Glu released by the glial cells. The actual contribution of astrocytes to exocytosis is still under investigation. However, there is another way to obtain an increase in extracellular Glu from these cells. Depending on the electrochemical gradient across the membrane, the transport of Glu into astrocytes can be reversed. Although such a process was primarily assumed to be involved in pathological conditions, there is also evidence that this occurs in physiological conditions in intact cells. The transmembrane gradient of amino acids may be the driving force of the transport, and the reversion of the transport likely results from weakening of such a driving force. The reversed transport in this situation is independent of both ATP and Ca^{2+} ions, and it contributes to increasing extracellular EAA levels, further reinforcing the neurotransmitter action on synaptic receptors and excitatory synaptic signaling when necessary. However, the reversion of Glu transport may be more frequently relevant in pathological conditions.

EAA Transport in Glial Cells Is a Highly Regulated Cellular Process

Fine-Tuning of Glu Uptake Rate at the Excitatory EAA Synapse

In the early 1980s, our laboratory developed the concept of a possible short-term regulation of Glu uptake rate with regard to changes in neuronal activity. Such a concept of activity-dependent regulation of neurotransmitter uptake rate was further extended since modulations of Glu uptake have been shown in the rat, for example, in relation to stress or even estrous cycle. Numerous studies have supported the proposal for a fine-tuning of EAA transport, especially in astrocytes. Regarding EAAT1/GLAST and EAAT2/GLT-1, numerous data have been obtained suggesting regulatory processes which involve both transcriptional and posttraductional mechanisms. This latter hypothesis was also supported by experiments from our group showing that Glu uptake may be modulated in response to activation of neurotransmitter receptors. Furthermore, numerous trophic factors have been shown to increase Glu uptake. Arachidonic acid, NO (indirect action through cytokines production), Zn^{2+} ions, as well as pharmacological activation or inhibition of various protein kinases were conversely shown to decrease Glu uptake rate, supporting the concept of posttraductional regulation of the activity of transporter molecules. Such a concept was further supported by the demonstration that EAATs exhibit putative consensus phosphorylation sites in their molecular structure. Finally, it is worth mentioning the special role of oxidative conditions in altering Glu transport. Oxidative conditions severely decrease transporter activity, possibly through oxidization of the cysteine residues of EAAT1/GLAST and EAAT2/GLT-1. This occurs in the presence of ROS in the cells, further emphasizing the deleterious role of oxidative processes on the functionality of the transporter molecules in addition to the action of cell integrity.

Regulation of Cell Expression of Glial EAATs

In addition to evidence for the regulation of Glu transport rate, numerous experiments have also shown that EAA transport can be influenced at the transcriptional level. Astrocytes in culture provided a useful model to assess such regulatory influence on EAAT expression. Data have shown, for example, that EAAT2/GLT-1 expression is induced by various trophic factors, such as epidermal growth factor, transforming growth factor-α, fibroblast growth factor-2, platelet-derived growth factor, or even brain-derived neurotrophic factor, suggesting a contribution of tyrosine kinase pathways. Interestingly, insulin-like growth factor-2 was evidenced to maintain cellular EAAT1/GLAST and EAAT2/GLT-1 expression. Transcriptional effects on EAAT genes thus primarily involve protein kinase (PK) activation. For example, in the HEK293 cell line, increasing PKC activity induced a decreased expression of EAAT1/GLAST. Conversely, activation of PKC in HeLa cells induced an increase in EAAT2/GLT-1 expression; in this case, the authors originally demonstrated that the transcriptional effect was due to direct phosphorylation of the transporter. Co-culturing astrocytes together with neurons also increased the expression of the two glial transporters. Different mechanisms have been proposed to explain such

a neuronal influence on astrocytes, possibly involving cAMP, CREB transcription factor, MAP/Erk kinase signaling pathway, or pituitary adenylate cyclase-activating peptide.

Additional Regulatory Processes of Glial EAATs Acting on Intracellular Trafficking of the Transporter Protein and Membrane Stabilization

A recent view of the processes involved in the regulation of EAA transport is related to changes in the trafficking and stabilization of the transporter proteins at the membrane from intracellular stores. Such a mechanism is well documented for the neuronal transporter EAAT3/EAAC1, which is subjected to numerous influences. For example, PKC activation facilitates the association of the transporter with the αPKC subunit, which contributes to stabilization of the transporter at the membrane. Biotinylation and immunoblotting experiments show similar processes for the glial transporters. Interestingly, EAAT1/GLAST and EAAT2/GLT-1 are differentially regulated but possibly expressed in the same astrocyte. For example, inhibition of PKA activity using the compound H89 or stimulation of PKC using PMA both resulted in decreased EAAT1/GLAST at the astrocytic membrane, whereas wortmannin acting as a specific inhibitor of PI3 kinase produced the opposite response. Conversely, H89 induced an increase in EAAT2/GLT-1 at the membrane, and PMA and wortmannin produced the opposite effect. These results illustrate differential posttraductional regulation of the two transporters. Interestingly, assuming that increasing the presence of the transporter at the membrane correlates with increased EAA uptake activity, in our experimental model *in vitro* (primary cultures from rat cerebral cortex) PI3K inhibition using wortmannin is only active to reduce the uptake process at 14 DIV, when EAAT2/GLT-1 is fully active. At 7 DIV, wortmannin is inactive but EAAT2/GLT-1 is not yet expressed by the astrocytes.

The molecular mechanisms by which the different PKs contribute to transporter trafficking, membrane stabilization, and cytosolic sequestration remain obscure. As in the case of EAAT3/EAAC1, regulatory cytosolic proteins may be involved. Since the protein septin 2 acting as a GTPase has been shown to interact with the C-terminal part of the EAAT1/GLAST protein, septin 2 may represent one of the cytosolic regulatory factors for stabilization of the transporter at the membrane and activation of astroglial Glu uptake rate. Similarly, the protein LIM associated with the N-terminal part of EAAT2/GLT1 may contribute to changes in its intracellular trafficking.

In summary, the concept of fine tuning the uptake of EAAs to further regulate extracellular concentrations of the neurotransmitter with regard to nerve activity is well documented. Regulatory processes involve both transcriptional and posttraductional mechanisms and have been demonstrated to influence Glu uptake rate. Interestingly, the activity of the excitatory neurons may be a critical factor for regulatory processes. Such a proposal is further reinforced by the fact that treatment of cell cultures with high concentrations of NMDA to activate Glu transmission downregulates EAAT2/GLT-1 expression but upregulates EAAT1/GLAST expression, further illustrating differential regulatory mechanisms for both transporters. Conversely, low extracellular concentration of Glu increases EAAT2/GLT-1 expression in astrocytic cultures. Possible EAAT2/GLT-1 expression in neurons has also been reported, but because the uptake process is not sensitive to DHK, it is likely that the transporter is inactive or represents an inactive variant of EAAT2/GLT-1.

Glial EAATs Are Likely Involved in Neurodegenerative Diseases

Numerous observations primarily from animal models have implicated alterations of Glu transport in various brain diseases (Table 1). EAAs have been associated with acute brain lesions related to stroke (ischemic, anoxic, and traumatic events) and to the so-called functional diseases involving an excess of excitatory transmission, such as different states of epilepsy or, possibly, some forms of schizophrenia. EAAs have also been proposed to be involved in numerous neurodegenerative diseases, such as Huntington's disease, Parkinson's disease, or even Alzheimer's disease, although direct evidence for the contribution of EAAs is generally lacking, except for ALS. The involvement of EAAs in brain pathological events has also been proposed in HIV-associated dementia, malignant glioma, or hepatic encephalopathy due to an increased level of ammonia in the brain since decreased expression of EAAT2/GLT-1 has been reported.

Putative Contribution of EAAT2/GLT-1 to ALS

Approximately 10 years ago, a selective loss of EAAT2/GLT-1 isoforms in motor and sensory cortical areas and concomitant decreased Glu transport activity in patients suffering sporadic ALS was shown. Aberrant splicing of the EAAT2/GLT-1 transcript, and also vulnerability of the protein to oxidative stress, was suggested to be the cause of decreased EAAT2/GLT-1 expression/activity. Furthermore, a mutation which substitutes an asparagine for a serine at position 206 in the EAAT2/GLT-1 gene (mutation N206S) was reported in sporadic ALS. Because this

Table 1 Putative implication of excitatory amino acid transporters and brain pathologies highlighted from experimental approaches

Disease	*Experimental model*	*Transporter subtype*	*Resulting phenotype*
ALS	SOD1 mutants	EAAT2/GLT-1 reduced	Progressive hind limb paralysis and death
	EAAT2/GLT-1 antisense strategy in rat	EAAT2/GLT-1 reduced	Progressive motor neuron loss and hind limb paralysis
Alzheimer's disease	Mutant APP over expression in mice	EAAT1/GLAST and EAAT2/GLT-1 protein reduced (mRNA levels normals)	Amyloid plaque formation; behavioral changes
	Cultured rat astrocytes	Peptide β-amyloid reversal of Glu uptake	
Parkinson's disease	Nigro-striatal dopamine denervation in rat	L-DOPA induced increase in striatal EAAT2/GLT-1 protein	
	Striatal dopamine denervation	EAAT1/GLAST and EAAT2/GLT-1 striatal reduction	
Huntington's disease	Expression of mutant huntingtin	Reduction of EAAT2/GLT-1 mRNA and striatal protein	
Epilepsy	EAAT2/GLT-1 knockout mice	EAAT2/GLT-1 protein reduced	Seizures and death at 6 weeks
	EAAT1/GLAST knockout mice	EAAT1/GLAST protein reduced	Increased sensitivity to convulsive agents
	EAAT3/EAAC1 antisense strategy	Reduced EAAT3/EAAC1 and GABA	EEG episodes with seizures
Stroke	Seven-day-old-rat hypoxia–ischemia (cortex; hippocampus)	All the three main transporters decreased at 12 h	
	Hippocampal slices from EAAT2/GLT-1 knockout mice	Reduced Glu uptake but no reversal related to EAAT2/GLT-1	
	Rat MCA occlusion	Decreased EAAT2/GLT-1 and EAAT3/EEAC1	Contralateral hemiparesis Contralateral hemiparesis
	Rat MCA occlusion	EAAT1/GLAST increased	
	Rat MCA occlusion with antisense strategy to EAAT1/GLAST and EAAT2/GLT-1	The two transporter proteins are reduced	45% increase in stroke volume and increased mortality
	Hypoxic neonatal pig	EAAT2/GLT-1 and EAAT3/EAAC1 reduced at 24 h (striatum)

mutation was demonstrated to alter Glu transport, it appeared that the excess of Glu in the extracellular space along with clearance deficiency of the neurotransmitter contributed to excitotoxicity and induced the death of motor neurons. The supranormal levels of Glu measured in the blood and possibly in cerebrospinal fluid from patients may be indicative of changes in EAA metabolism in ALS. The putative contribution of EAAs to neuronal death in ALS was further emphasized by the positive effect of the antiglutamatergic compound riluzole, which was shown to slow the rate of the disease.

The case of ALS pointed to the possible contribution of the EAAT system, and endogenous Glu, to the neurodegenerative processes. Because of the main glial expression of such transporters, results from ALS patients also emphasize the possible contribution of glial cells and especially astrocytes to motor neuron degeneration. Finally, the modest but real clinical effects of riluzole in ALS also point to the glutamatergic synapse as a possible target for development of further neuroprotective strategies. In the SOD1 mutant mice in which the function of EAAT2/GLT-1 is highly reduced, damaged astrocytes are detected in the spinal cord. Such astrocytic alteration is concomitant with motor neuron degeneration, which supports impaired locomotion. In this respect, as mentioned previously, increasing extracellular Glu levels using chronically implanted osmotic minipumps for local injections of the EAAT inhibitor PDC *in vivo* resulted in a loss of striatal neurons and astrocytes in the rat. The critical role of EAATs in neurodegeneration was also evidenced in the pioneer experiments of Rothstein and group, who elegantly showed that decreasing glial EAAT expression using antisense oligonucleotides in the rat resulted in elevated extracellular Glu levels, neurodegeneration, and progressive paralysis. As also mentioned previously, contribution of glial EAATs to

brain pathology was obtained from transgenic mice lacking expression of the transporters showing impaired motor coordination, cerebellar alterations, and spontaneous seizures depending on the transporter expressed. Interestingly, the decreased antioxidative defenses in astrocytes subjected to Glu depletion would explain the death of astrocytes. Therefore, such a hypothesis may be proposed for ALS in humans and for neurodegenerative processes in the SOD1 mutant mice. If such a hypothesis is correct, the death of motor neurons may therefore be secondary to lack of Glu transport in astrocytes and subsequent excitotoxicity.

Do the Glial EAATs Contribute to Alzheimer's Disease?

With the exception of ALS, the contribution of EAATs in other neurodegenerative diseases is not so evident. In Alzheimer's disease, it is generally accepted that the level of EAATs is normal, although specific reductions of EAAT2/GLT-1 have been reported in frontal cortex. However, abnormal neuronal expression of the two glial transporters has also been reported, notably in neurons concerned with tau protein accumulation. Interestingly, *in vitro* experiments have shown an inhibitory effect of the β-amyloid peptide on Glu transport, further indicating that in Alzheimer's disease the pathological process can contribute to neuronal death through impaired EAA transport. Consequently, the negative influence of the β-amyloid peptide on Glu transport may be viewed as initiating a 'cytotoxic cascade' which may be amplified by direct overstimulation of EAA receptors mediating neuronal death. The associated Glu astrocytic depletion, which may therefore decrease oxidative defenses of the cell, is then thought to induce astrocyte death and secondarily contribute to increase extracellular Glu concentrations since astrocytes cannot proceed to EAA uptake. However, such a hypothesis remains to be documented, and the contribution of EAAs to pathological processes in Alzheimer's disease has not been proved.

Brain Ischemia and Anoxia: Does Reversal of EAATs Represent One of the Key Steps of Degenerative Processes?

The involvement of EAATs in brain pathology may be related to a decreased uptake rate, decreased transporter tissue expression and/or altered trafficking of transporter proteins, and their putative implication in the transport of cytotoxic substances and also in the reversal of the transport direction, which likely contributes to increase extracellular Glu levels and decrease Glu astrocytic contents. EAA neuronal toxicity in severe ischemia is generally accepted to result from reversal of EAATs, especially the neuronal transporter EAAT3/EAAC1. However, the implication of the glial transporters is also evident since the driving force of transport is related primarily to the electrochemical gradient of ions associated with the uptake process in general. For example, the increase in extracellular Glu in experimental anoxic conditions is highly sensitive to DHK, suggesting a major contribution from EAAT2/GLT-1. Transient or more permanent disruptions of such a gradient in the case of deficient energy supply, as observed in ischemia or anoxia processes, will decrease EAA uptake and induce reversed Glu transport. Indeed, ATP depletion will result in rapid Na^+/K^+ ATPase loss of activity and reversal of the Na^+/K^+ gradient. The contribution of neurons to the increased extracellular Glu is related to their high content in the neurotransmitter compared to astrocytes, but depleting intracellular Glu stores in astrocytes is likely to induce a rapid decrease in GSH levels, thus reducing the antioxidative defenses of the cells. In this respect, in the ischemic area, cell death involves both neurons and glial cells as shown in many reports. Consequently, pharmacologically blocking the Glu transport to prevent reversal of the transport of Glu without altering uptake capacities may be of therapeutic interest to maintain low extracellular Glu in stroke.

Considerable delayed alterations of the EAATs have been observed in experimental models of ischemia following reestablishment of the blood supply. Although there is great variability due to major differences in animal models and experimental conditions *in vivo* and *in vitro*, the general feature is a decreased expression of most of the transporters, both glial and neuronal, until 72 h following the ischemic procedure. Interestingly, during the postischemic period abnormal neuronal expression of the glial transporters EAAT1/GLAST and EAAT2/GLT-1 as well as overexpression of EAAT1/GLAST have been reported in the region surrounding the ischemic areas, further supporting the idea that EAATs are involved either in long-lasting neurodegenerative processes following brain ischemia or in compensatory protective mechanisms that limit cellular damage.

Conclusion

Although direct evidence is lacking, numerous data from experimental models point to the contribution of EAAs to pathophysiological processes in several neurological and psychiatric disorders. However, the concept of the possible involvement of EAATs in such pathological processes is quite recent; for years, the involvement of EAAs was focused on excitotoxicity and the EAA receptors. Of course, excitotoxicity can

represent one of the final steps of neuronal death, but astrocytes are generally reported to be insensitive or less sensitive than neurons to excitotoxicity. Thus, the contribution to EAATs to degenerative processes in general is not restricted to simple impaired uptake into either neurons or glial cells. The dependence of astroglial cell survival on maintenance of sufficient intracellular Glu levels illustrates the key contribution of EAATs. Defective transport results in GSH depletion and increased susceptibility to oxidative stress, likely resulting in astrocytic death. Stimulating Glu uptake may therefore be a way to protect the neurons. Finally, because of the dependence of EAA transport on the electrochemical gradient, impaired energy results in reversal of the transport, which consequently can increase both excitotoxicity and astrocyte depletion in Glu. Therefore, the conservation of functional glial EAATs could contribute to neuroprotection. In this respect, developing new compounds aimed at keeping such EAATs active may be a useful strategy in the case of neurodegenerative diseases. Experiments in progress will contribute to developing this concept.

Molecular Diversity and Expression Patterns

The mammalian glutamate transporter gene family has five excitatory amino acid transporter (EAAT) members (*EAAT1–EAAT5*) that are expressed in the brain in highly specific regional and cell-type patterns (see Table 1). In some cases, transporter transcripts undergo alternative splicing, adding further complexity to these expression patterns. EAAT cDNAs have predicted amino acid sequences of approximately 500–600 residues, and subtypes share between 30% and 65% identity; typically greater than 80% identity is shared when comparing a particular subtype across species. Together with two structurally related neutral amino acid transporter genes (alanine/serine/cysteine transporter genes *ASCT1–ASCT2*), they make up a gene superfamily whose members are structurally distinct from other solute transporters, such as the vesicular glutamate transporters (GLTs) and the family of Na^+/Cl^--dependent neurotransmitter transporters responsible for uptake of GABA, glycine, serotonin, and catecholamines. Distinct EAAT subtypes are found on neurons and glia throughout the brain and spinal cord, and different functional roles are emerging for each. In the central nervous system (CNS), the vast majority of glutamate uptake activity is found on glial cell membranes (predominantly EAAT2/GLT-1 in forebrain and spinal cord, and EAAT1/GLAST in cerebellum). These glial transporters are densely packed in the membrane (up to $8500\,\mu m^{-2}$) and are often found in close apposition to neuronal synapses. Table 1 provides an overview of the nomenclature and expression patterns of the transporters.

Molecular Structure

Glt_{Ph} is an aspartate/glutamate transporter homolog from *Pyroccocus horikoshii* that exhibits approximately 35% identity to mammalian EAATs overall, with higher homology in domains that have been implicated in key functions such as substrate and ion binding. The three-dimensional structure of Glt_{Ph} has been determined by X-ray crystallography, revealing a rather complex trimeric bowl-shaped architecture. Each of the three subunits has eight transmembrane domains with two reentrant helical hairpin loops (HP1 and HP2) that dip into the membrane from opposite sides. Structural as well as functional evidence suggests that each subunit in the trimer binds substrate: in the crystal structure a molecule of bound aspartate is occluded between the tips of the two reentrant loops, with Na^+ ions above and below it. In an apo-state transporter crystallized without bound amino acid, the diffraction pattern reveals that the external reentrant loop (HP2) is swung outward approximately 10 Å, suggesting a possible docking trajectory and structural gating mechanism for the first hemicycle of an alternating access kinetic scheme (see later). In the occluded state, charge pairing between the bound aspartate and residues in the transporter stabilize the complex. A key determinant of substrate selectivity is a conserved arginine residue in transmembrane domain 8 (TMD8) that is coordinated with the distal carboxylate of the transported substrate (Figure 1). In the related ASC transporters, which selectively transport neutral rather than acidic amino acids, a cysteine or threonine residue is found in the analogous position in TMD8. Mutating the neutral residue to arginine in the ASC transporters or making the converse mutation in the EAATs switches the transporters' selectivity correspondingly.

All of the EAATs are stereoselective for L-glutamate, while both enantiomers of aspartate are transported. A number of glutamate and aspartate analogs, including some ring-constrained analogs such as pyrrolidine dicarboxylates (PDCs), are transported by the EAATs. More bulky aromatic analogs such as DL-*threo*-β-benzyloxyaspartate (TBOA) competitively inhibit glutamate transport but are not themselves transported. With the exception of kainate and dihydrokainate, which block EAAT2 with an affinity three to four orders of magnitude higher than the other transporter isoforms, there are no compounds available with which to distinguish the transporter subtypes with a high degree of selectivity *in vivo*.

Thermodynamics of Glutamate Transport

The influx of Na^+ and H^+ and the efflux of K^+ during glutamate uptake result in a net flow of positive charge into the cell that can be recorded and studied with a voltage-clamp circuit. A tight stoichiometric coupling is inferred from the effects of these cations' concentration gradients on the reversal potential of the pharmacologically isolated transport current. The transporter reversal potential (the equilibrium membrane potential at which there is no net transport) follows the predictions of the free energy equation for coupled transport of one glutamate molecule

Table 1 Glutamate transporter nomenclature and expression patterns

Human	*Other*	*IUBMB nomenclature*[a]	*Predominant expression pattern*
EAAT1	GLAST	SLC1A3	Astrocytic; cerebellum (Bergmann glia); retina (Müller cells); inner ear
EAAT2	GLT-1	SLC1A2	Astrocytic (most abundant transporter); brain and spinal cord, low levels in some neuron terminals
EAAT3	EAAC1	SLC1A1	Predominantly neuronal (widely expressed but levels much lower than EAAT1/2); predominant peripheral glutamate transporter
EAAT4	EAAT4	SLC1A4	Neuronal; cerebellum (Purkinje neurons)
EAAT5	EAAT5	SLC1A5	Retina: photoreceptors and bipolar cells, astrocytes (Müller cells)

with one proton and three Na^+ ions and countertransport of one K^+ ion during each uptake cycle. The equilibrium glutamate concentration gradient that can be maintained by stoichiometrically coupling movement of n Na^+, K^+, and H^+ ions is given by rearrangement of the zero-flux equation:

$$(\mathrm{Glu}_o/\mathrm{Glu}_i) = (\mathrm{Na}_i/\mathrm{Na}_o)^{nNa}(\mathrm{H}_i/\mathrm{H}_o)^{nH}(\mathrm{K}_o/\mathrm{K}_i)^{nK} \exp[(n_{\mathrm{Na}} + n_{\mathrm{H}} - n_{\mathrm{Glu}} - n_{\mathrm{K}})VF/RT] \quad [1]$$

where V= membrane potential, F = Faraday's constant, R = gas constant, and T = temperature. For astrocytes and neurons, this value exceeds 10^6; the free energy in the Na^+, K^+, and H^+ electrochemical gradients is sufficient to maintain nanomolar extracellular glutamate concentrations despite millimolar intracellular glutamate concentrations. Estimates of extracellular glutamate concentrations using dialysis probes in brain tissue suggest low micromolar values, but electrophysiological measurements in hippocampus are consistent with ambient glutamate levels below 100 nM. When ionic gradients are impaired, with elevated extracellular K^+ and intracellular Na^+, as can occur during severe ischemia, transporter reversal and efflux of intracellular glutamate may occur. Another distinct mode of transport, electroneutral glutamate exchange, can occur in the absence of K^+ when Na^+ and glutamate (or another substrate) are present on both sides of the membrane. This exchange can be monitored by measuring the unidirectional flux of radioactivity when radiolabeled substrate is added to one side of the membrane. The glutamate exchange mode can also be induced by mutations in the transporter near the substrate binding site that selectively interfere with K^+ binding (e.g., E404D; GLT-1 numbering).

Mechanism and Kinetics

Mechanistically, the observed transport modes are consistent with high-resolution glutamate transporter structures that appear to represent distinct kinetic states. Together, the structural and functional data suggest that the transporter cycles through three major states: one occluded state (T_{occ}), and two distinct states (T_o and T_i) that provide gated access of substrates to their binding sites from outside or inside the cell, respectively. The structures of the first two of these states have been solved (**Figure 1**) and the existence of the third state (T_i) is only inferred from kinetic data at this point. There is no evidence for a state with outer and inner gates simultaneously open (i.e., an open channel permeable to glutamate). Access for intra- and extracellular substrates appears to occur on a strictly alternating basis, providing a basis for tight thermodynamic coupling of glutamate and cation fluxes. A further tenet of the model supported by functional data is that Na^+ and K^+ binding are mutually exclusive. Na^+ and glutamate binding will occur in a coordinated fashion and their

occupancy precludes binding of a K^+ ion. Conversely, binding of a K^+ ion precludes Na^+ and glutamate binding. Kinetic evidence, primarily from the Na^+ and glutamate concentration-dependence of mammalian EAATs, suggests that binding of two Na^+ ions precedes glutamate binding, followed by the third Na^+ ion. The postulated sequence of events for one thermodynamic cycle (arbitrarily starting with the glutamate hemicycle) is as follows. Glutamate/Na^+/H^+ bind from outside (or inside) to a transporter in state T_o or T_i, respectively, thereby preventing binding of a competing K^+ ion. The two major states, T_o and T_i, are kinetically linked to each other through the occluded state. Unbinding of glutamate/Na^+/H^+ can occur from either state T_o or T_i after transition out of the occluded state; then a competition with K^+ for rebinding occurs. For a complete transport cycle to occur, the first hemicycle is completed when glutamate/Na^+/H^+ are translocated by unbinding from the side opposite to which they bound. A K^+ ion then binds and proceeds back through the same kinetic steps, completing the second hemicycle by its unbinding from the opposite side and restoring the initial state. The free energy change for the cycle is equal to the sum of the free energy changes for the individual ions. All of these kinetic transitions are reversible; the net flow through the states depends only on the transition rate constants, the concentration gradients for Na^+, glutamate, H^+, and K^+, and the membrane potential. The conformational transition of the unliganded transporter between the T_i and T_o states does not appear to proceed at a measurable rate; possibly occupancy by substrate is necessary to stabilize an unfavorable transition state. Overall, the mechanism bears notable similarity to the Na/K pump, with the primary difference being that the vectorial nature of transport in this case is a consequence of electrochemical gradients rather than ATP hydrolysis.

Studies of glutamate transport kinetics have utilized both steady-state and pre-steady-state techniques. The latter include analysis of transient currents following rapid concentration or voltage jumps. In transporters covalently labeled with fluorescent reporter probes, fluorescence changes can also be measured in response to perturbations of voltage or concentration. A prominent capacitive current (or fluorescence change) reflecting charge movements is present in the transporters that is analogous to gating charge movements seen in voltage-gated channels. This charge movement is Na^+ dependent, and it occurs in the absence of glutamate, providing evidence that Na^+ binding occurs prior to glutamate. The transient current or fluorescence change can be described by a Boltzmann function, similar to channel gating charge movements, and in the case of the transient current it can be used to estimate the number of transporters in a cell or patch. Using this approach, the turnover rate of the major glial transporter EAAT2 expressed in *Xenopus* oocytes is approximately $15\,s^{-1}$ at room temperature, or approximately $50\,s^{-1}$ at 37°, because of the transporter's temperature dependence. Because many rates in the transport cycle are voltage dependent, the turnover rate is also accelerated by hyperpolarizing membrane potentials (approximately e-fold per 75 mV in the case of EAAT2). Other techniques used to gain information about microscopic transport kinetics include rapid photo-uncaging or piezo-switched application of glutamate to cells or excised patches containing transporters. In the presence of extracellular Na^+ and intracellular K^+, a glutamate pulse produces a fast inward current that rapidly relaxes to a lower steady-state level (**Figure 2(a)**). This reflects fast glutamate binding ($\sim 10^7 M^{-1} s^{-1}$) and rapid charge movements across the electric field in the early steps of the transport cycle. Using paired concentration jumps applied to excised patches to measure the kinetics of recovery of the transient peak current, EAAT2 turnover rates exceeding $50\,s^{-1}$ have been estimated. This faster turnover (compared with steady-state oocyte measurements) likely reflects the absence of intracellular Na^+ and glutamate, which will slow the transport cycle in oocytes (as well as glia and neurons) because of the aforementioned microscopic kinetics. Even at 20 ms, the transport cycle time is roughly an order of magnitude slower than the estimated synaptic glutamate concentration decay. Nevertheless, the transporters near a release site may still theoretically influence the spatiotemporal profile of glutamate on a very fast timescale because the early steps in the transport cycle allow rapid glutamate capture and the transporters are present at high density

Figure 2 Outside-out patch recordings of glial transporter EAAT2, showing anion channel and glutamate transport kinetic responses to piezo-switched application of saturating (10 mM) glutamate. (a) Response predominantly reflects stoichiometrically coupled currents; (b) reflects anion currents carried by SCN^-. Pipette solution contained K-gluconate; bath contained NaCl (a) or NaSCN (b). Data are from the same patch held at −20 mV; trace above shows solution exchange time course measured following patch rupture.

(10^3–$10^4\,\mu m^{-2}$) on astrocyte membranes. Furthermore, more remote transporters surrounding synaptic release sites can play roles in restricting the heterosynaptic spillover of glutamate that occurs on a slower timescale (see later).

Chloride Channel Function

The aforementioned fluxes of stoichiometrically coupled ions through the transporter are not the only charge movements mediated by EAATs; chloride flux through the transporters also occurs. This was first suggested by the presence of a chloride current associated with activation of the native glutamate transporters in retinal neurons, and it has subsequently been demonstrated to occur with EAATs exogenously expressed in many different cell systems. Interestingly, this channel function can play roles in synaptic signaling that are entirely distinct from the effects of uptake on glutamate dynamics. Glutamate transporters (predominantly EAAT5) on the presynaptic terminals of rod bipolar cells mediate inhibitory signaling that serves to modulate the release of transmitter in a negative feedback loop. Several lines of evidence suggest that a chloride channel is intrinsic to all glutamate transporters. Mutation of residues clustered in TMD2 leads to discrete changes in anion selectivity. In addition, the net current activated by glutamate (reflecting both the stoichiometrically coupled and Cl^- currents) has a distinct reversal potential in each EAAT isoform, suggesting that each has a fixed and unique Cl^- current magnitude relative to the stoichiometrically coupled current. The relative magnitude of anion conductance to coupled current follows the sequence: EAAT4 ~ EAAT5 > EAAT1 > EAAT3 > EAAT2. In each transporter, the anion conductance displays a chaotropic selectivity sequence (e.g., SCN^- is approximately 70-fold more permeant than Cl^- is in EAAT1). The magnitude of the anion conductance through a particular EAAT is also substrate specific; for example, D-aspartate activates a relatively larger anion conductance through EAAT1 than does L-glutamate, resulting in different net current reversal potentials for these substrates. In the absence of glutamate, a small tonic anion leak is present that seems to require Na^+. The glutamate-dependent anion conductance is also affected by the identity of the alkali cation cotransported with glutamate; Li^+ can substitute for Na^+ in some isoforms to support glutamate transport but is much less efficacious at activating the anion conductance.

Importantly, in at least some of the EAAT isoforms, replacement of Cl^- with impermeant anions like gluconate does not affect glutamate flux. Cl^- flux thus is thermodynamically uncoupled from glutamate flux, and may involve a channel-like mechanism instead. Indeed, glutamate-dependent anion current fluctuations have been observed in whole-cell and excised patch recordings that are consistent with a stochastically gated channel mechanism related to but distinct from the alternating-access glutamate transport mechanism. Comparative analysis of the glutamate concentration dependence of both transport and chloride channel gating suggests that each subunit in the trimer harbors both a chloride channel and a glutamate transporter; furthermore, each subunit functions independent of the other two subunits. Activation of the anion current in response to rapid glutamate application reveals similar but somewhat slower dynamics than does the stoichiometrically coupled current (**Figure 2**). The structural determinants and kinetics of the anion channel and the transporter may indeed be intimately related despite the important differences between channel and carrier gating. Kinetic models may be able to reconcile these differences by representing a subset of the Markov states in the transport cycle as open-channel states. Covalent modification of several mutants with engineered cysteine residues (e.g., V417C; EAAC1 numbering) eliminates transport but does not prevent activation of the anion current by extracellular glutamate, suggesting that some or all of the open-channel states may be in the T_o or T_{occ} forms.

Synaptic Physiology

As previously discussed, the coupled fluxes of glutamate, Na^+, H^+, and K^+ would theoretically allow maintenance of ambient extracellular glutamate levels in the low nanomolar concentration range. However, estimates of actual glutamate levels in the brain tend to be significantly higher, and in some areas are above the threshold required to generate tonic activity of *N*-methyl-D-aspartate (NMDA) and/or metabotropic glutamate receptors. The tonic extracellular level reflects a nonequilibrium state determined by the rates of uptake and release. The latter includes both synaptic and nonsynaptic components. Factors influencing the extracellular glutamate concentration include the density of EAATs and the frequency of synaptic activity. Nonsynaptic routes of release, particularly from astrocytes, also contribute to the extracellular glutamate level. The nonsynaptic mechanisms are generally less well characterized, but appear to include swelling-activated anion channels, the system xc- glutamate–cystine exchanger, and possibly other routes.

In addition to playing a central role in determining ambient glutamate levels, EAAT activity can also influence the temporal concentration profile of synaptically

released glutamate. Following vesicle fusion, the glutamate concentration in the synapse briefly reaches millimolar values. The dynamics of the concentration decay are strongly influenced by the geometry of the synapse and surrounding barriers. Diffusion appears to account for the major component of clearance within the synapse, with a time constant of a few milliseconds. However, EAAT activity can also influence the kinetics of the postsynaptic response in a manner dependent not only on the synaptic and extrasynaptic geometry, but also on receptor affinity, receptor distance from release sites, and release frequency. Additionally, multivesicular release and/or heterosynaptic glutamate spillover between release sites can result in slower transmitter clearance and a larger relative contribution of EAATs to transmitter decay kinetics. There is a great deal of heterogeneity in the effect of transporter blockade on synaptic transmission at different synapses. In general, the influence of uptake on synaptic responses becomes more pronounced as postsynaptic receptor affinity for glutamate increases, receptor kinetics slow, and proximity to the release site decreases. Oftentimes there is a spectrum of effects on different components of the synaptic response according to these criteria. Thus, the response kinetics of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors within the synapse tend to be less influenced by glutamate transport than do the responses of extrasynaptic NMDA or metabotropic glutamate receptors. Synapse organization in the CNS exhibits a rich diversity, and the contributions of EAATs to synaptic signaling are correspondingly varied.

Glial Glycogen Metabolism: Introduction

The brain has a very high-energy metabolic rate and uses glucose as its main energy substrate. In most tissues glucose can be stored as glycogen, a highly branched polysaccharide. As a general and intuitive principle, glycogen is synthesized (glycogenesis) when glucose is in excess and is degraded (glycogenolysis) to meet increased energy needs. An interesting feature of glycogen is that it can be rapidly metabolized in a process that does not require ATP. Moreover, and in contrast to fatty acids, glycogen metabolization can yield ATP under anaerobic conditions. Thus, glycogen represents an advantageous means to store glucose. In the body, the major sites of glycogen deposition are the liver and the skeletal muscle. Glycogen reserves are also present in the brain but in a much lower concentration than in peripheral tissues. Indeed, normal glycogen concentrations in mouse liver, muscle, and brain are roughly in the proportion of 100:10:1. Despite its low level in the central nervous system (CNS), glycogen is the largest energy reserve of the brain. The precise functions of brain glycogen are still not fully characterized. Nevertheless, it has been shown that glycogen reserves are consumed during failure of energy supply and that its metabolism is modulated by neuronal activity in physiological conditions. The almost exclusive localization of glycogen in a particular type of glial cell, the astrocyte, in adult mammalian brain is further evidence for a significant metabolic interaction between neurons and glia.

Glycogen Metabolism

Most of our knowledge about the general pathways of glycogen metabolism originates from studies conducted in peripheral tissues, but these pathways are common to all tissues. Uridine diphosphate (UDP)-glucose is the source of all glucosyl residues added to glycogen (Figure 1). UDP-glucose is formed from the conversion of glucose-6-phosphate to glucose-1-phosphate, by phosphoglucomutase, which is then combined to UTP through the action of UDP-glucose pyrophosphorylase. This process is energy consuming, since regeneration of UTP from UDP requires formation of a high-energy phosphate bond. The first step in the biogenesis of glycogen is the autocatalytic attachment of glucosyl units to a single tyrosine residue of the enzyme glycogenin. Elongation of this 'primed' glycogenin is performed by glycogen synthase, which catalyzes the formation of an α-1,4-glucosidic linkage using UDP-glucose as a donor. When the elongating glycogen chain consists of at least 11 residues, a branching enzyme transfers the terminal oligoglycan (around six glucose units) onto a neighboring chain by an α-1,6-glucosidic bond. Thus, glycogen synthase elongates the glycogen chain, whereas the branching enzyme produces new branches, creating a mature glycogen molecule presenting so-called 'bush-like' structure. Branching is important because it increases the solubility of glycogen. Glycogen particles (β-particles) have a spherical shape, about 10–30 nm in diameter, and can contain up to 60 000 glucose units. In the liver, 20–40 β-particles are associated into larger complexes known as α-rosettes.

Glycogenolysis is a process that does not require energy; is not a reverse reaction of glycogen synthesis, but implies the concerted action of glycogen phosphorylase and the bifunctional debranching enzyme. In the presence of inorganic phosphate, glycogen phosphorylase cleaves the terminal glucose residue of an external chain and releases it as glucose-1-phosphate. Glycogen phosphorylase proceeds until the external chains have been shortened to four glucose units before a branch point. At this point, the transferase activity of debranching enzyme removes the outer three glucosyl units and attaches them through an α-1,4-glucosidic bond to the nonreducing end of the molecule, which then becomes available for action by glycogen phosphorylase. The single remaining α-1,6-linked glucose unit is then removed and liberated as free glucose through the amylo-1,6 glucosidase activity of debranching enzyme. Finally, glucose-1-phosphate is converted by phosphoglucomutase to glucose-6-phosphate, which is (with glucose) the final product of glycogen degradation. Glucose-6-phosphate can then reenter the glycolysis pathway or the pentose phosphate pathway, or can be released as glucose in the presence of glucose-6-phosphatase activity (Figure 1).

Regulation of Glycogen Metabolism

Glycogen is a highly dynamic pool of glucose, the metabolism of which is under complex regulation involving various allosteric factors as well as covalent modifications. In a general way, activation of glycogen synthesis results in the inhibition of the degradative pathway, and vice versa. Nevertheless, there is ample documentation demonstrating that

Figure 1 Schematic representation of glucose metabolism. Glucose enters cells through glucose transporters (GLUT) and is phosphorylated by hexokinase (HK) to produce glucose-6-phosphate (glucose-6-P). Glucose-6-P can be processed into different metabolic pathways: it can be metabolized through the pentose phosphate pathway (PPP) or through glycolysis, giving rise to pyruvate production. Pyruvate can enter mitochondria, where it is metabolized through the Krebs cycle and oxidative phosphorylation. Alternatively, pyruvate can be reduced to lactate by lactate dehydrogenase (LDH); lactate is released into the extracellular space through monocarboxylate transporters (MCT). Glucose-6-P can also be used to store glucosyl units as glycogen (see text for details). As a first step, glucose-6-P is converted to uridine diphosphate (UDP)-glucose through the action of phosphoglucomutase (PGM) and UDP glucose pyrophosphorylase (UDPGP). UDP-glucose is then incorporated into glycogen by glycogen synthase (GS). To meet energy needs, glycogen can be broken down by glycogen phosphorylase (GP) to produce glucose-1-P, which is converted back to glucose-6-P through the action of PGM.

simultaneous synthesis and degradation can take place at the tissue level. Such regulation is believed to involve distinct glycogen pools in individual or different cells, synthesis of one pool being in concurrence with degradation in another. It is generally accepted that glycogen synthase and phosphorylase represent two central elements of this regulation. Glycogen synthase is tightly controlled by the reversible phosphorylation of multiple serine residues. Generally, phosphorylation is associated with an inactivation of the enzyme (conversion of the active a-form to the b-form). *In vitro* studies have shown that glycogen synthase can be phosphorylated by various protein kinases, including protein kinase A (PKA), protein kinase C (PKC), phosphorylase kinase, casein kinase 1 (CK1), casein kinase 2 (CK2), calcium and calmodulin-dependent protein kinase II (CaMKII), glycogen synthase kinase-3 (GSK-3), and adenosine monophosphate (AMP)-activated protein kinase (AMPK). Moreover, glycogen synthase b is strongly activated by glucose-6-phosphate (high cellular energy status). Like glycogen synthase, glycogen phosphorylase is regulated by both ligand binding and phosphorylation. Glycogen phosphorylase is converted from the inactive b-form to the active a-form through phosphorylation of a single serine residue by phosphorylase kinase. Activation of phosphorylase kinase is mediated by increased cellular Ca^{2+} levels or phosphorylation by PKA. Glycogen phosphorylase is also allosterically activated by AMP (low cellular energy status) and inhibited by glucose-6-phosphate and ATP (high cellular energy status), which enables this enzyme to sense and respond to an intracellular need for energy. As described, kinase-catalyzed phosphorylation of both enzymes leads to glycogenolysis (by activation of glycogen phosphorylase and inactivation of glycogen synthase), whereas dephosphorylation favors glycogenesis.

Protein phosphatase 1 (PP1), upon its association with regulatory glycogen targeting subunits, appears to be responsible for dephosphorylation of glycogen synthase, glycogen phosphorylase, and phosphorylase kinase. Thus, both glycogen synthase and glycogen phosphorylase are under the control of extracellular

signaling (which controls phosphorylation state) as well as intracellular (allosteric) regulation (which drives synthesis and degradation of glycogen, depending on energy requirements). It is of importance to note that glycogenolysis is a very fast process (activated on a timescale of milliseconds) that can be used to match moment-to-moment cellular energy needs without requiring energy, in contrast to stimulation of glycolysis from glucose, which requires the investment of two molecules of ATP. Different isoforms of glycogen-related enzymes with different regulation properties are expressed in a tissue-specific manner to meet particular requirements. For instance, in liver, glycogenolysis leads to formation of glucose (due to the presence of glucose-6-phosphatase), which is released into the bloodstream when blood glucose levels fall; in skeletal muscle, glycogen is used as a local energy store during muscle contraction. Even though characterized in less detail than their peripheral counterparts, major components of glycogen metabolism have been described in mammalian brain; examples include glycogen phosphorylase and synthase, phosphorylase kinase, glycogenin, branching enzymes, debranching enzymes, and regulatory glycogen-targeting subunits of PP1. Moreover, our knowledge of isoform expression patterns and biochemical properties of enzymes involved in glycogen metabolism (in particular, glycogen synthase and phosphorylase) in the brain, as well as data on regulation of cerebral glycogen (see later) and the virtual absence of glucose-6-phosphatase activity, indicate that brain glycogen regulation closely resembles that in muscle cells.

Localization of Glycogen in the CNS

Glycogen molecules are electron-dense particles that are easily recognizable by electron microscopy. With this technique it has been possible to demonstrate that in the adult brain glycogen is almost exclusively localized in astrocytes, although its presence has also occasionally been shown in certain large neurons in the brain stem, as well as in choroid plexus and ependymal epithelia. Glycogen particles can be observed diffusely scattered through the cytoplasm of astrocytes and their processes (Figure 2). Developmental studies have indicated that in the immature CNS, glycogen particles are also present in relatively large amounts in neurons, but neuronal glycogen decreases with age and is practically absent in mature CNS neurons. The cellular expression patterns of glycogen phosphorylase and phosphorylase kinase show a very strong correlation with glycogen deposits. In contrast, the cellular distribution of glycogen synthase appears less selective, since, while present in astrocytes, it is also expressed in neurons.

Because ischemia is a strong activator of glycogenolysis and low levels of glycogen in the brain, precise postmortem measurements of glycogen levels are problematic. The lability of glycogen has been seen as a limitation in the determination of the regional localization and the role of this energy store. Technological breakthroughs, optimization of extraction procedures, and use of a high-energy focused microwave irradiation method to sacrifice animals (fast inactivation of glycogen metabolism) have partially overcome this problem. More recently, nuclear magnetic resonance (NMR) spectroscopy has emerged as a new powerful and noninvasive technique to follow glycogen content *in situ*. Using these new approaches, it has been shown that basal concentration of glycogen in rodent brain is in the range of 2–5 μmol g^{-1} of wet tissue, although higher values of up to 8–12 μmol g^{-1} of wet tissue have been reported. In rodent brain, glycogen presents regional variability, with higher levels in pons–medulla, cerebellum, and hippocampus, followed by hypothalamus, thalamus–midbrain, and cerebral cortex, which display similar concentrations, the lower concentration being found in striatum. Several studies tend to show that gray-matter structures possess higher levels of glycogen than does white matter, although a recent study indicates opposite results. In addition, variations of glycogen levels in particular structures have also been observed. For example, superficial layers of the mouse cerebral cortex possess higher glycogen content compared to the deeper layers.

Functions of Glycogen in the CNS

What are the functions of glycogen in the CNS? Is it used only as a local emergency reserve when there is a

decrease in brain energy supply, or is it mobilized to sustain normal brain functions, and if so, for what purposes? Despite numerous studies, these intriguing questions are still not fully answered. Concerning its role as an energy reserve, there is now no doubt that glycogen can be used to preserve cell integrity in pathological conditions such as hypoglycemia or ischemia. Nevertheless, several lines of evidence, obtained both *in vitro* and *in vivo*, also point to a physiological role of brain glycogen. First, glycogen content is under dynamic control by neurotransmitters, neurohumoral agents, and local energy status. Second, glial glycogen metabolism appears to be tightly coupled to neuronal activity.

Glial Glycogen Metabolism Regulation *In Vitro*

Numerous *in vitro* studies, conducted either in astrocyte cultures or in brain slice preparations, have shown that glycogen is under the dynamic control of neuroactive substances. Neurotransmitters such as noradrenaline (NA), serotonin, histamine, vasoactive intestinal peptide (VIP), and secretin have been shown to promote glycogenolysis through activation of the cyclic AMP (cAMP) signaling pathway (with PKA) or through elevation of intracellular Ca^{2+} levels. In addition to neurotransmitters, adenosine, ATP, and K^{+} also induce glycogenolysis. NA, VIP, and adenosine are of particular interest since they produce a biphasic effect in astrocyte cultures. Indeed, the rapid glycogenolysis induced by these neurotransmitters is transient and is followed by a delayed massive glycogen resynthesis (taking place several hours after stimulation) (Figure 3). Accordingly, this long-term effect is accompanied by dephosphorylation and activation of glycogen synthase. This effect also depends upon the activation of the cAMP signaling cascade and requires synthesis of new proteins. Glycogen resynthesis involves stimulation of expression of a regulatory glycogen-targeting subunit of PP1, named PTG (for protein targeting to glycogen). Thus, NA, VIP, and adenosine can cause glycogen mobilization and delayed replenishment of this energy store. Other compounds that favor the synthetic pathway include insulin, insulin-like growth factor 1 (IGF-1), and glutamate. The stress hormone glucocorticoids have been shown to exert long-term control on glycogen metabolism in astrocytes cultures by decreasing glycogen levels and by partial inhibition of glycogen synthesis induced by NA. Moreover, glycogen levels are very sensitive to energy supply or ATP production. Indeed, hypoglycemia, ischemia, and hypoxia are potent inducers of glycogen breakdown, whereas glycogen synthesis is promoted with increasing concentration of glucose. Interestingly, glucose-deprived astrocytes rapidly deplete their glycogen content, with the concomitant release of lactate but not glucose (Figure 1). This result not only argues for a glial glycogen metabolism comparable to its muscle counterpart as a local energy

Figure 3 Differential modulation of glycogen metabolism in cultured astrocytes. Activation of cyclic adenosine monophosphate (cAMP)-dependent intracellular signaling by noradrenaline (NA), as well as by vasoactive intestinal peptide and adenosine, results in a short-term (seconds to minutes, in green) glycogenolysis and in a delayed (hours, in red) glycogen resynthesis. The long-term response requires induction of gene expression and is accompanied by stimulation of mRNA expression of protein targeting to glycogen (PTG), a member of the glycogen-targeting subunits of protein phosphatase 1, and by the activation of glycogen synthase (GS). store, but also shows that glycogen mobilization can give rise to lactate release, which could be used by neighboring cells as an energy substrate.

A first line of evidence demonstrating the importance of glial glycogen to preserve neuronal integrity comes from studies on murine cortical cell cultures, containing both glia and neurons, in which depletion of astrocyte glycogen content reduces neuronal survival following glucose deprivation. This experiment also implies a metabolic coupling mechanism between both cell types. Interaction between neurons and astrocytes in terms of glycogen metabolism has also been demonstrated in honeybee retinal preparations, in which repetitive light stimulation induces glycogenolysis in Müller cells, retinal counterparts of astrocytes. Taken together, these observations are in agreement with the hypothesis that glycogen can play an active role *in vivo*, either during failure of energy substrate delivery or during physiological conditions. This conclusion is further supported by studies performed in rodent optic nerve preparations, representative of central white-matter tracts, showing that glial glycogen can sustain axonal function in either pathological or physiological conditions. Electrophysiological recordings demonstrate that functional activity of the optic nerve, as measured by the area under the supramaximal compound action potential (CAP) during aglycemic conditions, can be maintained for over 20 s, after which it rapidly fails, with a concomitant decrease in glycogen content. Manipulation of glycogen levels before induction of aglycemia demonstrates that there is a linear correlation between glycogen content prior to aglycemia and latency to functional CAP failure during aglycemia. Moreover, under normoglycemic conditions, glycogen content decreases during high-frequency axon discharge, while CAP function is fully maintained. During both aglycemia and high-frequency axon discharge, it has been shown that CAP failure is accelerated by pharmacological inhibition of glycogen phosphorylase. Moreover, in both of these paradigms, CAP failure is also accelerated when lactate transport is blocked, suggesting a net transfer of lactate as an energy substrate from astrocyte glycogen stores to the neuronal compartment. Overall, these studies demonstrate that astrocytic glycogen is not only available for use as an emergency reserve to preserve neuronal integrity and functions when energy supply is decreased, but that it can also be mobilized to support neuronal energy requirements during neuronal activity.

Pathological Conditions

In vivo, variation of glycogen levels has been studied in different pathological paradigms or pathologies. Even if these studies do not necessarily define a physiological role of glycogen, they have been important to highlight the fact that brain glycogen metabolism is sensitive to changes in the nature of the microenvironment in terms of energy supply, presence of neurohumoral agents, and in case of cell trauma or death. Thus, glycogen accumulation in astrocytes is observed in traumatic injuries at the periphery of tumors after X-ray irradiation, or in neurodegenerative disorders such as Creutzfeldt–Jakob disease and Alzheimer's disease. Moreover, pathologies such as glycogen storage diseases, with the exception of type 0, also lead to brain glycogen accumulation. *In vivo* experiments also support a role of glycogen to sustain cerebral integrity during periods of decreased energy availability.

Different studies demonstrate that insulin-induced systemic hypoglycemia reduces cerebral glycogen reserves. Using NMR spectroscopy, it has been possible to show in brain of anesthetized rats that depletion of glycogen induced by insulin occurs only when brain glucose levels decrease to very critical levels, approaching zero (with plasma glucose concentration below 2 mM). In this condition, a glycogen signal could still be observed even after 2 h of severe hypoglycemia, demonstrating that brain glycogen can survive extended periods of hypoglycemia. Thus, glycogen can serve as a significant energy reservoir during less severe hypoglycemia and can account for a partial deficit in glucose supply. Interestingly, following a single episode of hypoglycemia, hypoxia, or ischemia, brain glycogen concentration, measured several hours after the insult, exceeds preinsult levels, indicating a 'supercompensation' of glucose storage. The molecular mechanisms involved in this effect and its role are not well characterized. Nevertheless, this increase in glycogen deposition might correspond to a form of preconditioning. For instance, hypoxic preconditioning has been show to delay energy depletion from hypoxia–ischemia in the immature rat brain.

Physiological Conditions

Under physiological conditions, a close relationship between glycogen mobilization and neuronal activity has been demonstrated *in vivo*. Evidence linking brain glycogen metabolism and neuronal activity comes from the observation that glycogen levels increase under conditions of tonically decreased neuronal activity, such as anesthesia, hibernation, or sleep. It is well established that administration of general anesthetics (e.g., pentobarbital) to animals leads to great diminution of neuronal activity and increases glial glycogen levels. Interestingly, following pentobarbital anesthesia, changes in glycogen levels appear to be greatest in areas of high synaptic

density. Further evidence of a direct link between effect of anesthetics on neuronal activity and modulation of glycogen levels comes from the observation that anesthetics increase glycogen only when applied *in vivo*, and not in astrocyte cultures. Like anesthesia, hibernation is a state accompanied by deeply reduced neuronal activity and an increase in brain glycogen levels (e.g., in ground squirrels and hedgehogs). In addition, modulation of total brain glycogen levels has been described during the sleep–wake cycle, with maximum glycogen levels observed at the beginning of the sleep period. Since sleep is classically considered as an energy-saving state, it has been hypothesized that sleep may serve to restore brain glycogen levels that have decreased during wakefulness.

Direct evidence for an association between neuronal activation and glial glycogen metabolism has been obtained in awake rats following sensory stimulation or following generalized stimulation of sensory and motor pathways. Thus, tactile stimulation of the rat face and vibrissae accelerates local glycogen utilization in the somatosensory cortex as well as in the relevant thalamic nuclei (trigeminal, sensory, and motor nuclei) (**Figure 4**). These observations indicate that the physiological activation of a neuronal circuit results in the mobilization of glial glycogen stores. They also suggest that rapid increase in local energy demand during neuronal activation may be fueled by stimulation of glycogenolysis. A recent study has demonstrated that pharmacological inhibition of glycogenolysis in astrocytes interrupts memory consolidation in young chickens in a bead discrimination learning task. Whether similar phenomena occur in mammalian brain remains to be determined, but this presents an interesting challenge for the determination of brain glycogen functions. Such observations also lead to the question of why glycogen is mobilized in physiological conditions during neuronal activation. Indeed, in response to focal brain activation, local cerebral blood flow increases, adjusting glucose delivery to energy demands. This response is fast but not instantaneous. Thus, glycogen breakdown – which occurs in milliseconds and, unlike glucose utilization through glycolysis, does not require energy – may provide a readily available energy substrate to buffer any brief mismatch between metabolic demand and energy supply, suggesting a role of glycogen as a 'metabolic buffer.'

Another issue is the nature of the signal(s) triggering glycogen mobilization in relation to increased neuronal activity. *In vitro* studies (see earlier) demonstrate that glycogenolysis could be initiated by several neurotransmitters, such as VIP and NA. In view of the particular morphology of the neurons that contain VIP or NA, a function of these neuronal systems to locally regulate the availability of energy reserves has

Figure 4 Glycogen utilization in the rat somatosensory cortex during tactile stimulation. [^{14}C]Glycogen labeling was obtained by intravenous injection of [^{14}C]glucose, and its utilization was determined by autoradiography. Autoradiographs were prepared before (a) and after (b) removal of glycogen from the section by enzymatic digestion. (c) Digital subtraction of autoradiograph (b) from autoradiograph (a) shows the distribution of [^{14}C]glycogen in the section. As shown in autoradiograph (c), unilateral tactile stimulation of face and vibrissae causes a loss of [^{14}C]glycogen in the somatosensory cortex (arrowheads) contralateral to stimulation. Reproduced from Swanson RA, Morton MM, Sagar SM, et al. (1992) Sensory stimulation induces local cerebral glycogenolysis: Demonstration by autoradiography. *Neuroscience* 51: 451–461, with permission from Elsevier.

been proposed. Indeed, VIP neurons are bipolar intracortical cells with an arborization pattern that defines cortical columns; these neurons receive direct thalamocortical and corticocortical inputs, implying that they are activated by modality-specific afferents to a given cortical area. The noradrenergic system originates in the locus coeruleus in the brain stem, the site from which fibers diffuse virtually to all areas of the brain. In the cortex, noradrenergic axons enter the frontal pole and diffusely project across a vast rostrocaudal expanse of the cortex, suggesting that a given set of cortical noradrenergic fibers can affect vast areas of the cortex simultaneously (Figure 5). Given these morphological characteristics, it has been proposed that VIP neurons, by promoting glycogenolysis, can control energy availability locally, within cortical columns, while noradrenergic fibers can metabolically 'prime' the neocortex.

Fate of Energy Stored in Glycogen

There is compelling evidence that astrocytes and neurons function as a cooperative metabolic unit. For example, astrocytes are responsible for the reuptake of neurotransmitters such as glutamate, as well as for the clearance of K^+ released in the extracellular space

Figure 5 Diagrammatic representation of the anatomic substrate for the synergistic effects of noradrenaline (NA) and vasoactive intestinal peptide (VIP) following the concomitant activation of noradrenergic cortical afferents and a group of VIP-containing neurons. Such arrangement would allow for the establishment of temporary columnar 'hot spots.' Cortical layers are denoted by roman numerals. Note tangential orientation of NA fibers, and radially restricted domain of the VIP-containing neuron. The concomitant activation of noradrenergic fibers (large, horizontal yellow arrow at the base of the cylinders) by unexpected sensory stimuli, and of a group of VIP-containing intracortical neurons by specific thalamic inputs (small blue arrow, bottom left) would lead to a drastic increase of cyclic adenosine monophosphate levels within a discrete volume of somatosensory cortex, delineated here by the cylinder with the dark background. Adjoining gray-background cylinders represent nonactivated cortical volumes. For graphic clarity, only the VIP-containing (green) cells and the pyramidal cells (red) have been represented here. In particular, the principal target cells of the thalamocortical afferents (i.e., the small stellate cells in layer IV) have been omitted. However, any cell with the capacity for dendritic reception in layer IV may receive thalamic inputs. Furthermore, also for graphic clarity, only one VIP neuron per cylinder has been drawn, in representation of a group of VIP neurons. VIP, VIP-containing bipolar cell; NA, noradrenergic afferent; PYR, pyramidal cell furnishing major efferent projections; SA, specific afferent (i.e., from thalamus or from other cortical areas); W.M., subcortical white matter. Reproduced from Magistretti PJ and Morrison JH (1988) Noradrenaline- and vasoactive intestinal peptide-containing neuronal systems in neocortex: Functional convergence with contrasting morphology. *Neuroscience* 24: 367–378, with permission from Elsevier.

during neuronal activation. In parallel, astrocytes also release into the extracellular space energy substrates, such as lactate, which can be used by neurons to meet their own energy requirements. Considering that neurons are the prevalent site of energy consumption in the mature brain, this raises the question of the fate of energy stored in glial glycogen. Is it a 'neuronal' energy reserve or is it used by astrocytes for their own purposes? *In vitro* studies clearly show that glycogenolysis occurs in astrocytes, during glucose deprivation or following high neuronal stimulation, sustaining neuronal integrity and functions. Glycogen breakdown leads to the release of energy substrates (e.g., lactate) in the extracellular space, and these substrates are taken up and used by neurons to meet their energy needs.

Concluding Remarks

Glycogen represents the major energy store of the brain. During decades of research, glycogen has been perceived as an emergency reserve used in case of energy supply deficiency, but more recent data, obtained with the development of new techniques, now points to a physiological role for glycogen in relation to neuronal activation. Nevertheless, some questions as to glycogen physiological processes still need further exploration. In this context, the advent of noninvasive NMR spectroscopic methods may allow the development of very useful experimental approaches to investigate glycogen function in humans. The quite exclusive localization of glycogen in glia, and its mobilization upon neuronal activation, underline the tight metabolic cooperation occurring between neurons and astrocytes.

Glial Growth Factors

B M Reuss, University of Göttingen, Göttingen, Germany

© 2009 Elsevier Ltd. All rights reserved.

Glial cells are a major source of growth factors in the healthy and injured central and peripheral nervous systems. Glia-derived growth factors regulate differentiation and function of glial cells in an autocrine fashion, and they modulate neuronal process formation, migration, and survival during development. An important function of glial growth factors is the regulation of cellular repair processes after injury, degeneration, and demyelination in the peripheral and central nervous systems. Changes in growth factor synthesis, release, and action are also associated with the formation of glia-derived brain tumors.

Expression of Growth Factors by Different Glial Subpopulations

Satellite Cells

Satellite cells are specialized glial cells in the sensory ganglia ensheathing cell bodies of pseudounipolar sensory ganglion cells. During development, satellite cell-derived nerve growth factor (NGF) is an important determinant for neurite outgrowth from sensory neurons since, in the rat, neurite outgrowth from neonatal sensory neurons after removal of satellite cells is induced by NGF.

After peripheral nerve injury in the rat, NGF and neurotrophin NT-3 induce sprouting of noradrenergic nerve terminals in the dorsal root ganglia. Satellite cell-derived NGF also affects expression of the nicotinic acetylcholine receptor in rat sensory neurons. NGF also seems to affect satellite cells since NGF depletion reduces reactivity of rat trigeminal satellite cells after inferior alveolar nerve injury.

Other growth factors released from satellite cells are vascular endothelial growth factor (VEGF), the transforming growth factor (TGF)-βs, and TGF-α. Thus, VEGF plays an important role in the establishment and maintenance of blood vessels in the dorsal root ganglia during development, whereas TGF-β signaling is altered after peripheral nerve transection as indicated by changes in the distribution of TGF-β and the TGF-β type I and type II receptors in peripheral nerves and mechanoreceptors after traumatic injury. TGF-α and its receptor reveal strong upregulation in satellite cells in response to peripheral nerve lesioning.

Schwann Cells

Schwann cells are the myelinating cells of the peripheral nervous system and thus ensheathe with their processes axons in peripheral nerves. Perturbed Schwann cell functioning is a key feature of several demyelinating disorders, the most prominent of which is multiple sclerosis (MS). Schwann cells synthesize and release a wide variety of growth factors, such as neurotrophins, neuregulatory cytokines, TGF-βs, glial cell line-derived neurotrophic factor (GDNF), epidermal growth factors (EGFs), and platelet-derived growth factor (PDGF).

High levels of NGF are found in Schwann cells *in vivo* and in primary cell cultures *in vitro*. NT-3 mRNA is expressed at low concentrations in cultured Schwann cells but is upregulated upon immortalization. In response to nerve injury, neurotrophins are differentially up- or downregulated in Schwann cells. Thus, low levels of NGF in normal Schwann cells are greatly increased after injury. Also, transection of the sciatic nerve leads to an increase in the mRNAs for brain-derived neurotrophic factor (BDNF) and NT-4 but to a decrease of that for NT-3.

Schwann cells of the sciatic nerve also express ciliary neurotrophic factor (CNTF) beginning on postnatal day 8 and reaching adult levels on day 21. CNTF expression in Schwann cells is regulated by axonal factors since after axotomy, CNTF expression recovers only after regeneration of the axonal processes. Whereas in cultured Schwann cells mRNAs for CNTF and leukemia inhibiting factor (LIF), another neuregulatory cytokine, are high, myelinating Schwann cells *in vivo* show only CNTF expression and levels of LIF mRNA are low. However, retrograde transport of LIF and CNTF is increased after nerve lesioning.

In Schwann cells and their precursors *in vivo*, both TGF-β2 and -β3 are expressed, whereas TGF-β1 is upregulated only after injury. Thus, in the transected sciatic nerve, TGF-β1 mRNA is induced in the distal nerve stump, whereas that for TGF-β3 is repressed. Also during axon regeneration, TGF-β1 mRNA is transiently increased. In contrast to the *in vivo* situation, in cultured Schwann cells expression of TGF-β1 mRNA is high but decreases when axonal contact is mimicked by the application of forskolin. A striking feature of the effects of TGF-β on Schwann cells is that application of TGF-β together with tumor necrosis factor-α (TNF-α) can induce Schwann cell death, whereas either cytokine alone is ineffective.

Whereas in normal circumstances GDNF expression in Schwann cells and satellite cells is low, it shows transient upregulation after injury. Thus, GDNF is

upregulated in the distal nerve stump of the transected sciatic nerve, as well as in the satellite cells of the trigeminal ganglion.

Schwann cells are also known to express TGF-α and other neuregulins, as well as the neuregulin receptor ErbB1, on their surface. In accordance with this, neuregulins act as autocrine stimulators of Schwann cell proliferation during development. Similar observations have been made for PDGF, the expression of which in rat Schwann cells is high at birth, followed by a continuous postnatal decrease in nonmyelinating but persisting high levels in myelinating Schwann cells.

Oligodendrocytes

Oligodendrocytes are the myelinating cells of the central nervous system (CNS) and thus, like Schwann cells in the peripheral nervous system (PNS), ensheathe the axonal processes by their processes. Oligodendrocytes and their precursor cells also provide an important source of growth factors such as the neurotrophins and several TGF-β superfamily members. Thus, they express NGF, NT-3, and BDNF, probably mediating the autocrine control of proliferation and survival of immature oligodendrocytes and of O-2A precursor cells. In O-2A precursor cells, different TGF-β isoforms, such as TGF-β1 and -β3, are expressed, whereas mature oligodendrocytes express TGF-β2 and-β3. In cultured oligodendrocytes, all three TGF-β isoforms are present.

Astrocytes

Astrocytes in the CNS mediate the transport of nutrients and waste products between blood vessels and neurons, and they also modulate neuronal activity and synaptic transmission. Due to their important role during gliosis and neuronal repair, growth factor synthesis by astrocytes has been intensely studied. Thus, astrocytes in the healthy CNS release NGF, NT-3, and NT-4, whereas reactive astrocytes after gliosis start to express BDNF together with NGF, a process which at least *in vitro* seems to depend on interleukin (IL)-1β and interferon-γ (IFN-γ).

Astrocytes also release high amounts of fibroblast growth factor-2 (FGF-2), mRNA of which can be found in cortical, hippocampal, and spinal cord astrocytes with a strong postnatal increase. FGF-2 seems to act in an autocrine manner on astrocyte differentiation since in FGF-2$^{-/-}$ mice astroglial gap junction coupling and neurotransmitter sensitivity are changed. Astroglial FGF-2 is also responsible for the induction of endothelial tight junctions and thus for the formation of the blood–brain barrier in the CNS.

Astrocytes express neuregulatory cytokines such as CNTF, which can be found in type 1 astrocytes of the optic nerve and the olfactory bulb. Also, primary cultures of astrocytes contain CNTF mRNA and protein. Astroglial CNTF expression is upregulated during brain lesions such as entorhinal cortex lesions, hippocampal deafferentiation, optic nerve transection, and ischemia. Also, LIF is expressed in cultured astrocytes of variable origins and is upregulated after trauma and during inflammation.

However, astrocytes do not express EGF itself but synthesize other members of this growth factor family, such as TGF-α and the neuregulins. TGF-α has been found in astrocytes of the corpus callosum, striatum, and globus pallidum. Astrocytes also express ErbB1, the receptor for TGF-α, and therefore it is thought to act in an autocrine manner. In reactive astrocytes, TGF-α and its receptor are transiently reduced. Other neuregulins which can be found in cultured astrocytes are highly upregulated during reactive gliosis. Thus, GGF-2 and NDF have been detected in human white matter astrocytes of the spinal cord and in the cortex.

Of the insulin-like growth factors (IGFs), only IGF-1 is expressed in astrocytes, which *in vitro* has been shown to promote astroglial proliferation in an autocrine manner. During remyelination, IGF-1 is upregulated in astrocytes, together with its receptor, and is also increased after ischemia, probably acting in a protective manner.

With regard to the TGF-β superfamily members, in astrocytes a highly heterogeneous expression pattern can be found. Thus, astrocytes in the uninjured brain express only TGF-β2 and -β3, whereas after lesioning TGF-β1 is also upregulated. In contrast, GDNF is not expressed in astrocytes of the adult brain but can be found during early postnatal development. However, GDNF is released from cultured fetal human astrocytes and in astrocytes *in vivo* after brain damage. GDNF is also highly upregulated in gliomas *in situ* and in glioma cell lines.

Ependymoglia

Ependymoglia line the ventricular wall and the choroid plexus and, thus, are important for substance transport and for establishing the blood–liquor barrier. FGF-2 is expressed in the choroid plexus epithelia of both lateral and third ventricles, in ependymal cells of the third ventricle, and along the lateral sides of the lateral ventricles. All positive cells reveal a similar distribution with apical labeling, as well as some cytoplasmic staining. This suggests a transepithelial transport of growth factors such as FGF-2 via ependymal cells into the underlying brain parenchyma. However, FGF-2 also seems to play a role in the autocrine regulation of ependymal cells since both EGF and FGF-2 have been shown to cause proliferation of

ependymal precursor cells in the adult rat spinal cord. Another growth factor which is expressed in ependymal cells, at least during development, is GDNF, which has been demonstrated in human prenatal cortical plate ependyme from the age of 10 weeks onward.

Müller and Bergmann Glial Cells

Müller glial cells are persisting radial glial cells in the retina and express a large variety of cytokines and their receptors. Thus, expression of NGF, BDNF, and NT-3, along with neurotrophin receptors trkB and trkC, but not of trkA, has been reported. Also, glial maturation factor-β, another cytokine, is synthesized in these cells. Human Müller cells *in vivo* express high amounts of FGF-2. In addition, FGF-2 has been shown to downregulate IGF-1 in Müller cells. *In vitro*, Müller cells release TNF-α and nitric oxide upon stimulation with lipopolysaccharide and IFN-γ. TGF-β2 and -β3 are also expressed in Müller cells. Glucose and pH influence expression of VEGF in Müller cells. VEGF183 has been reported as a Müller cell-specific splice variant of this growth factor. Müller cells also express CNTF and FGF-2.

Bergmann glia, the persisting radial glia in the cerebellar cortex, express some growth factors and growth factor-related proteins. Thus, IGFBP2 is expressed in these cells during postnatal cerebellar maturation in parallel to the expression of IGF-1 in cerebellar Purkinje neurons. Bergmann glia cells also express IL-6.

Role of Glial Growth Factors in Glial Cell Differentiation and Function and the Formation of Glial Brain Tumors

An important function of glial growth factors is para- and autocrine regulation of the differentiation and maturation of glial cells, a feature which is of utmost importance for pathological changes of the nervous system (Figure 1).

Autocrine Regulation of Astrocyte Differentiation

With regard to autocrine regulation of astrocyte differentiation, studies from the 1980s reported that astrocyte-conditioned medium is able to inhibit astrocyte proliferation compared to fresh medium – a feature that has been attributed to the secretion of growth inhibitory factors by these cells.

The complex network of para- and autocrine effects of glial cells during astrocyte development is highlighted by the fact that differentiation of O-2A progenitor cells into either oligodendrocytes or type 2 astrocytes seems to depend on growth factors released from type 1 astrocytes. Type 1 astrocytes have been shown to secrete PDGF, thus stimulating O-2A progenitor cell proliferation and oligodendrocyte differentiation. Later, type 1 astrocytes secrete CNTF, thus initiating differentiation of type 2 astrocytes.

The LIF-receptor and its ligands play an important role in astrocyte differentiation. Thus, neural precursor cells isolated from LIFR$^{-/-}$mice fail to generate glial fibrillary acidic protein (GFAP)-positive astrocytes, whereas precursors from heterozygous mice differentiate normally. Also, *in vivo* LIFR$^{-/-}$ mice show low levels of GFAP. In contrast, animals deficient in LIF show reduced GFAP levels only in some brain regions, suggesting that LIF is not the predominant endogenous ligand for the LIF receptor.

Region-specific effects of glia-derived factors on astrocyte differentiation can also be observed in the cerebellar cortex, in which granule cell precursors are differentiated into astroglial cells by sonic hedgehog and bone morphogenic peptides. Growth factor-stimulated cells initially express both GFAP and neuronal markers and later switch to S100-beta, a marker of differentiated astrocytes.

Despite their important role in neuronal stem cell proliferation and differentiation, with regard to astrocytes, FGF-1 and FGF-2 are primarily involved in the regulation of astrocyte proliferation. Nevertheless, GFAP immunoreactivity is reduced in mice with a genetic defect in FGF-2. Also, Fgf-8b, a splice variant of this growth factor, has been shown to promote astroglial differentiation of a subpopulation of E15 cortical precursor cells in culture.

Regulation of Oligodendrocyte and Schwann Cell Differentiation by Glial Growth Factors: Importance for Etiology and Treatment of MS

A central role in paracrine and autocrine regulation of oligodendrocyte differentiation is played by neuregulins, which in the normal human CNS are produced by astrocytes and neurons. Thus, NRG-1α and -1β and their receptors can be found in cultured oligodendrocytes from neonatal rat pups. Under these conditions, less differentiated oligodendrocytes contain both NRG isoforms in the cell bodies but not in the processes, whereas only NRG-1β was found in the nucleus. In contrast, differentiated oligodendrocytes contained both isoforms only in cytoplasm and cell processes. Similar effects could be observed for embryonic striatal oligodendrocyte precursor cells, which express Nrg-1 as well as its specific receptors, ErbB2 and ErbB4, but not ErbB3. Likewise, inhibition of Nrg-1 activity by the addition of soluble ErbB3 decreases the mitotic activity of Nrg-1 on oligodendrocyte precursor cells.

Figure 1 Graphical summary of expression and effects of glial growth factors in the central and peripheral nervous systems. A sophisticated network of glia–neuronal, interglial, and autocrine actions of glial growth factors regulate normal development and function of the nervous system, degeneration and regeneration after nerve injury, as well as brain tumor growth.

Despite these *in vitro* findings, neuregulins seem to also be important for myelination *in vivo* since mice with a null mutation in the nrg-1 gene show defects in oligodendrocyte differentiation. This also seems to be important for the pathology of MS since in active and chronically active MS lesions, expression of astrocyte-derived neuregulin is reduced and thus may contribute to impaired remyelination in MS patients.

Other glial growth factors influencing oligodendrocyte differentiation and myelination are PDGF and IGF-1. Thus, in spinal cord explants, NRG-1 and PDGF, but not LIF, enhance myelination. PDGF has also been shown to be a potent regulator of oligodendrocyte progenitor migration and proliferation in oligodendrocyte cultures. IGF-1 acts on myelin-forming cells to promote normal myelination and remyelination after injury. Thus, in experimental MS models, the neuregulin isoform GGF-2, IGF-1, and several neurotrophins promote remyelination following inflammatory demyelination.

Differentiation-stimulating effects of IGF-1 on oligodendrocyte precursors have also been detected *in vitro*, in which the addition of IGF-1 induced a high proportion of precursor cells to differentiate into galactocerebroside-positive oligodendrocytes, whereas the proportion of type 2 astrocytes was unaffected. In addition, IGF-1 promotes proliferation of O-2A precursor cells.

Also in myelinating Schwann cells, growth factors released from glial cells are involved in remyelination after damage. Thus, in neuron–Schwann cell cocultures, GGF-1, an NRG-1 isoform, inhibits myelination by preventing axonal segregation and ensheathment. In addition, treatment of established myelinated cultures with GGF-1 results in demyelination that frequently begins at the paranodes and progresses to the internodes. In contrast, FGF-2 and TGF-β1 inhibited myelination but did not cause demyelination, suggesting that this effect is specific to the NRGs. The NRG receptor proteins erbB2 and erbB3 are expressed on ensheathing and myelinating Schwann cells and rapidly phosphorylate upon GGF-1 treatment.

In Schwann cells, both NRG-1β and -1α are colocalized in cytoplasm and its processes. The Schwann

cell nucleus has weak immunoreactivity for both NRG-1 isoforms, although NRG-1β is predominant. ErbB2 and ErbB3 receptors, transducing the NRG-1 signal in Schwann cells, are found throughout cytoplasm and processes and are also localized in the nucleus. Stimulation of Schwann cells with mitotic agents induces nuclear translocation of NRG-1β.

Regulation of Radial Glia Differentiation

Little information is available on the role of glial growth factors in the differentiation of radial glia. Thus, in the mammalian retina proliferation of Muller glia is stimulated by EGF in a dose-dependent manner, whereas astrocyte proliferation is stimulated by FGF-1 and FGF-2. In contrast, proliferation of glial precursor cells is stimulated by FGF-1, FGF-2, and PDGF, but not by EGF. The inhibitory role of FGF signaling for Muller cell differentiation is further supported by the fact that inhibition of the endogenous FGF receptor by cotransfecting a dominant-negative form results in an increased number of Muller cells, suggesting a balance between FGF signaling and other signaling cascades to modulate retinal precursor cell fate.

Growth Factors in Glial Brain Tumors

Genetic changes in glial cells and their precursors lead to some of the most devastating human brain tumors, such as glioma, glioblastoma, and astrocytoma. During the process of tumor transformation, para- and autocrine stimulation of tumor cell proliferation is a key mechanism for tumor growth providing at the same time a starting point for pharmacological intervention of this process.

Glioma cells are among the oldest known sources for a number of different growth factors, such as FGF-2 and GDNF, which have also been shown to affect glial cell proliferation in an autocrine manner. Thus, glioma cells express high levels of FGF-2 protein and high-affinity FGF receptors and therefore are mitogenically responsive to FGF-2. Likewise, a knockdown of GDNF or its receptor, GFR-α1, by antisense RNA results in reduced proliferation of rat C6 glioma cells, suggesting a role in autocrine growth stimulation.

A growth factor that has been implicated in the regulation of glioblastoma growth is PDGF, which is coexpressed with its receptor in this tumor type and has been shown to regulate tumor cell proliferation. Because it is a secreted factor, PDGF not only has autocrine effects on producing cells but also paracrine actions on other tumor cells and on the tumor microenvironment. Thus, PDGF is involved in the regulation of tumor cell migration and tumor angiogenesis. In addition, human glioblastoma cells show a general increase in the expression of autocrine growth regulators such as TGF-α, TGF-β, and FGF-2 compared to normal human brain tissue.

Also in astrocytomas, activity and regulation of a number of mitogenic signaling pathways is aberrant. Thus, upregulation of growth factor receptors such as EGFR, PDGFR, and c-Met, as well as signaling intermediates such as Ras, protein kinase C, and others which have been shown to positively regulate tumor proliferation and cell cycle progression, has been demonstrated.

Effects of Glial Growth Factors on Differentiation and Function of Neurons in Both Healthy and Injured Nervous Systems

Glial growth factors are important regulators of normal neuronal differentiation and of neuron survival in the developing and adult brain. Disturbances of glial growth factor release are therefore supposed to play a role during CNS and PNS lesioning and in the etiology of various neurological disorders (Figure 1).

Regulation of Neuronal Differentiation during Development

Glial growth factors are important for the migration of neuronal progenitors during development. Thus, intraventricular injection of NT-4 or overexpression of BDNF lead to defects in cortical layering. Cortical layering defects can also be observed in FGF-2 knockout mice. GGF-1 promotes the migration of neuronal progenitors along radial glial fibers.

Glial growth factors can also influence axonal pathfinding, as shown for netrin-1 in the internal capsule. Netrin-1 is released from oligodendrocytes but not astrocytes. Together with netrin-1, engrailed-1 is directing axons of association neurons, projecting ipsilaterally to motor neurons in the spinal cord. Consistent with this, axonal pathways are altered in netrin-1-deficient mice. A number of glia-derived growth factors, such as TGF-α, have been shown to induce neuritogenesis.

An important role for glial growth factors is the regulation of neuron survival during periods of ontogenetic neuron death. Thus, FGF-2 can prevent neuron loss in the chick ciliary ganglion. Ciliary neurotrophic factor is also able to rescue motor neurons in the embryonic chick lumbar spinal cord during ontogenetic cell death. Moreover, TGF-βs enhance survival of chick ciliary ganglionic neurons *in vitro* synergistically with different neurotrophins and CNTF. Surprisingly, immunoneutralization of TGF-βs during chick development *in vivo* enhances neuronal survival.

Glia-Derived Growth Factors during Puberty and Aging

A late developmental event is puberty, during which gonadal steroids induce plastic changes in certain brain regions. In hypothalamic astrocytes, this is accompanied by the production of TGF-α and neuregulins, which elicit astroglial secretion of prostaglandin E2, stimulating the release of neuronal luteinizing hormone-releasing hormone. Hence, overexpression of TGF-α in the hypothalamus accelerates puberty, whereas blockade of TGF-α or neuregulin delays this process.

Growth factor synthesis by glial cells is also changed during aging, in which, together with astrogliosis, a continuous upregulation of TGF-β1 can be observed. Also, a decrease in NGF has been observed in a senescence accelerated mouse strain. Likewise, in aging mice an increase in IL-6 and a decrease in IL-10 release from glial cells can be observed.

Glia-Derived Growth Factors during Neurodegenerative Diseases

Neuronal degeneration during Parkinson's disease (PD) and Alzheimer's disease (AD) is accompanied by astrogliosis and thus upregulation of several glia-derived growth factors. On the other hand, some glial growth factors are downregulated in these diseases, such as FGF-2 expression, which is reduced in the substantia nigra of PD patients, and NGF expression, which is reduced in the hippocampus of both PD and AD patients. *In vitro* studies on growth factors such as FGF-2, GDNF, CNTF, and BDNF suggest that they are important for survival of dopaminergic midbrain neurons.

According to this, altered levels of glial growth factors are common in postmortem samples of the brains of AD patients. Thus, β-amyloid of senile plaques induces IL-1β and FGF-2, probably stabilizing the disease conditions. Whereas FGF-2 is expressed in astrocytes in the center of senile plaques, FGF-1 can be found in astrocytes surrounding the plaque. Also, other growth factors are upregulated in astrocytes of the brains of AD patients, such as endothelin-1, TGF-β2, IGF-1, and hepatocyte growth factor. In contrast, expression of BDNF is reduced in astrocytes surrounding senile plaques.

Role of Glia-Derived Growth Factors in Neural Regeneration in the Central Nervous System

It has long been known that neuron regeneration after lesioning is enhanced by soluble proteins released from glial cells (Table 1). Thus, NGF prevents death and promotes fiber growth of transected cholinergic neurons. Similarly, the release of IGF-1 from astrocytes is involved in neuron regeneration after cuprizone-elicited demyelination of the CNS. Notably, IGFs are also potent regulators of remyelination following CNS damage.

Glia-derived factors such as Nogo are also involved in the inhibition of axonal regeneration after spinal cord lesioning. Inhibition of the Nogo receptor could provide a means to overcome this obstacle to neuronal regeneration after spinal cord transection. However, Nogo is not the only axon outgrowth inhibitor

since other astroglial molecules, such as collagen IV, are similarly active.

Also in brain regions in which axonal regeneration occurs throughout life, astrocyte-derived growth factors such as NGF, BDNF, GDNF, and neurturin seem to be involved since transplantation of astrocytes from the olfactory bulb to the spinal cord promotes axon regrowth after transection.

PDGF upregulation in astrocytes of the facial nucleus after transection of the facial nerve is important for neuronal regeneration. Similarly, astroglial CNTF expression is increased in fields of axonal sprouting in the deafferented hippocampus after entorhinal cortex lesioning. Likewise, BDNF, NT-3, and GDNF are induced in astrocytes of the spinal cord adjacent to a lesion.

Role of Glia-Derived Growth Factors in Regeneration of Peripheral Nerves

Transection of a peripheral nerve leads to apoptotic cell death of dorsal root ganglion neurons. This is probably due to a reduction in the expression of neurotrophins and neurotrophin receptors, and as a consequence, exogenously applied growth factors are able to counteract these effects. An important endogenous source for growth factor release in the distal nerve stump after peripheral nerve transection is Schwann cells, which release NGF, BDNF, NT-4/5, and p75. In addition to these factors, CNTF and LIF are needed for axonal regeneration, which act synergistically on nerve regeneration. Also, GDNF is upregulated in Schwann cells of the distal nerve stump after nerve injury and remains so for more than 5 months.

Glial Influence on Synaptic Transmission

C G Schipke and O Peters, Charité University Medicine, Berlin, Germany

Introduction

Glia cells in the central nervous system are composed of three major cell types – microglia, oligodendrocytes, and astrocytes. Microglia are the innate immune cells of the brain, and oligodendrocytes are the myelin-forming cells; thus, these two cell types, due to their morphology and specialized role in the mammalian brain, do not influence synaptic transmission directly at the synapse. Nevertheless, microglia release cytokines and chemokines and thus influence synaptic transmission in large areas or the whole brain by altering the levels of these neuromodulatory substances. Oligodendrocytes have not been described to be directly involved in the influence on synaptic transmission, although they do play an important role in potassium buffering (along fiber tracts) and therefore contribute to ion homeostasis, another important factor for synaptic transmission.

Direct influence on synaptic transmission has only been described for astrocytes that have the appropriate morphological properties and thus comply with the requirements to be directly involved in the functional control of single synapses. During the mid-1990s, the first indications that astrocytes might be involved in the modulation of synaptic transmission came from a number of independent studies of cell cultures, in which neurons and astrocytes were co-cultured in a single petri dish. These studies described the general ability of astrocytes to release glutamate in a Ca^{2+}-dependent manner and to consecutively influence neuronal calcium activity. However, a substantial limitation of studies in co-cultures is the artificial environment and the altered morphology of cells, especially astrocytes in culture. For this reason, this article focuses on the mechanisms of glial influence on synaptic transmission that have been described from experiments using acute tissue preparations of the mammalian central nervous system, with the exception of the section of this article on the glia-derived acetylcholine-binding protein. Apart from the brain, a well-studied model system for neuron–glia and glia–neuron interactions is the mammalian retina with its layered structure. The mammalian retina comprises different types of glial cells and the glial influence on synaptic transmission in this preparation has been shown in some pioneering work for both excitatory and inhibitory neuronal synaptic transmission. This work and the emerging concepts are discussed later.

As previously mentioned, the astrocyte morphology in the intact brain tissue preparation is an important prerequisite for the ability of astrocytes to directly influence neuronal transmission at the synapse: with their fine appendages, often measuring only a few hundred nanometers in diameter, the astrocytes protrude into the extracellular space surrounding neuronal structures. These fine astrocytic structures seal the synapses from the extracellular space, but they contribute much more than just morphological support. The tight astrocytic coverage of synaptic structures limits the room for diffusion for secreted neurotransmitters, thereby influencing the active concentration of transmitters at the synapse. For the major excitatory neurotransmitter glutamate, astrocytes possess high-affinity transporters, thereby also contributing largely to the termination of the synaptic signaling.

Based on the first studies of astrocyte–neuron co-cultures, a completely new concept of synaptic function and plasticity has evolved and is currently well accepted – the concept of the 'tripartite synapse' (Figure 1). The traditional view of the functional synapse consisting of the presynaptic terminal releasing the neurotransmitter into the extracellular space and binding to postsynaptic neurotransmitter receptors of the adjacent neuron has been modified by adding a third, functionally important element – the astrocyte. It is now clear that astrocytes can release a number of neurotransmitters and neuromodulatory substances, especially glutamate, ATP, and D-serine, thereby directly influencing neuronal signal transmission at single synapses. Most often, the release of neurotransmitters from astrocytes is accompanied by changes of their intracellular Ca^{2+} concentration in response to neuronal activity. Thus, the activation of astrocytes by neuronal activity and the regulation and function of calcium excitability in astrocytes are extremely important for any kind of astrocyte–neuron communication. This article focuses on the mechanisms that influence synaptic transmission following initial activation of astrocytes, measured as changes in the intra-astrocytic calcium level.

It is important to take into consideration that a single hippocampal astrocyte in the CA1 area of the hippocampus reportedly occupies a neuropilar volume

Figure 1 A glutamatergic synapse in the central nervous system. (a) The functional tripartite synapse consists of the presynapse (blue), the postsynapse (yellow), and the astrocytic coverage (orange). The presynapse is loaded with synaptic vesicles containing glutamate. On the postsynapse, different subtypes of glutamate receptors, AMPA- and NMDA-type receptors, are expressed. Also, extrasynaptic glutamate receptors are found on the postsynaptic element. The astrocyte is equipped with highly efficient glutamate transporters. (b) Upon the arrival of an action potential, glutamate is released into the synaptic cleft, binds to postsynaptic glutamate receptors, and excites the postsynapse. The influx of Na^+, K^+, and Ca^{2+} ions through glutamate receptors depolarizes the postsynapse. This depolarization is then propagated within the neuron. Glutamate is transported away from the synaptic cleft by the activity of astrocytic glutamate transporters. This transport determines the time course of the neuronal excitation because excitation stops when all glutamate is removed from the synaptic cleft. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; NMDA, *N*-methyl-D-aspartate.

of approximately 65 000 μm^3, thereby ensheathing thousands of synapses. Values for other brain regions have not been determined, but there is no indication that these values differ substantially. These thousands of astrocyte-ensheathed synapses can be of different kinds in terms of transmitters secreted. Thus, a single astrocyte is in position to locally react to neuronal activity but also to serve as an integrator of synaptic activation. In addition, astrocytes communicate over long distances via the intra-astrocytic propagation of calcium waves.

Taken together, astrocytes are in the position to react accordingly and are equipped with the instrumentation to modify synaptic transmission at synapses remote from those where the activity was sensed originally.

Influence of Glia-Derived Cytokines on Synaptic Transmission

It is unknown whether glia are involved in the rapid continual maintenance of synaptic strength. Synaptic strength is determined not only by the amount of transmitter released into the synaptic cleft or by the balance of excitation and inhibition but also by the availability of functional neurotransmitter receptors at the postsynapse. An influence on synaptic transmission via controlling the turnover of receptors cannot be exerted directly at the synapse but, rather, via influencing the receptor turnover by interfering with the neuronal function in general. In hippocampal slices, a cytokine produced by glia cells, tumor

necrosis factor-α (TNF-α), has been shown to be critically involved in the maintenance of synaptic strength by controlling the surface expression of AMPA-type glutamate receptors. Thus, only the continual presence of glia-derived TNF-α secures glutamatergic synaptic transmission at a constant level, thereby also introducing a possible way for glia modulation of synaptic transmission. A different form of influence on synaptic transmission is involved in the modulation by glia-derived interferon-γ (IFN-γ). The long-term presence of this proinflammatory cytokine influences the receptor clustering of AMPA-type glutamate receptors at the postsynapse, which modulates synaptic efficacy. Thus, by controlling the extracellular level of certain cytokines, glia have a role in the short-term (via TNF-α) and long-term (IFN-γ) modulation of synaptic transmission.

Astrocytic Modulation of Synaptic Transmission in the Retina

Since the beginning of research on the functional interactions at the tripartite synapse, the retina has been a very valuable preparation to study and describe the different mechanisms in glia–neuronal cross-talk. Numerous mechanisms that were first described in the retina were later demonstrated to also be functional in the brain. Astrocytes first activated by neuronal activity have been shown to be able to signal back and to modulate neuronal activity in this preparation. Three different, independent mechanisms of glial influence on synaptic transmission in this preparation have been demonstrated to be functional: inhibitory modulation of neuronal spiking, excitatory modulation of neuronal spiking, and hyperpolarization of neurons and thus inhibition of spontaneous spiking activity of neurons. The last mechanism has been shown to be dependent on ATP release from glia cells. The first two mechanisms need to be elucidated in detail, but it is clear that glial interaction with neuronal excitatory, as well as inhibitory signal transmission is involved.

Morphological Plasticity of Astrocytes as a Modulator of Synaptic Transmission

Although the morphology of astrocytes with regard to coverage at single synapses suggests a role for morphological plasticity in modulating synaptic transmission, there are few experimental paradigms to study this assumption. This is mainly because the size of a single synaptic structure is much smaller than the resolution of a conventional microscope. However, within the female rodent brain a remarkable form of glial morphological plasticity can be observed within a well-defined brain region, the supraoptic nucleus (SON), a structure within the hypothalamus. The morphological plasticity in this particular brain region is induced by strong secretion of neurohypophysial hormones in lactating animals and includes rapid and reversible changes in the astrocytic coverage of the neurons and their synapses. Consequently, the SON serves as a structure that allows the comparison of synaptic transmission in a specified subgroup of neurons under different conditions of astrocytic neuronal wrapping. As previously mentioned, an important functional role of astrocytes covering synaptic structures is to remove the neurotransmitter glutamate from the synaptic cleft, as well as limit the diffusion of neurotransmitters into the extracellular space. Thereby astrocytes influence glutamatergic neurotransmission. Astrocytes control the intersynaptic cross-talk with their fine processes. Furthermore, they are morphologically positioned to sense communication mediated by extrasynaptic transmission. A number of electrophysiological and histological studies have found that, indeed, astrocytes contribute to synaptic transmission in the SON by controlling the clearance and diffusion of glutamate in the extracellular space. Glutamate which is synaptically released in the SON not only binds to the postsynaptic ionotropic glutamate receptors but also binds to presynaptic modulatory metabotropic glutamate receptors (mGluRs). Activation of mGluRs leads to a reduction of glutamate release from glutamatergic synapse by a negative feedback loop. The activation of presynaptic mGluRs is a tonic action, thereby rendering this mechanism extremely sensitive to changing levels of glutamate. When neuronal signal transmission in virgin and lactating animals is compared, experiments clearly show that in lactating animals more glutamate is available in the extracellular space when astrocytic processes are farther away from the active glutamatergic synapses and thus are less effective in removing glutamate. This phenomenon can be measured as a strong reduction of efficacy at excitatory synapses accompanied by higher glutamate levels, leading to a stronger activation of presynaptic mGluRs, which in turn leads to a reduction of glutamate release. However, it appears that this is not the only influence of glia on synaptic transmission in the SON. In lactating animals, under conditions of reduced glial coverage of neurons and synapses, the intersynaptic cross-talk between glutamatergic and GABAergic synapses is also modulated. Glutamate which is released into the synaptic cleft also binds to presynaptic mGluRs at neighboring GABAergic terminals, leading to a potentiation of transmitter release and to a phenomenon called heterosynaptic depression. Heterosynaptic depression is much more pronounced in lactating animals, in which glutamate can easily diffuse to neighboring synapses and is cleared less

efficiently, than in virgin animals. Whether this effect is a consequence of less effective glutamate uptake or of facilitated diffusion of glutamate in the extracellular space is not clear. Taken together, these results from SON clearly demonstrate that alterations in the morphological relationship between astrocytes and neurons strongly affect synaptic function.

Release of Neurotransmitters and Neuromodulators from Astrocytes to Modulate Synaptic Efficacy

The discovery that astrocytes are capable of releasing neurotransmitters and that this process is a regulated action led to the assumption and, later, experiments clearly demonstrating that astrocytes are capable of modulating synaptic transmission and neuronal excitability via the release of gliotransmitters into active neuronal synapses. These gliotransmitters are not different from neurotransmitters; they are almost identical molecules. The term gliotransmitter is therefore mainly used to emphasize that a given molecule is released from glia cells. Generally, modulation of synaptic transmission via the release of neuroactive substances can be achieved in two ways:

1. Directly via the release of neurotransmitters, thereby either enhancing the stimulus or stimulating modulatory receptors at the active synapse.
2. Via the release of neuromodulatory substances, thereby modulating the function and efficacy of neurotransmitter and neurotransmitter receptors.

As mentioned previously, not all gliotransmitters are particular to astrocytes. Astrocytes use two of the most widely distributed transmitters – glutamate and ATP – to exert their influence on synaptic transmission. A third important gliotransmitter is D-serine. This potent modulator of synaptic transmission is exclusively synthesized by and released from astrocytes. It is therefore a special gliotransmitter in that neurons rely on astrocytes for the synthesis and release of this neuromodulatory molecule. D-Serine is a coagonist and potent modulator of *N*-methyl D-aspartate (NMDA) receptors. NMDA receptors are key players in glutamatergic excitatory synaptic transmission and have been implicated in many physiological processes, including learning and memory, but also in pathophysiological processes. Thus, influencing NMDA receptor function is a very potent way of modulating synaptic transmission with regard to the physiological process implicated in the basis of memory formation and learning. This might explain why a number of studies have demonstrated a direct action of astrocytes on neuronal NMDA receptors, either by activating or by modulating their function.

Release of Glutamate from Astrocytes to Influence Synaptic Transmission

One of the first molecules proposed to be released from astrocytes as a gliotransmitter was glutamate. The regulation and mechanism of its secretion from astrocytes have been well studied. Glutamate is released from vesicles in the same manner as it is released from presynaptic terminals. However, astrocytic release sites usually contain less vesicles and do not have a classical postsynapse as the target counterpart. Nevertheless, glutamate released from astrocytes exerts a number of important functions influencing and synchronizing neuronal activity. After the first results were obtained from *in vitro* co-culture (astrocyte plus neurons) models, the concept that astrocyte-derived glutamate can modulate synaptic transmission was first substantiated *in vivo* in the hippocampus. In these experiments, it was demonstrated that GABAergic activation of astrocytes, leading to an increase in the intracellular calcium concentration, can cause an NMDA receptor-dependent increase in miniature inhibitory postsynaptic current frequency detected in pyramidal neurons and a strengthening of certain inhibitory synapses. A number of experiments have shown that glia-derived glutamate acts on extrasynaptic ionotropic glutamate receptors or on presynaptic mGluRs to modulate neuronal transmitter release. A direct activation of neuronal NMDA receptors following glutamate release from astrocytes was first shown in the thalamus, in which spontaneously occurring Ca^{2+} elevations in astrocytes led to the induction of NMDA receptors-dependent currents in neighboring neurons. This again proves the Ca^{2+}-dependent glutamate release from astrocytes. Later, this finding was substantiated with comparable findings in the hippocampus, in which the astrocyte-mediated influence on synaptic transmission was analyzed in more detail. In these studies, a variety of stimuli, each of which led to astrocytic calcium oscillations, all caused NMDA receptor-mediated slow inward currents (SICs) in area CA1 pyramidal neurons. Detailed analysis of the pharmacology and kinetics of these currents and immunoelectron microscopy clearly demonstrates that the glutamate released from astrocytes selectively acts on extrasynaptic NMDA receptors that contain the NR2B subunit. The currents induced in neurons following astrocytic glutamate release are large and can lead to the modulation of neuronal function by influencing intraneuronal signaling pathways, such as modulating the pathways controlled by the cAMP response element binding protein. However, glial glutamate not only may be important for the function of single neurons but also may serve to synchronize neuronal activity as demonstrated in the hippocampus. A single astrocyte

can evoke simultaneous glutamate-mediated SICs in neighboring neurons. The functional consequences of this concerted excitation of neurons by astrocytes have yet to be determined, but it again proves the integrative role of astrocytes not only at single synapses but also across the multicellular network of the functional brain. Thus, glutamate released from astrocytes onto a number of different neuronal glutamate receptors is a potent way of influencing synaptic transmission either short term via modulating synaptic efficacy, synchronizing neuronal activity, or long term via modulating intraneuronal signal transduction pathways (Figure 2).

Release of D-Serine from Astrocytes to Influence Synaptic Transmission

D-Serine is emerging as one of the most important gliotransmitters because it strongly influences glutamatergic synaptic transmission and is exclusively released from astrocytes (Figure 3). The discovery and mode of action of D-serine are described elsewhere in this encyclopedia; however, the action of astrocyte-derived D-serine on neuronal NMDA receptors is briefly described here. The NMDA-type glutamate receptors require the binding of cofactors to allow the opening of the ion pore. Glycine is such a molecule, binding to the well-defined glycine binding site of the NMDA receptor as a required cofactor. In the past 15 years, it has become clear that D-serine is also an endogenous ligand at the glycine binding site of the NMDA receptor. D-Serine, the only D-amino acid to exert an important function in the human body, is solely produced in astrocytes. Astrocytic serine racemase converts the proteinogenic L-serine into D-serine. Evidence suggests that in some brain regions D-serine, and not glycine, is the only endogenous cofactor at the glycine binding site of NMDA receptors. Thus, secreted D-serine enables astrocytes to influence synaptic transmission by controlling the availability of D-serine and consequently the opening of NMDA receptors. Indeed, in hippocampal cultures devoid of astrocytes, the addition of D-serine is necessary to enable the induction of NMDA receptor-mediated synaptic plasticity, and in classical long-term potentiation (LTP) experiments the addition of D-serine can be a way to overcome the impairment of LTP induction in older animals. Interestingly, a role for astrocyte-derived D-serine in controlling metaplasticity has been demonstrated in the SON. In this brain structure, depending on the amount of glial coverage of synapses, the amount of D-serine released onto glutamatergic synapses is controlled. Because D-serine is the only cofactor for NMDA receptors in this brain region, astrocytes are able to determine whether a synapse exhibits LTP or long-term depression (LTD). When the astrocytic processes retract and the level of synaptic D-serine is reduced, LTD is induced, whereas in virgin rats that have a high degree of synaptic coverage, the same stimulus induces LTP. Thus, astrocytes also control forms of metaplasticity, influencing the overall signal integration in whole brain areas.

Release of Purines from Astrocytes to Influence Synaptic Transmission

In addition to glutamate, astrocytes also release the neurotransmitter ATP. There are much fewer studies

Figure 2 Glutamate released from astrocytes influences synaptic transmission. Astrocytes can release glutamate from vesicles in a Ca^{2+}-dependent manner. Following an increase in the cytosolic calcium concentration, glutamate is released and binds to presynaptic metabotropic glutamate receptors (mGluRs) and neuronal extrasynaptic NMDA receptors of the NR2B type. The activation of these receptors leads to modulation of synaptic transmission. Activation of mGluRs modulates the amount of transmitter released, and activation of NR2B receptors leads to activation of second messenger pathways that have long-term consequences in the signal integration in the neuron.

Figure 3 Astrocytes release D-serine. NMDA-type glutamate receptors require the binding of a cofactor to the so-called glycine site. This cofactor allows the receptor to open when glutamate binds. D-Serine is such a cofactor. D-Serine is exclusively synthesized in astrocytes and released into the synaptic cleft in a calcium-dependent manner. In certain brain regions, such as the supraoptic nucleus of the hypothalamus, D-serine is the only cofactor for the glycine site of NMDA receptors. Thus, the release of D-serine from astrocytes determines whether NMDA receptors on the postsynapse can open and transmit a signal when glutamate is released from the postsynapse.

on the release mode, as well as the mode of action of glia-derived ATP than studies on glutamate. Nevertheless, it has become clear, from studies of the retina and also from studies of the hippocampus, that glia-derived ATP very strongly modulates neuronal excitability. Purines in general, released from astrocytes, are emerging as the type of gliotransmitter that exerts its action even on remote synapses, at a distance far from synaptic activity that originally induced astrocytic activity. Purinergic modulation of synaptic transmission is mainly brought about by adenosine, although astrocytes originally release ATP. ATP is then rapidly degraded by different types of ectonucleotidases in the extracellular space to ADP, AMP, and, finally, adenosine. All these substances potentially activate different subtypes of purinergic receptors. ATP might be released in concentrations that are insufficient to activate neuronal P2 receptors but high enough to allow an accumulation of adenosine that will activate neuronal A1 receptors. Direct influence on synaptic transmission has been demonstrated for glia-derived ATP, degraded to adenosine in the hippocampus. It has been known for some time that presynaptically located adenosine A1 receptors cause presynaptic inhibition of transmitter release, a signaling pathway that is implicated in the physiological basis of heterosynaptic depression: active synapses that are potentiated as a consequence of their activation lead to the depression of neighboring synapses, thereby enhancing the contrast between different potentiated and unpotentiated pathways. It is clear that astrocyte-derived ATP, degraded to adenosine in the extracellular space, mediates this form of neuronal plasticity. A dramatically reduced level of heterosynaptic depression has been measured in the hippocampus of transgenic mice in which astrocytes are impaired in their ability to fuse vesicles at the membrane. Since the addition of ATP or adenosine rescues the effect, it is evident that vesicularly released ATP from astrocytes is the substance allowing the establishment of heterosynaptic depression. Astrocytes are activated by GABA following neuronal activation. GABA acts on astrocytic $GABA_B$ receptors and induces a calcium signal. The calcium signal is communicated in between astrocytes via gap junctions. Astrocytes remote from the synapses originally activated then release ATP, which, degraded to adenosine, leads to the presynaptic inhibition of transmitter release. This multicellular network, required for the induction of heterosynaptic depression, includes astrocytes as an important signaling partner; thus, the basis for functional modulation of synapses is not one astrocyte or two neurons but, rather, a network of astrocytes integrated into the neuronal signaling pathways (Figure 4).

Modulation of Synaptic Transmission Mediated by Astrocyte-Derived Acetylcholine-Binding Protein

A different way to influence synaptic transmission is to control the availability of active transmitter in the synaptic cleft by the presence of transmitter binding and thus neutralizing molecules. Such a molecule is known for acetylcholine. It is a protein that is secreted and binds acetylcholine. The acetylcholine-binding

Figure 4 Astrocytes release ATP and influence synaptic transmission at neighboring synapses. Astrocytes release ATP from vesicles and possibly also via other mechanisms. In the extracellular space, ATP is rapidly degraded by ectonucleotidases to ADP, AMP, and, finally, adenosine. Adenosine activates presynaptically located A1 receptors. The activation of these receptors leads to an inhibition of neurotransmitter release from the presynapse. In the hippocampus, this mechanism is the physiological basis of heterosynaptic depression, a phenomenon involved in synaptic plasticity. Following communication through the astrocytic syncytium, synapses distant from the original point of activity can also be modulated.

protein (AChBP) is secreted from glia cells in the central nervous system of the freshwater snail, *Lymnaea stagnalis*, in which it modulates synaptic transmission. Like the nicotinic acetylcholine receptors, this astrocyte-derived molecule assembles into a heptamer with ligand-binding characteristics typical of a nicotinic receptor. Presynaptic release of acetylcholine induces the secretion of this AChBP from astrocytes, and once in the synaptic cleft, it acts as a molecular trap, binding the transmitter and reducing its availability at the synapse. Evidence for the functionality of this influence on synaptic transmission at mammalian synapses is lacking. Nevertheless, an imbalance of cholinergic signal transmission in a number of diseases, such as Alzheimer's disease and schizophrenia, is well described. The functionality of the AChBP-mediated pathway of glial influence on synaptic transmission is proposed as an explanation for the unresolved issue of the profound imbalance of the cholinergic system in these diseases.

Glial Ion Homeostasis: A Fluorescence Microscopy Approach

J-Y Chatton, University of Lausanne, Lausanne, Switzerland

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Glial cells and, in particular, astrocytes have been assigned the main role of supporting neurons for their function in the brain, including buffering the extracellular potassium and providing energetic support. Advances in glial research have demonstrated a more active behavior of astrocytes, which are able to perform functions traditionally held by neurons, such as intercellular communication or neurotransmitter release, some of them directly or indirectly modulating neuronal network activity. To a large extent, the development of methodological approaches centered around fluorescence imaging has critically contributed to the new understanding of glial functions. This article discusses progress in imaging technology and then reviews some aspects of the current understanding of ion homeostasis in glial cells and their relationship with integrated cellular and network functions.

Technological Approaches

Fluorescence Imaging and Electrophysiology

Because glial cells do not generate action potentials and have a membrane potential that is generally maintained stable by an abundance of K^+ channels at their membrane, they have not attracted the attention of electrophysiologists as much as neurons have. Moreover, when studied in primary culture, astrocytes generally adopt an extremely flat shape with a thickness of a few micrometers, rendering them difficult to impale with microelectrodes. On the other hand, in the past decade a number of innovative imaging approaches of both high sensitivity and resolution – both temporal and spatial – that perfectly complement electrophysiological signal measurements have been developed.

The temporal resolution of electrophysiological techniques along with their exquisite sensitivity, which makes them useful for monitoring single channel kinetics, are currently not matched by those of imaging techniques, although the gap has become increasingly smaller. However, imaging approaches have several decisive advantages over electrophysiological techniques, the most obvious being the ability to monitor parameters with high spatial resolution. It is thus possible to simultaneously monitor responses from many cells or many sites within one cell. This approach has enabled several discoveries that encompass the long-range intercellular mode of communication called Ca^{2+} waves in glial cells.

The resolution of the optical microscope (~0.3 μm laterally and 0.5–1.0 μm axially) enables it to resolve subcellular structures such as organelles or large secretary vesicles. It can also detect, without spatially resolving them, a signal originating from smaller structures or even single molecules. Combining these two features has enabled the measurement of ion changes in microdomains barely accessible to microelectrodes, such as the mitochondrial matrix. Another advantage is that more than one fluorescent probe can be placed in a cell, which allows the monitoring of more than one parameter simultaneously, such as intracellular Ca^{2+} and Na^+ concentrations, or Ca^{2+} concentration changes in the cytosol and in organelles such as mitochondria. This feature provides a decisive advantage for a more complete and integrated understanding of cellular functions.

Organic Fluorescent Indicators

Since their first appearance in the late 1980s, a wide selection of ion-sensitive fluorescence molecules have been synthesized and made commercially available. A major advancement in the development of these probes was the idea of producing membrane-permeant analogs that render them capable of accumulating in cells. Cation-sensitive dyes are usually weak acids containing carboxyl groups and are normally negatively charged at physiological pH. Esterification of these molecules (using ethyl esters or acetoxymethyl ester) allows them to undergo passive diffusion across the cell membrane, and once inside the cell, esterases with broad selectivity hydrolyze the esters, releasing the free cation-sensitive and electrically negative molecule that remains trapped inside the cell. The following are major advantages of this loading method: (1) it is strictly noninvasive; (2) a large number of cells can be loaded simultaneously; (3) because the ester analog is continuously hydrolyzed inside the cell, there is an actual accumulation of the dye well above the concentration of the compound in the bath. Acetoxymethyl ester probes preferentially load into astrocytes in brain slices rather than neurons, which is a significant advantage for glial research.

Most of the probes discussed here can be purchased as membrane-permeant analogs from several sources. However, for fluorescent probes that do not exist as membrane-permeant precursors, other more invasive approaches have to be used, such as microinjection,

incorporation of the dye through the pipette in whole cell patch clamp studies, or pinocytosis.

pH Intracellular pH (i.e., H^+ concentration) was one of the first parameters successfully monitored by fluorescence imaging since the fluorescein molecule and several of its derivatives display intrinsic changes in their fluorescence characteristics (intensity and spectral shifts) depending on ambient pH. This opened the possibility of studying important membrane transporter activities involved in intracellular pH homeostasis. The most widely used pH dye is 2′,7′-bis-(2-carboxyethyl)-5- (and -6)-carboxyfluorescein, which has a p*K*a of ~7.00. This is close to the cellular pH and enables the monitoring of pH in an optimal dynamic range. This dye has an excitation maximum at a wavelength of ~490 nm, which shows pH sensitivity. When excited at ~440 nm, the fluorescence is no longer influenced by pH. This particular point in the spectrum is called the isosbestic point and is used as an internal reference point allowing correction for dye concentration changes or path length/thickness differences. This dye is called an excitation ratio probe. Other pH dyes, such as SNARF-1, display a similar pH dependency within their emission spectra and can be similarly used in the so-called emission ratio mode, which is particularly useful with confocal microscopy.

Ca^{2+} Intracellular Ca^{2+} has been recognized as a second messenger of prime importance critically influencing a number of normal cellular functions and playing a central role in pathological conditions, such as ischemia. The resting cytosolic Ca^{2+} concentration in glia is in the range of 100–200 nM and can reach low micromolar levels during transients. Its detection *in situ* by fluorescent probes is probably one of the elements responsible for the tremendous success of fluorescence imaging techniques. Ca^{2+} has thus become the most studied cation in cell biology, which is reflected by the wide array of probes made commercially available.

Ca^{2+} probes can be classified into low and high Ca^{2+} affinity probes, and they can also be classified according to their spectral properties (excitation in the ultraviolet (UV) or visible spectrum). The most widely used Ca^{2+} probes are Fura-2 (high affinity, UV) and Fluo-3 or Fluo-4 (high affinity, visible). Low affinity probes have a lower tendency to buffer intracellular Ca^{2+} changes and are more suited to resolve large amplitude Ca^{2+} transients. Examples of low-affinity probes are Fluo-5F (low affinity, visible) and Mag-Fura-2 (low affinity, UV). As a nonexcitable cell, the astrocyte does not usually generate large Ca^{2+} spikes, and high-affinity dyes are more often used.

In addition, changes in Ca^{2+} concentration in the microdomains facing the cell membrane (i.e., close to the channel mouth) are of different amplitudes and kinetics compared to bulk cytosolic Ca^{2+} changes. Lipophilic derivatives of Ca^{2+} probes (e.g., fura-C18 and FFP-18) that bind to the membrane surface can be used to selectively respond to Ca^{2+} changes only in the immediate vicinity of membrane channels and transporters. Finally, a class of Ca^{2+} probes can report changes in mitochondrial Ca^{2+}. These molecules (Rhod-2 AM and derivatives) harbor an intrinsic positive charge and preferentially localize in mitochondria of living cells, including glia and neurons.

Mg^{2+} Intracellular Mg^{2+} plays an important role as a mediator of enzymatic reactions, DNA synthesis, hormonal secretion, and muscular contraction. Cytosolic Mg^{2+} concentrations found in cells typically range from approximately 0.1 to 2 mM. Several probes exist with relatively good Mg^{2+} selectivity. As for Ca^{2+} probes, Mg^{2+} fluorescent indicators are available for visible or UV excitation. The most used Mg^{2+} probes are Mag-Fura-2 (UV) and Magnesium Green (visible). However, most Mg^{2+} probes exhibit substantial Ca^{2+} sensitivity, which makes them good low-affinity Ca^{2+} dyes but limits their application as Mg^{2+} probes in situations in which important intracellular Ca^{2+} changes are expected.

Monitoring of intracellular free Mg^{2+} has been used as an indirect but real-time *in situ* measurement of ATP hydrolysis. At the origin of this strategy is the fact that ATP displays a ~10-fold higher affinity for Mg^{2+} than ADP and binds a large proportion of cellular Mg^{2+}. As a consequence, upon hydrolysis of ATP into ADP, one Mg^{2+} ion is released, leading to a detectable increase in the free Mg^{2+} concentration.

Na^+ The development of fluorescent probes for measuring Na^+ has been more challenging than that of Ca^{2+} probes. The most widely used probe, sodium-binding benzofuran isophthalate (SBFI), is a UV excitable dye with similar spectral characteristics as the Ca^{2+} probe Fura-2. Its dissociation constant for Na^+ in the presence of physiological concentrations of K^+ is ~11 mM, whereas its selectivity for Na^+ is approximately 18-fold higher than that for K^+. Na^+ probes with visible excitation currently available (i.e., Sodium Green and CoroNa Green) have provided mixed results depending on the preparation studied. A red fluorescence emitting Na^+-sensitive dye, CoroNa Red, has been shown to localize in mitochondria and therefore may be used to monitor Na^+ concentration changes occurring in the mitochondrial matrix.

Cl^- Chloride has traditionally been difficult to monitor by fluorescence microscopy. Available dyes include MEQ, SPQ, and MQAE, which have in common the fact that their fluorescence decreases by collisional quenching when the intracellular Cl^- concentration increases. In contrast to cation-sensitive dyes, Cl^- dyes are not available in a membrane-permeant form (i.e., acetoxymethyl esters). However, MEQ can be loaded in cell populations in a noninvasive manner when administered in its chemically reduced form dihydroMEQ, which readily crosses cell membranes. Once inside the cell, it undergoes oxidation into a polar form that remains trapped inside the cell. However, because the reduced form is extremely labile, MEQ is not commercially available in this membrane-permeant form so that it is necessary to perform the chemical reduction reaction immediately before loading.

Genetically Engineered Sensors

One of the elements that considerably extended the range of applications of live-cell imaging was the development of the green fluorescent protein (GFP) of the jellyfish *Aequora Victoria*. This fluorescent label can be incorporated into proteins by genetic fusion. Since the original studies describing the use of GFP, several improved variants have been produced that have higher fluorescence quantum yield or improved stability. A powerful feature of these reporter proteins is the ability to target their expression to given cellular compartments such as mitochondria or endoplasmic reticulum, as well as to given cell types in living organisms. In particular, constructs bearing the glial fibrillary acidic protein promoter have been produced to specifically direct the expression of the fluorescent protein constructs to astrocytes in the brain and, as an extension, transgenic animals with this type of mutation have been produced. In parallel with the development of these reporters used as morphological markers, fluorescent protein constructs have also been modified to reflect the chemical environment. For instance, GFP mutants have been produced to report pH changes within acidic compartments such as secretory vesicles.

Another strategy has been employed to build biosensors, namely to rely on sensing elements (e.g., protein sequences) that are the result of the evolution of living organisms which use them to selectively detect changes in the environment. These sensing elements can be coupled to fluorescent proteins by genetic engineering to produce an optical biosensor. The optical detection relies on the fact that two fluorescent molecules with overlapping fluorescence spectra may transfer the absorbed energy from one to the other in a radiationless process called fluorescence resonance energy transfer (FRET). This occurs when the two molecules are situated within a distance of 1–10 nm. Based on this general scheme, an increasing number of optical sensors have been developed to detect ions (Ca^{2+}, H^+, and Cl^-), membrane potential, as well as compounds such as inositol-1,4,5-trisphosphate, cyclic nucleotides, or sugars. For example, the first generation of genetically encoded Ca^{2+} indicators made use of conformational changes in calmodulin induced by Ca^{2+} binding in the presence of a tethered calmodulin-binding peptide M13. The read-out was achieved by detecting changes in the FRET efficiency between two spectral variants of fluorescent proteins, namely cyan and yellow fluorescent proteins, linked to the calmodulin and the M13 part of the construct, respectively.

This approach for detecting ion changes has many advantages, but it suffers from several drawbacks in comparison with classical organic probes. For instance, the dynamic range and amplitude of the response is generally much smaller in FRET Ca^{2+} sensors than with dyes, and transfecting cells can be more invasive than dye loading using membrane-permeant indicators. In addition, protein sensors obviously have a much larger mass than conventional nonprotein indicators, and steric interactions can potentially perturb the normal physiology of the living cell. Nevertheless, the prospect of having transgenic animals expressing such biosensors in given cell types of the brain will push the development of these approaches.

Fluorescence Imaging and Detection Methods

Fluorescence microscopy approaches are generally classified as either wide-field (or conventional) imaging or confocal imaging. In both cases, however, the basic design is based on the epifluorescence principle, in which the strong excitation light is separated from the much weaker emitted fluorescence light by means of a dichroic mirror placed at 45° into the optical path of the microscope. Current research microscopes make extensive use of photonics technologies and routinely use lasers, acousto-optical devices for wavelength selection, and are equipped with high-performance interference filters.

Wide-field imaging In wide-field epifluorescence, the entire field of view is illuminated by the excitation light and fluorescence is visually observed through the oculars or detected using a camera. The main advantages of this approach are that it allows fast detection and requires lower levels of light, which are both crucial parameters for fluorescence imaging of living specimens. Until recently, low-light imaging

devices used for fluorescence microscopy belonged to the class of extremely sensitive and fast intensified cameras, with limited resolution, or to the digital charged-coupled device (CCD) cameras, with excellent resolution but lower sensitivity and reduced speed of acquisition at low light levels. Although digital CCD cameras have recently dominated the field of fluorescence imaging, the so-called electron multiplying CCD, the sensitivity and speed of which are similar to those of the intensified cameras, is becoming the camera of choice.

Confocal imaging In confocal microscopy, the excitation light originating from a laser beam is focused by the objective lens onto a diffraction-limited spot in the specimen plane, with the consequence that fluorescence is excited only in this specific point of the specimen (Figure 1). To obtain an image of the specimen, the whole field has to be exposed to the excitation light generally using a scanning device. Several variations of this basic principle are currently implemented in confocal microscopes, using either a single point scanner or multiple point parallel illumination (e.g., using Nipkow disks, line and slit scanners, array scanners). The second main characteristic of confocal imaging is that, to be detected, the fluorescent light has to pass through a so-called pinhole (i.e., a small aperture diaphragm) placed in the conjugate plane before the detector. Because light emanating from above or below the focal plane in the specimen will be rejected by the pinhole, this arrangement enables one to obtain sharp optical sections of the specimen that otherwise appear blurred in wide-field fluorescence imaging. In thick specimens, such as brain slice preparations, confocal microscopes enable one to obtain sharp images of fluorescent cells or cells loaded with indicators relatively deep into the tissue. This major advantage of confocal microscopy has to be balanced with the disadvantage of being slower and requiring much more intense illumination than its wide-field counterpart. It is beyond the scope of this article to describe the wide array of technological approaches used by confocal microscopes available today.

Advanced imaging and optical approaches In conjunction with or as extensions of wide-field or confocal imaging, several specialized optical approaches have become invaluable tools for neuroscience research.

Two-photon microscopy is a modification of confocal microscopy that considerably improves imaging in thick living tissue, such as brain slices or *in vivo* brains. The basic principle is that instead of exciting fluorophores at the maximum of absorption (e.g., 480 nm for GFP), a wavelength approximately twice this wavelength is used (e.g., ~930 nm for GFP), which corresponds to infrared light. Photons of this wavelength having approximately half the required energy would not be able to excite the fluorophore under normal conditions. However, when two such photons are delivered simultaneously (i.e., within 10^{-15} s) on the fluorophore, they can interact with it in a nonlinear manner to excite electrons of the molecule to an excited state molecular orbital. Relaxation from the excited state to the ground state occurs with the emission of a photon, as for conventional fluorescence. An extremely high density of photons needs to be produced by a pulsed infrared light source, and when focused by the microscope objective lens, multiphoton absorption can occur only at the focal point where light is both spatially and temporally compressed to have two infrared photons reaching the same molecule simultaneously. There are two major advantages to this method: Fluorescence will be emitted only from the focal point, eliminating the problem of out-of-focus background signal (Figure 2), and infrared light allows better penetration compared to

Figure 1 Comparison of fluorescence illumination in wide-field versus confocal microscopy. Whereas in wide-field fluorescence microscopes, the whole field of view is homogenously illuminated, point scanning confocal microscopes illuminate only a diffraction-limited spot focused by the objective lens. In this configuration, the intensity of excitation is maximal at the focal plane.

Figure 2 Comparison of fluorescence illumination in one-photon versus two-photon confocal microscopy. In two-photon microscopy, fluorescence excitation only occurs in a small focal volume where the light density is sufficient for simultaneous absorption of two infrared photons. No fluorescence is excited above or below this focal point, considerably reducing the background signal and allowing direct optical sectioning. Two-photon imaging is particularly useful for imaging in scattering media and thick specimens, such as a brain slice preparation or the whole living brain.

visible or ultraviolet light. Two-photon microscopy therefore enables imaging fluorescent reporter molecules or ion-sensitive probes deeper into the tissue. Although this technology has recently become somewhat easier to implement, the high cost of the laser source (generally a femtosecond Ti:Sapphire laser) remain a significant hurdle for its widespread use. Moreover, several fluorophores suffer from poor two-photon absorption capability.

Flash photolysis allows the fast and spatially defined application of bioactive molecules from photoactivatable inert precursors and is therefore a powerful tool for the dynamic study of the molecular mechanisms underlying physiological processes at the cellular level. The photoactivatable molecules, called caged compounds, are composed of active molecules that are bound to a photoabsorbing group resulting in a photolabile, biologically inert molecule. Upon brief and intense ultraviolet illumination, the photolabile caged compound releases the free, biologically active molecule along with the free caging group (Figure 3). It can be combined with electrophysiological techniques (e.g., patch clamp) or cellular imaging techniques (e.g., fluorescence microscopy) to monitor cellular responses to photoactivation of the caged molecules. Several classes of compounds, such as neurotransmitters, nucleotides, Ca^{2+} and Ca^{2+} chelators, fluorescent dyes, or second messengers, are commercially available as caged compounds and can be used for a wide variety of biological applications in neuroscience research.

Total internal reflection microscopy uses the property that a light beam reaching the interface between two media with different refractive indexes with an incident angle exceeding a critical value is totally reflected. Only a small portion of the radiation, called the evanescent wave, propagates into the distal medium. The evanescent wave will continue to travel into the medium of higher refractive index, but its strength will decay exponentially. Light escaping in this restricted region of the specimen immediately adjacent to the glass–water interface has a thickness usually less than 200 nm and can serve to selectively illuminate and excite fluorophores. This technique is particularly useful with cultured cells to visualize processes such as vesicle exocytosis and trafficking occurring in the close vicinity of the cell membrane facing the coverslip. For instance, it has been used to demonstrate that astrocytes possess a vesicular pool involved in glutamate release.

Glial Transporters and Channels

Glial cells express a large array of transporters and channels at their membrane that allow them to play a central role in regulating the extracellular milieu in the brain. The main primary element energizing these transmembrane ion fluxes comes from the Na^+/K^+-ATPase, which is abundantly expressed by glial cells. This pump utilizes the energy liberated by the hydrolysis of ATP into ADP to export three Na^+ ions and takes up two K^+ ions per cycle, thereby enabling the buildup of Na^+ and K^+ gradients in opposite directions. Because glial cells are not excitable, the Na^+ gradient has the main purpose of serving as the driving force of secondary active transport systems (i.e., cotransporters and antiporters). It is estimated that Na^+/K^+-ATPase accounts for approximately half of the total cellular ATP consumption.

Transporters

Glial cells, and astrocytes in particular, express several Na^+-coupled transport systems, such as those involved in pH regulation (Na^+/H^+ exchanger and

Figure 3 Intracellular Ca^{2+} photo release by ultraviolet flash photolysis. (a) Upon intense illumination by ultraviolet light, the caged Ca^{2+} molecule, nitrophenyl EGTA, with a bound Ca^{2+} ion undergoes a photochemical reaction leading to the breakdown of the molecule into two parts, liberating the free Ca^{2+} ion. (b) Ca^{2+} uncaging performed in astrocytes loaded with the caged Ca^{2+} compound NP-EGTA AM and the Ca^{2+} probe Fluo-4 AM (top). The UV beam, produced by a powerful light-emitting diode, was aimed at cell 1 in the center. The false color overlay in the bottom image shows that only the targeted cell 1 exhibited a significant elevation of cytosolic Ca^{2+} shown as Fluo-4 fluorescence intensity. (c) Fluo-4 fluorescence intensities plotted against time, showing that repetitive Ca_i^{2+} responses can be triggered by NP-EGTA uncaging in the targeted cell. Scale bar = 100 μm. (b, c) Adapted from Bernardinelli Y, Haeberli C, and Chatton JY (2005) Flash photolysis using a light emitting diode: An efficient, compact, and affordable solution. *Cell Calcium* 37: 565–572, with permission from Elsevier.

Na^+/HCO_3^- cotransporter), Ca^{2+} homeostasis (Na^+/Ca^{2+} exchanger), neurotransmitter uptake (glutamate, GABA, serotonin, and glycine), and amino acid uptake, as well as the $Na^+/K^+/2Cl^-$ cotransporter. They also express anion exchangers (Cl^-/HCO_3^- and Cl^-/OH^-) with a role in pH regulation.

Ion channels

Several ion conductances have been described in glial cells. The most studied are K^+ channels, which represent the most abundant conductance detected in glia and dominate all other ion conductances. They have been assigned the main role of buffering increases in interstitial K^+ concentration resulting from neuronal excitation. In addition, voltage-gated Ca^{2+} channels or voltage-gated Na^+ channels (TTX sensitive) have been reported in several studies, although it is unclear what role this latter channel could play in nonexcitable glial cells. Finally, anion channels are also expressed in glial cells and probably involved in volume regulation.

Ionotropic Receptors

Initially thought to be a genuinely neuronal attribute, ionotropic neurotransmitter receptors have been found to be functionally expressed in glia, such as non-NMDA glutamate receptors (AMPA and kainate receptors) and acetylcholine nicotinic receptors. NMDA receptors appear to be primarily associated with oligodendrocytes rather than astrocytes. No clear consensus exists on the purpose of their presence in glial cells. $GABA_A$ receptors as well as nicotinic acetylcholine receptor currents have also been observed.

Gap Junctions and Connexins

Connexins are proteins that form hexameric structures in the plasma membrane, called hemichannels, which harbor a central pore. When hemichannels of two adjacent cells dock to each other, they form a gap junction channel that enables the intercellular

diffusion of ions and molecules of up to 1 kDa. It is generally assumed that gap junctions contribute to long-range intercellular signaling as well as tissue homeostasis, including the transport of nutrients across the glial network and the spatial K^+ buffering. The gap junction channels can be gated by several stimuli, such as low pH and various pharmacological agents, and hemichannels not apposed to another cell are normally closed. However, under certain conditions, such as low extracellular Ca^{2+} levels, they can open and mediate the release of molecules such as ATP or glutamate from the cell as well as equilibrate ion gradients. Whether such hemichannel openings have significance in nonpathological conditions is currently debated.

Investigating Ion Homeostasis in Relation to Cellular Functions

The availability of fluorescent indicators coupled to sensitive detection devices has allowed the exploration of detailed mechanisms underlying the regulation of H^+, Na^+, Ca^{2+}, and, to a lesser extent, Mg^{2+}. In several cases, a link could be drawn to their role in certain functions at the level of the cell or the tissue. A few examples are discussed next.

Ca^{2+} Homeostasis and Signaling

Researchers began to recognize the decisive advantage of fluorescence imaging technology with the development of the ability to monitor intracellular Ca^{2+} with spatial resolution using indicators that reliably report changes in free Ca^{2+} concentration in the nanomolar to submillimolar range. Imaging techniques have demonstrated that glial cells, although not electrically excitable, show a complex repertoire of Ca^{2+} responses to various electrical, mechanical, and chemical stimuli. For example, astrocytes are able to generate Ca^{2+} signals by Ca^{2+} entry via voltage-gated Ca^{2+} channels, via AMPA receptor activation, and by IP_3-induced Ca^{2+} release following metabotropic receptor stimulation. Ca^{2+} transients in astrocytes have been shown to trigger the release of various transmitters such as glutamate or ATP, which in turn can drive neuronal excitation. In addition, astrocytes are also involved in long-range signaling because they can initiate and propagate the intercellular spreading of Ca^{2+} signals, known as Ca^{2+} waves (Figure 4). Until recently, this type of communication was thought to be an exclusive property of neurons. This form of excitability, also called calcium excitability, required optical approaches to be uncovered.

pH Regulation

Glial cells play a prominent role in overall H^+ homeostasis in the nervous system. Fluorescent indicators are a considerable improvement over ion-sensitive microelectrodes since they are not as invasive as cell impalements, and they provide spatial information on intracellular pH distribution. Studies using fluorescent indicators have provided crucial details on cytosolic H^+ buffering, transmembrane movements of acid–base equivalents, metabolic production of H^+, or sequestration of H^+ into intracellular organelles. Intracellular pH is regulated passively by the buffering capacity of the cell and, most important, actively by mechanisms that glial cells share with other cells types, such as exchangers (Na^+/H^+ or Cl^-/HCO_3^-) or cotransporters (Na^+/HCO_3^-). Changes in glial pH following various physiological stimuli can last from seconds to minutes or longer. They may also occur in pathological situations such as ischemia or epilepsy.

Activation of neurotransmitter receptors and transporters expressed by glial cells can induce pH transients. For instance, stimulation of $GABA_A$ receptor-coupled chloride channels, which present significant permeability to bicarbonate and are expressed in astrocytes, leads to cellular alkalinization because the HCO_3^- gradient is outwardly directed. Conversely, glutamate causes intracellular pH to drop by activating AMPA and kainate receptors, as well as by activation of Na^+–glutamate transporters which cotransport with one proton (or exchange a hydroxyl ion). pH changes in glial cells are thought to be important regulatory signals for function and metabolism, such as the glutamate–glutamine conversion.

Na^+ Homeostasis and Energy Metabolism

Studying Na^+ homeostasis with high spatial and temporal resolution, which cannot be achieved using radioactively labeled tracers or ion-sensitive microelectrodes, can be performed using fluorescent indicators. The transmembrane Na^+ gradient generated by Na^+/K^+-ATPase plays a central role in providing the driving force for secondary transport systems, such as the Na^+/H^+ or Na^+/Ca^{2+} exchangers, which are important regulators of intracellular pH and Ca^{2+}, respectively. One of the most specific functions of glial cells is the recapture of extracellular glutamate by Na^+–glutamate cotransporters, thereby preventing its buildup to excitotoxic levels during neuronal activity. Because of the prominent activity and density of Na^+-dependent glutamate transporters in glia, glutamate transport is accompanied by a substantial Na^+ influx that causes a three- or fourfold increase in the intracellular Na^+ concentration

Figure 4 Intercellular Ca^{2+} wave in cultured astrocytes. Sequence of images of mouse astrocytes in primary culture loaded with the Ca^{2+} probe Fluo-4 AM. A Ca^{2+} response was triggered using a stimulation microelectrode placed 20 μm above the surface of one cell in the center of the field. The time course of the Ca^{2+} wave spreading from the center can be seen.

(Na_i^+), which is detectable with good accuracy using dyes, particularly SBFI. Such measurements are therefore an indirect means of detecting the spatial distribution of glutamate transport activity in real time. Studies have shown that Na_i^+ is the result of the balance between the rate of Na^+ influx and extrusion by Na^+/K^+-ATPase. Fluorescence imaging studies have demonstrated that glutamate transport activity causes a substantial energy burden to the cell by increasing the overall activity of Na^+/K^+-ATPase by a factor of two or three, increasing in turn its associated ATP consumption by a corresponding factor.

Astrocytic Processes Ensheathe Hypothalamic Neurons and Synapses

As in all brain areas, astrocytes are the most numerous glial cells in the hypothalamus. They have a variable, complex morphology, consisting of relatively small somata, several thick processes extending into the neuronal network (Figure 1), and numerous thin processes (Figure 2). At times, the latter consist merely of two membranes enclosing little cytoplasm and few organelles (Figures 3 and 4). These lamellipodia-like processes ensheathe neuronal somata, dendrites, and synapses, to a varying degree. Bulges at their tips can surround several synapses, thereby creating glial microdomains which permit neuron–glia interactions in a restricted microenvironment. In addition to supportive and nutritive functions, astrocytic processes, by their mere presence, act as a physical barrier to restrict spillover and diffusion of locally released neuroactive substances in the extracellular space (Figure 5).

These include ions (e.g., K^+), neurotransmitters (e.g., glutamate and γ-aminobutyric acid (GABA)), steroids, various neuropeptides (e.g., oxytocin and vasopressin), and amino acids (e.g., taurine and D-serine). On the other hand, since astrocytic processes carry many neurotransmitter receptors, transporters, and ion channels on their surfaces, they can intervene actively and rapidly in neuronal communication. For example, the numerous transporters on their surface (Figure 2) assure quick and efficient removal of glutamate released from synapses, thereby contributing to the regulation of presynaptic glutamate receptors on these and neighboring GABA terminals (Figure 6). This and similar observations have led to the concept of the synapse as a tripartite structure, of which astrocytes play a role as necessary as that of their pre- and postsynaptic neuronal components.

Astrocytes respond rapidly to neuronal activity by increases in free intracellular Ca^{2+}; Ca^{2+} increases, in turn, set off different intracellular signaling mechanisms and gene activation. Such activity-dependent Ca^{2+} signaling ultimately regulates glial structure and function. Ca^{2+} signaling can be bidirectional, since increased astrocytic Ca^{2+} in turn can enhance cytoplasmic levels of calcium in neurons. Astrocytes can thus potentially modulate neuronal activity. Moreover, they can release a variety of neuroactive molecules, termed gliotransmitters (Figure 7), including glutamate, D-serine, and adenosine triphosphate (ATP), that in turn affect synaptic function and neuronal excitability.

Astrocytic Ensheathement of Neurons Varies with Neuronal Activity

Observations from hypothalamic centers such as the supraoptic nucleus (SON), paraventricular nucleus (PVN), and arcuate and preoptic nuclei have revealed that astrocytes are not static cells, since they can undergo significant morphological transformations under different physiological conditions. This structural glial plasticity occurs together with remodeling of adjacent neurons and their afferent inputs and highlights the adult brain's remarkable capacity for restructuring to meet particular functional requirements.

The cytoskeletal protein, glial fibrillary acidic protein (GFAP), accumulates in astrocytic somata and thick processes, and its modified expression may indicate gross restructuring of the cells. Such a phenomenon appears to occur in the SON, where large glial processes, visualized by their immunoreactivity for GFAP (Figure 1), appear to change from a vertical to horizontal orientation during stress conditions (e.g., dehydration), which strongly activate SON neurons. In the arcuate nucleus, the neurons of which participate in the regulation of reproduction, there are significant changes in the expression of GFAP in relation to fluctuating systemic levels of the sex hormone, estrogen. Probably the most striking example of modified GFAP expression in the adult hypothalamus is offered by the suprachiasmatic nucleus, which regulates the diurnal clock and in which GFAP levels and distribution change dramatically in relation to circadian rhythmicity. Nevertheless, it must be kept in mind that since fine astrocytic processes are devoid of GFAP, changes in GFAP expression offer no clue as to their motility.

It is the rapid motility of the lamella-like distal processes of astrocytes that appears initiated by neuronal activity and which is the basis of glia–neuron crosstalk. Convincing evidence for this has been offered by morphological and electrophysiological observations of the SON and of the magnocellular portions of the PVN. These hypothalamic areas are composed of magnocellular neurons that secrete the neurohormones oxytocin and vasopressin and that show enhanced activity during conditions such as parturition, lactation, and osmotic regulation. In the SON,

Figure 1 The majority of astrocytes in the rat supraoptic nucleus (SON) of the hypothalamus have a radial morphology, with somata aligned along the base of the brain, giving rise to long, thick processes traversing the nucleus. Confocal microscopy of a coronal section after immunofluorescence labeling for the cytoskeletal protein, glial fibrillary acidic protein. Figure 4 Electron micrograph of glutamatergic (glut+) terminals in the supraoptic nucleus after ultrastructural immunogold labeling for glutamate. The terminals make synaptic contact (at arrowheads) on a neuronal soma (S). They are ensheathed by fine astrocytic (astro) processes. Adapted from Oliet SHR, Piet R, Poulain DA, et al. (2004) Glial modulation of synaptic transmission: Insights from the hypothalamic supraoptic nucleus. *Glia* 47: 258–267, with permission.

glial remodeling is detectable within a few hours of the onset of parturition or within 1 h of exposure to oxytocin, and results in a significant reduction of astrocytic coverage of oxytocin neurons and their synapses. Thus, under normal conditions, about 90% of any SON neuronal soma is surrounded by astrocytic processes, but at lactation, this is reduced to 70% for oxytocin somata, the surfaces of which become directly

Figure 5 Schema depicting the presence of fine astrocytic processes between supraoptic nucleus (SON) neurons and around axonal terminals in unstimulated (e.g., virgin and postweaned rats) and stimulated (e.g., lactating and dehydrated rats) conditions of neurosecretion. Under stimulation, retraction of astrocytic processes permits diffusion (black arrows) of synaptically released glutamate into the extracellular space; glutamate can then act on the same and/or adjacent synapses (homo- and heterosynaptic interactions; GABA, γ-aminobutyric acid). Adapted from Theodosis DT, Piet R, Poulain DA, and Oliet SH (2004) Neuronal, glial and synaptic remodeling in the adult hypothalamus: Functional consequences and role of cell adhesion and extracellular matrix adhesion molecules. *Neurochemistry International* 45: 491–501, with permission.

juxtaposed (Figure 5). Concomitantly, glial coverage of their dendrites is diminished, which gives rise to the appearance of numerous bundles of directly juxtaposed dendrites. There is also an important reduction in astrocytic ensheathement of synapses impinging on their somata and dendrites. The axons of these neurons project to the neurohypophysis, where significant glial rearrangements take place concurrently. During lactation, for example, there is a reduced ensheathement of neurosecretory axons, retraction of glial processes from the basal lamina around fenestrated capillaries, multiplication of neurosecretory terminals, and, ultimately, an increased neurovascular contact zone. A similar remodeling occurs in the hypothalamic magnocellular nuclei and neurohypophysis in response to persistent osmotic stimulation and, interestingly, this affects essentially the oxytocin system. These morphological changes represent physiological plasticity, since glial coverage is reestablished rapidly upon arrest of activation, as after weaning the young, rehydration, or reduction of ambient oxytocin levels.

Rapid, activity-dependent structural plasticity occurs in the basal hypothalamus as well. In the rodent arcuate nucleus, which, as noted earlier, is composed of neurons that participate in reproductive and metabolic functions, the proportion of neuronal somatic surface covered by astrocytic processes fluctuates with changing sexual steroid levels, being high at estrus when plasma estrogen is elevated, and low 24 h later at metestrus when estrogen levels have diminished. Administration of estrogen to ovariectomized animals mimics the effects of the estrus cycle, and it is possible to detect a modified glial coverage of neurons within 2 h of steroid injection. The infundibulum and preoptic

Figure 6 Schematic illustration of intersynaptic cross-talk in the supraoptic nucleus (SON). Under unstimulated (control) conditions of neurosecretion, glutamate transporters (GLT-1) on astrocytic processes ensure clearance of synaptically released glutamate. Under stimulated conditions (lactation, chronic dehydration), astrocytic withdrawal results in accumulation of glutamate in the extracellular space. The amino acid then reaches and activates presynaptic metabotropic receptors (mGluR) on glutamate terminals, thereby diminishing release probability (Pr) of glutamate. In addition, lack of astrocytic processes promotes spillover of glutamate, which activates mGluR on adjacent γ-aminobutyric acid (GABA)ergic terminals; NMDAR, *N*-methyl-D-aspartate receptor; AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor. Figure 7 Schema illustrating gliotransmission in the supraoptic nucleus (SON). D-Serine (red squares) is released from astrocytes and, together with synaptically released glutamate (gray dots), activates *N*-methyl-D-aspartate (NMDA) receptors on (SON) neurons. Note that after retraction of astrocytic processes, there is less D-serine for NMDA receptor activation. Diagram courtesy of A Panatier and SHR Oliet.

areas in primates are analogous to the rodent arcuate and in these structures, glial ensheathement of gonadotropin-releasing hormone (GnRH) neurons controlling gonadotropin secretion in the pituitary varies significantly in relation to fluctuating levels of circulating sexual steroids. The axons of basal forebrain neurons project to the external layer of the median eminence where changing sex steroid levels give rise to dynamic axon–glial changes similar to those characterizing the neurohypophysis during different conditions of neurosecretion. Thus, in the median eminence, when plasma GnRH levels are elevated, there is retraction of glial end-feet from the perivascular zone, and this exposes GnRH terminals to fenestrated portal capillaries. Both in the neurohypophysis and median eminence, therefore, glial rearrangements ultimately permit direct access of neurosecretory terminals to perivascular areas, an anatomical configuration that will favor release of neurosecretory products into the circulation.

Consequences of Glial Plasticity

On Extracellular Homeostasis

Astrocytes remove ions from the extracellular milieu, thereby contributing to fluid homeostasis. A lack of intervening astrocytic processes during enhanced neuronal activity can result, therefore, in the accumulation of ions such as K^+, which can facilitate further neuronal excitability. Such increases have been recorded in the SON and neurohypophysis coincident with activation of oxytocin neuron firing during lactation.

On the other hand, the extracellular space is a diffusion channel for molecules implicated in extrasynaptic or volume transmission. If we consider astrocytic processes as a physical barrier in this channel, then, in their absence, diffusion of neurotransmitters (e.g., glutamate, GABA, and catecholamines) will be greatly facilitated (Figures 5 and 6). This then promotes actions distant from their release sites and allows cross-talk between neighboring synapses and neurons (Figure 6). Likewise, locally released neuropeptides (e.g., oxytocin and vasopressin) may diffuse more freely in the absence of intervening glial processes, and this will potentiate their autocrine and paracrine actions.

The extracellular matrix is composed of glycoproteins – cell adhesion molecules, proteoglycans, and tenascins – that are secreted by astrocytes. Some of these molecules are considered permissive factors for glial and neuronal remodeling. However, they can intervene in neuron–glia interactions more directly as well. They are large, complex molecules, potentially hindering access to receptors and transporters. In addition, they can interact heterophilically with other extracellular matrix components to affect neuronal activity directly. The expression of these matrix molecules is often reduced or absent when there are no intervening astrocytic processes between neuronal elements, and this will affect molecular interactions in the external milieu and, therefore, intercellular communication.

On Glutamate and GABA Neurotransmission

Astrocytic processes in the vicinity of glutamatergic synapses limit glutamate spillover and are therefore critical for ensuring point-to-point synaptic transmission. Their absence will enhance levels of ambient glutamate, since the amino acid escapes

reuptake (Figure 6). Glutamate then reaches and stimulates inhibitory metabotropic receptors at presynaptic sites of glutamate and neighboring GABA synapses, leading to homo- and heterosynaptic depression of neurotransmitter release, respectively. The resulting reduction in synaptic efficacy will also diminish background synaptic noise, which renders the neuron more electrically compact, increasing input resistance and the gain of its input–output response. Such changes can be critical for tuning neurons to respond to pertinent synaptic information. Overall, these effects will reduce tonic excitatory input to postsynaptic neurons. On the other hand, the attenuation of inhibitory GABA neurotransmission will ultimately increase their excitability.

On Gliotransmission

The amino acids glutamate and D-serine are produced by astrocytes and have been identified as gliotransmitters mediating astrocyte–neuron cross-talk. Since they are co-agonists in the activation of *N*-methyl-D-aspartate (NMDA) receptors (Figures 6 and 7), the degree of astrocytic coverage of neurons will govern the availability of these receptors for activation. In addition to affecting rapid transmission at glutamatergic synapses, there will be effects on long-term synaptic changes, the direction – long-term potentiation (LTP) or long-term depression (LTD) – and magnitude of which depend on the number of activated NMDA receptors. These phenomena are clearly illustrated by the glial changes in the SON. Since SON astrocytes release D-serine, the levels of the amino acid and its occupancy of NMDA receptors are closely related to the degree of astrocytic coverage. In this nucleus, then, NMDA-dependent phenomena such as LTP and LTD are modified by glial remodeling. By simply getting close to or away from the synaptic cleft, astrocytic processes change the direction of these long-term functional changes. Thus, at the time of glutamate activation, their proximity will make D-serine available, thereby favoring LTP, while in their absence, D-serine levels are reduced, which will favor LTD.

Another identified gliotransmitter is the purine ATP. In the PVN, noradrenalin increases the amplitude of postsynaptic excitatory currents via increased insertion of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors due to a concomitant release of ATP from adjacent astrocytes. In the absence of astrocytic processes, there will be reduction in ATP and, in consequence, reduction of postsynaptic efficacy at these glutamatergic synapses.

On Structural Synaptic Plasticity

Because of their contiguous positioning with respect to neuronal elements and because of their capacity for rapid morphological changes, astrocytes can intervene in synaptic remodeling. Observations from several neuroendocrine systems in which circuits remain plastic throughout life support such a contention. Here also, the oxytocin (OT) system is exemplary, since its astrocytic transformations are invariably accompanied by changes in afferent inputs controlling its activity. Coincident with reduced astrocytic coverage of its somata and dendrites, an increased density of inhibitory (GABA) and excitatory (glutamate, noradrenalin) synapses is always found; synaptic numbers return to unstimulated levels on reestablishment of glial coverage. Both synapse formation and elimination occur rapidly, in a matter of hours.

A similar rapid synaptic remodeling, closely correlated to astrocytic ensheathement of postsynaptic elements, occurs in the rodent arcuate nucleus, where the number of inhibitory axosomatic synapses diminishes at proestrus and is reestablished at estrus, effects that can be mimicked by gonadectomy or estrogen replacement. Likewise, the number of inhibitory synapses on GnRH neurons is modified in relation to puberty in primates and seasonal breeding in ewes. It is noteworthy that synaptic rewiring has been described in the basal hypothalamus of rodents under varying conditions of energy expenditure and food intake, and it is not unlikely that it is accompanied by astrocytic transformations like those in the arcuate nucleus and GnRH system during different reproductive states.

How astrocytic processes actually participate in structural synaptic plasticity remains unknown. Nevertheless, the mere interposition of even the thinnest astrocytic lamella between pre- and postsynaptic partners can prevent synapse formation; their retraction is necessary to free neuronal surfaces on which new synapses can be formed. On the other hand, the reinsertion of astrocytic processes at the end of a period of neuronal activation can facilitate detachment of synaptic terminals from postsynaptic sites (Figure 8), and this will contribute to reestablish synaptic numbers to prestimulation levels.

Glial Participation in Neuroendocrine Regulations

Parturition and Lactation

These key events in mammalian reproduction are under the control of oxytocin acting on the uterus and mammary gland, respectively. The pulsatile release of the neurohormone, before the birth of each offspring and before each reflex milk ejection during lactation, is due to an intermittent, high-frequency firing of oxytocin neurons, synchronized throughout the population in the hypothalamus. At first sight, it

Figure 8 Schema showing possible cell mechanisms that may underlie astrocytic participation in synaptic remodeling in the adult supraoptic nucleus. (a) Synapses may result from hyperactivity in certain terminals that then induce postsynaptic density formation in adjacent neuronal elements. (b) Withdrawal of fine astrocytic processes (arrow) will facilitate this process by freeing neuronal surfaces for new synapse formation. (c, d) Upon diminution of synaptic activity, astrocytic processes reinsert themselves and can thus participate in the undoing of synaptic contacts. Adapted from Theodosis DT and Poulain DA (1993) Activity-dependent neuronal–glial and synaptic plasticity in the adult mammalian hypothalamus. *Neuroscience* 57: 501–535, with permission from Elsevier.

may appear paradoxical that, concurrent to this neuronal excitation, there is a reduction in astrocytic ensheathement of glutamatergic synapses which diminishes the efficacy of excitatory neurotransmission by activating their presynaptic metabotropic receptors (Figure 6). Nevertheless, the action of glutamate on its own release may depend on the level of presynaptic activity, so that during high-frequency firing, an increase in transmitter release probability due to calcium accumulation in the terminals overcomes metabotropic receptor-mediated inhibition. Thus, information transmitted via high-frequency firing would be less affected by inhibitory feedback in contrast to information from inputs displaying low-frequency activity. Such a high-pass filter would serve to increase the signal-to-noise ratio for information transmitted by inputs displaying high-frequency activity, as is the case of glutamatergic inputs driving oxytocin neurons when they are activated. To these effects of glutamate must be added the consequences of intersynaptic cross-talk, which is also facilitated by a reduced astrocytic coverage. As described previously (Figure 6), during intense glutamatergic activity, the amino acid activates metabotropic receptors on neighboring GABA terminals, and this heterosynaptic inhibition of GABA release will disinhibit oxytocin neurons and further facilitate their bursting firing. Changes in gliotransmission will be of consequence to this activity as well. In the absence of astrocytic processes, there is less D-serine in the vicinity of glutamatergic synapses, and this will diminish NMDA receptor activation (Figure 7). Since activation of these receptors is essential for long-term synaptic changes, reduction in glial coverage shifts their activity dependence toward higher activity levels, thereby favoring potentiation of glutamatergic synapses displaying high activity.

Removal of astrocytic processes from between oxytocin neurons will promote the diffusion of other molecules, such as oxytocin produced by oxytocin neurons, which facilitates their bursting and synchronized activity. It is obvious that in the absence of intervening astrocytic processes, the range of action of the peptide will be enhanced and this will result in the recruitment and synchronization of additional bursting neurons.

Finally, there will be facilitation of oxytocin neuron firing because of the increased number of synapses associated with reduced glial coverage. It is obvious that an increase in glutamatergic inputs will potentiate such firing, to which can be added that provided by additional excitatory noradrenergic synapses. As for inhibitory GABAergic inputs, at first glance it might appear incongruous that an increase in their numbers could facilitate enhanced neuronal firing. Nevertheless, the increase in inhibitory input may serve to prevent oxytocin neurons from being activated by factors other than those relevant to parturition and lactation. This kind of 'filtering' action may

contribute to maintain the neurons at a level of depolarization that would facilitate their subsequent synchronous activation just before milk ejection.

To these phenomena in the hypothalamus must be added the facilitatory action on oxytocin secretion provided by glial rearrangements in the neurohypophysis; these result in a significant reduction in glial processes in the vicinity of fenestrated capillaries through which the hormone diffuses. It is obvious that the mere absence of glial processes or end-feet from the perivascular space will promote diffusion of secreted hormones into the circulation, as well as any paracrine actions they may produce within the gland. In addition, the enlarged neurovascular contact area represents both an increased neuronal surface for exocytotic release of the neurohormones and a readier exposure of neurosecretory terminals to capillaries and therefore to the general circulation.

Osmotic Regulation

Oxytocin neurons do not display intermittent high-frequency discharges in hyperosmotic conditions, but they do develop enhanced continuous firing during persistent dehydration. Astrocytic coverage of oxytocin neurons is reduced during chronic dehydration to the same extent as that during lactation, and it is not unlikely that many of aforementioned mechanisms serve to facilitate this kind of activated firing as well.

In addition, there will be effects from other neuroactive molecules known to intervene in osmoregulation, like the amino acid taurine. Taurine is released by astrocytes of the magnocellular nuclei in an osmodependent fashion. It acts on neuronal glycine receptors and, at high concentrations, GABA-A receptors, contributing to mechanisms that inhibit neuronal activity. This kind of regulation may be affected significantly by a reduced glial ensheathement, since the distance between the release site of taurine and its target receptors will be enhanced, thereby reducing the level of glycine and GABA-A receptor activation. Such a reduction may then account, even partly, for the reduced osmosensitivity of oxytocin neurons noted in lactating animals.

The Ovarian Cycle and Reproduction

The neurohormone GnRH, synthesized in neuronal somata scattered in the basal forebrain, is secreted from neurosecretory terminals into the portal circulation of the median eminence to reach the pituitary, where it modulates the secretion of gonadotropins essential to gonadal function and reproduction. As described earlier, the astrocytic ensheathement/synapse relationship of GnRH neurons in various species varies in relation to fluctuating levels of gonadal steroids in the circulation. Even though we lack direct evidence, it is highly likely that astrocytes contribute to estrogen-dependent increases in neuronal firing that are correlated in time with GnRH release. Enhanced levels of the steroid augment astrocytic coverage of GnRH neurons, and this could contribute to an elimination of inhibitory GABAergic inputs that takes place concurrently. A greatly reduced inhibitory input will then certainly increase neuronal excitability and ultimately, secretion of GnRH. As in the hypothalamic–neurohypophysial system, concurrent morphological changes in the median eminence will further contribute to enhance such secretion, since retraction of glial end-feet from the perivascular area exposes GnRH terminals directly to capillaries, thereby facilitating passage of GnRH into the circulation.

Glial Responses to Injury

P G Popovich, L B Jakeman, and D M McTigue, The Ohio State University College of Medicine, Columbus, OH, USA

© 2009 Published by Elsevier Ltd.

Introduction

Glia of the central nervous system (CNS) have largely been considered as support cells that, if injured, become activated but do not necessarily affect neurological function directly. Our current understanding of astrocytes, microglia, and oligodendrocytes reveals that this is a dramatic oversimplification. Collectively, glia outnumber neurons and are tightly integrated with all aspects of neurological function. Moreover, injury-induced activation of glia can directly and indirectly cause both neuronal death and repair. Here, we present the principal glial components of the CNS, their roles in homeostasis, and their responses to injury.

Astrocytes in Normal CNS

Astrocytes were named in the late nineteenth century for their characteristic starlike morphology revealed by silver staining of the intermediate filament cytoskeleton. Dye-filling techniques have revealed a more complete picture of astrocyte morphology. Specifically, astrocytes have a bushy appearance and exhibit larger and more elaborate processes than revealed by silver stains. Astrocytes are the most abundant cells in the CNS and are homogeneously distributed throughout the brain, spinal cord, and retina.

During development, astrocytes arise from progenitor cells found within the ventricular zone and subventricular zone (SVZ). Throughout life, the SVZ is maintained as a thin layer of proliferating cells that can give rise to neurons and glia. Astrocytes and their precursors help sustain neuronal growth and migration by providing essential guidance cues and structural and trophic support.

Astrocytes also help regulate neural and vascular homeostasis. Astrocytic processes closely appose synapses, blood vessels, and the pial surface. Consequently, astrocytes are ideally situated to respond to perturbations. For example, as neurons fire, extracellular K^+ rises, causing astrocytes to depolarize and increase intracellular glycogen reserves. Subsequently, astrocytes release glucose, which supports neuronal energetics. Astrocytes also modulate excitatory neurotransmission by quickly removing glutamate from synapses and converting it to glutamine. Astrocytes interact with endothelia to form and maintain the blood–brain barrier and water balance. The latter is mediated by aquaporin 4 channels on astrocytic end feet found along microvessels. Because mature astrocytes are coupled to one another through gap junctions, they are highly sensitive to physiological and pathological alterations in the CNS. In response to injury, astrocytes represent a syncitium of multifunctional cells that coordinate cellular responses at each interface of the CNS.

Astrocytes in the Injured CNS

CNS injury kills neurons and glia at the site of trauma due to shearing, loss of membrane integrity, and failure to restore ionic homeostasis. However, many astrocytes, microglia, and oligodendrocytes surrounding the site of injury survive. It is the collective interactions of these surviving glia that influence repair and glial-mediated injury processes in the CNS.

The signals that activate astrocytes are multifaceted. Tissue culture experiments show that mechanical stretching or cytokines can elicit a coordinated wave of calcium influx in adjacent astrocytes. Once thought to occur exclusively through gap junctions, this form of intercellular communication requires astrocyte-derived ATP acting at P2X7 receptors. Astrocyte ATP also activates adjacent microglia. As neurons and glia die, astrocytes sequester extracellular K^+ and glutamate through specific transporters. Water uptake is also enhanced through upregulation of aquaporin channels associated with blood vessels. Subsequent failure in Na^+/K^+ exchange causes intracellular solute concentrations to increase and astrocytes to swell. In cases of mild injury, astrocytic swelling and enhanced glutamate transport promote amino acid metabolism, glycogen synthesis, and glutathione release. These compensatory changes evoked by reactive astrocytes constitute a beneficial response to injury. However, more severe CNS damage can overwhelm the buffering capacity of astrocytes, causing them to lose their ability to remove extracellular glutamate. In fact, astrocytes can kill neurons and glia by releasing glutamate and oxidative molecules including nitric oxide. Astrocyte swelling and subsequent loss of contact with endothelia may also exacerbate vasogenic edema, whereas release of K^+ and nitric oxide contributes to vasodilation at the injury site. Activated astrocytes also regulate microglial activation and subsequent neuroinflammation through release of ATP, cytokines, and chemokines. In time, the inflammatory

environment – rich with microglia, macrophages, and the molecules they release – causes astrocytes to transition from an activated to a reactive state.

Reactive Astrocytes and the Glial Scar

Reactive astrocytes are most often identified at the injury site by increased synthesis of glial fibrillary acidic protein (GFAP) and changes in expression of other intermediate filaments, including vimentin and nestin. Astrocyte hypertrophy, visible using GFAP immunohistochemistry, occurs in gray and white matter within a few days after injury and can persist for weeks or months (Figures 1(a) and 1(b)). Astrocytes migrate toward the lesion, where they extend their processes toward and along the borders of the

Figure 1 Astrocytes. (a) Reactive astrocytes in mouse spinal cord gray matter ~7 mm rostral to the site of contusion injury (2 weeks postinjury). Stained with rabbit anti-GFAP and Texas Red donkey anti-goat antibodies. (b) Reactive astrocytes in transverse section of mouse spinal cord white matter ~2 mm rostral to the site of a contusion injury (6 weeks postinjury). Stained with rabbit anti-GFAP and FITC goat anti-rabbit antibodies. (c) Transverse section through spinal cord ventromedial white matter at the site of a moderate contusion injury (6 weeks postinjury). Reactive astrocytes circumscribe the lesion in spared tissue but do not enter into the lesion center (star, unstained regions). Stained with rabbit anti-GFAP and FITC goat anti-rabbit antibodies. (d) Toluidine blue-stained 1 μm-thick section from the glial border of a moderate contusion injury in C57Bl/6J mouse (6 weeks postinjury). Macrophage clusters occupy the lesion site (left of dotted line) and contain degenerating myelin. Closely aligned and interwoven astrocyte processes are evident along the borders of the macrophage-dense region (right of dotted line). (e) Longitudinal section through the site of a spinal contusion in mouse (2 weeks postinjury). A dense border of laminin reactivity is seen along the edges of the injured spinal cord separating the central core of injury (star) from spared or residual tissue. This illustrates the formation of the glial limitans at the lesion edge. Stained with rabbit anti-laminin and Texas Red goat anti-rabbit antibodies. (f) Immunostaining for CSPG glycosaminoglycans (GAGs) on longitudinal sections from an injured mouse spinal cord (1 week postinjury). Note the increased CSPG GAG staining in the glial scar immediately surrounding the lesion (star), with little staining in the lesion center. Positive staining is associated with cellular processes resembling astrocytes and with the surrounding extracellular matrix. Stained with CS56 and goat anti-mouse antibodies. Scale bar = 20 μm (a); scale bar from (a) = 10 μm (b, d), 125 μm (c), 250 μm (e), 100 μm (f).

injury (Figure 1(c)). As these processes encounter activated inflammatory cells and invading mesenchymal cells, they circumscribe the zones of inflammation but do not advance beyond the lesion edge (Figure 1(d)). There, they secrete extracellular matrix (ECM) molecules required for the assembly of a basal lamina or a reconstituted glial limitans (Figure 1(e)). Reactive astrocytes are also seen in distal regions of axonal degeneration, where cell–cell communication with axons, neurons, or microglia may be the triggering factor. In cases of severe injury, astrocyte proliferation can occur, although most proliferation is associated with other cell types. Together with microglia and $NG2^+$ cells, the reactive astrocyte syncitium forms the glial scar.

Increased GFAP expression after injury is a stereotypical response associated with numerous signaling cascades, which are triggered by cytokines, growth factors, hormones, and extravasated blood components such as thrombin. This cardinal feature of reactive astrocytes has been exploited experimentally. By placing transgenes under the control of the GFAP promoter, various adhesion molecules, growth factors, cytokines, and transcription factors have been deleted or overproduced, thereby revealing their biological potential at sites of CNS injury.

Consequences of the Glial Scar

The glial scar serves a dual role in CNS repair. Historically, reactive astrocytes were thought to form a mechanical barrier to axonal growth. Indeed, axons are often found growing along, but not through, an intact or reconstructed glia limitans. However, because reactive astrocytes and other glia in the region produce ECM molecules that cause axon repulsion or die-back, the glial scar is now considered to be primarily a molecular barrier to axonal growth.

Chondroitin sulfate proteoglycans (CSPGs) are a family of ECM molecules upregulated by reactive astrocytes surrounding an injury site (Figure 1(f)). During CNS development, CSPGs are essential because they restrict diffusion of growth factors and limit sprouting and cell migration into inappropriate regions. These same properties can impede regeneration after CNS injury. Indeed, numerous studies have shown that CSPGs contribute to abortive sprouting and failed CNS axon regeneration.

Although the glial scar serves as a barrier to regeneration, experimental data also show that astrogliosis and glial scarring are essential for restoring tissue homeostasis and limiting secondary neurodegeneration after CNS injury. For example, if glial scarring is inhibited by killing reactive astrocytes or by preventing their migration to the injury site, traumatic lesions become larger, neuronal death is greater, neuroinflammation is enhanced, blood–brain barrier function is impaired, and functional recovery can be reduced. Thus, although activated astrocytes are an essential component of the CNS injury response, their growth-inhibitory effect must be titrated or fundamentally changed in order to promote axonal growth.

Microglia

In the early 1900s, del Rio-Hortega recognized microglia as a distinct glial subpopulation. Using a stab wound model in brain, he concluded that microglia had properties similar to macrophages. Nearly 75 years later, microglia are known to be resident CNS macrophages and are often referred to as the brain's immune system. Once activated, microglia rapidly change shape, newly express surface antigens that facilitate cell–cell interactions, and release molecules with neurotrophic and neurotoxic effects. This latter feature of activation has stoked a controversy regarding the biological effect of activated microglia in the injured CNS. Indeed, countless *in vitro* studies have shown that microglia can kill neurons and glia; however, few *in vivo* studies have proven such a cause–effect relationship. This is because it is difficult to determine which process occurs first – neuronal injury or microglial activation. Newer *in vivo* imaging techniques and conditional knockout or transgenic mice will undoubtedly help answer these questions. Despite these ambiguities, our understanding of microglia at rest and in response to injury has changed dramatically during the past 20 years. The following section provides a summary of the various concepts and primary research data that have shaped how we think about microglia after CNS injury.

Microglia in the Normal CNS

Microglia comprise up to 20% of all glia and are homogeneously distributed throughout the CNS (Figure 2(a)). Historically, microglia were believed to have little or no physiological role in the normal CNS. However, using multiphoton imaging to visualize 'green' microglia in the uninjured brain of genetically modified mice, we now know that microglia constantly extend and retract filopodia in a random pattern around their cell bodies. This dynamic surveillance mechanism provides a complete scan of the extracellular space every few hours and is dependent on ATP derived from astrocytes. Clearly, complex interactions between astrocytes and microglia help to maintain CNS homeostasis.

Figure 2 Microglia. (a) Microglia in intact rat spinal cord white matter. OX42 labeling with DAPI counterstain. (b) Activated microglia in lumbar spinal cord of C57BL/6 mouse with an active CNS inflammatory disease (EAE). Microglia labeled with Iba-1 antibody. (c) Phagocytic microglia/macrophages at the center of a mouse spinal contusion lesion (7 days postinjury). Macrophages labeled with FA/11 antibody specific for CD68. Scale bar = 20 μm (a–c).

Microglia in the Injured CNS

Almost immediately after CNS injury, microglia extend filopodia toward the site of damage and undergo a dramatic morphologic and phenotypic transformation. The stellate cell that predominates prior to injury becomes hypertrophied and starts to proliferate (Figure 2(b)). At sites of blood–brain barrier injury, microglia interact with newly recruited phagocytes (Figure 2(c)). In fact, using conventional histology or immunohistochemistry, it is not possible to distinguish between phagocytic microglia and macrophages derived from blood monocytes. As microglia change shape and proliferate, they begin to newly express adhesion molecules, major histocompatability complex antigens, and cytokine/growth factor receptors. These surface proteins facilitate intercellular communication and are closely coupled to the transformation of microglia into immune effector cells capable of secreting an array of bioactive molecules with neurotrophic and neurotoxic effects.

Cytokines, Chemokines, and Microglial-Mediated Injury and Repair

Given their rapidity of activation, their homogeneous distribution in the CNS, and their ability to effectively engage infiltrating leukocytes by the release of cytokines and chemokines, microglia are pivotal in coordinating pathological and repair sequelae after CNS injury. Of the cytokines that are released by microglia after injury, interleukin-1β (IL-1β) and tumor necrosis factor-α (TNF-α) have received the most experimental scrutiny. Still, our understanding of these molecules is incomplete.

Logically, it is difficult to envision that microglia are programmed to release cytokines with the intent to kill. It makes little intuitive sense that the CNS would develop with a well-distributed mechanism for self-destruction. Rather, the magnitude and timing of cytokine release and the microenvironment in which target cells (e.g., neurons and oligodendrocytes) encounter cytokines will determine death or survival. For example, before injury, physiological levels of TNF-α help control synaptic activity by modulating AMPA receptors. In the initial phases of injury, low but rising levels of TNF-α can protect neurons from oxidative and excitotoxic injury; however, as TNF-α levels surpass an undefined threshold, cell death occurs. The differential effects of TNF-α may also be dictated by whether target cells preferentially express TNFR1 (p55) or TNFR2 (p75) receptors. TNF-α binding to TNFR2 initiates signaling pathways that promote cell survival. Activation of TNFR2 also promotes proliferation of oligodendrocyte progenitor cells (OPCs) and subsequent remyelination. Although IL-1β can exert similar reparative effects on neurons and oligodendrocytes, the predominant view is that IL-1β potentiates or causes neurotoxicity. For this reason, analogs of the naturally occurring IL-1 receptor antagonist (IL-1ra) are being tested in clinical trials to treat stroke and are under consideration for use in other CNS disorders.

Data indicate that fractalkine (CX3CL1), a chemokine released exclusively by neurons, influences and regulates microglial activation at rest. As neurons die, their ability to control microglia is impaired. This specificity of control is due to the fact that microglia are the predominant cells expressing fractalkine receptor (CX3CR1) in the CNS. Using CX3CR1-deficient mice, investigators revealed the importance of this ligand–receptor interaction in controlling microglia-mediated neurotoxicity. In response to an inflammatory challenge, neuronal degeneration was enhanced when microglia lacked CX3CR1. Surprisingly, the magnitude of microglial activation and neuronal degeneration was not changed in models of mechanical or traumatic nerve injury (e.g., facial nerve axotomy). These disparate results illustrate the complexity of microglial activation and subsequent cytokine synthesis and emphasize our incomplete understanding of the role of microglia after CNS injury.

Microglial-Derived Growth and Trophic Factors

In addition to their role in amplifying and coordinating inflammation, microglia also release classical neurotrophins, including brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), and NT-3. Consequently, activated microglia have been associated with improved neuronal survival and axonal elongation in the injured CNS. Despite the inherent advantages of having a resident source of neurotrophins, the uncoordinated release of these molecules in an injured microenvironment can also evoke maladaptive responses. For example, focal activation of microglia with subsequent increases in NGF or BDNF can elicit aberrant sprouting of sensory afferents or alter neuronal firing in dorsal horn neurons, causing neuropathic pain.

Transforming growth factor-β1 (TGF-β1) is another microglial-derived cytokine with pleiotropic effects on glia, leukocytes, endothelia, and neurons. The biological importance of this cytokine in peripheral wound healing and scarring is well established. Although data indicate that microglial TGF-β1 may support neurogenesis, this cytokine/growth factor is consistently implicated in promoting glial scarring and the deposition of an extracellular matrix (ECM) that impairs axon regeneration.

Microglia and Extracellular Matrix Molecules

After CNS injury, there is a dramatic change in ECM composition within and around the site of injury. Although astrocytes are pivotal in forming this matrix, components of the ECM activate microglia. Microglia in turn regulate production and degradation of select ECM proteins via the release of cytokines (e.g., TGF-β1) and metalloproteinases. After injury, OPCs and a subpopulation of microglia also upregulate expression of NG2. Like other CSPGs, NG2 inhibits axon growth *in vitro* and perhaps *in vivo*.

Oligodendrocytes and OPCs in the Normal CNS

Oligodendrocytes were first described by Robertson in 1899 as small cells with few processes. In 1921, Rio Hortega officially named these cells oligodendrocytes, which means 'few tree cells.' Like other glia, oligodendrocytes are found throughout the CNS gray and white matter, where individual oligodendrocytes can myelinate as many as 40–50 axons. This important function enables rapid saltatory conduction throughout the CNS. Although myelination is the typical, and sometimes only, function attributed to oligodendrocytes, these cells do more than just ensheath axons. Oligodendrocytes can influence neuron survival, axon transport, axon caliber, and ion channel clustering along axons. Many of these effects are independent of myelination. For instance, simple wrapping of axons by oligodendrocyte processes in the absence of compacted myelin triggers local neurofilament accumulation and axon caliber expansion. In addition, studies of transgenic mice in which oligodendrocytes lacked proteolipid protein or cyclic nucleotide phosphodiesterase revealed marked axon degeneration in the absence of demyelination.

Because oligodendrocytes are postmitotic, trauma or disease of the CNS can cause demyelination with subsequent loss of neurological function. However, in some circumstances, oligodendrocytes may be replaced by $NG2^+$ OPCs, which exist throughout the adult CNS. Currently, the complete functional repertoire of $NG2^+$ cells is unknown; however, it is clear that at least a subset function as OPCs and contribute to oligodendrocyte replacement in the injured or diseased CNS.

Oligodendrocytes and OPCs in the Injured CNS

Oligodendrocytes and OPCs are particularly vulnerable to CNS injury and subsequent secondary injury cascades. For instance, the release of proinflammatory cytokines such as TNF-α and interferon-γ (IFN-γ) from microglia and leukocytes can induce oligodendrocyte apoptosis. OPCs and oligodendrocytes are also extremely sensitivity to oxidative stress, due to low glutathione levels and high intracellular iron content.

In injury or disease states, activated macrophages, dying neurons, and dysfunctional or overloaded astrocytes contribute to the rise in extracellular glutamate. Because oligodendrocytes express AMPA, kainite, and NMDA glutamate receptors, they can succumb to glutamate excitotoxicity. Excess glutamate also decreases OPC proliferation and ultimately causes OPC death. Since these progenitors are needed to produce new oligodendrocytes, the health and survival of OPCs is paramount if endogenous remyelination is to occur.

As oligodendrocytes die, their myelin sheaths unravel and myelin breakdown products accumulate, which can lead to demyelination and functional loss. In addition, degenerating myelin can impair axonal regeneration. Several studies have shown that components of CNS myelin (e.g., myelin-associated glycoprotein (MAG) and Nogo) inhibit growing axons. As described previously, axonal growth inhibition is also mediated in part by reactive astrocytes and the glial scar. Ironically, as the glial scar inhibits growth, it may also protect oligodendrocytes and OPCs by

sequestering these cells from the toxic lesion environment. Moreover, through direct contact and by secretion of growth factors (e.g., ciliary neurotrophic factor, basic fibroblast growth factor (bFGF), and platelet-derived growth factor (PDGF)), astrocytes can promote oligodendrocyte health and replacement.

OPC Responses

OPCs are activated rapidly by CNS injury. Within 24 h, OPCs in and around areas of CNS injury hypertrophy and increase expression of NG2 (Figures 3(a) and 3(b)). OPCs also proliferate and migrate into and around lesioned CNS tissue. On a molecular level, OPCs increase expression of developmentally important transcription factors, such as Olig2 and Nkx2.2. Although the mechanisms responsible for OPC activation are not well defined, *in vitro* data have shown that OPCs are responsive to growth factors and inflammatory by-products produced within the lesion environment. For instance, proliferation is promoted by leukemia inhibitory factor and the chemokine CXCL1, which acts through the CXCR2 receptor on OPCs to stimulate mitosis and prevent migration. OPC survival and differentiation can be enhanced by IL-4. Classical proinflammatory cytokines such as TNF-α and IFN-γ are deleterious to OPC survival, an effect which can be potentiated by the high intracellular iron levels within OPCs.

Figure 3 Oligodendrocytes and NG2+ cells. (a) In normal CNS tissue, NG2 cells display small cell bodies with elongated processes. Anti-NG2, red; DAPI, blue nuclei. (b) NG2 cells within a spinal cord lesion site are hypertrophied with fewer processes. Anti-NG2, red; DAPI, blue nuclei. (c) Oligodendrocyte remyelination after spinal cord injury (70 days postinjury). Note that the thickness of the myelin sheath in the cluster of axons remyelinated by oligodendrocytes (dotted line) is consistently thinner than that of normal intact oligodendrocyte myelin (arrows). Scale bar = 20 μm (a, b).

For effective remyelination to occur, proliferating OPCs must undergo a differentiation process. As OPCs differentiate, they upregulate expression of myelin proteins (e.g., PLP) while downregulating NG2 and PDGFαR. Functional maturation is considered complete when the cell processes of an oligodendrocyte engage bare axons and form compacted myelin. Although this can occur in the adult CNS, the thickness of oligodendrocyte remyelination does not recapitulate the preinjury state (Figure 3(c)). Still, relative to a demyelinated axon, thin oligodendrocyte myelin sheaths support efficient conduction of action potentials. Thus, manipulating OPCs is a theoretically feasible mechanism for promoting functionally significant CNS repair. However, in practice this may be difficult. Indeed, the repair potential of OPCs has been largely defined and examined using chemically induced demyelination in rodent CNS where remyelination is typically complete. The situation is less optimistic in human CNS. Studies examining human multiple sclerosis (MS) plaques have shown that OPCs often infiltrate demyelinated plaques but they do not always differentiate into remyelinating oligodendrocytes. This may be due to a lack of appropriate growth factors in MS tissue or to active inhibition of this process by the bare axons, nearby astrocytes, or infiltrating inflammatory cells.

OPC responsiveness to changes in the environment requires appropriately timed signals from the surrounding tissue. Although many of these signals have been identified in the developing CNS, those required for adult remyelination are still under investigation. Likely candidates include PDGF and bFGF. Inflammation and activated microglia are also likely contributors to remyelination. Specifically, there is a surprising impairment of remyelination in the pathological CNS of animals deficient in TNF-α or MCH class II. Depletion of peripheral macrophages also reduces remyelination after toxin-induced demyelination. The situation is not completely straightforward, however, because the same depletion of macrophages promotes sparing of myelinated axons and neurons in models of CNS autoimmune demyelination, stroke, and trauma.

Potential Roles for OPCs Other Than Oligodendrocyte Replacement

Because NG2 cell processes contact nodes of Ranvier, blood vessels, and synapses, it has been proposed that OPCs serve functions other than predecessors of remyelinating oligodendrocytes. In the hippocampus, NG2 cells have been shown to express glutamate receptors and 'synapse' with glutamatergic neuron terminals. After electrical stimulation of neurons, ion fluxes have been described within NG2 cells. Thus, NG2 cells, along with astrocytes, may help maintain synaptic function.

NG2 cells also may represent an endogenous CNS stem cell. *In vitro* studies have shown that under certain culture conditions, NG2 cells can be induced to differentiate into astrocytes, oligodendrocytes, or neurons. Currently, there is no independent confirmation that astrocyte or neuron formation from $NG2^+$ cells occurs *in vivo*. However, based exclusively on the *in vitro* data, there is hope that boosting the spontaneous gliogenic or neurogenic potential of OPCs may be a viable approach for cell replacement in the injured CNS.

Conclusion

CNS injury triggers a stereotypic cascade of glial activation. The consequences of this response are complex and involve the coordinated interaction of astrocytes, microglia, and oligodendrocytes. Apparent in every aspect of gliosis is the potential for repairing the injured CNS; however, this potential appears to be inefficient and constantly at odds with the ability of all glia to either cause damage (e.g., astrocytes and microglia) or inhibit endogenous repair (e.g., glial scar and myelin inhibitors).

Glial Responses to Virus Infection

Introduction

The nonneuronal cells of the central nervous system (CNS) that provide support to and promote normal neuronal function are termed glia or glial cells. As described elsewhere in this encyclopedia, astrocytes and oligodendrocytes arise from ectodermal tissue just like neurons. Microglia, the immune cells of the CNS, are derived from the bone marrow and migrate into the nervous system at various points during embryonic development and beyond. Many viruses target cells of the central and/or peripheral nervous systems, and glial cells, infected or not, respond with a battery of mechanisms that to a large extent determine, together with the specific characteristics of the pathogen, the eventual outcome of the infection. The final result depends on both the cell type and the virus causing the infection; different cell types have a variable response to different pathogens, and even to the same pathogen, and different pathogens induce different responses in various cell types. We provide an overview of these responses together with a more detailed description of the glial response to human immunodeficiency virus infection of the CNS.

Glial Cells

Glial cells, neuroglia, or simply glia, the most abundant cells in the nervous system, have been described as nonneuronal cells that provide support and nutrition, regulate the internal environment of the brain (especially the fluid surrounding neurons and their synapses), form myelin, and participate in signal transmission in both the peripheral nervous system and the CNS. They also have important developmental roles and are active participants in synaptic transmission (e.g., regulating clearance of neurotransmitters from the synaptic space). Information regarding the biology and functions of astrocytes or astroglia, the most abundant type of glial cell, and oligodendrocytes is provided in other articles in this encyclopedia. Microglia are the resident brain macrophages and, together with the perivascular macrophages that are found around blood vessels in the brain, they perform immune surveillance in the CNS and are capable of phagocytosis and initiating the inflammatory and immune response to most insults. Despite their mesodermal origin, they are commonly categorized as glia because of their supportive role for neurons. Their roles are discussed in more detail later. Perivascular macrophages and microglia arise from bone marrow elements that settle in the CNS at various times during embryonic development and throughout adult life. Perivascular macrophages and perhaps macrophages associated with other CNS regions such as the choroids plexus and the meninges have a relatively short life span within the CNS and, therefore, a considerable turnover in adult life. The parenchymal microglial cells are long-lived and estimated to have an extremely low turnover on the basis of murine and human studies. This has important implications considering that pathogens that establish persistent infections in cells such as microglia ensure their replication for long periods of time after the initial infection.

Glial Responses

Microglial cells are quiescent in the normal CNS and are generally considered to be unable to perform effector functions such as antigen presentation to other immune cells until they are activated by injury or infection. At that time, microglia become the first line of defense. *In vitro* studies have shown that microglia can present antigens and perform other effector functions when activated by proinflammatory cytokines. In addition, infection of mice with Theiler's murine encephalomyelitis virus (TMEV; a natural mouse pathogen that causes an autoimmune demyelinating disease associated with a persistent infection of the CNS and that is used as a model for multiple sclerosis) has been shown to be persistent in murine microglial cells and perivascular macrophages. In this model, chronic demyelinating disease is dependent on $CD4^+$ T cells responding to myelin epitopes presented by microglial cells, suggesting that microglia most likely play an effector role and are critical in establishing an inflammatory response in autoimmune diseases and during viral infection.

The innate immune response is the initial antigen nonspecific response to insults such as traumatic injury and viral or microbial infection. It leads to the rapid production of chemokines and proinflammatory cytokines and subsequent expansion of the intra-CNS immune response. Cells of the innate immune system use the toll-like receptors (TLRs) to recognize 'danger' signals, microbial structures, and pathogen-associated molecular patterns (PAMPs), which are molecules or molecular structures expressed by various classes of pathogenic organisms that are not normally expressed

by eukaryotes. TLRs are members of an ancient superfamily of proteins, also present in invertebrates and plants, that not only activate the innate immune response but also orchestrate the development of adaptive immune responses. By discriminating between diverse stress or danger molecules, microbial structures, and PAMPs, TLRs are able to mount tailored or signal-specific cellular immune responses.

At least 11 such TLRs have been identified in humans and mice, and some of their known ligands are listed in Table 1. TLR2 recognizes peptidoglycan (PG) and associates with TLR1 to recognize bacterial triacyl lipopeptides and with TLR6 to recognize diacyl lipopeptides. TLR3 recognizes double-stranded RNA (dsRNA) which is produced during the replication of many RNA viruses, whereas TLR4 binds to lipopolysaccharide (LPS) from gram-negative bacteria in association with the LPS-binding protein, CD14. TLR9 recognizes unmethylated CpG DNA primarily found in bacteria. Upon engagement of the TLRs by their ligands, TLR-induced signaling leads to the induction of NF-κB, ultimately resulting in upregulation of transcription of chemokines, proinflammatory cytokines, and cell surface molecules involved in the initiation of adaptive immune responses to pathogens. TLRs are present on a wide variety of cells, but specific cell types show preferential expression of certain TLR molecules, probably related to the specific functions that the particular cell types will execute. Monocytes/macrophages have been shown to express most TLRs (with the likely exception of TLR3) during different stages of maturation, whereas dendritic cell expression of TLRs seems to be dependent on both the cell subset and the maturation state: immature dendritic cells express TLR1, -2, -4, and -5 (responding to LPS and PG with upregulation of expression of proinflammatory cytokines such as interleukin (IL)-12 and costimulatory molecules B7-1 and B7-2) and their expression decreases upon maturation, whereas TLR3 expression is increased. Finally, in addition to the recognition of dsRNA by TLR3, other TLRs have been identified as being capable of sensing and mediating responses to viral infections. Thus, TLR2 binds to a cytomegalovirus protein and to the hemagglutinin protein of wild-type, but not vaccine strain, measles virus; TLR4 interacts with the fusion protein of respiratory syncytial virus and with the envelope protein of mouse mammary tumor virus; TLR9 binds to herpesviral genomic dsDNA in mouse cells; and TLR7 in murine dendritic cells and TLR8 in human dendritic cells and macrophages bind to viral ssRNA.

Most TLR molecules signal through a common adaptor protein, MyD88, which binds to the conserved

Table 1 Toll-like receptors in the central nervous system

TLR	*Ligands*	*CNS cell types*		
		Microglia	*Astrocytes*	*Oligodendrocytes*
TLR1	Triacyl lipopeptides (associated with TLR2)	+++	++	
TLR2	MALP-2 (mycoplasma)	+++	++	+
	LAM (mycobacteria)			
	Lipoproteins (gram-positive bacteria)			
	Zymozan (yeast)			
	Hemagglutinin protein of wild-type measles virus[a]			
	Virion protein of cytomegalovirus[a]			
TLR3	Viral dsRNA[a]	++	+++	+
TLR4	LPS (gram-negative bacteria)	+++	++	
	Hsp60, fibronectin, hyaluronan (host-derived factors from stressed or damaged cells)

TLR11	Unknown	?	?	

[a]Viruses or viral molecules that bind to these receptors.

cytoplasmic domain on the TLRs. Following stimulation, MyD88 activates the IL-1R-associated kinase, which associates with tumor necrosis factor receptor (TNFR)-associated factor 6, leading to activation of the NF-κB family of transcription factors. MyD88-independent pathways unique to TLR3 and TLR4 have also been identified, including the activation of interferon regulatory factor-3 and subsequent upregulation of expression of several interferon-inducible genes. Thus, engagement of the TLRs leads to transcriptional activation of cytokines, chemokines, effector molecules, costimulatory molecules, and major histocompatibility complex (MHC) class I and II molecules.

Research has begun to elucidate the expression of TLRs in microglia, as well as their activation by various stimuli. Studies conducted directly on human tissue showed that the brain expressed all TLR molecules except for TLR6 and TLR8, although at levels lower than those observed in a peripheral organ such as the spleen. Slightly different results have been obtained with isolated adult human microglia, which expressed all TLR molecules except for TLR9. Human brain tissue specimens also showed that astrocytes and oligodendrocytes only expressed TLR2 and TLR3. Similarly, it has been shown that cultured neonatal murine microglia expressed all the TLR molecules, although expression in *in vitro* culture and in the CNS environment may vary, thus explaining the slight differences. *In vitro* stimulation of quiescent murine microglia with various TLR agonists, including LPS (TLR4), PG (TLR2), polyinosinic–polycytidylic acid (poly(I:C)) (TLR3), bacterial CpG DNA (TLR9), as well as infection with TMEV, induced the cells to upregulate innate and effector immune cytokines and chemokines (e.g., CCL3/MIP-1α, CCL2/MCP-1, and CCL5/RANTES) that are required for attraction of peripheral macrophages and T cells into the CNS. In addition, TLR stimulation upregulated MHC class II and some costimulatory molecules (B7-1, B7-2, CD40, and ICAM-1), enabling the microglia to effectively present myelin peptide to $CD4^+$ Th1 cells.

Interestingly, microglial cells apparently develop a stronger response to infection with viable TMEV than when stimulated directly with TLR ligands, including poly(I:C), which signals through TLR3. This suggests that the virus may activate innate immunity via multiple TLRs or through other mechanisms that trigger innate immune recognition, such as through dsRNA-activated protein kinase, which binds intracellular viral dsRNA and induces expression of type I interferons. TLR molecules other than TLR3 have been shown to recognize viruses, viral proteins, or viral nucleic acids. Examples are the TLR4-dependent inflammatory immune response to respiratory syncytial virus protein F and to mouse mammary tumor virus envelope protein, or the TLR2/CD14-dependent inflammatory cytokine production in response to human cytomegalovirus infection. Therefore, it is apparent that a more robust innate immune response can be achieved by stimulation/recognition through several TLR molecules (although a combination of LPS and poly(I:C) does not seem to result in a stronger response than either ligand alone in microglial cells). Genetic susceptibility to herpes simplex virus encephalitis has been mapped to UNC93B, a protein involved in the mediation of the response to TLR3, TLR7, and TLR8, and it has been suggested that a deficient interferon response is specifically responsible for this phenotype. The available data therefore suggest that microglia play a key role in both innate and adaptive immune responses, providing the CNS with the means to rapidly and efficiently respond to a wide range of pathogens.

Astrocytes and oligodendrocytes may also aid in the innate and adaptive immune responses, although microglial cells appear to be the most potent CNS resident antigen presenting cells. Studies on oligodendrocytes are more limited, but TLR expression seems to be low and limited to TLR2 and TLR3. In comparison with microglia, astrocytes also express a somewhat limited set of TLR molecules, with predominant expression of TLR3; adult human astrocytes in culture also express TLR4 to high levels.

The astrocytic response to TLR ligands is similar to that of microglia, with some notable differences. For example, TLR-mediated activation of microglial cells results in positive feedback for TLR2 and TLR3 expression but in downregulation of TLR4 expression. However, astrocytic TLR3 ligation and subsequent activation of astrocytes has been shown to result in upregulation of expression of all TLR2, TLR3, and TLR4. In addition, TLR3 can be found in astrocytes both within the cytoplasm and at the cell surface, whereas it is localized almost exclusively in the former in microglial cells. Another striking difference is that although other TLR molecules may be expressed on astrocytes, cellular activation of *in vitro* systems is limited to TLR3 ligands. The underlying reason for the absence of an astrocytic response to other TLR ligands is unknown, but it may be related to expression levels. Finally, activation of adult human astrocytes through TLR3, but not through TLR4, has resulted in suppression of astrocyte growth, promotion of endothelial cell growth, and enhancement of neuronal survival, providing a comprehensive neuroprotective response rather than a polarized proinflammatory reaction. Some differences in TLR expression and responsiveness have been observed in studies on murine and human astrocytes, although data on murine and human microglia appear to be much more consistent.

Thus, the evidence suggests that more cell type-specific, and possibly species-specific, differences in the responses mediated by TLRs are likely to be found as knowledge accumulates. In addition, in a disease context, multiple TLRs may be engaged by multiple ligands in multiple cell types and the ultimate functional outcome will be dependent on the timing of stimulations and cross-regulation of TLR-mediated signaling.

Viral Infections of the CNS

Viruses from many diverse RNA and DNA families and genera can infect the CNS. Some are only neurotropic – they can infect the nervous system – but are not neuropathogenic in normal circumstances, for example, in individuals who have intact immune systems. Others target the CNS principally, and their importance as pathogens is limited to their neurological disease. Some of these are listed in Table 2. In many ways, viral infection of the CNS is more complex than that of peripheral tissues. First, the presence of the blood–brain and blood–cerebrospinal fluid barriers limits viral trafficking into and out of the CNS. Primarily for this reason it was thought for many years that the neural route was the major route of viral entry into the nervous system, and experimental systems documented the retrograde axonal transport along the peripheral nerves of rabies virus, herpes simplex virus, and some nervous system-adapted strains of polioviruses. The olfactory mucosa is a unique anatomical site where distal processes of neural cells are directly exposed to the environment while the processes at the opposite site of the same neural cells establish connections within the CNS. This extremely specialized mucosal site is exploited by some aerosol-borne and respiratory infections to spread to the olfactory bulbs directly from the olfactory mucosa. Importantly, in most natural and experimental infections, viruses invade the brain from the bloodstream (in the so-called hematogenous route). When present at sufficiently high titers in the blood, viruses may infect endothelial cells and spread from them into the nervous tissue, be transported across the endothelial cells within vesicles, or be carried inside the brain within infected cells such as leukocytes migrating into the brain across the blood–brain barrier (BBB).

Once in the CNS, some viral infections in the brain, such as rabies and polioviruses, involve only neurons, and spread within the CNS most likely occurs through dendrites and other neuronal processes. The type and extent of neuropathology also relate to the target cell population and type of infection. Thus, polioviruses infect motor neurons and cause flaccid paralysis, whereas rabies virus infects neurons of the limbic system and cortical neurons leading to behavioral abnormalities in addition to eventual paralysis. Others, such as herpes simplex virus, infect both neurons and glial cells and cause a more focal encephalitis, preferring the temporal lobes. In contrast, some arboviruses (arthropod-borne viruses) cause generalized encephalitis by widespread infection of neurons and other cells. Murine and human cytomegaloviruses preferentially cause lytic infection in immature glial cells during brain development but mainly establish persistent infection in neuronal cells. Finally, the polyomavirus JC virus is an example of selective infection of oligodendrocytes that can lead to a focal or multifocal demyelinating disease, as seen in progressive multifocal leukoencephalopathy.

Cell damage due to viral infection in the nervous system may occur through necrosis induced directly by the virus, as a by-product of the immune response to the infection, or through apoptosis – a mechanism of programmed cell death that is critical in the normal development of the nervous and lymphoid systems, two organs in which excess cells are generated. At the same time, postmitotic cells such as many neuronal populations are not replenished easily and have mechanisms that are designed to protect them from

premature apoptosis, such as expression of antiapoptotic genes. Moreover, they do not express histocompatibility antigens, which exempts them from most T cell-mediated cytotoxicity. In many instances, the balance between these two competing effects results in moderate or no cytopathology, leading to mild or slowly progressing disorders instead of a rapidly fatal encephalitis. In contrast to neurons, virus-infected glial cells can be destroyed not only by the virus but also by immune-mediated mechanisms since they have the capacity to express viral antigens on the surface and are subject to both humoral and cell-mediated immune responses. Neurons have been shown to initiate an innate immune response through poly(I:C) and viral dsRNA interaction with neuronal TLR3 with subsequent induction of β-interferon.

Finally, the association of HIV-1 infection with neurological diseases has raised the significance of viral infections of the nervous system to a new level. The extent of the HIV-1 epidemic and the fact that the virus is present in the CNS of the majority of infected patients have made HIV-1 the most prevalent neuropathogenic viral infection ever recognized. HIV/AIDS-related neurological complications are among the most frequent neurological diseases worldwide. In the developed world, highly active antiretroviral therapy has decreased the incidence of, but not eradicated, the most severe forms (e.g., HIV-1-associated dementia and vacuolar myelopathy), whereas the prevalence of milder cognitive disorders remains high and may even be increasing due to the longer survival and more advanced age of HIV-infected individuals. Because of the intensity and breadth of the many studies that have analyzed HIV infection of the CNS, this lentiviral complication now serves as a paradigm for the relationship between a virus and brain cells, specifically glia, since HIV does not infect neurons in significant levels.

Neurotropism of HIV-1

The CNS is susceptible to infection by retroviruses of various species and in particular by members of the lentivirus family, such as HIV-1. The specific requirements for entry into the brain and the variety of cell types within the CNS increase the complexity of virus–cell interactions in this organ, but the BBB is not an absolute barrier for many viral pathogens, such as HIV-1, since it is selectively permeable rather than impermeable. Cells of the immune system can cross the BBB and enter the brain within the context of immune surveillance in a process that is carefully regulated. Using the lentivirus visna virus of sheep as a model, Haase first proposed that HIV-1 and other lentiviruses enter the CNS as passengers in cells trafficking into the brain as part of normal immune surveillance mechanisms (the 'Trojan horse' hypothesis). For HIV-1, which infects $CD4^+$ T cells and monocytes in the circulation, this model is the most intuitively appealing and, unlike alternative mechanisms, has the most compelling evidence.

Figure 1 schematically shows the potential mechanisms of entry of HIV-1 into the brain. *In situ* hybridization and immunohistochemical analyses have demonstrated virus accumulation in perivascular regions, principally in $CD14^+$ cells. CD14 is an LPS receptor present as a membrane-bound form at the surface of myeloid cells, including monocytes, macrophages, and granulocytes. Therefore, the bulk of HIV-1 entry into the brain takes place within infected monocytes crossing the BBB and migrating into the brain to replenish the population of perivascular macrophages (Figure 1, A). In addition, phenotypic analysis of HIV-1-infected monocytes demonstrates an activation pattern that promotes migration into tissues such as the brain. The infected monocytes differentiate into macrophages and release new virions into the brain's extracellular space, spreading infection to additional perivascular macrophages and microglial cells present within the brain parenchyma (Figure 1, B). Microglial cell activation may also play a role in neuropathogenesis.

T cells also travel into the brain as part of the immune surveillance process, and HIV-1-infected T cells could therefore bring virus into the brain (Figure 1, C). However, the contribution of virions produced by infected $CD4^+$ T cells migrating into the brain to the pool of replicating virus present in the CNS may not be significant since genotypic and phenotypic analyses show that HIV strains from brain are closer to those from monocytes/macrophages than to those from T cells.

There is very limited pathological evidence of HIV-1 infection of endothelial cells, although BBB abnormalities due to HIV infection have been demonstrated (Figure 1, D). Other mechanisms, such as macropinocytosis, transcytosis, or localized loss of BBB functionality, might constitute additional pathways for viral penetration of the BBB, but they are unlikely to account for the bulk of the virus entering the brain.

Several mechanisms for HIV-1 infection of astrocytes have been described (Figure 1, E); however, it is accepted that infection of these cells is mostly nonproductive and that they do not contribute significantly to viral replication in the brain since few astrocytes express viral antigens or RNA. The mechanism of viral entry into astrocytes is also unclear since these cells are CD4 negative and do not express large amounts of the major HIV coreceptors (although detection of corresponding mRNAs has been reported). However,

Figure 1 HIV-1 entry into the CNS, spread, and multinucleated giant cell formation.

it seems likely that the very limited HIV-1 gene expression in astrocytes, the astrocytosis induced in HIV-associated dementia, and the deregulation of cytokine and chemokine signals due to infection of macrophages and microglia all play a role in the alteration or loss of astrocytic functions and brain homeostasis leading to neuropathogenesis.

The HIV-1 envelope glycoproteins expressed on the surface of infected cells mediate cell-to-cell fusion with receptor- and coreceptor-positive cells; in the brain, cell-to-cell fusion involves macrophages and microglia and results in the formation of large multinucleated giant cells or syncytia that also produce virus before they eventually die (Figure 1, F). Their life span after undergoing fusion is unknown, but it is estimated to be days to weeks.

There is no *in vivo* evidence of HIV infection of oligodendrocytes, although *in vitro* infection has been reported. However, binding of gp120 to galactosylceramide or other proteoglycans present on the membranes of oligodendrocytes may reduce myelin synthesis and increase intracellular Ca^{2+} levels, which could lead to apoptosis.

Finally, neurons, as major effectors of cognitive and motor function, must be involved in HIV neuropathogenesis, and indeed there is significant accumulated neuronal cell death in HIV-infected brains. However, neuronal infection has been reported only by some investigators using very sensitive techniques, in agreement with the fact that neurons lack expression of the main HIV-1 receptor CD4. However, different neuronal subsets express some of the chemokine receptors that serve as coreceptors for HIV-1 infection, where they may be involved in cell migration.

The Chemokines and Chemokine Receptors Network

In the CNS, chemokines and their receptors are involved in cell migration, differentiation, activation, and proliferation of glial and neuronal cells. They are essential components of glial and neuronal physiology and play a crucial role in the balance between neuroprotection and neurodegeneration by counteracting the apoptotic signals that may be produced in response to injury and infection. CXCR4 and its only ligand, CXCL12/SDF-1α, are both widely expressed in the normal CNS and may be implicated in neuropathogenesis since they appear to be elevated in the cerebrospinal fluid and brain of HIV-1-infected individuals. Members of the CCR subfamily of receptors have also been detected in physiological conditions and upregulated during inflammatory and neurodegenerative diseases (including in the CNS of simian immunodeficiency virus (SIV)-infected macaques and HIV-1-infected patients), mostly in perivascular macrophages and microglia. Although β chemokines are only weakly or not expressed at all in the normal human brain, altered expression is observed in SIV and HIV encephalitis and could contribute to neuronal

degeneration and dysfunction. However, no neurotoxic effects of β chemokines have been demonstrated. In contrast, several studies have shown that CCL4/MIP-1β and CCL5/RANTES can protect cultured neurons against apoptosis induced by gp120. Therefore, reported alterations in expression of chemokines and their receptors in the lentivirus-infected CNS may have either protective or deleterious effects.

The primary protective role of β chemokines and CCR5 in viral infections of the CNS seems to be better established in the case of West Nile virus (WNV) encephalitis. CCR5 presumably functions normally in antimicrobial host defense because it mediates leukocyte chemotactic responses; however, evidence of antimicrobial functions for CCR5 in humans has been elusive. In a mouse model of WNV infection, CNS expression of CCR5 and its ligand CCL5/RANTES were prominently upregulated by the virus, and this was associated with CNS infiltration of $CD4^+$ and $CD8^+$ T cells, natural killer cells, and macrophages expressing CCR5. Infection of mice engineered to knock out CCR5 expression resulted in increased viral burden and was rapidly and uniformly fatal. This indicated that CCR5 is a critical antiviral and survival determinant in WNV infection of mice that acts by regulating trafficking of leukocytes to the infected brain. In addition, an increased frequency of homozygosity for CCR5Δ32, a defective CCR5 allele found predominantly in Caucasians, has been described in two independent cohorts of patients with laboratory-confirmed, symptomatic WNV infection (4% and 8% vs. 1% in a healthy control population), suggesting that CCR5 also mediates resistance to symptomatic WNV infection in humans. Thus, the same chemokine receptor can protect from fatal encephalitis or mediate infection, depending on the virus. Following WNV infection of the CNS, inflammatory chemokines are expressed by trafficking leukocytes and resident cells (microglia and astrocytes), and chemokine-dependent T cell recruitment to infected CNS tissues is likely to modulate viral pathogenesis. WNV infection also seems to induce neuronal production of CXCL10, which will recruit effector $CD8^+$ T cells through its cognate receptor, CXCR3. Also, a genetic deficiency in CXCL10 has been shown to correlate with reduced T cell trafficking to the CNS, greater viral loads, and enhanced mortality. Although CCR5 is a logical target for drug development in HIV/AIDS, blocking CCR5 could result in an increased risk of WNV disease for these patients.

HIV-1 Neuropathogenesis

Despite highly active antiretroviral therapy, HIV-associated dementia and especially milder psychomotor and cognitive disorders remain an important complication of HIV-1 infection in the developed world and even more so in the developing world, where access to therapy is limited. One potential explanation for the increased prevalence of mild to moderate HIV-associated neurological disorders in developed countries is that low-level viral replication, consistent with all but the most successful antiretroviral regimens, together with the longer life span of treated patients and the insufficient penetration of at least some of the currently used antiretroviral drugs into the brain, leads to slow, progressive neurodegeneration. Absent direct infection of neurons, microglia/brain macrophages and astrocytes will be the key cell types involved in HIV-1-associated neurodegeneration. Two non-mutually exclusive, probably coexisting mechanisms have been proposed (Figure 2):

1. The direct injury mechanism suggests that the production of viral proteins such as gp120, Tat, or Vpr from infected microglia/perivascular macrophages and perhaps astrocytes can cause disruption of normal neurological functions.
2. The indirect or bystander mechanism proposes that neurons are damaged mainly as a consequence of the inflammatory processes triggered in the brain by infected and activated cells, and it has been suggested that once the inflammatory process has taken hold, it may be a self-sustaining chain reaction leading to neurodegeneration.

Direct Injury Mechanism

In vitro experiments have shown that the HIV-1 surface glycoprotein gp120 seems to interact with chemokine receptors in neurons leading to neuronal injury. However, this interaction likely requires previous CD4 engagement, at least for infection, and CD4 is absent in neurons, putting into question its *in vivo* relevance. Alternative scenarios have been proposed since gp120 may induce neuronal cell death through direct interaction with the *N*-methyl-D-aspartate receptor or by further activation/stimulation of macrophages/microglia leading to increased TNF-α production and triggering of caspase-mediated cell death in neurons.

Two other viral proteins, Tat and Vpr, have also been suggested as potential effectors in HIV neuropathogenesis. Tat, a transcriptional transactivator, if secreted from infected cells (as shown *in vitro*) could alter tight junction protein expression and BBB function, upregulate expression of inflammatory mediators such as CCL2/MCP-1 promoting monocyte infiltration, and result in neurotoxicity by multiple intracellular signaling pathways. Viral protein Vpr is involved in cell cycle arrest, transcription, and

Figure 2 Potential mechanisms for HIV-1 neuropathogenesis and neuroprotection.

integration, and it has been shown to activate replication in latently infected cells and to induce caspase-dependent apoptosis of bystander cells such as neurons.

Bystander Effects: Toxicity of Glial Products

HIV encephalitis is associated with immune activation that is seemingly out of proportion to the amount of virus present, due to the alteration of the secretory functions of microglia and brain macrophages. Glutamate, cytokines such as TNF-α and IL-1β, chemokines and other soluble products, macrophage activation markers, quinolinic and arachidonic acids and related metabolites, as well as free radicals, have all been related with astrocytic proliferation and apoptosis and with the activation of uninfected cells, probably contributing to the amplification of HIV-induced neurotoxicity. In addition, some of these macrophage products modify the permeability of the BBB and promote further monocyte migration into the brain.

Glutamate, the major excitatory neurotransmitter, and other excitatory molecules are thought to be involved in HIV-induced neurotoxicity. Increases in extracellular glutamate concentration mediate uncontrolled Ca^{2+} influx and loss of cellular homeostasis, leading to neuronal death through excitotoxicity in a mechanism common to many neurodegenerative disorders. The clearance of extracellular glutamate involves high-affinity uptake by several excitatory amino acid transporters (EAATs), which are mainly expressed in astrocytes which therefore play a key role in neuroprotection against glutamate excitotoxicity. However, in the course of HIV infection, expression of certain astrocytic EAATs is reduced, resulting in a greatly decreased glutamate uptake by astrocytes. On the other hand, expression of certain EAATs has been described in human macrophages and macrophages and microglia in rat models and in simian and human AIDS, suggesting that they may also exhibit neuroprotective properties. This expression seems to be modulated by macrophage/microglia activation and infection, but it suggests that macrophages/microglia can have a protective role against glutamate excitotoxicity during HIV infection, contributing to the maintenance of homeostasis and the prevention of neuronal degeneration.

TNF-α seems to be clearly involved in neuropathogenesis, primarily by promoting additional production of inflammatory cytokines by macrophages and astrocytes, which results in amplification of glutamate release and decrease of glutamate uptake mainly by astrocytes. However, *in vitro* studies have shown that TNF-α can be neurotrophic as well. It has been reported that TNF-α has a neuroprotective role by preventing or attenuating Ca^{2+} accumulation in the

cytosol of neurons as well as through the activation of the antiapoptotic kinase Akt (a major component of pro-survival signaling pathways) and NF-κB signaling (which promotes expression of genes vital for the response to insults).

Finally, β chemokines and CX_3CL1/Fractalkine have also been shown to protect neurons from gp120 toxicity upon receptor interaction, again through Akt and NF-κB, suggesting that neuronal chemokine receptors mediate the neurotrophic effects of β chemokines and Fractalkine. Since TNF-α induces production of β chemokines by activated glial cells and of Fractalkine by astrocytes, it is likely that these cytokines and chemokines are involved in an extremely complex network of both paracrine and autocrine interactions between neurons and glial cells, with outcomes and functional consequences that are difficult to predict.

Concepts of Steroid Hormones, Neurosteroids, and Neuroactive Steroids

The finding that the nervous system is a target for steroid hormones is a well-ascertained concept. Indeed, several observations have shown that steroid hormones may regulate the development and function of the nervous system and affect mood, behavior, and cognition. It has been construed for a long time that steroids exert their actions in the nervous system exclusively by a classical endocrine mechanism involving steroid production by endocrine glands; steroids secreted by the adrenals and gonads, for example, enter the blood stream, cross the blood–brain barrier, and then regulate the central nervous system (CNS) and peripheral nervous system (PNS) in various ways. However, further findings have suggested that the effects of steroids in the nervous system are also due to paracrine and/or autocrine mechanisms. This concept is based on observations obtained by Baulieu and co-workers in 1981 indicating that the synthesis of steroids is not only a peculiarity of peripheral glands but may also occur in the CNS (i.e., the formation of the so-called neurosteroids). More recent observations by the same group indicate that also PNS synthesizes neurosteroids. On the other hand, because in many circumstances it is difficult to discriminate whether the steroid effect is due to *in situ* synthesis (i.e., neurosteroids), to the peripheral hormones (i.e., steroid hormones), or to an enzymatic conversion of steroids in metabolites which are more active and in some cases utilize a different mechanism of action, some investigators in this field use now the term 'neuroactive' steroids.

Steroid Synthesis and Metabolism by Glial Cells

Glial cells play a central role in the synthesis, metabolism, and action of steroids in the nervous system. It has been demonstrated that in the rodent and human CNS, astrocytes and oligodendrocytes express several enzymes involved in steroidogenesis (Figure 1), such as, cytochrome P450 side-chain cleavage (P450scc), 17α-hydroxylase/C17,20-lyase (P450c17), 3β-hydroxysteroid dehydrogenase (3β-HSD), and 17β-hydroxylase/C17,20-lyase (17β-HSD), and consequently these types of glial cells are able to produce different kinds of steroids. In particular, astrocytes appear to be the most active steroidogenic cells in the brain, since cultures of these cells produce pregnenolone, progesterone, dehydroepiandrosterone, androstenedione, testosterone, and estradiol. On the contrary, oligodendrocytes seem to be able to form only pregnenolone and androstenedione. The steroidogenic activity of microglia has not been assessed. However, systemic macrophages that share many properties and a common origin with microglia express aromatase and produce androgenic and estrogenic derivatives.

The capability to synthesize steroids seems not to be a peculiarity of the CNS, since the PNS also expresses cytochrome P450scc (i.e., the enzyme converting cholesterol to pregnenolone), and 3β-HSD, which converts pregnenolone into progesterone. Interestingly, both P450scc and 3β-HSD are also present in dorsal root ganglia (DRG) neurons. Indeed, P450scc-immunoreactive cells are localized in DRG neurons, and incubation of DRG tissue homogenates with labeled cholesterol has yielded data indicating formation of different steroids, including pregnenolone. Moreover, *in situ* hybridization of small and large sensory neurons from thoracic and lumbar DRG of adult male rats shows expression of 3β-HSD. Furthermore, in co-culture conditions, sensory neurons and Schwann cells are able to stimulate each other via diffusible molecules, representing the expression and activity of enzyme 3β-HSD. The capability to produce steroids is also present in human PNS. Indeed, very high levels of pregnenolone have been measured in human sciatic nerves.

Steroidogenic Acute Regulatory Protein, Peripheral Benzodiazepine Receptor, and Mitochondrial Transformation of Cholesterol in Pregnenolone

The synthesis of pregnenolone from cholesterol by P450scc is the first enzymatic step of steroidogenesis. However, there is a previous step that is rate limiting and hormonally regulated: the transfer of cholesterol from the outer to the inner mitochondrial membrane, where the P450scc enzyme is located. In this mechanism, two proteins located in the mitochondrial membranes, such as the peripheral benzodiazepine receptor (PBR) and the steroidogenic acute regulatory protein (StAR), take an active role (Figure 2). PBR was initially described on peripheral tissues as a second binding site for diazepam, which binds with higher affinity to γ-aminobutyric acid ($GABA_A$)

Figure 1 Biosynthesis of steroids in glial cells. Cholesterol is converted to pregnenolone, catalyzed by cytochrome P450 side-chain cleavage (P450scc), and pregnenolone is converted to progesterone, catalyzed by 3β-hydroxysteroid dehydrogenase (3β-HSD). Pregnenolone and progesterone can be further converted, via 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively, to dehydroepiandrosterone and androstenedione, catalyzed by 17α-hydroxylase/C17,20-lyase (P450c17), and from there to androstenediol and testosterone, respectively, catalyzed by 17β-hydroxylase/C17,20-lyase (17β-HSD). Androstenedione and testosterone can be converted to estrone and estradiol, respectively, catalyzed by aromatase (P450aro). In addition to these pathways, which produce androgens and estrogens, progesterone and its derivative 17-hydroxyprogesterone can be converted to the glucocorticoids corticosterone and cortisol, respectively. Cortisol can be further converted to the glucocorticoid cortisone, catalyzed by 11β-hydroxysteroid dehydrogenase (11β-HSD), and corticosterone, via 18-hydroxycorticosterone, can be converted to the mineralocorticoid aldosterone.

receptors on the nervous system. Further studies have then demonstrated that the PBR is pharmacologically and structurally distinct from the central benzodiazepine/$GABA_A$ receptors. The PBR is an 18 kDa peptide located predominantly in the mitochondrial membranes and represents a critical component of the permeability transition pore, a multiprotein complex implicated in the regulation of apoptosis. In addition, PBR has been related with the regulation of several physiological events, including the control of steroidogenesis. PBR is expressed in the nervous system and predominantly in glial cells of the CNS and PNS. Neural injury and different neuropathological conditions result in the induction of the expression of this molecule. Indeed, PBR basal expression is upregulated in gliomas, in neurodegenerative disorders (e.g., Alzheimer's disease), as well as in various forms of brain injury and inflammation induced by neurotoxins. The induction of PBR expression after injury in the CNS is mainly restricted to microglia and astrocytes. A very similar effect occurs in the PNS. Indeed, the expression of the PBR in Schwann cells increases after nerve lesion and returns to normal levels when regeneration is completed.

StAR is formed as a 37 kDa protein; it is rapidly transported into mitochondria, where it is cleaved, generating a mature 30 kDa intramitochondrial StAR protein that is inactive. This molecule appears to be widely distributed throughout the brain, although different levels of expression have been detected between different brain areas. Moreover, StAR expression seems to be restricted to very specific neuronal and astroglial populations in each brain area, although it is predominantly expressed by neurons. In the PNS, StAR is expressed by Schwann cells. Therefore, both neurons and glial cells may participate in the conversion of cholesterol into pregnenolone.

Figure 2 The synthesis of pregnenolone from cholesterol by the cholesterol side-chain cleavage enzyme (P450scc) is the first enzymatic step of steroidogenesis. However, there is a previous step that is rate limiting and hormonally regulated: the transfer of cholesterol from the outer to the inner mitochondrial membrane, where the P450scc enzyme is located. Proteins located in the mitochondrial membranes, such as the peripheral benzodiazepine receptor (PBR) and the steroidogenic acute regulatory protein (StAR), allow cholesterol to cross the hydrophilic intermembrane space. Both PBR and StAR expression have been detected in glial cells.

Synthesis and Metabolism of Progesterone

As mentioned previously, glial cells of the CNS and PNS may convert pregnenolone in progesterone. Moreover, these cells also possess several enzymes able to transform native steroids into neuroactive steroids. In particular, glial cells are able to metabolize native steroid hormones into their 5α- and 3α-hydroxy-5α-reduced derivatives via the enzymatic complex formed by the 5α-reductase (5α-R) and the 3α-hydroxysteroid dehydrogenase (3α-HSD) (Figure 3). This enzymatic complex is very versatile, since every steroid possessing the Δ^4-3-keto configuration may be first 5α-reduced and subsequently 3α-hydroxylated. Progesterone is a substrate for this enzymatic complex. Namely, in the CNS, astrocytes and oligodendrocytes convert this steroid, by the action of 5α-R, to dihydroprogesterone (DHP) and subsequently, via the action of 3α-HSD, to tetrahydroprogesterone (THP), also known as allopregnanolone. However, among glial cells the conversion of DHP to THP seems to be different. Indeed, observations obtained in culture have indicated that this enzymatic conversion is very high in type 1 astrocytes (which probably correspond *in vivo* to protoplasmatic astrocytes) in comparison to what observed in type 2 astrocytes (which probably correspond *in vivo* to fibrous astrocytes) and in oligodendrocytes. However, the conversion of DHP to THP in oligodendrocytes is significantly higher than that in type 2 astrocytes.

These enzymatic conversions may have an important impact on the mechanism of action of progesterone. In fact, DHP, like progesterone, acts on a classical steroid receptor, such as the progesterone receptor, whereas THP acts on a nonclassical steroid receptor, like the $GABA_A$ receptor. Progesterone

Figure 3 Metabolism of testosterone and progesterone by the action of the enzymes 5α-reductase and 3α-hydroxysteroid dehydrogenase (3α-HSD).

metabolism by glial cells is developmentally regulated. Namely, the formation of DHP in fully differentiated oligodendrocytes is fivefold higher than in oligodendrocyte pre-progenitors and in oligodendrocyte progenitors. On the contrary, the formation of THP is higher in oligodendrocyte pre-progenitors and decreases with oligodendrocyte differentiation. These findings emphasize that not only differentiated CNS cells possess the 5α-R/3α-HSD system, since considerable enzymatic activities converting progesterone are also present in undifferentiated cells, as shown in studies performed on stem cells originating from the mouse striatum.

The ability to convert steroid hormones into 5α- and 3α-hydroxy-5α-reduced derivatives is also present in myelin-forming cells of PNS (i.e., Schwann cells). However, the extent of progesterone metabolism seems to be different with respect to what is observed in the cellular counterpart in the CNS. Therefore, the conversion of progesterone to DHP as occurs in Schwann cells is at least 4 times higher than that in oligodendrocytes, whereas conversion of DHP to THP is lower than that in oligodendrocytes.

Metabolism of Androgens

Testosterone is a substrate for the action of 5α-R and 3α-HSD enzymes. Similar to the aforementioned case for progesterone, testosterone can be converted to dihydrotestosterone (DHT) by the enzyme 5α-R and then to 5α-androstane-3α,17β-diol (3α-diol; also known as androstanediol) by the enzyme 3α-HSD (Figure 3). Both enzymatic steps occur in glial cells. However, again, similar to what was reported for progesterone, these enzymatic steps are different, depending on the types of glial cells considered. For instance, the conversion of testosterone to DHT in type 2 astrocytes and in oligodendrocytes occurs at statistically higher levels than occurs in type 1 astrocytes. Moreover, the conversion of DHT into 3α-diol appears to be mainly localized in type 1 astrocytes. Also, in this case, enzymatic conversions of DHT to its reduced metabolites may have an important impact on the mechanism of action of the steroid. While DHT, like its precursor testosterone, is able to bind the classical steroid receptor for androgens, 3α-diol is able to bind to a nonclassical steroid receptor (e.g., the $GABA_A$ receptor).

Testosterone metabolism by glial cells is also affected by cellular interactions, since the presence of neurons stimulates the activity of 5α-R and 3α-HSD enzymes in astrocytes. The nature of these neuronal signals has been investigated. In mixed glial cultures the formation of DHT is increased by exposure to cAMP analogs (e.g., 8-Br-cAMP). In agreement with this finding, in cultures of glioma cells the stimulation of the β-adrenergic receptor induces activation of the cAMP/protein kinase A-mediated signaling pathway and a rapid elevation of 5α-R mRNA levels. The other alternative metabolic pathway of testosterone is its conversion to estradiol, as discussed in the following section.

Synthesis of Estradiol

The enzyme aromatase (P450aro), which is able to convert testosterone into estradiol, is not expressed by glial cells of the CNS of rodents under normal circumstances; only neurons typically possess such activity. However, rodent astrocytic cultures from the cerebral cortex of neonatal rats are able to produce estradiol and estrone. It is possible that specific culture conditions may induce aromatase expression in astrocytes. Indeed, stressful conditions, such as serum deprivation, induce aromatase expression in cultured rat astrocytes. Furthermore, aromatase is expressed by astrocytes in the brain of birds and mammals after brain injury, indicating that the enzyme may be induced *de novo* in these cells under specific circumstances. In contrast to rodents, aromatase is expressed in radial glia in the brain of teleost fish under normal conditions and also in a subpopulation of astrocytes in the human brain. Aromatase expression in glia seems to be regulated by steroid levels. A first demonstration in testosterone- and estradiol-treated females of a species of vocal (generation of acoustic signals) fish, the plainfin midshipman, shows in the preoptic area and dimorphic sonic/vocal motor nucleus an increase of aromatase mRNA levels.

Functional Implications of Glial Steroidogenesis

Glial cells are not only able to synthesize neurosteroids and to metabolize these or steroid hormones into neuroactive steroids, but these cells are also targets for their own actions. This is not surprising, because it has been clearly demonstrated that central (oligodendrocytes and astrocytes) and peripheral (Schwann cells) glia possess classical intracellular receptors for many families of hormonal steroids (e.g., receptors for glucocorticoids, mineralocorticoids, androgens, estrogens, and progesterone). Moreover, central and peripheral glial cells also express nonclassical steroid receptors – for instance, γ-aminobutyric acid type A and type B receptors ($GABA_A$ receptor, $GABA_B$ receptor), *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), and an atypical intracellular receptor like the sigma-1

protein, which have also been demonstrated to be a target for neuroactive steroid actions.

Schwann cells, oligodendrocytes, astroglia, and microglia are all affected by neuroactive steroids. Namely, these molecules affect proliferation, gene expression, differentiation, metabolism, and morphology of glial cells. For instance, estradiol and progesterone enhance the proliferation of Schwann cells and of oligodendrocyte precursors, but decrease in females the astrocyte proliferation that occurs following brain injury in the cerebral cortex and the hippocampus. Estradiol also decreases proliferation and increases cell death in primary cortical astrocytic cultures, while glucocorticoids decrease oligodendrocyte precursor proliferation.

Examples of effects on gene expression are those exerted by progesterone and derivatives (DHP and THP) or testosterone and derivatives (DHT and 3α-diol) on the expression of myelin proteins in Schwann cells and oligodendrocytes. Moreover, these neuroactive steroids also modulate the expression of transcription factors regulating expression of myelin proteins in Schwann cells.

Steroid effects on glial gene expression and morphology have also been extensively studied in astroglia. Corticosterone and dexamethasone inhibit glial fibrillary acidic protein (GFAP) expression in neonatal and adult rat brain. Pregnenolone, dehydroepiandrosterone, and sex steroids affect astroglia cell shape and regulate GFAP in different brain areas. However, it is important to highlight that the effects of steroids may be different, depending on whether they are acting under physiological or pathological conditions. For instance, estradiol increases GFAP expression and promotes extension of GFAP-immunoreactive processes under physiological conditions, while the same steroid decreases GFAP and vimentin expression in gliotic injured tissue.

Examples of other molecules affected by steroids in astrocytes and microglia are apolipoprotein E, heat shock proteins, metalloproteinase-9, aquaporin-4, glutamate transporters GLUT-1 and GLAST, and a variety of growth factors and cytokines, such as transforming growth factor-α, transforming growth factor-β1, transforming growth factor-β2, basic fibroblast growth factor, insulin-like growth factor 1, tumor necrosis factor-α, and interleukin-12. Furthermore, steroids may also affect neuronal function by the modification of glial metabolism. For instance, glucocorticoids are able to influence the metabolism of glutamate in astrocytes and Schwann cells, increasing expression of both glutamine synthetase and glutamate dehydrogenase in astrocytes and expression of glutamine synthetase and cytosolic aspartate aminotransferase in Schwann cells.

Altogether, these observations indicate that glial steroidogenesis has important functional implications, including regulation of synaptic function and connectivity and neuroendocrine regulation. It has been demonstrated that sex steroids affect synthesis, accumulation, and release by hypothalamic astrocytes and tanycytes of different growth factors that regulate neurons synthesizing and secreting the luteinizing hormone-releasing hormone (i.e., the hormone deputed to the neuroendocrine control of reproductive functions). Moreover, another important functional implication is based on the effects exerted by neuroactive steroids on myelin formation and neuronal survival. These promising effects have recently raised the hypothesis that neuroactive steroids may be considered not only as key regulators of nervous function, but also as protective agents. Examples supporting this hypothesis have been obtained in an experimental model of Niemann–Pick type C disease (a fatal, autosomal recessive childhood neurogenerative disease), Alzheimer's disease, Parkinson's disease, ischemic or spinal cord injury, and acquired (after trauma, during aging, etc.) or inherited peripheral neuropathy, such as Charcot–Marie–Tooth disease.

A possible therapeutic strategy for neurodegenerative events might be treatment with neuroactive steroids, or with synthetic ligands for their classical or nonclassical steroid receptors. However, taking into consideration the *in situ* formation and conversion of steroids at the levels of the glial compartments might be extremely important. In fact, as demonstrated in several experimental models, a local increase in the levels of steroids, or activation of steroidogenic enzymes, may be observed during neurodegenerative events. These findings have suggested that an increase in steroidogenesis is part of an overall mechanism used by the nervous tissue to cope with neurodegenerative conditions. Consequently, modulation of steroidogenesis or of enzymes able to increase neuroactive derivatives (e.g., 5α-R, 3α-HSD, aromatase) at the level of glial compartments might be also considered as an interesting therapeutic strategy. Recent observations have indicated that ligands of PBR – which, as already mentioned, is involved in the first step of steroidogenesis – exert protective effects both in the CNS and PNS, and that *in situ* inhibition of aromatase activity increases neurodegeneration.

Summary

The observations here reported indicate that glial compartments (i.e., astrocytes, oligodendrocytes, Schwann cells, and microglia) play a fundamental role in the production of steroids in the CNS and PNS. Steroids so formed, or activated in glial

compartments, may then act by autocrine pathway on the same cells, or by paracrine pathway on different glial types or on neuronal compartments. Indeed, classical and nonclassical steroid receptors have been reported in both neuronal and glial cells. Paracrine and autocrine effects are then integrated with classical endocrine mechanisms exerted by steroid hormones. Thus, the nervous system is a target for two different pools of steroids, one coming from the peripheral glands and the second one originating directly in the nervous system. The finding that neuroactive steroids may be considered as signaling molecules in glia–neuron and glia–glia cross-talk, together with the effects exerted by these molecules in physiological and pathological conditions, strengthens the concept that they are important key regulators of nervous function.

Introduction

Primary brain tumors are abnormal tissue expansions that result from the uncontrolled proliferation of brain cells. According to the Central Brain Tumor Registry of the United States, approximately 14 per 100 000 people in the United States (i.e., 40 000 patients) will be diagnosed with a primary brain tumor each year. On average, half of these tumors are benign and respond well to treatment. The other half, however, are malignant brain tumors with a poorer prognosis. The vast majority of these (78%) are called gliomas because they appear to be derived from cells of glial origin. These include primarily oligodendrocytes and astrocytes but also the ependymal cells lining the ventricles. Gliomas account for less than 2% of adult cancers. However, despite their rarity, gliomas are the leading cause of cancer-related deaths in men 20–39 years of age and the second most common cause of cancer-related deaths in children. Furthermore, they represent the most common solid tumor in children. The incidence rate for gliomas is highest in patients older than 55 years, for whom the prognosis is also poorest. Patients diagnosed with gliomas typically present with signs of increased intracranial pressure (e.g., headache, vomiting, and papilloedema) and local or generalized brain dysfunction (e.g., seizures and alterations in consciousness). Although a few patients may develop a tumor as a result of an uncommon genetic disorder such as neurofibromatosis types I and II, Li–Fraumeni syndrome, or tuberous sclerosis, or as the result of exposure to ionizing radiation at a young age, for most patients a risk factor for developing a glioma cannot be identified.

Classification

The term 'glioma' refers to a collection of tumors that can be stratified into four well-defined tumor grades based on histopathological criteria. These have been developed by the World Health Organization (WHO) and are now commonly adopted by scientists and physicians. According to this classification system, gliomas are graded on a scale of I to IV, with higher numbers representing more malignant tumors. The grade is based on the presence or absence of the following features: atypical morphology of cells, nuclear atypia, mitotic activity, the presence of necrotic tissue, and the presence of newly formed blood vessels (Table 1). At least three of these features characterize the highest grade IV gliomas, typically necrosis, neovascularization, and enhanced mitosis. The two features that characterize grade III gliomas are most typically mitosis and nuclear atypia. Low-grade, I and II gliomas do not show mitosis but present primarily with cellular and nuclear atypia. The former may be the only feature present in grade I gliomas. Histopathological tumor grading requires a tissue biopsy, ideally taken from the most atypical region of a patient's tumor. As the disease progresses, it is not uncommon for tumor cells to transform into more malignant cells over time. Indeed, many grade II gliomas progress toward a grade IV cancer over a period of years. Tumor grading is not merely academic but instructive with regard to treatment strategies. Low-grade gliomas (I and II), which are less common and more typically diagnosed at a younger age, carry a more favorable prognosis than high-grade tumors. Indeed, patients diagnosed with a grade I astrocytoma have a 5-year survival rate of greater than 90%, and many may not need to receive treatment at all. By contrast, patients diagnosed with a grade IV astrocytoma have a survival rate of less than 4% despite aggressive chemo and radiation therapy. Although lower grade tumors typically have a lower mitotic activity than high-grade tumors, both low- and high-grade gliomas can be highly infiltrative and therefore are rarely surgically curable.

Ependymomas

Tumors deriving from the linings of the ependymal cells lining the ventricle are called ependymomas and also classified as gliomas. Although these tumors are the most common gliomas encountered in the spinal cord and filum terminale, they represent only 5 or 6% of all gliomas and occur predominantly in children and adolescents. Histopathologically, ependymomas often contain tapered, elongated cells (sometimes referred to as 'carrot' or 'ice cream cone' cells) that are arranged around miniature ventricles (forming 'rosettes') or around blood vessels (forming 'pseudorosettes') (Figure 1). Ependymomas tend to carry a more favorable prognosis, with 10-year survival rates greater than 60%.

Oligodendrogliomas

Oligodendrogliomas account for 9 or 10% of all gliomas. They are characterized by an absence of markers associated with astrocyte differentiation and a uniform population of cells that contain round nuclei and very little cytoplasm (the classic 'fried egg' or

Table 1 Characteristics of WHO grade I–IV gliomes

WHO grade	*Characteristics*	*Examples*
I	Low mitotic activity; little nuclear atypia	Pilocytic astrocytoma; demoplastic infantile astrocytoma
II	Low mitotic activity; nuclear atypia; may be infiltrative; may recur	Diffuse astrocytoma (fibrillary, gemistocytic, or protoplasmic); xanthoastrocytoma
III	High mitotic activity; infiltrative; cellular and nuclear atypia; often recur	Anaplastic astrocytoma; anaplastic oligodendroglioma
IV	High mitotic activity; high degree of infiltration; cellular and nuclear atypia; necrosis; neovascularization	Glioblastoma multiforme

Figure 2 Cells of an anaplastic oligodendroglioma demonstrate the classic 'fried egg' appearance: round nuclei with clear, perinuclear halos. Figure 1 Ependymoma cells forming a perivascular pseudorosette demonstrate GFAP immunoreactivity. Reproduced from Lehman N, Jordan M, Huhn S, et al. (2002) Cortical ependymoma: A case report and review. *Pediatric Neurosurgery* 39: 50–54, with permission.

'fish eye' appearance) (Figure 2). Occasionally, these tumors may contain branching vessels that appear to divide the tumor into pseudolobules. Areas of hemorrhage and calcification are more commonly observed in oligodendrogliomas compared to astrocytomas, which may help in making a diagnosis. It is important to distinguish oligodendrogliomas from other gliomas because they are more likely to respond to chemotherapy than other gliomas of the same grade and are less likely to progress to a higher grade tumor. One indication that an oligodendroglioma will respond to chemotherapy is the loss of the 'short arm' of chromosome 1 (1p). This genetic feature along with loss of the 'long arm' of chromosome 19 (19q) are considered to be early events in the oncogenesis of oligodendrogliomas. These deletions are found in 88–100% of tumors of oligodendroglial origin, and they are less frequently found in mixed oligoastrocytomas (tumors that demonstrate histopathological features of both oligodendrogliomas and astrocytomas). Oligodendrogliomas occur more frequently in middle-aged adults. When pediatric tumors do occur, loss of 1p and 19q is less frequently observed, suggesting that these tumors may have a different genetic origin. Oligodendrogliomas most commonly form in the cerebral hemispheres, often expanding along gyri, obscuring the white–gray matter junction.

Astrocytomas

In contrast to oligodendrogliomas, low-grade astrocytomas (WHO grades I and II) are typically found within the margins of white matter. Tumors of this type more frequently show evidence of mutations in p53, a protein responsible for inducing apoptosis and limiting progression through the cell cycle when a cell is damaged. Higher grade astrocytomas may also exhibit amplification of cyclin-dependent kinases and MDM2 (a protein responsible for inhibition of p53) as well as high expression of platelet-derived growth factor ligands and receptors. The end effect of these genetic alterations is an upregulation of survival pathways and a decrease in pro-apoptotic pathways. Low-grade astrocytomas include pilocytic or diffuse astrocytomas, pleomorphic xanthoastrocytomas, and subependymal glial cell astrocytomas. Pilocytic astrocytomas are grade I, noninfiltrating tumors that account for approximately 8% of all gliomas and

are the most common gliomas found in children. These tumors may be fully enclosed by cysts and are sometimes fully resectable. Hence, the prognosis for these tumors is very good because they are often cured with surgery alone. Tumors that contain cells resembling both oligodendrocytes and astrocytes are referred to as mixed oligoastrocytomas. These WHO grade II gliomas carry a better prognosis and longer median survival than pure astrocytomas of the same grade but a less optimistic prognosis than pure oligodendrogliomas. Pure grade II astrocytomas with minimal cellular and nuclear atypia are classified as diffuse astrocytomas. The peak incidence of these tumors occurs in people 25–50 years of age. There are several variants of diffuse astrocytomas, including fibrillary, protoplasmic, and gemistocytic (Figure 3). The cells of fibrillary astrocytomas look similar to astrocytes, with many multipolar processes that look like many small fibers under a microscope. The nuclei of these cells may be cigar shaped and are surrounded by limited cytoplasm. Fibrillary tumors are often immunoreactive for GFAP, vimentin, and S-100 (markers associated with astrocytes in various stages of differentiation). The cells of protoplasmic astrocytomas are more stellar, have smaller processes, and are less likely to be GFAP reactive. Their nuclei often appear vesicular with a prominent nucleolus. Gemistocytic astrocytomas progress more rapidly to grade III and IV astrocytomas. The cells of these tumors contain extensive eosinophilic cytoplasm and odd nuclei. Grade III astrocytomas, anaplastic astrocytomas, account for 8% of all gliomas. Compared to lower grade astrocytomas, these tumors have increased cellularity, obvious nuclear atypia, and enhanced mitotic activity. However, these tumors often do not show evidence of necrosis or microvascular proliferation. The prognosis for this grade of astrocytoma is not as optimistic as that for lower grade astrocytomas because these tumors tend to recur, often as a grade IV glioma.

Glioblastomas

Grade IV gliomas are more commonly referred to as glioblastoma or glioblastoma multiforme (GBM). These most malignant tumors account for 23% of all primary brain tumors and 50% of all gliomas. Although GBMs are more common in older adults, they do account for 8% of all childhood brain tumors. Histopathologically, these tumors are characterized by a lack of uniformity and boundaries. They may contain cysts, calcium deposits, blood vessels, and a mixture of cell types, including giant cells. Typically, these tumors contain focal areas of necrosis with a border of pseudopalisading cells (Figure 4). GBM cells are highly infiltrative and often migrate far from the main tumor site. GBMs may develop from previously diagnosed lower grade tumors. When this occurs, the tumor (sometimes referred to as a 'secondary

(2004) Pseudopalisades in glioblastoma are hypoxic, express extracellular matrix proteases, and are formed by an actively migrating cell population. *Cancer Research* 64: 920–927, with permission.

GBM') is more likely to have evidence of mutations in p53. In addition, secondary GBMs are also frequently observed to have mutations in Rb1 (a protein important in cell cycle progression), in the PI3K/Akt pathway (a pathway that promotes survival), and in growth factor receptors. In fact, amplification of the epidermal growth factor receptor occurs in up to 35% of GBMs, although it is less common in patients younger than 35 years of age. Some mutations occur more frequently in GBMs that appear to arise *de novo* (also known as 'primary GBMs'). One example is a mutation in PTEN, a protein involved in the PI3K/Akt pathway, which appears to occur almost exclusively in primary GBMs.

The prognosis for patients diagnosed with this most common glioma is very poor. The average survival for newly diagnosed individuals is 9–12 months, with a 5-year survival rate of less than 4%.

Other Gliomas

Less common tumors account for the remaining 15% of gliomas. Examples of some less common gliomas include vestibular schwannomas and ganglioneuromas. Vestibular schwannomas are most commonly benign tumors surrounding the nerves supplying the inner ear. Bilateral vestibular schwannomas may occur in patients with neurofibromatosis type II. One of the rarest gliomas observed is a ganglioneuroma. This slow-growing tumor is actually composed of cells with both glial and neuronal characteristics.

Biology

Proliferation

Cancers only develop from cells that are intrinsically able to divide. Consequently, in the brain, neurons which are postmitotic are excluded from this process. However, nonmalignant glial cells appear to retain their ability to proliferate such that they can respond to injury by forming a glial scar that seals off the wound. Furthermore, the brain contains a population of progenitor cells that are also able to proliferate. Although these processes appear well controlled, tumor cell proliferation is uncontrolled due to the underlying genetic mutations that regulate the cell cycle. In fact, several of the genetic mutations found in human gliomas, including mutations in p53, Rb1, and the PI3K/Akt pathways, primarily affect cell cycle progression or the 'brakes' that would normally halt cycle progression (often leading to apoptosis) in mutated cells. The increased proliferative rate of glioma cells allows these cancers to rapidly expand. This causes unique problems as physical tumor expansion in the central nervous system is limited by the confines of the bony skull and spine. Although gliomas can, and do, expand into the ventricles, there are few other spaces into which the tumor mass can grow. One of the means by which gliomas overcome this problem is by destroying surrounding nervous tissue. Peritumoral neuronal necrosis is indeed a characteristic feature of more mitotic gliomas and may be the result of excitotoxicity via an increase in extracellular glutamate. Unlike nonmalignant glial cells which take up glutamate, glioma cells actually release glutamate through the system X_c exchanger, and this glutamate may trigger peritumoral seizures and ultimately the demise of neurons in the vicinity (Figure 5).

Angiogenesis

Expansion of tumor cells can also be limited by the availability of oxygen and nutrients from nearby blood vessels. Glioma cells located ten cell layers or more away from a vessel become hypoxic, which may lead to cell death and would limit the growth of the tumor. To compensate for this problem, more mitotic and atypical gliomas (grade III and IV) form new blood vessels through a process known as angiogenesis. In fact, angiogenesis is one of the criteria used by pathologists to classify grade III and IV tumors. Angiogenesis, or the formation of new blood vessels from preceding vessels, is a well-characterized process that involves increased vascular permeability, extravasation of plasma proteins, breakdown of the existing basement membrane, deposition of proangiogenic matrix molecules, and the subsequent proliferation and migration of endothelial cells. This cascade of events can be initiated by the signaling of vascular endothelial growth factors (VEGFs) through

Figure 5 Role of cystine–glutamate exchange (system X_c) in glioma cell biology. Cystine uptake through system X_c serves as precursor for the synthesis of the antioxidant glutathione. Hence, tumor growth is dependent on the continued supply of cystine via this pathway. Glutamate release is an obligatory by-product of the cystine import and may cause excitotoxic neuronal cell death in peritumoral regions.

Figure 6 HIF-1α (a) and -β (b) are expressed in pseudopalisading cells surrounding central areas of necrosis. Reproduced from Zagzag D, Zhong H, Scalzitti J, Laughner E, Simons J, and Semenza G (2000) Expression of hypoxia-inducible factor 1α in brain tumors. *Cancer* 88: 2606–2618, with permission.

their receptors (VEGFRs). In glioma cells, the vascular endothelial growth factors VEGF-A and PDGF (platelet-derived growth factor) are upregulated. These ligands bind to and activate the VEGF receptors VEGFR-1 and VEGFR-2, which are located in endothelial cells and also appear to be upregulated in the endothelial cells associated with gliomas. One mechanism for the upregulation of VEGFs and their receptors (especially VEGFR-1) is through the transcriptional regulator hypoxia inducible factor-1 (HIF-1). Although HIF-1 can be degraded under normoxic conditions, the hypoxia that occurs as a tumor mass outgrows the normal blood supply can stabilize HIF-1, allowing it to bind to the hypoxia responsive elements located on several genes, resulting in enhanced transcription of these genes. This transcription factor has been detected in the pseudopalisading cells that form the leading edge of GBMs (Figure 6).

Angiopoietins have also been implicated in glioma angiogenesis. These proteins act by signaling through the receptor tyrosine kinase, Tie-2, on endothelial cells. Ang-1 signaling through this receptor is necessary for the stabilization and maturation of blood vessels. By contrast, Ang-2 signaling occurs during early angiogenesis and may block the stabilizing effect of Ang-1, allowing for the disruption of the contacts between endothelial cells and pericytes, thus permitting the sprouting of new vessels. Ang-2 and Tie-2 expression is absent in normal endothelium but upregulated, along with Ang-1, in many gliomas.

Migration

Unlike tumors of the body, primary brain tumors rarely metastasize by distribution through the blood or lymph vessels. Instead, glioma cells infiltrate the normal brain tissue, often traveling great distances along myelinated axons, the basement membranes of blood vessels, or tracking along the ependyma of ventricles. This aggressive cell migration is highlighted by case studies in which patients with high-grade gliomas underwent hemispherectomies and were still found to harbor tumor cells that had extended beyond the limits of the surgical resection. Migration, however, is not a property that arises *de novo* in tumor cells but characterizes many nonmalignant cells during normal brain development or their response to injury. Migration in any context requires a complex interaction with extracellular matrix (ECM) molecules, reorganization of the cytoskeleton, and the creation of an intercellular space through which a cell invades.

In all cell types, adhesion to the ECM occurs through interactions between ECM proteins and cell surface adhesion molecules. A number of ECM molecules have been demonstrated to be particularly efficient at promoting the migration of glioma cells. These include the proadhesive collagen, fibronectin, and laminin as well as the antiadhesive SPARC, tenascin-C, and thrombospondin. These proteins are often located in the perivascular space, which may be why glioma cells prefer to migrate along blood vessels. In addition to utilizing the native ECM molecules, glioma cells may synthesize and deposit matrix proteins such as tenascin-C, which has been shown to be overexpressed in these tumors. The cell surface adhesion receptors that interact with the ECM include lectins, cadherins, and integrins. Binding to these receptors promotes the rearrangement of the cytoskeleton and upregulation of prosurvival (antiapoptotic) pathways. Several antibodies and competitive substrates for cell surface adhesion molecules have been used to limit the migration of glioma cells *in vitro*.

In addition to being able to form attachments to the ECM, glioma cells must also be able to extend and retract processes in order to move in a particular direction. This involves the polarization of the actin cytoskeleton so that actin is concentrated at the leading edge of the cell. From this region, filopodia, invadopodia, lamellopodia, and pseudopodia extend and form new adhesion complexes. The microtubule cytoskeleton is also important in retracting the rear end of a cell.

The extent of glioma cell migration is surprising in light of the physical constraints imposed by the surrounding brain tissue and skull/spine. Indeed, the extracellular space of the brain has been estimated to be approximately 20 nm in width, which is only a fraction of the cell's diameter. The invasion of glioma

cells, therefore, must also involve mechanisms of creating intercellular spaces or shrinking to fit within already existing narrow spaces. Degradation of the extracellular space is one mechanism by which a glioma cell may create a space to invade. This can be accomplished through the expression and secretion of enzymes such as matrix metalloproteinases and cathepsin-B. Indeed, expression of these molecules appears to be upregulated in glioma cell lines and patient biopsies. Another option employed by glioma cells to invade through narrow spaces is for the cells to become smaller through shrinking and elongation. Electron micrograph images of glioma cells confirm that these cells do assume an elongated morphology as they invade through brain tissue (Figure 7). The process of cell shrinkage, in any cell type, requires the movement of osmolytes (most commonly Cl^- and K^+) out of a cell, followed by the concomitant movement of water. Glioma cells have been shown to express voltage-gated chloride channels (*in vitro* and *in vivo*) and GABA-gated chloride channels (*in vivo*). In addition, chloride channels have been shown to be clustered on the protruding edges of the glioma cell membrane, and movement of chloride through channels has been demonstrated to be necessary for glioma migration in transwell migration assays. However, it is not clear if the volume changes that would accompany chloride movement out of the cell are global or restricted to the protruding process of the cell. Interestingly, chlorotoxin, a drug known to block Cl^- channels, is currently in clinical trials to treat malignant gliomas.

Although gliomas contain the machinery permissive for migration, one must ask the question, what instructs a glioma cell to migrate? The cues that signal a glioma cell to migrate are potentially complex and are not completely understood. One of these signals may involve glutamate-induced Ca^{2+} oscillations, similar to those observed in the well-characterized migration of cerebellar granular cells. Unlike neurons, however, glioma cells do not express NMDA receptors. Instead, glioma cells have been shown to express a Ca^{2+}-permeable AMPA receptor. As mentioned previously, glioma cells efflux glutamate, thereby increasing its concentration in the extracellular space. Increased glutamate has been demonstrated to cause Ca^{2+} changes in glioma cells. Both the glutamate-induced Ca^{2+} changes and the ability of the glioma cells to grow can be inhibited by rendering the AMPA receptor Ca^{2+} impermeable through the adenoviral expression of GLUR2, suggesting that these Ca^{2+} alterations are indeed necessary for glioma cell migration. Although glutamate may serve as an agonist for glioma migration, other signals are also likely to be involved.

Figure 7 An electron micrograph shows an elongated glioma cell advancing through two normal rat brain cells. Scale bar = 1μm. Cell Death

Tissue necrosis is a characteristic feature of GBMs and a defining feature in diagnosing the highest grade tumors. The underlying cellular death occurs by both programmed (mainly apoptosis) and nonprogrammed (mainly necrosis) cell death mechanisms. Necrosis describes the cell death that occurs when the nutritional demands of a growing tumor exceed the nutrient supply from the vasculature. An imbalance in the nutritional supply and demand can occur when the tumor outgrows the existing blood supply or when the supply is reduced as might occur, for example, when a vessel collapses or a clot is formed. This imbalance results in alterations in energy metabolism (specifically reduced oxidative phosphorylation), cell swelling, loss of membrane integrity, and the activation of proteases and other destructive enzymes. In GBMs, necrosis does not occur in single cells but, rather, in a focal population of cells. When imaged by magnetic resonance imaging, intravenous administration of a contrast agent will enhance these foci (Figure 8).

By contrast, apoptosis occurs in single cells within a tumor. Apoptosis is more common in higher grade, more proliferative gliomas but accounts for only a very small fraction of the dead cells in a tumor. However, understanding the mechanisms of apoptosis is important because suppression of apoptosis may contribute to tumorigenesis. Furthermore, because apoptosis does not trigger an inflammatory response, it is the ultimate goal of many anticancer therapies. Apoptosis describes the type of cell death that occurs when specific pathways are activated by either

Figure 8 Post-contrast T1-weighted MRI image of a glioblastoma. Reproduced from Okamato K, Ito J, Takahashi N, et al. (2002) MRI of high-grade astrocytic tumors: Early appearance and evolution. *Neuroradiology* 44: 395–402, with permission.

'extrinsic' (e.g., extracellular ligands binding to receptors) or 'intrinsic' (e.g., DNA damage) signals. This type of death is characterized by cell condensation, chromatin fragmentation, and the formation of membrane-bound apoptotic bodies that are cleared by nearby cells through phagocytosis. In the development of gliomas, genetic mutations that enhance survival (e.g., mutations in the PI3K/Akt pathway) or disrupt the intrinsic signaling pathways (e.g., p53 mutations) may disrupt the balance between proliferation and cell death, favoring cell growth and mass formation. However, although apoptosis is not favored in glioma cells, it is able to occur in specific environments. For example, the pseudopalisading cells that surround the necrotic foci of GBMs show an increased percentage of apoptotic cells than the rest of the tumor. This phenomenon demonstrates that the apoptotic signaling pathways of glioma cells are still intact and can be manipulated. This is the objective of many anticancer treatments. Most of these therapies act via the intrinsic apoptosis pathway by producing DNA damage, inhibiting the synthesis of new proteins, or a number of other mechanisms. Other targets for the induction of apoptosis include signaling through extrinsic pathways such as CD95 and DR4 (death receptor 4) and DR5.

The Origin of Glioma Cells

No discussion of gliomas is complete without a brief mention of the two most popular hypotheses concerning the origin of these tumors. Before it was discovered that populations of neural stem cells exist in the adult human brain, it was believed that all gliomas arose from fully differentiated glial cells that had undergone neoplastic transformation. This hypothesis is supported by the fact that the overwhelming majority of primary brain tumors appear to contain cells of glial, rather than neuronal, lineage. Because glia cells are the only differentiated cells of the brain capable of dividing, they are most susceptible to transformation. However, tumors of mixed origin (e.g., oligodendrogliomas) are less likely to develop unless the transformed cell was multipotent, having the ability to differentiate into one of several cell types. Although mature glial cells are not known to be multipotent, investigators have been able to transform them into less differentiated cells using different growth factor treatments and expression systems. Therefore, it is conceivable that a mature, fully differentiated glial cell could be de-differentiated into a less mature, multipotent cell capable of forming a tumor.

Since the discovery of populations of neural stem cells and glial progenitor cells in the adult brain, however, other investigators have hypothesized that it is more conceivable that these cells are responsible for the origin of gliomas. Glioma cells do share characteristics with stem cells, including their affinity for blood vessels and white matter tracts, ability to proliferate, and migratory capacity. In addition, stem cells and progenitor cells are able to differentiate into a limited variety of cell types, accounting for the existence of 'mixed' gliomas. In further support of this hypothesis, many gliomas are located near the ventricles, an area of the brain that is enriched with progenitor cells.

In conclusion, experimental evidence exists to support both of these hypotheses, and the cellular origin of human gliomas will continue to be debated.

Glutamate

S P H Alexander, University of Nottingham Medical School, Nottingham, UK

Introduction

Glutamate is easily the most abundant transmitter in the nervous system and is reported to be the transmitter at 40% of all synapses in the brain. Indeed, it has been said that if a neuron fails to respond to glutamate, it is either not a neuron or it is dead. In itself, therefore, this abundance can lead to some issues. For example, a wide distribution of multiple pharmacological targets suggests that agents targeting the glutamate system will either lack target selectivity or impact on multiple bodily functions. However, it has become clear in recent years that the numerous receptors for glutamate and their localized expression have allowed the development of several potentially exciting therapeutic agents, although relatively few are sufficiently advanced as to reach a clinical setting.

In common with many other neurotransmitters (γ-aminobutyric acid (GABA), acetylcholine, 5-hydroxytryptamine, and adenosine 5′-triphosphate), the action of glutamate is mediated via both rapidly acting transmitter-gated channels (ionotropic receptors, Table 1) and more slowly acting seven-transmembrane (7TM), G-protein-coupled (metabotropic, Table 2) receptors.

Metabolism, Uptake, and Release

Since glutamate is a component of every cell, there is no clear synthetic route that sets apart neurotransmitter glutamate. One intriguing aspect of glutamate metabolism, however, is glutamic acid decarboxylase activity. This enzyme performs an elegant switch in emphasis, by catalyzing conversion of the major excitatory neurotransmitter (glutamate) to the major inhibitory neurotransmitter (GABA).

Glutamate Transport: Plasma Membrane and Vesicular Mechanisms

Due to the major roles of glutamate as an extracellular signaling molecule and as an intracellular building block for proteins combined with the toxicity associated with elevated extracellular levels, effective mechanisms exist for removal of glutamate from the extracellular fluid and also for concentrating the amino acid in synaptic vesicles. Thus, at least five cell-surface glutamate (and aspartate) transporters have been defined as members of the solute carrier family 1 (SLC1), while three vesicular transporters (of the SLC17 family) have also been identified. The cell-surface transporters are multisubunit, homo- or heteropentameric structures in which each subunit appears to have 8TM spanning domains and at least one re-entrant loop that 'dips' into the plane of the membrane. One of the physiological roles for the avid glial glutamate transport system is to allow glial conversion of glutamate to glutamine, which is then exported via the extracellular space into neurons as a means of regenerating neurotransmitter glutamate.

Determination of glutamate uptake in tissue slices or cultured cells is most often accomplished through the use of radiolabeled glutamate, as metabolism to other entities may confound direct assessment of glutamate accumulation.

Detection of Glutamate Release

In order to define a role for glutamate as a mediator of a physiological or pathophysiological mechanism, it is fundamental to be able to measure changes in extracellular glutamate in nervous tissues. *In vitro*, this is commonly accomplished through the use of [^{3}H]-D-aspartate as a surrogate marker, since the D-isomer is less likely to be metabolized. However, there are doubts as to whether [^{3}H]-D-aspartate accumulates in synaptic vesicles and thus the assay may more accurately reflect cytoplasmic glutamate release. It is, therefore, preferable to assess glutamate release directly. One means is to label tissue with [^{3}H]-L-glutamine, with a view to labeling preferentially the neuronal glutamate precursor pool. However, this approach has the drawback that a chromatographic separation of glutamate from glutamine and GABA is required, although it may be useful in some cases to identify simultaneously levels of both excitatory glutamate, as well as inhibitory GABA. A means of directly measuring glutamate release *in vitro* is through the use of high-performance liquid chromatography (HPLC) separation of extracellular fluid following amino acid derivatization with o-phthaldehyde. This has the potential advantage of allowing levels of glutamate and GABA (as well as other bioactive released amino acids such as glycine, aspartate, and taurine) to be assessed concurrently, although it has the disadvantage that a certain period of accumulation (usually 15–20 min) is required to obtain sufficient material to detect. Two 'real-time' *in vitro* assays for glutamate have been described: an enzyme-coupled spectrophotometric version making use of exogenous glutamate dehydrogenase activity and a glutamate-selective electrode.

Table 1 Ionotropic glutamate receptors: composition and pharmacology

	AMPA	*Kainate*	*NMDA*	
Other names	Quisqualate			
Subtypes	GLU_{A1}, GLU_{A2}, GLU_{A3}, GLU_{A4}	GLU_{K1}, GLU_{K2}, GLU_{K5}, GLU_{K6}, GLU_{K7}	GLU_{N1}, GLU_{N2A}, GLU_{N2B}, GLU_{N2C}, GLU_{N2D}, GLU_{N3A}, GLU_{N3B}	
Composition	Homo- or hetero-tetramers	Homo- or hetero-tetramers	Heterotetramers	
Ions gated	Na^+, K^+, (Ca^{2+})	Na^+, K^+	Na^+, K^+, Ca^{2+}	
Channel blockers	Polyamines, argiotoxin, Joro toxin	Polyamines	Dizolcipine, ketamine, phencyclidine, memantine, amantidine	
			Glutamate site	*Glycine site*
Endogenous ligand(s)	L-Glutamate	L-Glutamate	L-Glutamate, L-Aspartate	Glycine, D-Serine
Selective agonists	AMPA, (S)-fluorowillardiine	ATPA, (S)-5-iodowillardiine, (2S,4R)-4-methylglutamate, LY339434, domoic acid	DL-(tetrazol-5-yl) glycine, homoquinolinic acid	(+)HA966
Selective antagonist	NBQX, ATPO, LY293558, GYKI53655	UBP302	D-AP5, CGS19755	5,7-DCKA, L689560, L701324

In vivo detection of extracellular glutamate has been conducted through the use of microdialy coupled to HPLC separation and o-phthaldehyde detection or alternatively through the use of a glutamate-sensitive electrode.

Receptors and Signaling

Twenty-four separate gene products which make up the cell-surface receptors for glutamate have been identified and are divided into two major classes both structurally and functionally; rapidly responding 'ionotropic' transmitter-gated channels and slower responding 'metabotropic' 7TM receptors (Figure 1). The ionotropic receptors consist of three groups of receptors (yellow highlight in Figure 1), identified by the selective synthetic agonists α-amino-3-hydroxy-5-methyl-4-isoxazole proprionic acid (AMPA), kainate, and *N*-methyl-D-aspartate (NMDA). Metabotropic glutamate (mGlu) receptors also consist of three groups as identified by similarities in primary sequence (blue highlight in Figure 1), known simply as group I, group II, and group III.

Ionotropic Glutamate Receptors: AMPA, Kainate, and NMDA Glutamate Receptors

Rapid responses (<1 s) to glutamate in neurons are mediated through cell-surface transmitter-gated channels. These are tetrameric proteins arranged in a radially symmetrical fashion around a central pore, which is permeable to cations (Table 1). Each subunit comprises a large extracellular N-terminus (S1), which interacts with an extracellular loop (S2) to form the agonist binding site. There are three transmembrane segments (TM1, TM3, and TM4) with a single channel lining re-entrant segment (termed MD2 or p-loop) that inserts into the plane of the membrane from the cytoplasmic face (Figure 2) between TM1 and TM3. The cytoplasmic C-terminus is the site for interaction of a number of protein partners (*vide infra*).

Nomenclature and composition As ionotropic glutamate receptors are multi-subunit proteins with few selective pharmacological ligands, nomenclature of the individual subunits is based on physical (i.e., primary sequence) distinctions rather than pharmacological means. Of the eight subunits identified as NMDA receptor components, a minimal configuration in heterologous expression of the NMDA receptor appears to be two pairs of GLU_{N1} and GLU_{N2} subunits, although it appears more likely that, physiologically, NMDA receptors are mixtures of all three subunit groups (GLU_{N1}, GLU_{N2}, and GLU_{N3}, encoded by the genes *GRIN1*, *GRIN2A/2B/2C/2D*, and *GRIN3A/3B*). The GLU_{N3} subunits appear to have a generally inhibitory influence on NMDA receptor function. Many of the genes encoding NMDA receptor subunits undergo alternative splicing, which can generate multiple isoforms with differing pharmacological profiles.

AMPA receptors appear to be made up of any permutation of GLU_{A1}, GLU_{A2}, GLU_{A3}, and GLU_{A4} subunits (derived from the genes *GRIA1–4*, respectively); although GLU_{A2} subunits appear to require co-expression with other AMPA receptor subunits for cell-surface localization. A feature of the AMPA receptor subunit GLU_{A2} is the ability to function as two versions inter-converted following RNA editing (resulting in a switch from a glutamine to arginine residue; a Q/R switch) from a channel highly permeable

Table 2 mGlu receptors: biochemistry, localization and pharmacology

	Group I		*Group II*		*Group III*			
Signalling	$G_{q/11}$, PLC-β, Ca^{2+}		$G_{i/o}$, ↓AC, ↓cAMP, ↑K^+		$G_{i/o}$, ↓AC, ↓cAMP, ↑K^+			
Group selective ligands								
Endogenous	L-Glutamate, L-Aspartate		L-Glutamate, L-Aspartate, NAAG		L-Glutamate, L-Aspartate, L-Serine-*O*-phosphate			
Synthetic agonists	Quisqualate, 3.5-DHPG		DCG-IV, 2R,4R-APDC, LY354740		L-AP4, (RS)PPG			
Antagonists	LY393675		EGLU, LY307452		MAP4, MSOPPE			
Subtypes	*$mGlu_1$*	*$mGlu_5$*	*$mGlu_2$*	*$mGlu_3$*	*$mGlu_4$*	*$mGlu_6$*	*$mGlu_7$*	*$mGlu_8$*
Protein partners	Homer, TRPC1, PIKE	Homer, FMR1, PIKE						
Selective agonists		CHPG		NAAG	(−)−PHCCC	Homo-AMPA		
Selective antagonists	3-MATIDA	ACDPP	PCCG-4			THPG		MPPG
Allosteric enhancers	Ro67-4853	DFB	LY487379				AMN082	
Allosteric inhibitors	CPCCOEt	MPEP, MTEP						
Impact of gene disruption	Altered synaptic transmission in the hippocampus and cerebellum; symptoms of cerebellar ataxia; increased pain tolerance	Disruption of hippocampal synaptic transmission & LTP; weakened spatial learning and memory acquisition; reduced cocaine self-administration; a deficit in prepulse inhibition	Reduced hippocampal LTD associated with an absence of agonist-induced inhibition of glutamate release		Disruption of spatial learning and memory acquisition; loss of efficacy of the anti-epileptic agent baclofen	Normal retinal structure but marked impairments in visual receptiveness	A shortened lifespan associated with epileptic seizures	Heightened anxiety in behavioural tests

Figure 1 Phylogram of the human glutamate receptor subunit peptide sequences. Picked out in yellow highlight are the three families of ionotropic receptor (AMPA, kainate, and NMDA receptors). Blue highlighting identifies the three groups of mGlu receptor.

Figure 2 An ionotropic glutamate receptor subunit. Indicated is an extracellular N-terminus agonist binding site (S1, S2), the transmembrane domains (TM1, TM3, TM4, and re-entrant loop) and the intracellular C-terminus.

to calcium ions, to one much less permeable. All AMPA receptor subunits are subject to alternative splicing, which results in two variants termed 'flip' and 'flop' with distinct desensitization characteristics.

Of the kainate receptors, GLU_{K1} and GLU_{K2} subunits (from the genes *GRIK1* and *GRIK2*, respectively) are a subfamily which exhibits high-affinity agonist binding without function and which appear to require co-expression of members of the other kainate receptor subfamily, GLU_{K5}, GLU_{K6}, or GLU_{K7} subunits (from *GRIK3*, *GRIK4*, and *GRIK5* genes, respectively) to show functional activity. In contrast, the latter subfamily of subunits appears capable of generating functional kainate receptors as homotetramers.

Pharmacology and signaling The NMDA receptor is primarily located postsynaptically and is only activated in the presence of both glutamate and glycine, this dual requirement being unique amongst transmitter-gated channels. Glutamate acts on GLU_{N2}

subunits, while glycine binds to both GLU_{N1} and GLU_{N2} subunits, with receptor activation requiring two molecules of each ligand. Under resting conditions, the NMDA receptor ion channel is blocked by Mg^{2+} ions, which dissociate when the cell is depolarized. The open channel exhibits a relatively high permeability to Ca^{2+}, along with the monovalent cations Na^{+} and K^{+}. Similar to the $GABA_A$ receptor, the NMDA receptor exhibits multiple allosteric modulatory sites, including inhibitory responses to Zn^{2+} and protons, as well as subunit-selective potentiatory responses to neurosteroids and polyamines.

Selective agonists exist for both glutamate- and glycine-binding sites of the NMDA receptor (Table 1 and Figure 3), as well as selective antagonists. However, the most widely employed antagonists function as channel blockers and include dizocilpine (previously MK-801), ketamine (Figure 4), and phencyclidine (Table 1). It is thought that the abuse of the latter two agents (known as 'special K' and 'angel dust' or PCP, respectively), originally produced as dissociative anesthetics, is mediated at the molecular level through blockade of the NMDA receptor. Antagonists at the strychnine-insensitive glycine co-agonist binding site of the NMDA receptor, such as 5,7-dichlorokynurenate (Figure 4), are effective *in vitro* and *in vivo* inhibitors of NMDA responses.

AMPA receptors can be activated by high concentrations of kainate (>30 μM), while activation of kainate receptors by AMPA is dependent on the constituent subunits, with the GLU_{K2} subunit appearing to confer AMPA sensitivity (Figure 3). The quinoxalinedione antagonists, such as NBQX (Figure 4) and CNQX, show some limited selectivity in distinguishing AMPA from kainate receptors (Table 1). Synthetic allosteric inhibitors of AMPA and kainate receptor function (GYKI5246 and NS3763, respectively) have also been described. Intriguingly, a number of natural toxins (e.g., from Joro spiders, Figure 4) have been described which function as channel blockers for AMPA (and, to a lesser extent, kainate) receptors. Presumably, these have evolved as a means of predators disabling insect prey, since glutamate is the neurotransmitter at the invertebrate neuromuscular junction, acting on postsynaptic AMPA-like receptors.

In addition, aniracetam, cyclothiazide, and diazoxide are widely used to interfere with the channel desensitization characteristics of AMPA (and, to a lesser extent, kainate) receptors through an undefined allosteric interaction.

Protein partners A key area of regulation of (particularly) AMPA and kainate receptors is desensitization and intracellular trafficking. An intracellular protein

Figure 3 Glutamate receptor agonists. The top row indicates the eponymous agonists at AMPA, kainate, and NMDA ionotropic glutamate receptors. The middle row indicates mGlu receptor agonists: the nonselective agonist 1S,3R-ACPD, the mGlu3-selective NAAG, and the mGlu4/7/8-selective L-serine-*O*-phosphate. The bottom row shows the endogenous excitatory amino acids, L-glutamate and L-aspartate.

Figure 4 Glutamate receptor antagonists. The top row illustrates the three classes of NMDA receptor antagonist: antagonists competing for glutamate (D-AP5) and glycine (DCKA) binding sites, as well as an uncompetitive (open channel blocker, ketamine) antagonist. The middle row presents competitive AMPA (NBQX) and kainate (UBP302) receptor antagonists and a spider venom-derived AMPA channel blocker (JSTX3). The bottom line illustrates a nonselective mGlu receptor competitive antagonist (LY341495) and noncompetitive mGlu5 (MTEP) and competitive mGlu4/6 (MAP4) receptor antagonists.

called glutamate receptor-interacting protein (GRIP) appears to allow interaction between GLU_{A2} subunits and other proteins, including protein interacting with C kinase (PICK, which recruits protein kinase C) and kinesin (an intracellular molecular motor associated with the cytoskeleton). AMPA receptors also interact with Lyn, a protein kinase, which in turn signals via the extracellular signal-regulated kinase signaling pathway, leading to an increased expression of brain-derived neurotrophic factor. This growth factor is associated with neurogenesis in the adult brain and its expression is reduced following exposure to stress.

mGlu Receptors

mGlu receptors are members of the family C of 7TM receptors, which also includes $GABA_B$ and calcium-sensing receptors. This family is made up of long polypeptides (~1000 aa) and is characterized by the presence of a large extracellular N-terminus (~600 aa, Figure 5). This portion of the receptor contains the agonist binding site and a cysteine-rich domain, which appears to stabilize the three-dimensional structure of the receptor. The 7TM domains bear little sequence homology with the classical biogenic amine receptors (members of the rhodopsin class, family A), which make up the ligand-binding site in the plane of the plasma membrane. The N-terminus binding site is often described as a 'Venus fly-trap' arrangement in which the ligands bind within the hinge region (Figure 5). Conceptually, there is thus an obstacle to overcome as to how ligand binding at some distant extracellular point is able to influence G-protein activity across the hydrophobic plasma membrane. The means by which this appears to be mediated is through dimerization of the receptor, thereby allowing conformational changes in the extracellular region to be transduced through the membrane. A further consequence of the extended structure of the C family of 7TM receptors is the regulation of receptor activity through ligands binding at sites other than the cognate ligand-binding site. Thus, for many of the mGlu receptor subtypes, selective positive and/or negative allosteric modulators have been described which extends the potential for pharmacological/therapeutic exploitation considerably (*vide infra*). The cytoplasmic C-terminus is also enlarged in comparison with most members of the rhodopsin group of 7TM receptors and this is the site for interaction with a number of intracellular protein partners (*vide infra*).

Figure 5 A dimeric mGlu receptor. Indicated are the extracellular N-terminus glutamate binding site, cysteine-rich conformation stabilizing regions, the transmembrane domains (TM1–7) and the intracellular C-terminus site for protein:protein interactions.

Eight subtypes of mGlu receptor have been identified. They are usually classified into three groups on the basis of similarities in primary sequence (Figure 1), signaling characteristics and pharmacology. Thus, group I mGlu receptors ($mGlu_1$ and $mGlu_5$) couple primarily to elevation of calcium, while group II ($mGlu_2$ and $mGlu_3$) and group III ($mGlu_4$, $mGlu_6$, $mGlu_7$, and $mGlu_8$) receptors evoke an inhibition of cAMP.

Localization mGlu receptors are located throughout the brain and spinal cord, and are also found in the retina ($mGlu_6$), pancreas ($mGlu_1$, where they appear to subserve a role in the monitoring of nutritional status), and in taste buds ($mGlu_4$, where they mediate sensation to the 'umami' taste). In neural tissues, there is evidence for differential neuronal and astrocytic locations of mGlu receptors. $mGlu_1$ receptors appear to be exclusively expressed in neurons, while $mGlu_5$ receptors are found on both astrocytes and neurons. Similarly, $mGlu_2$ receptors are selectively neuronally expressed, while $mGlu_3$ receptors have been identified on both neurons and astrocytes. Of the group III receptors, $mGlu_6$ receptors appear to be exclusively retinal, while the remainder are primarily neuronally located.

Pharmacology and Signaling

Although glutamate is an endogenous ligand at all of the mGlu receptors, the potency of glutamate varies widely. $mGlu_1$, $mGlu_3$, and $mGlu_5$ receptors respond to submicromolar glutamate, while $mGlu_2$, $mGlu_4$, $mGlu_6$, and $mGlu_8$ receptors respond to glutamate at concentrations up to $\sim 10\,\mu M$. In contrast, $mGlu_7$ receptors only respond to concentrations of glutamate approaching the millimolar range, leading to the suggestion either that glutamate is not the principal endogenous ligand or that the $mGlu_7$ receptor acts presynaptically as a glutamate autoreceptor, sensing synaptic release of glutamate and switching off further release as 'toxic' levels are reached.

Metabotropic receptors may be activated selectively compared to the ionotropic glutamate receptors by 1S,3R-ACPD (Figure 3), while LY341495 is a useful antagonist with a similar selectivity (Figure 4). Selective agonists and antagonists exist for the three groups of, if not the individual, mGlu receptors (Table 2). Thus, quisqualate is a high potency group I agonist, although it also activates AMPA receptors potently, while LY393675 acts as a group I-selective antagonist. A useful group II agonist is LY354740, while EGLU antagonizes group II receptors, albeit with low affinity. L-AP4 is a nonselective group III agonist, while MAP4 blocks most of these receptors (Figure 4).

Some members of the mGlu receptor family also respond to other endogenous ligands, raising the possibility of native activation in the absence of glutamate. Thus, *N*-acetylaspartylglutamate (also known as spaglumic acid) is a selective $mGlu_3$ receptor agonist, while L-serine-*O*-phosphate activates group III mGlu receptors (Table 2 and Figure 3).

A relatively unusual feature of the family C of 7TM receptors is the regulation of receptor activity through allosteric sites. Thus, both positive and negative allosteric modulators have been described for $mGlu_1$, $mGlu_2$, $mGlu_4$, $mGlu_5$, and $mGlu_7$ receptors. This means (for example) that $mGlu_5$ receptors can be activated by 2-chloro-5-hydroxyphenylglycine, a response which can be enhanced by 3,3′-difluorobenzaldazine,

which alone is ineffective. Activation of the $mGlu_5$ receptor can be inhibited either competitively (3-hydroxy-6-methyl-*N*-(6-methylpyridin-2-yl)pyridine-2-carboxamide) or noncompetitively (3-[(2-methyl-1,3-thiazol-4-yl)ethynyl]pyridine, Table 2).

The group I mGlu receptors, $mGlu_1$ and $mGlu_5$, couple primarily via activation of members of the $G_{q/11}$ family of G-proteins to phospholipase C-β and, hence, to elevation of intracellular calcium ion levels. The primary mode of signaling of the remaining mGlu receptors is via pertussis toxin-sensitive $G_{i/o}$ family members. This results in inhibition of adenylyl cyclase activity and the subsequent reduction in cyclic AMP levels. Arguably of more importance in neuronal cells is the activation of potassium channels and the subsequent hyperpolarization, resulting (typically) in a reduction in transmitter release. The $mGlu_6$ receptor, expressed in ON retinal bipolar cells, couples to activation of PDE6, a cyclic GMP-selective phosphodiesterase, thereby leading to the closure of cGMP-activated cation channels.

Protein partners It is apparent that the expanded C-terminus of the mGlu receptors has a role in the interaction with intracellular proteins, beyond the archetypal G-proteins. In particular, the group I mGlu receptors are associated with an immediate early gene product, Homer, which is enriched at the postsynaptic density. Homer appears to play an anchoring role, bringing together elements of the signaling cascade, including $mGlu_1$ and $mGlu_5$ receptors, phospholipase C, cell-surface transient receptor potential canonical (TRPC) calcium channels, intracellular inositol 1,4,5-trisphosphate receptors, and the phosphatidylinositol 3-kinase enhancer protein, PIKE. It has been suggested that the major function of Homer is to act as a 'brake' on group I mGlu receptor activity through the calcium mobilization pathway and to enhance coupling via PI 3-kinase.

These protein partners may also be involved in bringing together mGlu and NMDA receptors, leading to a functional interaction, such that $mGlu_5$ receptor activation enhances NMDA receptor function, while NMDA receptor activation reverses $mGlu_5$ receptor desensitization.

Physiological Functions

The primary physiological action of glutamate in the central nervous system (CNS) is as an excitatory transmitter, allowing neuronal pathways to function throughout the brain. At the same time, glutamate is thought to be the major transmitter underlying the acquisition of memory. The molecular correlates of memory acquisition appear to differ according to the synapse and (possibly) the maturity of the animal. The phenomenon of long-term potentiation (LTP), which has been suggested to occur at every excitatory synapse in the CNS, is demonstrated as an increased efficacy of synaptic transmission following a period of high frequency stimulation. It is well described at synapses of the Schaffer collateral–commisural pathway in the hippocampus, in which high-frequency stimulation of the perforant path input from the entorhinal cortex causes a long-lasting enhancement of low-frequency activation of the CA1 pyramidal cell output pathway. Cerebellar long-term depression (LTD) is a model of synaptic memory in which the efficiency of synaptic transmission (activation of Purkinje neurons) is reduced following high-frequency stimulation (coincident activation of parallel and climbing fiber presynaptic pathways).

One explanation of these changes in efficacy of synaptic transmission, which does not hold true at all synapses, is that the underlying mechanisms involve trafficking of AMPA receptors, such that LTP may be associated with an increase in postsynaptic AMPA receptor expression (possibly resulting from recruitment of cryptic receptors), while LTD may result from phosphorylation and internalization of AMPA receptors, reducing postsynaptic receptor numbers. This plasticity, therefore, is consistent with an increased and decreased efficiency of synaptic conductance, respectively.

One of the most insightful means of determining physiological roles of particular proteins is though the use of gene disruption models, although a caveat with embryonic knockout models is that the possibility exists for compensatory mechanisms to lessen or alter the true role of the gene and protein in question. Table 2 identifies some of the findings from such gene disruption studies focusing on mGlu receptors. A common theme is an alteration in synaptic plasticity, observed with disruption of $mGlu_1$, $mGlu_2$, $mGlu_4$, and $mGlu_5$ receptors, further underlining the importance of neurotransmitter glutamate in memory acquisition.

Glutamate as a Peripheral Neurotransmitter

There is good evidence that glutamate subserves an excitatory transmitter function in the gastrointestinal tract, with indications of glutamate release, ionotropic and mGlu receptors, and glutamate transporters in enteric ganglia. In addition, application of glutamate and its analogs has been shown to regulate gastrointestinal motility and solute secretion. Synapses in the enteric nervous system undergo

LTP-type plasticity, and it is thought that group I mGlu receptors mediate this phenomenon, at least in part.

Pathology

Stroke, Ischemia, and Neurodegenerative Diseases

An overabundance of extracellular glutamate is associated with excitotoxicity of neurons, which appears to involve activation of NMDA receptors. The mechanism of excitotoxicity is not absolutely defined, but there is a crucial role of a prolonged elevation of intracellular calcium ions, leading to mitochondrial damage and apoptosis. The NMDA receptor antagonist dizocilpine reached an advanced preclinical level as a potential antistroke therapy, failing on the basis of damage to unstressed brain areas due to a narrow therapeutic window. This drug may have been a victim of its own success, in that the high affinity and low reversibility displayed as an open channel blocker allowed little differentiation between positive and harmful effects. The generation of a lower-affinity agent, memantine, which exhibits greater reversibility and an increased tolerability has allowed approval for its use in man. The current indication for memantine is for treatment of Alzheimer's disease. The rationale for its use is that the prolonged presence of glutamate (albeit at lower concentrations) leads to protracted NMDA receptor activation and excitotoxicity of neurons and a cognitive deficit. By reducing NMDA receptor activation, it is hoped to reduce the excitotoxicity and reduce the cognitive deficit.

The accumulation of plaques positive for β-amyloid in Alzheimer's disease is associated with neurodegeneration and, since processing and secretion of γ-secretase (an enzyme which cleaves the amyloid precursor protein) is enhanced by activation of group I mGlu receptors, these receptors have also become a focus for research in this area.

Another neurodegenerative disorder in which glutamate overactivity has been implicated is Parkinson's disease. The glutamatergic pathways involved may be either thalamostriatal or corticostriatial, and so it has been suggested that group II agonists or $mGlu_5$ antagonists might be therapeutically useful by inhibiting glutamate release or action, respectively, at these synapses. Indeed, LY354740 has been observed to display efficacy in animal models of Parkinson's, although the $mGlu_5$ antagonist 2-methyl-6-(phenylthynyl) pyridine was ineffective.

A further potential exploitation of glutamate signaling in combating the effects of neurodegenerative diseases, such as Alzheimer's and Parkinson's, is the use of 'AMPAkines,' agents which enhance AMPA receptor function. As described above, a number of agents interfere with AMPA receptor function as allosteric modulators or by impeding desensitization. Aniracetam is an example of such an agent, which has been exploited as a nootropic substance, also known as 'smart drugs.' These agents have a positive profile in animal models and those in clinical and 'street' use are reported to enhance cognitive powers (concentration, memory, etc.); their use has yet to be approved in the treatment of Alzheimer's, although piracetam is used to treat the involuntary twitches suffered by Parkinson's patients.

Epilepsy

In vitro and *in vivo* focal application of glutamate results in epileptiform activity. This action appears to be mediated by the ionotropic receptors, and postmortem examination of the brains of epileptics suggests a neurodegenerative profile consistent with overactivity of these receptors. One potential therapeutic avenue is the exploitation of $mGlu_4$ and $mGlu_7$ receptors, which have been suggested to be glutamate autoreceptors, acting presynaptically to reduce glutamate release at the synapse. As noted in Table 2, disruption of either of these receptors leads to changes in seizure susceptibility further highlighting the potential for exploitation of glutamate signaling in treating this disorder.

Anxiety and Depression

In preclinical assessments for leads as anti-anxiety/anti-depressant action, there are promising results for both $mGlu_2$-selective agonists and $mGlu_5$-selective antagonists. It is hypothesized that the $mGlu_2$ agonists function by reducing frontal cortex transmitter release presynaptically, while the $mGlu_5$ antagonists regulate postsynaptic glutamate excitability.

Pain

Several observations suggest that mGlu receptors represent an excellent target for the treatment of pain. Members of all three groups of mGlu receptors are present at the primary afferent-spinal cord synapse or the subsequent ascending pathway. There is particular interest in group I mGlu receptors, partly because of evidence for diminished pain sensitivity in transgenic mice (Table 2), but also because of the efficacy of antagonists in multiple pain models.

Schizophrenia

Schizophrenia is suggested to be the consequence of an imbalance of glutamatergic and dopaminergic signaling systems. Phencyclidine, which blocks

NMDA receptors (as well as dopamine uptake), induces schizophrenia-like symptoms in man. In animal models, the group II agonist LY354740 was observed to reduce some of the behavioral effects of PCP, with a distinct pattern to traditional neuroleptics. In addition, the observation that $mGlu_5$-knockout mice have an altered behavioral trait observed in schizophrenics (Table 2) has led to heightened interest in the therapeutic exploitation of these receptors for this condition.

Addiction

There is extensive interest in the use of group I antagonists and group II agonists as potential therapeutic agents in the treatment of drug addiction. In animal models, these agents reduce the symptoms of withdrawal from nicotine and morphine. In addition, there is evidence for sensitization of group II mGlu receptors in particular brain areas associated with drug dependence, following chronic exposure to morphine.

Cerebellar Ataxia

Animal models of disrupted $mGlu_1$ receptors suggest many similarities with cerebellar ataxia, but of arguable greater significance is the observation of auto-antibodies against $mGlu_1$ receptors in patients suffering from paraneoplastic cerebellar degeneration. These antibodies were observed to inhibit cerebellar function *in vitro* and *in vivo* arguing for a pivotal role for $mGlu_1$ receptors in this disorder.

Concluding Remarks

Although there has been an abundance of research investigating the physiological and pathophysiological roles of glutamate, as well as extensive medicinal chemistry programs to develop selective ligands, there is still an under-representation of therapeutic agents focusing on this pivotal transmitter.

Glutamate Receptor Clusters

Clustering of receptors is important for synapse formation and plasticity. In order to achieve efficient synaptic transmission, neurons must aggregate neurotransmitter receptors at the active zone of the synapse, and, in turn, stabilize and limit the lateral mobility of the clustered receptors. The most well-studied example of this is found in the peripheral nervous system where the postsynaptic membrane of the neuromuscular junction (NMJ) is enriched with a density of acetylcholine receptors (AChRs) $>10\,000\,\mu m^2$, 1000-fold higher than the density of extrasynaptic AChRs. Agrin, a heparan sulfate proteoglycan, mediates postsynaptic differentiation by clustering and enriching the postsynaptic membrane with AChRs. Agrin has been shown to initiate postsynaptic signaling through a postsynaptically localized muscle-specific receptor tyrosine kinase (MuSK) that leads to the clustering of AChRs. Mice deficient in agrin exhibit low levels of AChRs as well as an altered postsynaptic distribution within the myotubes. Some synapses were found to lack postsynaptic specializations entirely within these mutant mice. Thus, agrin clustering of AChRs contributes to the organization and resulting function of the postsynaptic membrane to respond rapidly and reliably to neurotransmitter released from the overlying nerve terminal.

Analogous extracellular and transmembrane proteins in the central nervous system (CNS) that contribute transynaptically to receptor clustering and synapse formation have been sought and a few candidate receptor clustering molecules within the CNS have been identified. EphB2 receptor, stargazin, and Narp are three well-studied examples of proposed receptor clustering molecules that function in the CNS (Figure 1).

EphB2/Ephrin

The first Eph receptor discovered, EphA1, was identified from a screen of a human cDNA library using the viral oncogene v-*fps* as a probe for low-stringency cross-hybridization to other tyrosine kinases. Since then, at least 14 Eph receptors have been identified in vertebrates, making them the largest subfamily of receptor tyrosine kinases. Eph receptor ligands are ephrins, which are tethered to the cell membrane of opposing Eph receptor-expressing cells by a transmembrane domain or a glycosylphosphatidylinositol anchor.

The protein structure of EphB2 is similar to that of the canonical Eph receptors. EphB2 is a type I transmembrane protein. The N-terminal extracellular domain contains motifs typically found in adhesion molecules: a putative immunoglobulin (Ig) domain, a cysteine-rich region, and two fibronectin type III repeats. The cysteine-rich region contains two C*n*C*x*C*n*C repeats ($n = 12$–15 acids and x is any amino acid) that are frequently found in epidermal growth factor (EGF)-like repeats of extracellular matrix proteins. The EphB2 cytoplasmic domain contains a tyrosine kinase domain that is conserved in all Eph receptors. EphB2 contains a potential postsynaptic density/disk/zonula occludens-1 (PDZ) binding domain at the C-terminus, possibly linking EphB2 to cytoskeletal and/or signaling proteins. A yeast two-hybrid screen using this domain has identified two synaptic PDZ proteins implicated in α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptor trafficking, PICK1 and GRIP, as potential binding partners.

Since all Eph receptors are expressed in the developing nervous system, they were originally hypothesized to play a role in development. Indeed, Eph/Ephrin signaling complexes have been implicated as regulators of contact-mediated axon growth cone guidance and neuronal cell migration. Recent evidence, however, suggests that Eph receptor, specifically EphB2, and their cognate ligands, the ephrin-B subgroup of ephrin ligands, play an additional role in synaptic development and plasticity. In the hippocampus, EphB2 is localized postsynaptically at excitatory neurons of the CA1 region of the hippocampus. Ephrin-B is expressed presynaptically and binding to EphB2 receptors induces clustering and activation of the receptors.

The formation of EphB2 clusters is important for signal initiation that is activated by ephrin binding. Unlike most other ligands for receptor tyrosine kinases, ephrins do not act as soluble mediators of receptor activation. Instead, ephrins are membrane bound and require membrane linkage that is necessary for cluster formation. Interaction of membrane ephrin-B and EphB2 at sites of cell–cell contact initiates cluster formation of both molecules in their respective plasma membranes. Ephrin-B binding to EphB2 results in the assembly of higher-order tetramers composed of ephrin-B/EphB2 dimers resulting from high-affinity protein–protein interactions between specific domains. Other mechanisms that contribute to cluster formation include enrichment of ephrin-B and EphB2 in lipid rafts as well as EphB2 interaction with PDZ

Figure 1 Receptor clustering. See text for discussion.

proteins. The ephrin-B/EphB2 clustered complex results in the initiation of intracellular signal transduction by EphB2 receptor tyrosine kinase domain. Interestingly, cluster formation also initiates 'reverse signaling,' in that cluster formation also results in signal transduction activation in ephrin-expressing cells.

A possible role for EphB2/ephrin-B complex in synapse function and formation is suggested by the interaction between EphB2 and *N*-methyl-D-aspartate (NMDA)-type glutamate receptors (NMDARs). EphB2 interacts directly with the NMDAR subunit NR1 via extracellular domain interaction. Cultured neurons treated with preclustered recombinant ephrin-B ligands to mimic *in vivo* activation of EphB2 receptors result in an increase in the number of endogenous EphB2 clusters. Increased clustering of EphB2 increases the number of co-clusters with NR1 and the number of synapses. Structure–function analyses in combination with experiments that block EphB2 signaling using dominant negative constructs demonstrate distinct function of the EphB2 extracellular domain and the intracellular kinase domain. That is, NMDAR cluster formation by EphB2 requires only the extracellular domain interaction, but subsequent stages of synapse assembly require the kinase domain. Although the kinase domain is not required for NR1 clustering, it has been shown to be required for NMDAR function, synaptic plasticity paradigms such as long-term potentiation (LTP) and long-term depression (LTD) at the mossy fiber/CA1 synapse of the hippocampus, and spine morphogenesis.

The role of EphB2 in clustering of NR1 and synapse formation and plasticity has been confirmed in mice lacking EphB2. Although these mice exhibit deficits in axon guidance and boundary formation in some regions of the brain, the fundamental circuitry and structure of the hippocampus are unaffected. Mice that lack EphB2, however, exhibit a 40% reduction in the number of NR1 receptors at synapses. Electrophysiological recordings performed at the Schaffer collateral/CA1 synapse in the hippocampus of these mice show that they have normal basal transmission. Studies examining synaptic plasticity within these mice show that although the early phase of LTP is also normal, LTP is not maintained over 100 min. Similarly, LTD is attenuated in EphB2 null mice. Surprisingly, mice expressing EphB2 lacking the intracellular catalytic domain exhibit normal LTP and LTD at this synapse, suggesting that extracellular EphB2 interaction with ephrin-B and NMDAR is sufficient to maintain synaptic plasticity.

EphB2 null mice exhibit deficits in spatial memory as measured by the Morris water maze, suggesting a defect in hippocampal memory function. However, it is difficult to interpret these results because the EphB2−/− mice exhibit a significant reluctance to participate in the task and a reduced swim speed.

Stargazin

Interest in stargazin began when a mutant mouse spontaneously arose within the A/J inbred strain at the Jackson Laboratory. These 'stargazer' mice exhibit mild gait ataxia beginning early in development, and later demonstrate a periodic tossing of their head backwards, so as to stare up and gaze at the stars.

Electrocorticographic recordings of these mice revealed prolonged, frequent spike-wave seizures with behavioral arrest, characteristic of absence epilepsy. Mapping of the stargazer gene (*stg*) led to the discovery of an early transposon insertion into the second intron at the voltage-dependent calcium channel $\gamma 2$ subunit locus (*Cacng2*) on chromosome 15, which results in decreased Cacng2/stg/$\gamma 2$ mRNA expression. Further characterization of this gene revealed a 36-kDa integral membrane protein, named stargazin, which contains four membrane-spanning domains, with both N- and C-termini present on the cytoplasmic side.

Weak protein sequence identity (25%) with the γ-1 calcium channel subunit of muscle suggested a possible role as a neuronal voltage-dependent calcium channel (VDCC) regulator. However, there is only modest evidence supporting the role of stargazin in regulating VDCCs, and the magnitude of the contribution is still in question. Alternatively, stargazer mice display an impairment of AMPA-type glutamate receptor (AMPAR) function, suggesting a role for stargazin in AMPAR regulation. Consistent with this notion, the cerebellum of *stg* mutant mice exhibits a lack of functional AMPARs within granule cells of the cerebellum. Functional studies of these *stg* mutant mice show an impairment in acquisition of eye-blink conditioning. Interestingly, although stargazin is expressed in other various regions throughout the brain, including the olfactory bulb, cerebral cortex, thalamus, and hippocampus, *stg* mice possess functional AMPARs within these areas.

Stargazin is a member of the family of transmembrane AMPAR regulatory proteins (TARPs), which includes $\gamma 3$, $\gamma 4$, and $\gamma 8$. All members of this family are expressed in brain but exhibit differential distribution patterns and are capable of direct interaction with the AMPAR subunits – GluR1, GluR2, or GluR4. Chimeric analysis between the TARPs and an inactive TARP homolog, $\gamma 5$, which cannot associate with AMPARs, revealed that the interaction between AMPARs and TARPs requires both the first extracellular loop as well as a 50-amino-acid region within the C-terminal intracellular domain of stargazin. Disruption of either of these domains, either through deletion, insertion, or $\gamma 5$ domain-swapping, leads to abolishment of AMPAR binding.

Stargazin facilitates the trafficking and clustering of AMPARs (but not kainite- or NMDA-type glutamate receptors) at excitatory synapses in two distinct ways. First, stargazin mediates delivery of functional AMPAR from the Golgi complex to the plasma membrane. Co-microinjection of stargazin and GluR1 into *Xenopus laevis* oocytes results in a greatly increased surface expression of AMPARs, when compared to oocytes injected with the GluR1 subunit alone. This function is dependent upon binding of a 50-amino-acid region within the C-terminal intracellular domain of stargazin to the AMPAR, as disruption or abolishment of this domain results in the impaired insertion of AMPAR into the membrane. In addition, binding of glutamate to AMPAR results in disruption of the stargazin/AMPAR interaction, perhaps via a conformational change in AMPAR. This is consistent with the notion that stargazin plays a role in activity-dependent cycling of AMPARs at the synapse. Surprisingly, although the first extracellular domain of stargazin has been shown to be necessary for AMPAR interaction, this domain is not necessary for the trafficking of AMPAR to the surface.

Second, the final four amino acids of stargazin (TTPV) constitute a type I PDZ-binding domain, and thus stargazin is capable of binding PDZ domain-containing proteins. The proper targeting and clustering of AMPAR to synapses is dependent upon binding of stargazin with the PDZ domain-containing synaptic scaffolding protein PSD-95. Deletion of the last four amino acids in the C-termini results in loss of AMPAR at the synapse. Despite the loss of synaptic AMPAR, however, trafficking of AMPAR to the plasma membrane is unaltered. This PSD-95/stargazin interaction is regulated by protein kinase A (PKA). Phosphorylation of the PDZ-binding domain by PKA results in the inability of stargazin to bind PSD-95. This in turn results in the loss of AMPAR at the synapse, and consequent attenuation of synaptic AMPAR currents.

In addition to trafficking AMPARs, stargazin has recently been shown to modulate AMPA receptor gating. Whereas AMPARs normally deactivate and desensitize quickly after activation, co-transfection of stargazin with AMPAR in *Xenopus* oocytes results in a slower deactivation and desensitization, an increased amplitude of steady-state currents in response to both glutamate and especially kainate, and an increased open channel probability. This effect is independent of the increased trafficking effect of stargazin on AMPAR. Subsequent chimeric analysis between stargazin and the $\gamma 5$ subunit (an inactive TARP homolog) found that the first extracellular domain of stargazin is necessary for this AMPA channel regulation.

Narp

Neuronal activity-regulated pentraxin (Narp; also termed NP2) binds and clusters AMPARs. Narp is a member of the neuronal pentraxin family of secreted, calcium-dependent lectins, originally named for their ability to form pentamers of five noncovalently bound subunits. Members within this family include

neuronal pentraxin 1 (NP1) and neuronal pentraxin receptor (NPR). Other nonneuronal pentraxins include apexin, serum amyloid P component (SAP), and C-reactive protein (CRP), which are involved in the innate immune response. Narp is a 432-amino-acid protein with an N-terminal signal sequence, followed by two coiled-coil domains and a 'pentraxin signature' sequence of H*x*C*x*S/TW*x*S in the C-terminus. Narp was identified using a differential and subtractive cloning strategy to isolate genes that are rapidly upregulated in response to neuronal activity, and that contribute to protein synthesis-dependent synaptic plasticity. Narp mRNA expression increases following maximal electroconvulsive seizure (MECS) with a time course that peaks at 2 h and returns to pre-MECS levels by 24 h. In addition to induction via MECS, Narp is upregulated by experimental forms of synaptic plasticity, including long-term potentiation. Moreover, high-level expression in rodent cortex is maintained in a steady-state manner by natural synaptic activity, since blockade of input from the eye via monocular injection of tetrodotoxin (TTX) results in a rapid reduction of Narp mRNA within the contralateral visual cortex. Narp protein is highly expressed in both brain and testes. In brain, Narp is enriched within layers 2/3 and 5/6 of the cortex as well as in the CA3 and dentate gyrus of the hippocampus. Narp accumulates at dendritic excitatory synapses on both excitatory and inhibitory neurons and can be secreted from both the pre- and postsynaptic membranes.

The role of Narp in the formation and remodeling of synapses was first proposed based on the observation that Narp co-clusters with AMPARs in cultured hippocampal neurons. Follow-up co-immunoprecipitation experiments demonstrated that Narp interacts directly with all AMPAR subunits, presumably via one of the extracellular AMPAR regions. Narp cluster formation is correlated with its ability to act as a synaptogenic agent. Overexpression of Narp increases the number of excitatory synapses in cultured spinal neurons. Conversely, dominant-negative Narp mutants that cause the rapid degradation of native Narp reduce the number of AMPAR clusters, suggesting a role for Narp in synapse formation.

The molecular basis of Narp's ability to form clusters has been examined. Narp assembles into higher-order quaternary structures of hexameric units, involving three position-specific intermolecular disulfide bonds as well as intermolecular protein–protein interactions. Narp contains three cysteine residues located within or near the N-terminal coiled-coil domains (residues 14, 26, and 79). Cysteine-14 and cysteine-26 mediate formation of hexameric units of Narp assembly; cysteine-79 mediates linkages between Narp hexamers. These specific disulfide linkages as well as protein–protein interactions by the coiled-coil domains mediate Narp cluster formation. The other neuronal pentraxins, NP1 and NPR, form assemblies via the same mechanism. Moreover, the neuronal pentraxins can form disulfide-linked heteromultimers that function cooperatively at excitatory synapses.

Conclusion

The molecular mechanisms of neurotransmitter receptor clustering are fundamental for the modification of synaptic strength and maturation of synapses. Although many of the molecular mechanisms of synaptic maturation and plasticity might be shared, they are distinct processes occurring at different time periods. Here, we have discussed the known roles that EphB2 receptor, Narp, and stargazin play in receptor clustering. The future challenge will be to more clearly define the individual and concerted roles of these proteins, their family members, and other yet-to-be identified proteins in receptor clustering during synaptic maturation and synaptic plasticity.

Glutamate Receptor Organization: Ultrastructural Insights

Y Fukazawa and R Shigemoto, National Institute for Physiological Sciences, Okazaki, Japan

© 2009 Elsevier Ltd. All rights reserved.

L-Glutamic acid, glutamate, is a main excitatory neurotransmitter in the vertebrate central nervous system. Various subtypes of ionotropic and metabotropic glutamate receptors are expressed depending on the types of synaptic connections and regions of the brain. The precise and quantitative localization of glutamate receptor subtypes is thus indispensable for understanding the mechanisms of excitatory synaptic transmission, information processing, memory formation, and neuronal degeneration ascribed to excessive glutamate receptor activation. However, the small size of synapses (~1 μm wide, with a surface area of ~0.5 μm^2) hampers analysis of their precise localizations by light microscopy, which has limited spatial resolution (~500 nm). Electron microscopy with immunogold labeling has revealed highly differentiated distributions of glutamate receptors in the neuronal plasma membrane with a resolution up to 20 nm. Three immunogold labeling techniques – preembedding, postembedding, and freeze-fracture replica labeling – have different advantages and technical limitations and are used in combination to elucidate distinct distribution patterns and quantitative localizations of the receptors.

Localizations of Glutamate Receptors in Distinct Membrane Compartments of Postsynaptic Neurons

Twenty-two subtypes of glutamate receptors (GluRs) have been identified in the mammalian genome, and these are categorized into two major classes – ionotropic glutamate receptors (iGluRs) and metabotropic glutamate receptors (mGluRs). The former class has been further categorized into four types based on their pharmacological properties: the *N*-methyl-D-aspartate receptors (NMDARs) type, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs) type, kainic acid receptors (KARs) type, and orphan glutamate receptors (δ_1 and δ_2 glutamate receptors). The latter class has also been categorized into three groups, groups I–III, based on their pharmacological properties and second messenger signaling pathways. Ultrastructural localizations of these receptors have been conducted extensively in the hippocampus and cerebellum. NMDARs, AMPARs, δ_2 GluR, and group I mGluRs ($mGlu_1$ and $mGlu_5$) have been localized in the excitatory postsynaptic plasma membrane at the ultrastructural level, whereas group II and III mGluRs have been localized preferentially in the presynaptic neuronal plasma membrane. The ultrastructural localizations of KARs and δ_1 GluR have not been well demonstrated.

The postsynaptic dendritic plasma membrane can be subdivided into three subregions: postsynaptic membrane specialization and perisynaptic and extrasynaptic regions. The excitatory postsynaptic membrane specialization has postsynaptic density and directly faces the presynaptic active zone, where the release of neurotransmitter occurs. At the electron microscopic level, the postsynaptic membrane specialization can be identified by the asymmetrical appearance of electron densities between pre- and postsynaptic membranes (type I synapses). The perisynaptic region surrounds the postsynaptic membrane specialization and is 60–200 nm wide, with no clear boundary with the extrasynaptic region. NMDARs, AMPARs, and δ_2 GluR have been shown to accumulate over the postsynaptic membrane specialization, whereas group I mGluRs are mainly enriched in the perisynaptic plasma membrane (Figure 1). Expression of NMDARs/AMPARs and group I mGluRs has also been found in the extrasynaptic plasma membrane with lower density than in synaptic or perisynaptic regions, respectively.

Intrasynaptic Distribution of iGluRs

Tangential distribution of NMDARs and AMPARs in the excitatory synapse has been investigated in several brain regions. NMDARs have been shown to be relatively abundant in the center of the postsynaptic membrane specialization of pyramidal cells in the hippocampus and neocortex. On the other hand, AMPARs have been found to be localized in the synaptic specialization in various patterns depending on the types of synapses. AMPARs in the mossy fiber–pyramidal cell synapses and Shaffer collateral/commissure fiber–CA1 pyramidal cell (SC–Py) synapses in the hippocampus have been shown to be localized evenly over the synaptic specialization, whereas those in the synapses of entorhinal and neocortical cells are reported to be prevalent in the center and periphery of the specialization, respectively. On the other hand, microcluster-like distribution of AMPAR labeling within synapses has also been reported in the hippocampal synapses by postembedding immunogold labeling. Freeze-fracture replica labeling, which visualizes two-dimensional localization of membrane

Figure 1 Differential distribution of three types of glutamate receptors at synapses on dendritic spines (s) in the cerebellar cortex (a and c) and in stratum radiatum of the CA1 hippocampal area (b). The AMPA-type glutamate receptor is enriched in the postsynaptic membrane specialization (a; GluR 2/3 subunits, postembedding immunogold reaction, 5 nm particles). The NMDA-type glutamate receptor is also enriched in the postsynaptic membrane specialization (b; NR1 subunit, postembedding, 5 nm immunogold reaction). The mGluR1α-type glutamate receptor is enriched in the perisynaptic region of parallel fiber–Purkinje cell synapses (c; preembedding silver intensified immunogold labeling). Scale bar = 0.1 μm in (a, b), 0.2 μm (c).

molecules with high resolution, has also revealed AMPAR microclusters within the postsynaptic specialization of parallel fiber–Purkinje cell (PF-PC) synapses in the cerebellum (Figure 2). These clusters have various subsynaptic localizations depending on individual synapses. Such microclusters have not been detected in the climbing fiber–Purkinje cell synapses, which have denser and more homogeneous localization of AMPARs (Figure 2). δ_2 GluRs have been shown to localize evenly over the synaptic specialization of the PF–PC synapses.

Taken together, it seems likely that NMDARs are preferentially distributed in the center of the postsynaptic membrane specialization in a wide variety of glutamatergic synapses, whereas intrasynaptic distribution of the AMPARs is regulated in highly differentiated forms in individual synapses. It is not clear how these highly differentiated distributions of iGluRs develop and take part in shaping characteristic features of synaptic transmission at each type of synaptic connection. It seems likely that synaptically localizing scaffold proteins associating with specific types of glutamate receptors are involved in the regulation of postsynaptic localization of glutamate receptors.

Glutamate Receptors and Their Associating Proteins

Biochemical and molecular biological studies have revealed large numbers (~500) of cytoplasmic and membrane-spanning proteins in the postsynaptic density fraction containing the postsynaptic membrane specialization. These proteins are thought to form a large protein complex as visualized as postsynaptic density in electron microscopic images. Some of these cytoplasmic protein members act as scaffold proteins for glutamate receptors at the postsynapse, taking part in controlling receptor localization, function, and signaling. MAGUK proteins such as postsynaptic density-95 (PSD-95; also known as SAP90) and Shank proteins (also known as ProSAP, SSTRIP, CortBP, Synamon, and Spank) are thought to be key proteins for regulating glutamate receptor localizations in the synapses. They have multiple protein–protein interaction domains and can act as a hub of protein networks in the postsynaptic density. MAGUK proteins directly interact with NMDARs and also interact with AMPARs through transmembrane AMPA receptor regulatory proteins (TARPs) assembled in the AMPA

Figure 2 Two distinct patterns of intrasynaptic distribution of AMPA-type glutamate receptors. Distribution of the AMPA-type glutamate receptor in two types of synapses in the cerebellum was visualized by SDS-digested freeze-fracture replica labeling. (a) Microcluster-like aggregations of immunoparticles (5 nm) for AMPA-type receptors are found within the postsynaptic membrane specialization (blue) of the parallel fiber–Purkinje cell synapse identified by immunoparticles (15 nm) for the δ_2 glutamate receptor. (b) AMPA receptor immunoparticles (5 nm) in the climbing fiber–Purkinje cell synapse were distributed evenly over the postsynaptic specialization. Scale bar = 100 nm.

receptor complex. Shank proteins interact with group I mGluRs through Homer proteins (also known as Vesl, PSD-ZIP45, and Cupidin) and also interact with MAGUK proteins through GKAP. As a result, these key proteins assemble a large protein complex beneath the postsynaptic membrane specialization and provide scaffolds for GluRs regulating their intrasynaptic localization. Localization of these key proteins beneath the postsynaptic membrane specialization in the hippocampal synapses has been shown with immunoelectron microscopy. However, tangential localization of these proteins accountable for the distinct localization of NMDARs, AMPARs, and group I mGluRs has not been well documented.

The iGluRs also interact with various cytosolic proteins through their cytoplasmic domains. These interactions regulate expression levels of the receptors in the postsynaptic plasma membrane during development and synaptic plasticity via trafficking mechanisms of receptor-containing vesicles. Therefore, interaction of GluRs with these cytosolic proteins in the postsynaptic membrane specialization can account for differential localization of iGluRs. For example, adaptor protein complex-2 (AP-2) is known to couple NMDARs to the clathrin-mediated endocytic machinery, and these AP-2–NMDAR complexes are retrieved from the plasma membrane. It has been reported that the introduction of a point mutation in the NR2B subunit of NMDAR at a tyrosine phosphorylation site, which is necessary for interaction with α-actinin2, results in displacement of NMDARs toward the peripheral region of the postsynaptic membrane specialization. Similarly, a protein interacting with C-kinase 1 (PICK1) is known to interact with the GluR2 subunit of AMPAR and trigger internalization of the receptor complexes via endocytotic mechanisms. Knockin mice expressing a mutated GluR2 subunit lacking PICK1 interaction show altered distribution of the AMPARs in the postsynaptic plasma membrane of PF–PC synapses.

These observations clearly indicate that the postsynaptic distribution of GluRs is dynamically regulated through interactions with their associate proteins.

Expression Levels of GluRs Are Governed by Both Pre- and Postsynaptic Factors

Glutamatergic transmissions show large variability in their functional characteristics within and across populations of synapses, and changes in their efficacy are thought to be regulated by the different numbers of receptors in individual synapses.

Moreover, glutamatergic synaptic specializations in certain brain regions also show large variability in size. The quantity of receptors expressed within and across populations of synapses is related to anatomical parameters such as synapse sizes. Ultrastructural investigation has demonstrated not only the distinct spatial distribution patterns of receptors but also the number and density of receptors, which are differentially regulated at individual synapses.

NMDARs are expressed at all SC–Py synapses in the CA1 region of the hippocampus, and the expression level has no correlation with the size of the postsynaptic membrane specialization. Moreover, the density of synaptic NMDARs has shown a negative correlation with the size of synapse. On the other hand, SC–interneuron synapses in the same region express NMDARs in proportion to the synapse size,

maintaining constant densities at individual synapses. These observations indicate that the levels and the mode of the NMDAR expression are different among postsynaptic cell types.

Expression of AMPARs shows very different patterns from that of NMDARs. Among the SC–Py synapses, those smaller than 180 nm in diameter have been shown to be AMPAR immunonegative (AMPAR-lacking synapses comprise 50, 25, or 15% of all SC–Py synapses, depending on individual reports). In larger synapses, the level of AMPAR expression has been shown to be positively correlated with the synapse size. Thus, the ratio of AMPARs to NMDARs seems to be positively correlated with the synapse size. Similarly, the synapses between CA3 pyramidal cells (association/commissure (A/C) fiber–Py synapses) in the hippocampus have been shown to be AMPAR immnonegative in 15% of the population. Also, similar to the CA1 synapses, AMPAR-immunopositive synapses have shown a strong positive correlation between the expression level of AMPARs and the synapse size. Synapses made on the same type of cells but with input from the dentate gyrus granule cells (mossy-fiber synapses) have been found to be AMPAR immunopositive in all synapse populations and also show a strong positive correlation between the expression level of AMPARs and the size of synapse. These facts clearly indicate that the level of AMPAR expression depends on the identity of the presynaptic input. Moreover, comparison of AMPAR expression in A/C fiber synapses between pyramidal cells and GABAergic interneurons in the CA3 region revealed that all of the latter synapses express AMPARs and the expression levels, on average, were four times higher than those in the former synapses. Thus, the AMPAR expression level is governed by both pre- and postsynaptic factors.

Although perisynaptic $mGlu_5$ expression has been detected in 50% of SC–Py synapses, quantitative localization of group I mGluRs in respect to anatomical parameters has not been well elucidated. The level of mGluR expression at individual synapses also seems to be regulated by unknown mechanisms.

Conclusions

Ultrastructural investigation of the glutamate receptor organization in the postsynaptic plasma membrane has revealed both a unified view of highly compartmentalized and subtype-dependent localization and a highly variable view of their quantities within individual synaptic populations. The unique and highly variable distribution of each glutamate receptor subtype may reflect prerequisites for their proper functioning, which is crucial for controlling excitability of neurons in given neuronal networks and for processing and storage of information in the brain.

Glutamate Regulation of Dendritic Spine Form and Function

Introduction

During synaptogenesis, pyramidal cell dendrites in the hippocampus extend numerous filopodia. These filopodia are highly motile and can extend up to 10 μm; in comparison, spine extension is generally <2 μm. It has been suggested that a filopodium initiates contact with a growing axon nearby. This contact results in the accumulation of active zone exocytotic proteins in the axon at the site of contact, followed by the accumulation of postsynaptic density (PSD) proteins in the filopodium or at the shaft to which the filopodium retracts. It is therefore thought that the contact between a filopodium and an axon is the initial step in the formation of a mature axospinous synapse. The filopodium then evolves directly into a spine or facilitates the formation of a shaft synapse from which a spine arises at later stages of synaptogenesis. Dendritic spines are small protrusions of the dendritic membrane; they represent the postsynaptic component of the majority of the excitatory synapses in the central nervous system (Figure 1). More than 90% of the excitatory presynaptic terminals impinge on postsynaptic parts that reside on spines. A human brain thus contains over 10^{13} spines. Dendritic spines are found on excitatory and inhibitory neurons, including glutamatergic pyramidal neurons of the neocortex and hippocampus as well as γ-aminobutyric acid (GABA)ergic cerebellar Purkinje neurons. They were first described over a century ago by Santiago Ramón y Cajal. However, their ultrastructural and molecular organization has only recently become accessible, due to advances in microscopy and molecular biology.

Spine Shape and Size Are Correlated with Synaptic Strength

There is tremendous heterogeneity in the shapes and sizes of dendritic spine heads and in the lengths and thicknesses of the spine neck (Figure 2). Considerable progress has been made in correlating dendritic spine morphology with the strength of the synapses formed with the spines. Differences in the size of the spine head are correlated with differences in the size of the postsynaptic density. Because of the molecular links between the proteins of the postsynaptic density and glutamate receptors, it is postulated that the size of the spine head is correlated with the number of glutamate receptors expressed.

The relationship between spine size and sensitivity to glutamate has been addressed recently using state-of-the-art photorelease of chemically caged glutamate. This technique permits the release of glutamate in a small volume, comparable to the size of a single spine head. It is thus possible to stimulate α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid-preferring glutamate receptors (AMPARs) on single dendritic spines and to measure the resulting postsynaptic currents with whole-cell voltage-clamp recording. A strong correlation between spine head volume and the amplitude of the excitatory postsynaptic current has been observed, suggesting that larger spine heads do contain more AMPARs.

Electrophysiological and immunocytochemical studies have demonstrated that *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors are not colocalized at all synapses. Rather, it appears that a significant proportion of synapses express only functional NMDA, and not AMPA, receptors. Because the NMDA receptors do not produce substantial current flow at the resting membrane potential, these synapses can appear 'silent.' The proportion of such silent synapses is high in early postnatal life and declines gradually during development. Synaptic maturation and induction of long-term potentiation (LTP) are accompanied by the appearance of functional AMPA receptors at previously silent synapses. The morphological correlates of silent synapses are not known. One hypothesis is that morphological maturation of spines, from long, thin filopodia with small heads to adultlike spines, occurs in parallel to insertion of AMPA receptors at silent synapses.

The diameter of the spine neck has also been predicted to affect synaptic efficacy. Long, narrow necks should result in a region of high electrical resistance between the synapse in the spine head and the parent dendrite. Shorter, fatter necks should have a lower electrical resistance, and the lower resistance might facilitate the transfer of dendritic depolarization for a given size of synaptic current. Other modeling studies have suggested that the neck resistance should have only an insignificant effect on synaptic transfer, however. Use of glutamate photostimulation techniques has allowed this question to be addressed directly. In cortical pyramidal cells, the length of the spine neck is inversely correlated with the amplitude of the electrical response to photostimulation. Remarkably, stimulation of those spines with the longest, thinnest

Figure 1 Morphology of dendritic spines. Figure 2 Diversity of spine shape. Dendritic spines are classified into three main types: (a) short, stubby spines (<0.5 μm in length), (b) mushroom-type spines, consisting of a short neck and mushroom-shaped head, or (c) thin, long spines with an elongated neck and small head. (Top) Three-dimensional volume-rendered portion of the dendritic tree of a CA1 pyramidal cell from a green fluorescent protein-expressing mouse brain.

necks (>2 μm in length) fails to induce a detectable depolarization at the cell soma, even though positive evidence of responses at the spine has been obtained. The spine neck thus appears to possess a significant electrical resistance that shapes the transfer of synaptic depolarization generated in the spine head to the parent dendrite and cell body.

The realization that voltage-dependent channels are also located in spines raised the possibility that spine neck resistance can influence the probability that a synaptic current would depolarize the spine sufficiently to trigger the activation of these channels. Lower spine neck resistance (i.e., shorter, fatter spine necks) should act to minimize spine depolarization and hence decrease synaptic activation of voltage-dependent conductances. In addition, the placement of synapses on spines may serve to keep the resistance of the dendritic shaft relatively constant and high so that it serves as an effective 'cable' from the synapses to the soma. If synapses were formed with the dendritic shaft directly, activation of synaptic conductances would decrease dendritic resistance, thereby diminishing its electrotonic properties.

Spine Shape and Intracellular Ca^{2+}

The influx of Ca^{2+} via NMDAR channels is the key triggering event in the induction of LTP and long-term depression (LTD). The positioning of synapses on spine heads may reflect the function of spines to act as 'compartments' that isolate and confine synaptically generated signals, such as second messengers, activated enzymes, and NMDAR-mediated Ca^{2+} influx, to the synapse at which they have been generated. Changes in the size of spine necks and heads might thus affect the induction of conventional NMDA receptor-dependent synaptic plasticity. In particular, because short spine necks should allow synaptically generated intracellular Ca^{2+} transients to readily diffuse out of spines and into dendrites, it has been theorized that LTP induction should be hampered at synapses formed with such spines. It has been determined that the narrow channel of cytoplasm within the spine neck slows diffusion of cytosolic molecules by about 100-fold, compared to free diffusion. This diffusional barrier allows ions in the spine head cytosol to be at a significantly different concentration than they are in the dendritic shaft, for >100 ms. The mechanisms governing the recovery of basal Ca^{2+} concentration in the spine after synaptic NMDAR activation remain controversial. There is evidence favoring both diffusion through the neck into the dendritic shaft and active extrusion.

It is also interesting to note that the spine neck also acts as a barrier to the rapid diffusion of plasma membrane proteins. Studies of the movement of fluorescently labeled plasma membrane molecules indicate that lateral diffusion is tenfold slower from the dendritic shaft to the spine head than it is for

diffusible cytosolic proteins. For integral membrane proteins, such as receptors, rates of diffusion have been measured at 0.01–0.4 $\mu m^2 s^{-1}$, and for proteins anchored at the intracellular surface of the membrane rates vary between 0.03 and 0.5 $\mu m^2 s^{-1}$. These values are in good agreement with measurements of the diffusion of labeled synaptic glutamate receptors (0.06 μm^2 s^{-1}), which is fivefold less than in the extrasynaptic regions. In this case it is believed that anchoring proteins link receptors to the cytoskeleton and reduce their mobility.

Maintenance of Spine Shape and Number

As dendritic spines are thought to be the sites of memory storage, any loss of a dendritic spine would result in the loss of a memory. It is important to determine how dendritic spines can be maintained. The influence of synaptically released glutamate on postsynaptic structure has been investigated by comparing the effects of deafferentation, receptor antagonists, and blockers of glutamate release in hippocampal slice cultures. CA1 pyramidal cell spine density and length decreased after lesioning of Schaffer collaterals and after application of AMPA receptor antagonists or blockade of spontaneous glutamate release by the addition of botulinum toxin to unlesioned cultures. These results suggest that the lack of AMPA receptor activation following degeneration of presynaptic afferents initiates the process of spine retraction in postsynaptic CA1 pyramidal cells. Loss of spines and synapses induced by lesion or by botulinum toxin could be prevented by simultaneous AMPA application. Synaptically released glutamate thus exerts a trophic effect on spines by acting at AMPA receptors, sufficient to maintain dendritic spines. Interestingly, the larger spine numbers do not change after chronic AMPA receptors blockade, and there are more asymmetric shaft synapses. It still remains to be determined if the thin spines retract with their presynaptic terminal attached, to form an asymmetric shaft synapse. Nonetheless, despite this loss of synapses and spines, the remaining synapses have no significant change in frequency of miniature excitatory postsynaptic currents, indicating a compensatory rearrangement to preserve synaptic function.

Myristoylated alanine-rich C kinase (MARCKS) is a major target of activity-dependent phosphorylation of protein kinase C, and this function is thought to be important in synaptic plasticity and in memory. Surprisingly, ablating MARCKS expression by small interfering RNA (siRNA) leads to destabilization of spine morphology, as exhibited by a decrease in spine number and length. There is no effect on dendritic arborization, suggesting that MARCKS has a specific role in dendritic spine stability. Interestingly, overexpressing wild-type MARCKS also reduces spine number and length, indicating that the level of MARCKS is critical for spine maintenance.

In adult visual cortex (V1), brain-derived neurotrophic factor (BDNF) has been shown to play a fundamental role in dendritic spine maintenance through activation of its receptor, TrkB. Staufen 2, a member of a double-stranded RNA-binding protein family, has also been shown to play an important role in spine maintenance. Interfering with Staufen 2 expression in neurons results in neurons with reduced numbers of dendritic spines. More recently, the Ca^{2+}/calmodulin-dependent protein kinase (CaMK) has been shown to act as a structural protein that can bind to F-actin through a very specific and stoichiometric interaction associated with the B subunit, in addition to its well-known role as a signaling protein critically involved in synaptic plasticity in the brain. This binding is necessary for the maintenance of dendritic spines.

The Rho family of GTPases, a subgroup of the Ras superfamily, are key regulators of the actin cytoskeleton. The Rho GTPases RhoA, Rac, and Cdc42 all have been investigated with regard to their role in spine formation and shape determination. Rac and Rho have opposite effects on spine number. Constitutively active RhoA decreases spine length and number, whereas constitutive expression of an active Rac1 leads to the formation of many small dendritic spines. The roles of some of the guanine nucleotide exchange factors (GEFs) or GTPases in activating proteins that regulate Rho family GTPases have recently been elucidated. One such example, the GEF kalirin-7, activates Rac1, as well as its downstream effector p21-activated kinase (PAK), a protein kinase. PAK phosphorylates and inactivates ADF/cofilin, which alters spine actin turnover and thereby alters spine morphology.

Morphological Changes Accompanying Synaptic Plasticity and Learning: LTP

It has long been speculated that lasting memories must be encoded as a quasi-permanent morphological change in the activated synapses. There has been an extensive search for correlations between morphology and changes in synaptic function during learning, with the hope that some spines would be shaped differently because they took part in the storage of some piece of critical information. An increase in the strength of the synaptic connection might be encoded morphologically as (1) an increase in the number of contacts between two cells, (2) an increase in the size of the spine head to make room for more receptors, or (3) a dilation of the spine neck, so that currents generated in the spine head more readily depolarize the

dendrite. There are at least some data indicating that all three changes accompany induction of LTP in brain slices or learning in whole animals. Most persuasively, recent advances in fluorescent microscopy, utilizing two-photon and laser-scanning instruments, for example, have made it possible to obtain high-resolution images of fluorescently labeled dendritic spines in living *ex vivo* brain slices at the same time as the induction and expression of LTP.

An increase in the number of synapses should result in an increase in spine density, and several studies have found strong evidence of an increase in the number of dendritic protrusions following LTP induction protocols in the CA1 pyramidal cells. In some studies these processes appear to be mature spines from the start. In others, they first resemble filopodia, only later maturing into spines, suggesting a recapitulation of the normal developmental sequence of events (**Figure 3(a)**). The induction of new dendritic processes shares some of the same requirements as does the induction of LTP and learning: induction is largely NMDAR dependent and requires activation of CaMK. These data are consistent with *in vivo* spine density changes.

Hebb's postulate states that learning a particular bit of information depends on the correlated action potential discharge of two cells. In order for the new spines to strengthen existing connections, they must be formed with presynaptic partners whose activity was correlated with the postsynaptic cell. Some data suggest that the new spines are formed by the splitting of existing pre- and postsynaptic partners, whereas other data suggest that new spines grow out and preferentially contact presynaptic terminals whose activity induced the new spine to form. Indeed, there is strong evidence that glutamate may act as a chemoattractant for growing dendritic processes, which then grow preferentially toward the active presynaptic terminal releasing glutamate.

There is equally compelling evidence indicating that LTP induction is accompanied by changes in the size of dendritic spines. Induction of LTP using photostimulation or tetanic synaptic stimulation, while visualizing spines loaded with fluorescent dyes, is accompanied by a 50% increase in spine head volume within 1–5 min after stimulation. The degree of spine head enlargement depends strongly on the initial, naive spine size (**Figure 3(b)**). Although almost all spines show a transient enlargement, only small spines become persistently increased in volume after stimulation with caged glutamate. Like LTP, spine head enlargement requires activation of NMDARs and CaMK. These data suggest that the spine head must become bigger in order to accommodate newly inserted AMPARs. Spine head growth may not be an obligatory concomitant of LTP, however, since it is not seen in all studies, despite equivalent LTP induction (**Figure 3(c)**).

Morphological Changes Accompanying Synaptic Plasticity and Learning: LTD

The strength of naive and previously potentiated synapses can be reduced in the process known as long-term depression, usually induced with prolonged periods of stimulation at moderate frequencies (1–10 Hz). The induction of LTD has recently been shown to be accompanied by morphological changes that are opposite to those accompanying LTP induction, including decreases in spine number and spine head size.

Loss of preexisting dendritic spines in response to tetanic stimulation reportedly occurs within 3 h of the stimulation and results in the loss of two to three spines per 100 μm of dendrite, with any one spine retracting over the course of 10 min to 1 h. Like LTD, this stimulation-induced spine retraction is prevented by blocking NMDARs. Interestingly, the loss of spines associated with LTD becomes progressively less pronounced with increasing age. The most spine loss is triggered in tissue slices from animals that are 12–20 days old. This finding supports the concept of a developmentally defined critical period in which morphological plasticity can most easily be induced, and that the loss of this plasticity contributes to brain maturation and stabilization.

Induction of LTD with low-frequency stimulation also triggers a decrease in spine head diameter of about 70%, which persists for >30 min. Induction of LTD thus triggers morphological changes that oppose those observed to accompany LTP. Indeed, low-frequency stimulation can reverse the increase in spine head volume triggered with high-frequency stimulation, and high-frequency stimulation can enlarge spine heads previously reduced by low-frequency stimulation.

Spine Shape and Cytoskeletal Rearrangement

The cytoskeleton of the dendritic spine is characterized by a loose network of actin filaments. Interestingly, dendritic spines lack microtubules, unlike the cytoskeleton in the dendritic shafts, except for the occasional microtubule in highly complex spines. It has been shown that the spine cytoplasm is composed of actin and actin-regulating proteins which are longitudinally situated in the spine neck and organized into a dense lattice surrounding the smooth

Figure 3 Spine changes in long-term potentiation (LTP). Images of fluorescent dye-filled dendrites of CA1 pyramidal cells before and after induction of LTP with synaptic stimulation (a) or photolysis of chemically caged glutamate (b, c). Time after induction, in minutes, is indicated in images. (a) LTP induction leads to outgrowth of dendritic filopodia, which are later replaced by spines. (b, c) Photostimulation was used to induce LTP at a single dendritic spine, indicated by a yellow arrowhead. (b) A rapid, transient enlargement of the spine head was seen in both examples, but persisted only in the small spine (upper row), not in the larger spine (lower row). (c) No enlargement of the spine head was seen, despite a similar level of potentiation. Scale bars = 10 μm (a), 1 μm (b, c). (a) Reprinted from Maletic-Savatic M, Malinow R, and Svoboda K (1999) Rapid dendritic morphogenesis in CA1 hippocampal dendrites induced by synaptic activity. *Science* 283: 1923–1927. (c) Reprinted from Bagal AA, Kao JPY, Tang CM, et al. (2005) Long-term potentiation of exogenous glutamate responses at a single dendritic spine. *Proceedings of the National Academy of Sciences of the United States of America* 102: 14434–14439.

endoplasmic reticulum (SER) or spine apparatus in the head. This organization of the actin filaments suggests that they provide the scaffolding for the basic spine structure, as well as mediating changes in spine shape. Many actin-binding proteins, such as Arp2/3, cortactin, ADF/cofilin, drebrin, profillin, gelsolin, spectrin, and neurabin, have been identified within dendritic spines.

Increasing evidence suggests that inactivity extending for days induces changes in the structure and

Figure 4 The formation of spine head protrusions. Tetrodotoxin (TTX; 1 μM) induces the formation of spine head protrusions. Example of a portion of dendrite double-labeled with membrane-bound green fluorescent protein (green) and FM 4–64 (red) at the beginning (left panel) and after a 15-min treatment with 1 μM TTX (right panel). Arrows indicate the location of a spine that converts into a spine head protrusion. Reprinted from Richards DA, Mateos JM, Hugel S, et al. (2005) Glutamate induces the rapid formation of spine head protrusions in hippocampal slice cultures. *Proceedings of the National Academy of Sciences of the United States of America* 102: 6166–6177.

function of hippocampal synapses, although the characteristics of these reported changes differ. For instance, long-term exposure of neurons to tetrodotoxin (TTX) leads to increases in spine density in the lateral geniculate nucleus, and in the number of dendritic filopodia on CA1 pyramidal cells. Under conditions of reduced synaptic input, spines establish new contacts with nearby boutons in a glutamate-receptor-dependent fashion, suggesting that this may occur in response to glutamate spillover (Figure 4). The formation of spine head protrusions is blocked by the AMPA kainate receptor antagonist 2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo[*f*]quinoxaline-2,3-dione (NBQX), which prevents spines from sensing glutamate via AMPA receptors, and also by AMPA, which stabilizes spines due to the depolymerization of actin. These spine head protrusions 'reach out' to contact nearby boutons and appear to form new synapses. This is further strengthened by the observation that exogenously applied glutamate triggers the formation of spine head protrusions. Further investigation will determine whether these branched spines are forerunners to boutons splitting and new spines emerging. These findings suggest that if a spine has not been recently activated by glutamate released by its associated bouton, it can respond to glutamate released by a neighboring synapse. Furthermore, if there is too much activity or release of glutamate, the dendritic spines can retract and lose their contacts. Spines can thus 'compare' their individual recent history with the level of activity of neighboring synapses and modify hippocampal microcircuitry accordingly.

Conclusion

A variety of psychiatric and neurological diseases are associated with abnormalities in dendritic spine morphology or deficient spine density (notably, in virtually every disease in which cognitive performance is impaired). This spectrum includes epilepsy, stroke, trauma, schizophrenia, dementia, major depression, and chronic substance abuse, as well as normal aging. For the majority of these conditions it is not known whether spine abnormalities are a direct cause of synaptic dysfunction, resulting in cognitive deficits, or are secondary to some other event. Although still far from complete, the molecular understanding of the pathogenetic process seems to be most advanced in some hereditary forms of mental retardation, such as fragile X syndrome, in which proteins that regulate spine development and maintenance have been found to be affected.

A better understanding of the role dendritic spines play in determining synaptic efficacy and the expression of synaptic plasticity will provide a better insight into the relationship between cognitive deficits and changes in spine morphology, shape, and number in these various diseases.

Introduction

Neurotrophins (NTs), including brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), and neurotrophin-3 and neurotrophin-4 (NT-3, NT-4), were originally viewed as endogenously secreted glycoproteins that functioned in facilitating long-term neuronal survival and in stabilizing the phenotype of neurons. In the mammalian central nervous system (CNS), NTs have emerged in recent years as being more particularly involved in the modulation of activity-dependent processes, such as synaptic development and plasticity. The close apposition of NT signaling, which involves activation of the tropomyosin family of receptor tyrosine kinases (Trk) and the p75 NT receptors, with glutamate and γ-aminobutyric acid (GABA) synapses, as well as short- and long-term changes in excitatory and inhibitory synwaptic transmission induced by NTs, have identified this family of proteins as potent modulators of synaptic strength in the developing and mature brain. Given that the inability of neuronal networks to adapt is likely to impair cerebral function, it is not surprising that abnormal NT signaling has been linked to a wide range of neurological and psychiatric disorders. Herein, we review recent advances relative to the role of NTs in the developmental control and function of glutamatergic and GABAergic systems and discuss the possible mechanisms involving impaired trophic support in normal aging and pathological states, focusing on epilepsy and schizophrenia.

Developmental Regulation of Glutamatergic and GABAergic Systems by NTs

Proper function of the CNS results from the establishment of precise synaptic connections within neuronal networks during development. This occurs through a complex, multistep process that involves neurogenesis, migration, differentiation (dendritic and axonal growth), and synaptogenesis. Although NTs and their receptors are highly expressed in the developing brain during times of active neuronal growth and differentiation, their direct involvement in the maturation of excitatory synapse has remained elusive for a long time. BDNF facilitates the formation of excitatory synapses *in vitro* and promotes new synapses *in vivo*, but reduced levels of cerebral BDNF in mutant mice do not significantly affect synapse density, spine morphology, or synaptic vesicle distribution in cortical circuitry. NTs were initially proposed to indirectly act on excitatory connections through homeostatic mechanisms resulting from an alteration in inhibitory synapse formation, because GABAergic interneurons are established well before pyramidal neurons are, and GABA receptors and synapses are operative before glutamatergic synapses become operative during development in all brain structures and species studied to date. However, evidence for a direct effect of NTs on excitatory synapses has recently emerged using genetic manipulations or time-lapse imaging in dissociated cultures of cortical neurons. Knocking out the receptor TrkB specific for BDNF decreases the number of glutamatergic synapses, while conditional deletion of this receptor specifically at presynaptic or postsynaptic site clearly assigns a cell-autonomous role of TrkB signaling for normal development of both components of the hippocampal excitatory synapses. Visualization of the subcellular localization of TrkB receptors during synaptogenesis also provides convincing clues for a significant role of NTs as molecules dynamically involved in the formation of excitatory synapses between cortical neurons. During synapse maturation, TrkB receptors, which are highly mobile, concentrate in axonal growth cones and dendritic filopodia, thus actively participating in setting excitatory connections. At the postsynaptic level, BDNF, NT-3, and NT-4 control the length and complexity of dendrites of pyramidal neurons in slices of neonatal neocortex, and removal of TrkB receptors induces extensive dendritic retraction. Basal, but not apical, dendrites of neurons respond more strongly to a single NT, and increase or decrease in dendritic elongation and branching depends on cell layer. The growth and differentiation of dendritic processes induced by BDNF may be altered by NT-3 and reciprocally. This spectrum of neurotrophic actions and the laminar specificity of these effects in mammalian neocortex implicate endogenous NTs as regulatory signals in the development of specific patterns of dendritic trees of glutamatergic neurons.

Compared to glutamatergic systems, much more evidence indicates a link between NTs and many aspects of GABAergic interneuron development in the rodent CNS. Different proliferative regions of the subpallium telencephalon give rise to interneurons populating the neocortex and the hippocampus. At the earliest developmental stages, the medial ganglionic eminence (MGE) and the lateral ganglionic eminence (LGE) have been identified to be the sources of cortical and striatal GABAergic interneurons. The MGE is also the source of hippocampal interneurons,

but only those that will migrate to hippocampal layers of the cornus ammoni. Interneurons of the dentate gyrus (but also GABAergic cells of the cortex, striatum, amygdala, and nucleus accumbens) originate from the caudal ganglionic eminence (CGE). BDNF and NT-4 promote the migration of GABAergic precursors into the cortex and hippocampus. NT-4 is expressed along the migratory path of MGE-derived cells and increases the motility of stationary and migrating interneurons. BDNF and NT-4 stimulate tangential migration, whereas pharmacological inhibition or genetic deletion of TrkB receptors significantly decreases the number of cells migrating tangentially in the developing cortex. The effects of BDNF and NT-4 in MGE cells are mediated through the activation of the phosphatidylinositol 3-kinase (PI3K), inhibition of which also alters interneuron migration.

Once interneurons have migrated accurately to their final destination, they extend processes that form elaborate dendritic trees. As already mentioned for glutamatergic neurons, NTs promote dendritic elongation and branching in the developing interneurons. NTs not only induce the morphological but also the neurochemical maturation of hippocampal or neocortical interneurons. In cultured hippocampal neurons, exogenous BDNF application increases the level of glutamic acid decarboxylase 65 (GAD65), one of the two isoforms of GABA synthesis enzymes; GAD65 resides mainly in GABAergic terminals. BDNF also exhibits important effects on the neuropeptide expression that co-localizes with GABA within inhibitory interneurons. Application of NT-3 increases neuropeptide levels in neuropeptide Y (NPY)-containing and somatostatin-containing hippocampal interneurons, whereas NGF has no effect. BDNF and NT-4 enhance expression of NPY but exert no conspicuous effect on somatostatin content. Furthermore, levels of NPY are reduced in interneurons of BDNF-deficient mice.

A final crucial step in neuronal development is synaptogenesis. BDNF and NT-4 promote the formation of functional inhibitory synapses in cell cultures. *In vivo*, BDNF overexpression accelerates the maturation of GABAergic synaptogenesis in the visual cortex. Neuronal activity also enhances synaptogenesis of inhibitory connections, and antibodies against BDNF or NT-4 applied in cerebellar or hippocampal slice cultures prevent or reduce this activity-dependent maturation of GABAergic synapses. Finally, NTs optimize synaptic function of newly established synapses during development. At presynaptic level, NTs modulate the release of GABA. BDNF increases the vesicle release probability and vesicle replenishment with no effect on quantal size, the number of release sites, and the readily releasable pool. In addition, levels of several presynaptic proteins implicated in the mechanisms of release, such as synaptobrevin, synatophysin, and syntaxin, are upregulated. NTs also regulate the number of postsynaptic GABA receptors, and BDNF has been shown to increase the formation of $GABA_A$ receptor clusters at synapses.

Appropriate development of the GABAergic system is highly important for neonatal network activity, as GABA is the principal neurotransmitter that induces depolarization of the postsynaptic neurons up to postnatal day 10 in the rodent brain. The conversion of GABAergic transmission from excitatory to inhibitory is dependent on the progressive expression of the chloride extruder, the K^+/Cl^- cotransporter 2 (KCC2), occurring from embryonic stages to postnatal day 15 (P15). This operation of GABA as excitatory before and around birth may represent the first network activity necessary to drive the activity-dependent release of NTs, and therefore to play a role in the maturation of glutamatergic transmission.

Regulation of Glutamatergic and GABAergic Transmission and Plasticity by NTs

Brain expression of NTs and of their receptors is not limited to development; neurotrophic factors are still present and Trk receptors largely expressed in almost all neurons and inhibitory interneurons in adult CNS. These proteins therefore have functions clearly extending the maturation of synapses. An extensive body of literature indicates that NTs can modulate several distinct aspects of synaptic transmission, including glutamatergic and GABAergic transmission. NTs, both *in vivo* and *in vitro*, induce changes in glutamatergic synaptic transmission in the adult brain through a positive feedback modulation, which is mediated by the activation of Trk, but not p75, receptors. Brief application of NTs enhances the efficacy of synaptic transmission in a tetanized pathway without altering synaptic strength of an untetanized set of synapses monitored simultaneously, indicating that NTs act preferentially on active synapses. Reciprocally, the expression and release of NTs are tightly regulated by electrical activity. This close relationship between the level of neuronal activity and NT effects points out for a role of neurotrophic factors in long-lasting activity-dependent synaptic changes, such as long-term potentiation (LTP). LTP is an experience-dependent increase in synaptic strength involved in memory formation, which is experimentally induced by a high-frequency stimulation (HFS) of excitatory afferents, and it can last for weeks and months *in vivo*. Glutamatergic *N*-methyl-D-aspartate receptors (NMDARs) play a pivotal role in an early phase of LTP lasting for a couple

of hours, by rapidly elevating intracellular Ca^{2+} in postsynaptic dendritic spines, although other effectors such as voltage-gated Ca^{2+} channels or metabotropic glutamate receptors may also be involved. Early LTP depends on the phosphorylation of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate subtype of glutamate receptors (AMPARs), already present at neuronal membranes and trafficking of new receptors at synapses, thus increasing the strength of synaptic transmission (Figure 1). Stronger induced HFS promotes longer-lasting LTP, referred to as late LTP or synaptic consolidation. Late LTP requires the activation of cyclic adenosine monophosphate (cAMP)-dependent protein kinase A (PKA) and extracellular signal-regulated kinase (ERK), acting through phosphorylation of the transcription factor cAMP/calcium response element-binding protein (CREB), leading to gene transcription and protein synthesis. Results from genetic deletion and pharmacological studies indicate multiple contributions of NT signaling to early and late LTP. First, NTs facilitate the induction of LTP through a permissive effect, which is characterized by the property of BDNF to prevent the decrease in synaptic transmission normally occurring during repetitive stimulations, namely synaptic fatigue. Following successive trains of stimulation, BDNF synthesis is stimulated in dendritic processes and is rapidly released from secretogranin II-positive secretory granules. This release evokes a TrkB receptor-dependent Ca^{2+} entry into presynaptic glutamatergic terminals through activation of voltage-gated Ca^{2+} channels, or through intracellular Ca^{2+} release from inositol 1,4,5-trisphosphate (IP_3)-gated Ca^{2+} stores. Phosphorylation of synapsin I, the membrane-associated protein of transmitter vesicles, by mitogen-activated protein kinases (MAPKs) is then promoted, which releases synaptic vesicles from the cytoskeleton and facilitates their entry into the exocytosis cycle. Additionally, NTs provide relieve of synaptic fatigue by promoting the docking of synaptic vesicles to presynaptic membranes.

Figure 1 Neurotrophin (NT) signaling and synaptic potentiation. In response to repetitive presynaptic activation of afferent fibers (theta burst activation), glutamate is released and binds mainly on postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs). Membrane depolarization is generated, increasing intracellular Ca^{2+} concentration by Ca^{2+} entry through *N*-methyl-D-aspartate receptors (NMDARs) and voltage-gated calcium channels (VGCCs). The increase in intracellular Ca^{2+} activates intracellular pathways, such as the Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) pathway, inducing synaptic potentiation. In addition, it promotes the postsynaptic release of NTs into the synaptic cleft, where NTs bind to tyrosine Kinase (Trk) receptors located on glutamate fiber terminals. Activation of Trk receptors results in presynaptic increase in intracellular Ca^{2+} through the recruitment of VGCCs or Ca^{2+} release from the endoplasmic reticulum (ER), which facilitates subsequent release of glutamate from the vesicle pool. This mechanism allows NTs to relieve the synaptic fatigue that normally occurs during repetitive activation. On the other hand, increase in presynaptic intracellular Ca^{2+} also promotes release of NTs from presynaptic terminals. Activation of postsynaptic Trk receptors then enhances NMDAR activity, which reinforces the increase in postsynaptic intracellular Ca^{2+} and, consecutively, synaptic potentiation. It also directly modulates synaptic potentiation by locally facilitating the synthesis of proteins such as CaMKII.

Independently of preventing synaptic fatigue, NT signaling is also causally involved in the induction of LTP through an acute instructive effect. Brief application of BDNF induces a calcium rise in dendritic spines and a burst of action potentials in the cell body; these events trigger LTP when pairing with a weak HFS. However, these effects are prevented by NMDAR antagonists, suggesting that NTs are able to directly affect functional properties of this glutamatergic receptor subtype necessary for synaptic plasticity. Accordingly, BDNF, but not NT-3 or NGF, reversibly enhances the magnitude of the NMDAR-mediated synaptic currents, whereas AMPAR-mediated responses are not affected. This facilitation of NMDAR currents specifically involves the phosphorylation of the NR2B subunit through activation of the tyrosine kinase Fyn. In addition to a direct modulation of functional properties of NMDAR, activation of TrkB-mediated signaling also enhances the number of NMDAR clusters at postsynaptic membranes as well as the proportion of clusters apposed to presynaptic terminals.

Besides its modulation of early NMDAR-mediated LTP, NTs also interact with protein synthesis-dependent late LTP through a delayed instructive effect. Pharmacological and genetic manipulations of NT signaling alter synaptic consolidation. TrkB antibodies prevent development of late LTP but only when they are applied during a specific time delay window after LTP induction (between 30 and 60 min, and not later), indicating that TrkB signaling is critically involved at a specific step in the expression of synaptic consolidation. In the absence of any HFS, a persistent potentiation of synaptic transmission is induced by a long-lasting application of BDNF or NT-3 (but not NGF) in the hippocampus. This pharmacological form of LTP is occluded during late LTP, revealing that both NT-dependent LTP and synaptic consolidation share common mechanisms. Accordingly, BDNF-mediated LTP induced at medial perforant path–granule cell synapses *in vivo* also requires ERK activation and *de novo* gene expression. How NTs contribute to mechanisms of synaptic consolidation remains to be definitively determined. One possibility should be a role in synaptic tagging. HFS sets a synaptic tag that allows the capture of proteins required for late LTP. A recent postulate considers a critical role of TrkB receptor activation, promoting translation of newly synthesized immediate-early genes or regionally stored mRNAs, such as those for Ca^{2+}/calmodulin kinase II, and tagging dendritic spines that could locally enhance protein synthesis and generate a pool of proteins required for synaptic consolidation.

Modulation of synaptic strength by NTs in neuronal networks also involves changes in GABAergic transmission. The effects of NTs on inhibitory synaptic currents are age dependent, as they enhance GABAergic transmission in immature neurons but reduce inhibitory currents in adult CNS. BDNF and NT-3 acutely suppress GABAergic transmission in mature synapses, by decreasing the frequency of spontaneous GABAergic activity, indicating a presynaptic locus of action. BDNF inhibits GABA release via activation of TrkB receptors, but independently of Ca^{2+} entry in presynaptic GABA terminals through voltage-gated Ca^{2+} channels, and rather by altering the activity of GABA transporters.

In addition to presynaptic effects on GABA release, NTs also act via postsynaptic mechanisms. TrkB signaling modulates the clustering of postsynaptic $GABA_A$ receptors that controls a subsequent upregulation of NMDAR clusters. These NT-mediated effects on postsynaptic clustering participate in the balance of excitatory and inhibitory synaptic transmissions in mature neuronal circuitry. In adult isolated hippocampal neurons, application of GABA evokes a fast inward current that is inhibited by BDNF. Combined electrophysiology and cell surface staining indicate that this inhibitory effect depends on a weaker phosphorylation and a rapid internalization of $GABA_A$ receptors. In addition, BDNF downregulates Cl^- transport, and both BDNF and NT-4 alter the neuronal capacity of Cl^- extrusion by reducing the expression of KCC2, the K^+/Cl^- cotransporter that maintains an effective Cl^- gradient. In nociceptive dorsal root ganglion neurons in culture, NGF treatment facilitates desensitization and deactivation of $GABA_A$ receptor-mediated currents that underlie the algogenic action of the NT.

Results from long-term treatments with BDNF suggest that the modulation effects of NTs on $GABA_A$ receptor-mediated responses may be a complex mechanism. Indeed, chronic application of BDNF on cortical and hippocampal adult neurons enhances rather than decreases GABA release probability. In these conditions, AMPAR-mediated currents, but not NMDAR-triggered responses, are increased in neocortical GABAergic neurons in culture. In parallel, the amplitudes, but not frequencies, of spontaneous miniature excitatory postsynaptic currents are elevated in these interneurons. These findings indicate that chronic treatment with NTs may also enhance the input sensitivity of GABAergic neurons, facilitating their inhibitory function in the neocortex.

Contribution of NTs in CNS Pathology

In addition to trophic effects on target neurons, NTs appear to be part of a general mechanism for activity-dependent modification of synapses in the developing and adult nervous system. Thus, diseases of abnormal

Figure 2 Schematic model outlining the possible contribution of abnormal neurotrophin (NT) signaling in epilepsy, schizophrenia, and aging. Increased NT signaling in response to various stimuli (e.g., ischemia, traumatic brain injury) may impair the glutamate/γ-aminobutyric acid (GABA) balance, leading to hyperexcitability of neuronal networks and ultimately to seizures. Decreased NT (BDNF, brain-derived neurotrophic factor; Trk, receptor tyrosine kinase) signaling in the prefrontal cortex during development may alter parvalbumin (PV)-containing GABAergic interneurons (and expression of glutamic acid decarboxylase isoform 67; GAD67), inducing an inhibition of pyramidal neurons and an impaired working memory, contributing to schizophrenia.

excitability (e.g., epilepsy and central pain sensitization), which are characterized by a disruption of the balance between excitatory and inhibitory synaptic transmissions, may be related to impaired NT signaling (Figure 2). On the other hand, synaptic plasticity, such as LTP, is known to underlie the acquisition and/or consolidation of certain forms of cognitive processes (e.g., learning and memory). Considering that synaptic plasticity is tightly regulated by NT signaling through multiple mechanisms, the question arises as to whether abnormal trophic support could be involved in cognitive deficits associated with normal aging and with brain pathologies such as schizophrenia.

A Role in Epilepsy?

Epilepsy is a cerebral disorder that is characterized by the recurrent appearance of spontaneous seizures due to neuronal hyperactivity. Since the discovery that limbic seizures increase NGF or BDNF expression, much has been learned about the contribution of abnormal NT signaling to the lasting structural and functional changes underlying epileptogenesis. The 'kindling' model of epilepsy – generated *in vivo* by repeated induction of pathological activity in the form of focal seizures – has identified a causal role for Trk receptors in epileptogenesis. Seizures are absent after hippocampal conditional deletion of TrkB receptors and a BDNF scavenger (TrkB–imunoglobulin G, which inhibits TrkB activation) suppresses kindling development. The exact nature of the endogenous ligand mediating Trk receptor activation during limbic epileptiform activities still remains to be determined. BDNF mRNA and protein are upregulated in areas implicated in epileptogenesis, while kindling development is reduced in mice in which one BDNF allele has been inactivated by gene targeting. In addition, epileptic seizures are enhanced in mice overexpressing BDNF. However, the results of these genetic manipulations must be regarded with caution, given potential developmental effects of altered BDNF levels. Indeed, only a modest effect on seizures is found in the hippocampal conditional BDNF knockout mice, despite a marked reduction of protein expression. Also, NT-4 null mutant mice are not affected with respect to any facet of the development or persistence of kindling. Endogenous NT-3 levels can influence the rate of epileptogenesis but NT-3 mRNA levels are significantly decreased in kindling. Evidence has been provided for a role of TrkA receptors in the development of epileptiform activities, since specific inhibition of TrkA–NGF binding and intraventricular infusion of anti-NGF antisera delay perforant path kindling progression.

The permanent hyperexcitability of the hippocampal network that generates status epilepticus occurs and is maintained through an imbalance between

glutamatergic-dependent excitation and GABAergic-mediated inhibition. Part of this imbalance may be dependent on altered NT signaling, since seizures have been shown to stimulate the expression of mRNA and protein for NTs and Trk receptors. Decrease in inhibition in hippocampal granule cells is reported in patients with medial temporal lobe epilepsy. A reduction of inhibition can trigger epileptiform activities or can sensitize the tissue to seizure activity, and may therefore represent one of the critical mechanisms allowing NTs to contribute to epileptic activity. It has been recently reported that seizure activity results in expression of synaptic $GABA_A$ receptors with an increased pool of α4 subunits; these are normally expressed only in extrasynaptic receptors with different functional properties. Early growth response factor 3 (Egr3) is the plasticity trigger for aberrant α4 subunit gene expression after status epilepticus. Interestingly, BDNF is the endogenous signal that induces Egr3 expression via a protein kinase C/MAPK-dependent pathway. This finding provides additional support for a role of NTs in epileptogenesis through disinhibition of neuronal networks.

NTs not only contribute to the maintenance of epileptic activity through changes in neuronal excitability but they also promote dendritic and axonal sprouting, morphological alterations, and synapse formation on a slower timescale. This abnormal remodeling, which reinforces the hyperexcitability of neuronal networks, is illustrated by the clear-cut sprouting of hippocampal mossy fibers in the epileptic brain. Mossy fiber sprouting is inhibited by either selective TrkA–NGF or p75–NGF antagonists, and it is also dependent on NT-3 signaling. On the contrary, BDNF administration has no effect on remodeling of the mossy fiber system in naive or kindled brain, suggesting that this NT acts on epileptogenesis by its effects on cell excitability.

A Role in Aging?

Aging is associated with defects in learning and memory, one of the most frequently noted features in the elderly. In early studies, cognitive impairments were linked to an age-dependent decline in forebrain cholinergic function, which was intensively investigated as being related to NT dysregulation. This hypothesis was eventually weakened, based on findings that age did not change the prevalence or regional distribution pattern of BDNF or TrkB mRNA throughout the life span. Learning and memory deficits in aged individuals are now known to be closely related to impaired induction of NMDAR-mediated LTP as well as of PKA-dependent synaptic consolidation. BDNF-induced LTP and the associated signaling are significantly impaired in the dentate gyrus of aged rats. In addition, recent evidence indicates that an increase in endogenous BDNF following treatment with a positive AMPAR modulator, AMPAkine, can reverse LTP deficit in aged rodents. Also, the stable LTP in AMPAkine-treated aged animals can be eliminated by infusion of the extracellular BDNF scavenger TrkB–Fc. These results indicate that managing BDNF signaling during aging can offset deficits of synaptic plasticity and strongly suggest that NTs may significantly contribute to age-related memory impairments. Accordingly, frontal cortex NGF and BDNF levels are positively, and hippocampal NT-3 levels are negatively, correlated with number of errors made as working memory load increases in aged animals, thus confirming that cerebral NTs may relate to working memory proficiency in aging.

A Role in Schizophrenia?

Schizophrenia is a devastating illness that affects approximately 1% of the world's population. Impairments of specific cognitive functions, such as prefrontal cortex-mediated working memory, are core features of schizophrenia. One of the most favored hypotheses for the etiology of schizophrenia is the neurodevelopmental hypothesis. Preclinical and clinical data indicate that dysfunction of NGF, BDNF, and NT-3 signaling may contribute to impaired brain development, neuroplasticity, and synaptic dysfunction, leading to the schizophrenic syndrome. Recent findings indicate that impairment in GABA-mediated inhibition in the prefrontal cortex may provide a critical mechanism for the disturbances in working memory. Postmortem tissue concentrations of the mRNA that encodes the 67 kDa isoform of glutamic acid decarboxylase (GAD67) are reduced in prefrontal cortex of individuals with schizophrenia, whereas mRNA and protein levels of GAD65 remain unchanged. This specific alteration may be critical, considering that genetic deletion of the GAD65 gene in mice does not alter cortical levels of GABA, whereas loss of the GAD67 gene is associated with a marked decrease in cortical GAD activity and GABA content. Because signaling through TrkB receptors stimulates the expression of GAD67, the reduced mRNA and protein levels for both BDNF and TrkB receptors that occurs in the prefrontal cortex of individuals with schizophrenia may thus contribute to the development of the illness through impaired GABAergic activity. Not only the mRNA and protein levels of GAD67 are altered in schizophrenia, but also the expression of parvalbumin (PV), a calcium-binding protein specifically localized in certain types of GABAergic cells. This effect is selective for PV-containing interneurons, as TrkB receptors are predominantly expressed by GABA neurons that contain PV, but not by calretinin-containing GABAergic interneurons. Since

stimulation of TrkB signaling increases the expression of PV, it has been suggested that deficiency in signaling through TrkB receptors possibly alters GABA synthesis in the PV-containing inhibitory interneurons in the prefrontal cortex of patients, thus disrupting perisomatic inhibition of pyramidal cells. This could induce a diminished capacity of the neuronal encoding that is required for working memory, thus contributing to the disease. In contrast to BDNF and TrkB signaling, the mRNA expression level for TrkC, the receptor tyrosine kinase for NT-3, is unchanged in schizophrenia. Therefore, alterations in the BDNF/TrkB system expression may specifically underlie the reduction of GABA-related genes (GAD67; GAT-1, the GABA transporter; and PV) observed in the prefrontal cortex in schizophrenia.

Conclusions

Many roles of NTs in glutamatergic and GABAergic systems have been elucidated. These roles include development, neuronal survival, maintenance of differentiated neuronal phenotype, regulation of synaptic connections, activity-dependent synaptic transmission, and plasticity in the adult brain. Evidence has accumulated indicating that alteration of one or several of these roles significantly contributes to the impaired brain functions that occur during normal aging, leading to cognitive defects, as well as to the impaired brain functions in pathological states such as schizophrenia and epilepsy. Interestingly, these roles have been complicated by the recent discovery that unprocessed forms of NTs (the pro-NTs) often induce effects that oppose those of mature NTs. Interaction of mature NTs with Trk receptors leads to cell survival and synaptic potentiation, whereas binding of pro-NTs to p75 NT receptors leads to apoptosis and synaptic depression. To what extent the proteolytic cleavage of pro-NTs determines the direction of NT regulation therefore represents a new challenge for scientists in the search of pharmacological treatments reducing NT-dependent brain pathologies.

Introduction

The amino acid neurotransmitters glycine and γ-aminobutyric acid (GABA) mediate inhibition in the vertebrate mature central nervous system by activating chloride conductance. Their ionotropic receptors belong to the canonical nicotinic acetylcholine receptor superfamily mediating fast synaptic transmission. Two features of this family, also known as the Cys-loop receptors, are its members' heteropentameric structure delineating the channel pore, and their assembly from distinct gene products or subunit splice variants that all possess a strictly conserved disulfide loop in their extracytoplasmic domain. Upon transient neurotransmitter binding, a pore opens in the pentamer that is responsible for the selective movement of ions through the plasma membrane according to their electrochemical gradient. In fully mature neurons, glycine binding to its receptor mediates inhibition by eliciting an influx of chloride ions. Whereas GABAergic transmission is widespread in the nervous system, glycine-mediated inhibition and the glycine receptor (GlyR) are predominantly encountered in the brain stem and spinal cord.

In the mid-1980s, GlyR was the first CNS receptor shown, by Triller and co-workers, to accumulate at postsynaptic differentiations (PSDs), in front of presynaptic release sites. Later on, variable subcellular organizations were demonstrated for many other receptors, including $GABA_A$ receptors (GABARs), which were analyzed by electron microscopy. Inhibitory synapses are intriguing, as both glycine and GABA open chloride channels and have a similar effect on the postsynaptic membrane. In the spinal cord, as well as in the brain stem and cerebellum, these synapses are either GABAergic, glycinergic, or mixed (i.e., respond to both neurotransmitters). The respective receptors accumulate in microdomains enriched with GABAR, GlyR, or a mixture of both, and it is the identity of the presynaptic element which imposes the composition of the postsynaptic membrane.

Another protein, named gephyrin, has been copurified with GlyR on an affinity column. Antisense experiments and work with knockout mice demonstrate that gephyrin is required for the synaptic localization of both GlyR and GABAR. The GABAR γ2 subunit is influential in synaptic insertion, since its absence in mouse results in a reduced number of GABA receptor clusters at synapses. The γ2 subunit role is mediated through gephyrin, but no direct link between GABARs and gephyrin has been demonstrated.

Molecular Biology and Topology of the Glycine Receptor

GlyR was the first neurotransmitter receptor to be isolated from the mammalian brain more than two decades ago. The purification of the native molecule was achieved in H Betz's laboratory, using affinity chromatography and taking advantage of the high-affinity interaction ($K_D \approx 1$–10 nM) of the receptor with its main antagonist, the well-known convulsant plant alkaloid, strychnine. The receptor appeared to be a complex of three proteins of 48 (α), 58 (β), and 93 kDa, in various vertebrate species.

Several biochemical studies of purified (or the membrane-anchored) form of GlyR have established that the integral membrane glycoproteins α and β represent the constitutive subunits of the receptor. Cross-linking techniques showed that α and β assemble to build up the channel-containing transmembrane core of GlyR. The size of the complex (250 kDa) logically suggested a pentameric assembly of the subunits, a quaternary structure well established for other Cys-loop receptors (Figure 1).

Unlike the α and β subunits, the 93 kDa co-purifying protein, gephyrin, is a nonglycosylated polypeptide able to interact reversibly with the α/β pentamer. Gephyrin is a cytoplasmic extrinsic membrane protein which binds tubulin dimers *in vitro* in a cooperative interaction of high affinity in the nanomolar range. It can also link brain microtubules to GlyR in a copolymerization assay. This finding underpinned the important notion that gephyrin could be a physical link between microtubules and GlyR in the postsynaptic membrane, as discussed in the following sections.

The Glycine Receptor as a Member of the Ligand-Gated Ionotropic Receptor Family

Analysis of the primary structures of the α and β proteins revealed the high homology of GlyR subunits, with amino acid sequence identity close to 50%. The GlyR subunit domain organization is comparable to that of other subunits of the Cys-loop receptor family. Hydropathy analysis of the mature polypeptide predicted a conserved region of four hydrophobic segments (M1–M4) able to cross the membrane bilayer at positions identical to those of transmembrane segments of acetylcholine and GABAR subunits (Figure 1(a)). GlyR subunits are polytopic type I membrane proteins. In contrast to M4, the

Figure 1 Structure of the glycine receptor. (a) Membrane topology of the α subunit, indicating the position of disulfide bridges, including the common Cys-loop delineated by Cys138 and Cys152 (red). Amino acid residues functionally important for agonist binding or modulation of the channel activity are shown. (b) Arrangement of α and β subunits in the mature $\alpha_2\beta_3$ receptor. One α subunit is depicted in cross-section, and one β subunit is rendered transparent to show the four packed M1–M4 transmembrane regions (cylinders). The pore-forming domain M2 of the α subunit is dark brown. (c) The α/β complex viewed from the extracellular space along the fivefold symmetry axis. Shown are the N-terminal regions of the five protomers (dashed lines) the counterclockwise organization of the four transmembrane domains.

transmembrane domains M1–M3 are highly conserved among the various subunits of GlyR. All subunits possess an extended N-terminal domain, bearing potential glycosylation sites, which were detected early by immunocytochemistry in the synaptic cleft. Finally, a large region of significantly lower homology is represented by a hydrophilic loop between the M3 and M4 segments; this loop protrudes into the cytoplasm (M3–M4 loop). Thus GlyR exhibits the molecular design and transmembrane topology of the acetylcholine receptor superfamily, based on four membrane-spanning domains able to form α helices (M2) and/or β strands (M1, M3, M4), and is assumed to function as an allosteric protein.

Our knowledge of this structure arose from extensive biochemical and electron microscopy data on the nicotinic acetylcholine receptor; these findings were recently refined by electron diffraction studies. The tertiary and quaternary structure of the soluble pentameric acetylcholine-binding protein (AChBP), which shares 20–24% and 17% sequence homology with nAChR and GlyR, respectively, has been useful in confirming or determining structure–function parameters for receptors of the family. Aside from an understanding of glycine and strychnine binding (see later), AChBP crystal structure provides a powerful model of the N-terminal domain of the Cys-loop receptor family. It shows that it is mainly a sandwich of antiparallel β sheets positioning conserved residues in order to stabilize the protomers, whereas variable residues are at their interface.

The topology of the transmembrane domains (Figure 1) delineates the ion permeation pathway away from the hydrophobic core of the phospholipid bilayer. For all Cys-loop receptors, the subunit's α-helical M2 domain lines the central water-filled pore, while M1, M3, and M4 form the interface with the lipids and isolate M2 from a hydrophobic environment. Recent studies on the GlyR α1 subunit have challenged the four-helix model and provide evidence that whereas M2 and M4 are entirely helical, M1 and M3 also contain β strands.

Assembly of GlyR

Initial studies of purified and membrane-anchored GlyR had suggested that α1 and β subunits assemble as a pentameric complex of α3β2 stoichiometry (Figures 1(b) and 1(c)). Short amino acid sequences (named assembly boxes), all located in the N-terminal extracytoplasmic domain of the β subunit and corresponding to three diverging motifs in α and β subunits, have been identified as having a role in precisely governing receptor assembly. Replacement of these motifs in the β subunit by the corresponding α1 motifs results in the loss of the subunit ratio in α/β oligomers, suggesting that different amino acid positions are determinants in the early step of subunit–subunit interaction. On the other hand, α1 and α2 co-assemble at variable subunit ratios. Importantly, these residues impose a mutually exclusive mode of assembly, either in complexes of invariant α/β stoichiometry or in homo-oligomers. A different stoichiometry (α2β3) has recently been established using affinity purification of expressed engineered tandem subunits. It confers on the β subunit a dominant role in the agonist binding properties of hetero-oligomeric α1/β GlyR, since ionic

interactions at the α/β interface are required to stabilize glycine. Such a structure for GlyR is consistent with the concept that neurotransmitter binding in the Cys-loop family requires extracellular segments from two adjacent subunits.

Molecular Diversity and Expression of Subunit Isoforms

The initial discovery of glycine receptor subtypes resulted from biochemical and immunochemical studies during rat spinal cord development. A comparison of GlyR immunoreactivities in neonatal and adult membrane extracts revealed a distinct form of GlyR predominating around birth (neonatal receptor, GlyRN) that displays a relatively low strychnine-binding affinity and only one major polypeptide band of 49 kDa. The discovery of functional $\alpha2$ pentamers predominantly found during the fetal and neonatal stages supported the idea of a developmental switch from GlyRN to the adult form, GlyRA, corresponding to the formation of $\alpha1/\beta$ heteromers. This switch, taking place within 3 weeks after birth, is not as complete in other regions of the nervous system where mixtures of $\alpha1$, $\alpha2$, and β subunits remain throughout adulthood. One current view is that postsynaptic GlyR corresponds to a mixture of $\alpha2$ pentamers and $\alpha2/\beta$ heteromers in immature neurons, while $\alpha1/\beta$ heteromers predominate in mature synapses.

A greater diversity of GlyR subunits than anticipated was established and includes not only the original $\alpha1$ and $\alpha2$ but also the $\alpha3$ and $\alpha2^*$ subunits. A murine $\alpha4$ subunit has also been identified which is absent in rat and human. These isoforms are highly homologous, with amino acid sequence identities on the order of 80%, and display a very low degree of interspecies variation (identity close to 99%). These isoforms can form glycine-gated chloride channels of comparable strychnine sensitivity, except $\alpha2^*$, which is more than 99% identical to human $\alpha2$ but exhibits a $\approx$500-fold lower strychnine sensitivity. Further generation of diversity resides in alternative exon usage. For the $\alpha1$ subunit, a variant mRNA encodes the form denoted '$\alpha1$ins,' a subunit containing eight additional amino acids. This sequence, inserted in the M3–M4 loop, bears a serine residue, representing a potential phosphorylation site and allowing a functional modulation of the $\alpha1$ subunit. Alternative splicing was also found for the $\alpha2$ and $\alpha3$ subunits.

The distribution of individual GlyR subunits was determined using *in situ* hybridization. However, transcription is not necessarily correlated with surface expression of functional receptors and the identification of the actual composition of GlyR in particular areas is not yet firmly established. The gene encoding the $\alpha1$ subunit and that encoding the $\alpha3$ subunit, though to a lesser extent, are mainly transcribed in spinal cord and brain stem at later postnatal stages. The $\alpha3$ subunit mRNA is present in the infralimbic system, the hippocampal complex, and the cerebellar granular layer. Expression levels of the $\alpha2$ subunit, by contrast, are high in the embryonic and perinatal stages but barely detectable in the adult brain, with some expression in higher cortical regions. The $\alpha4$ subunit, which is expressed at low levels in the adult but forms functional GlyRs, is restricted to the spinal cord and the sympathetic nervous system. The β subunit mRNA is more widely expressed throughout the embryonic and adult nervous system as compared to α subunit transcripts, and is found in brain loci devoid of strychnine-binding sites or GlyR immunoreactivity. The physiological significance of this widespread expression of the β subunit transcript is not understood, as so far there is no evidence that it assembles with α subunits of other receptors.

Gephyrin and Gephyrin-Binding Proteins

The Gephyrin Polypeptide

Gephyrin is the best characterized GlyR-interacting protein. Biochemical characterization and heterologous expression have shown that gephyrin binds cooperatively to tubulin dimers with a high affinity, and to GlyR via an 18-amino-acid sequence in the β subunit M3–M4 cytoplasmic loop. It was therefore postulated that gephyrin is a linker of the receptor to microtubules, adapted to anchor GlyR at synapses via the cytoskeleton. Gephyrin exists as several splice variants, as indicated by the characterization of the mouse gephyrin single gene and of its exonic structure, and the cloning of several different full-length coding sequences. Gephyrin variants, differing by the presence of distinct nucleotide sequences termed cassettes, are differentially expressed in numerous tissues, including brain, heart, skeletal muscle, and kidney, liver, lung, spleen, or testis, illustrating the ubiquitous nature of gephyrin.

Tertiary and Quaternary Structures of Gephyrin

The gephyrin polypeptide originated during evolution from the fusion of two genes of bacterial origin, respectively encoding the MogA and MoeA proteins involved in the biosynthesis of the molybdenum cofactor in *Escherichia coli*. These proteins are homologous to the gephyrin N- and C-terminal domains (G- and E-domains), respectively, flanking a 170-residue unique linker region. Intriguingly, in gephyrin these domains are enzymatically functional, and

disruption of the gephyrin gene leads to molybdoenzyme activity deficiency. These results indicate that gephyrin maintains MogA and MoeA activities in various tissues. Gephyrin tertiary and quaternary structures were determined following the crystallization of MogA and MoeA, and of gephyrin G- and E-domains. The G- and E-domains are compact structures forming stable trimers and dimers, respectively, which can be detected in crystals. If conserved in the gephyrin molecule, these oligomerization properties allow the construction of a two-dimensional hexagonal gephyrin lattice. This oligomerization pattern confers on gephyrin its function as a scaffold core protein and its ability to recruit GlyR at postsynaptic localizations. The GlyR-binding activity of gephyrin has been assigned in the E-domain to a pocket adjacent to the dimer interface.

Gephyrin-Interacting Proteins

Gephyrin is the core of the inhibitory postsynaptic scaffold (Figure 2). Binding partners for gephyrin other than GlyR have recently been identified, but their exact functions in receptor postsynaptic clustering have not yet been determined. Gephyrin may also be implicated in the modulation of signaling pathways. Gephyrin could thus participate in translational controls by binding to the RAFT1 kinase (a rapamycin and FKB12 target protein). The dynein light chains 1 and 2 (Dlc1/2) were recently identified as gephyrin-binding proteins. Further, gephyrin interaction with collybistin, a GDP/GTP exchange factor for GTPases of the Rho/Rac family, or with proteins such as profilin and Mena/VASP, could be a determinant for microfilament organization. This hypothesis

Figure 2 Molecular partners of the glycine receptor (GlyR)/gephyrin complex. Gephyrin is the only glycine receptor-interacting protein known so far. At synapses, it could form intermolecular trimers and dimers via its G- and E-domains, respectively. The localization of the receptor at synaptic loci relies on the ability of the former to interact directly with microtubules and indirectly with other proteins (collybistin and actin-binding proteins; yellow) able to modulate the dynamics of microfilaments. Until now the existence at synapses of a complex built up via simultaneous interactions involving all of these proteins has not been demonstrated. Double arrows indicate interactions disclosed by biochemical or two-hybrid strategies. A rapamycin and FKB12 target protein (RAFT1) is a translational activator which could mediate the synthesis of proteins required at synapses (Dlc2, dynein light chain 2; MoCo, molybdenum cofactor). Membrane binding sites for some partner proteins such as collybistin and profilin can be provided by phosphatidylinositol 3,4,5-trisphosphate (PIP3). Functions fulfilled by components of the proposed interaction network are shown by red arrows.

is consistent with results supporting the role of microfilaments in the control of postsynaptic gephyrin–GlyR co-cluster density. A feature of gephyrin is the presence of sequence stretches predicted to be WW (class IV) domain interaction motifs (ELM database search). A WW domain which is encountered in dystrophin/utrophin polypeptides might mediate phosphorylation-dependent binding to gephyrin. Interestingly, dystrophin, which is co-localized with dystroglycans, is present in a subset of inhibitory GABAergic synapses in the hippocampus, where it could be involved in a link between the extracellular matrix and the cytoskeleton.

Glycine Receptor Dynamics

Postsynaptic membrane domains and associated PSDs have long been viewed as stable multimolecular assemblies ensuring that a specific set of functions is performed locally. However, in recent years the notion has emerged that the postsynaptic domain is a highly dynamic protein complex adapted to the mechanisms underlying the plasticity of synaptic contacts. On the one hand, as for cellular multimolecular assemblies, postsynaptic complexes that contain GlyR correspond to the equilibrium between the exo- and endocytic delivery routes for membrane proteins. On the other hand, interactions involving cytoplasmic scaffolding proteins are pivotal in this steady-state balance that can be modified by cell differentiation or receptor activity.

Activity and GlyR Stability at Synapses

Receptor stabilization and aggregation, mediated by interactions with scaffold elements, are coupled at synaptic loci. The formation of GlyR clusters retained in the postsynaptic membrane in relation with receptor activation has been studied using an activity blockade by strychnine of cultured spinal cord neurons. This blockade leads to a reversible intracellular redistribution of GlyR which disappears from synaptic loci without alteration of gephyrin. Therefore, aggregation of gephyrin and that of GlyR are governed by distinct mechanisms. GlyR redistribution results from a defect in biosynthetic routing. At the steady state, the spinal cord neurons incorporate only a minor fraction of newly synthesized GlyR in synapses. It turns out that the stability of glycinergic synapses is due to a tight control of the relative rates of receptor synthesis, synaptic anchoring, and degradation. In order to explain selective positioning of active GlyR in front of glycinergic terminals, it has been proposed that glycine, which depolarizes immature neurons, triggers a calcium influx promoting the assembly of the postsynaptic scaffold.

Ubiquitination has recently been proposed to account for the regulation of cell surface GlyR $\alpha 1$ subunit endocytosis and degradation, thus determining postsynaptic receptor density. This hypothesis is based on the demonstration that ubiquitination of homopentameric GlyR occurs almost exclusively at the plasma membrane rather than during intracellular transport of the receptor.

Routing of Newly Synthesized GlyR to Synapses

The mechanisms of selective accumulation of receptors at synaptic sites are not fully understood. However, newly synthesized homomeric receptors spontaneously form microaggregates devoid of gephyrin in the neuronal plasma membrane. Although they can also in part remain in the extrasynaptic space, they associate with endogenous synaptic gephyrin according to a mechanism depending on the formation of the inhibitory innnervation. Interestingly, newly synthesized GlyR molecules are inserted in the plasma membrane as stable clusters which initially appear in the extrasynaptic space of the soma and dendritic proximal segments. Subsequently, they are redistributed over the dendritic tree. This occurs by diffusion of cell surface molecules, but not via exocytosis of vesicles routed to dendrites. Therefore, GlyR postsynaptic accumulation results from a diffusion/retention mechanism. This posits the crucial role of the retention signal, and in turn the anchoring role of gephyrin emerges. The complexity of the mechanisms of postsynaptic anchoring process, which relies on the exocytosis site, diffusion velocities, and on the concentration of synaptic binding sites, is illustrated by glutamate receptors of different compositions which accumulate at excitatory synapses with different apparent rates.

Gephyrin associates with vesicular compartments of GlyR intracellular trafficking and is a mediator of the insertion of newly synthesized receptor molecules in the plasma membrane, a process dependent on microtubule integrity. It has been further proposed that a nonsynaptic gephyrin/GlyR complex can be recruited to microtubules by dynein for retrograde transport along neurites. The existence of intracellular gephyrin/GlyR complexes indicates a dual function in trafficking and in assembly of postsynaptic scaffolds, as for proteins of excitatory synapses.

Local dendritic insertion of newly synthesized receptors is also a means of changing receptor numbers at synapses via mRNA localization. The discovery of the dendritic localization of GlyR α subunit mRNAs supported the view that local synthesis plays a role in synaptic plasticity. Remarkably, a microsecretory apparatus able to participate in the translation of membrane proteins is present in the subsynaptic cytoplasm.

Diffusion Properties of Cell Surface GlyR

In addition to membrane traffic, lateral diffusion within the plasma membrane has been demonstrated for GlyR. This concept has been extended to almost all excitatory and inhibitory receptors so far studied. The single-particle tracking (SPT) approach showed that receptor movements display interspersed periods of high and low diffusion rates in the extrasynaptic and synaptic membrane, respectively. Whereas periods of fast diffusion correspond to Brownian movement, those of slow mobility mainly result from transient association of GlyR with clusters of gephyrin. This association, which reduces diffusion coefficients from up to 0.5 $\mu m^2 s^{-1}$ to less than $10^{-2} \mu m^2 s^{-1}$, imposes a restricted area of exploration (confinement) similar to that generated for other proteins by insertion into lipid rafts or by contact with protein fences or obstacles. The fact that the receptors are not irreversibly retained in gephyrin domains, but can also exit from them, is a key finding which sheds light on how receptor clusters are formed or modified during plastic processes. It favors the new notion that any postsynaptic cluster of gephyrin can behave as donor or/and acceptor of GlyR. Therefore, the dynamic properties of GlyR–gephyrin interactions are also a means whereby the number of synaptic receptors can be regulated. It remains to be seen how the stabilizing scaffold molecules regulate these transitions, both in synaptogenesis and synaptic plasticity.

Because of its interaction with scaffold proteins, the cytoskeleton is a component of the postsynaptic differentiation, at least during differentiation or plastic changes. Because gephyrin is thought to link GlyR to microtubules, depolymerization of the latter would disrupt GlyR clusters. Interestingly, microtubule depolymerization alters the number and density of synaptic GlyR/gephyrin clusters, but the same treatment has no effect on GABA receptor/gephyrin clusters. This discrepancy may reflect the structural heterogeneity of inhibitory synapses that likely relies on receptor-specific assemblies of cytoplasmic proteins.

Pathology – Molecular Biology of Spastic Syndromes

Defects in glycinergic transmission are the cause of several neurological diseases. Some hereditary motor disorders in humans, mice, horses, and cattle result from the expression of mutated glycine receptor genes. The hallmark of these disorders is an exaggerated startle reflex in response to sudden stimuli, giving rise to rapid generalized responses in the form of hypertonia. Startle syndromes related to distinct genetic defects in glycine-mediated neurotransmission correspond either to impairment of GlyR agonist binding function or to reduced expression of functional channels. Both mechanisms lead to inefficient glycinergic inhibition and increased muscle tone.

Human Hyperexplexia

Hyperexplexia is a disorder in which unexpected sensory stimuli provoke exaggerated startle reflexes. Hereditary hyperexplexia, or Kok's disease or familial startle hyperexplexia (STHE), is a rare autosomal dominant neurologic disorder characterized by marked and continuous, sometimes fatal, muscle rigidity in infancy which progressively evolves into transient massive muscle contractions, a reaction that persists throughout adulthood.

Several missense mutations identified in the α1 subunit of GlyR can be responsible for higher glycine EC50 and/or lower channel conductance. The defective phenotype often results from mutations within, or in the vicinity of, the M2 transmembrane domain.

Startle Syndromes in the Mouse

Studies of mutants in the mouse reveal that defects in two genes can cause recessive disorders with clinical and pharmacological features reminiscent of STHE. The inherited spasmodic and spastic phenotypes are autosomal diseases characterized by muscle tremor, hypertonia, and pronounced startle reactions. They are rarely lethal, with the exception of the oscillator phenotype, and during the first 2 weeks after birth homozygous mutant mice have a normal phenotype.

The phenotypic similarity of spasmodic (spd) phenotype and STHE prompted the identification of the GlyR α subunit as the defective protein. A missense mutation, A52S, close to the protein N-terminus, decreases glycine sensitivity without changing the affinity for strychnine, in agreement with the normal binding of the antagonist in the *spd* spinal cord. The mechanism of action of this mutation is unknown, since the region of the mutation is not involved in ligand binding, receptor assembly, or gating.

The phenotype of the mutant mouse 'oscillator' (spdot) is characterized by a fine motor tremor and muscle spasms. Oscillator is allelic with spasmodic but corresponds to a microdeletion coincident with the cytoplasmic extremity of the M3 transmembrane segment. A translational frameshift generates a truncated form of the α1 subunit lacking the M3–M4 loop and the M4 domain.

The highly penetrant recessive 'spastic' mutation is associated with a dramatic reduction in the number of expressed GlyRs in the adult spinal cord and brain stem, but residual receptors exhibit normal subunit

structure and function. The delayed onset of the spasticity coincides with the developmental switch of GlyR, suggesting a selective lack of the adult form, in the absence of transcriptional alteration of the $\alpha 1$ subunit. A mutation affects a β subunit gene allele, which results from the intronic insertion (intron 5) of a LINE-1 transposable element. As a consequence, full-length β mRNAs are barely detectable, and truncated β subunits are generated by creation of premature stop codons.

The general loss of surface receptors in 'spastic' animals is consistent with the role of the β subunit, and results from the lack of a gephyrin-binding site in (hetero-)oligomers. However, it should be noted that a reduction in transport to, and insertion in, specific membrane areas may alternatively arise from an altered quaternary structure that does not allow exit from the endoplasmic reticulum and leads to degradation of the misassembled receptor.

Concluding Remarks

GlyR, which plays essential roles in inhibitory neurotransmission via a heterogeneous composition, has been the center of numerous studies during recent years. Better understanding has been gained at various levels, from structure–function relationships to the cell biology of synapses, including the associated postsynaptic density built up on gephyrin. Remarkably, pioneering work exploiting GlyR as a model molecule has helped develop new concepts concerning not only the biology of neurotransmitter receptors, but also the characterization of the dynamic equilibrium of GlyR-enriched postsynaptic membrane domains; such equilibrium accounts for the strength of synapses via control of their receptor number. GlyR and gephyrin are central to the assembly and activity of a nanomachine, which exploits the diffusion properties of the receptors in order to participate in the excitation–inhibition balance that is modified during plastic events within neuronal networks.

Introduction

Glycogen is the readily mobilized storage form of glucose in most mammalian tissues, including the brain. It is a branched chain polysaccharide molecule that can contain thousands of glucose residues. Glucose can be stored in the form of glycogen during periods of adequate exogenous glucose availability, to be liberated for use during periods of glucose need. The presence of glycogen in the brain has been known for many years, where it is estimated to contribute about 0.1% of the total brain weight (0.5–1.5 g). This is a very low concentration compared to skeletal muscle and liver, calling into question whether brain glycogen is functionally important. Glycogen is unlikely to act as an energy reserve in the conventional sense, since calculations have shown that there is only enough glycogen present to support brain activity for a few minutes in the total absence of glucose (see the section titled 'Roles of brain glycogen in neural function'). A more likely role is to provide energy substrate during short periods of increased demand when the supply of glucose does not match the increased demand by the brain.

Another reason that brain glycogen has been neglected is that it is contained exclusively in astrocytes. While glycogen 'turns over' quite actively in astrocytes, intact glucose residues derived from glycogen do not appear outside of astrocytes. Thus, it was concluded that brain glycogen would be of no benefit for neurons, which are known to be glucose dependent. A number of developments, including the discovery that neurons can generate ATP when provided substrates other than glucose, led to a resurgence of interest in brain glycogen. This molecule is highly regulated, and its concentration and availability is under physiological control. This article summarizes the biochemistry of brain glycogen and offers a current view of its roles in brain function, topics once again dynamic, after decades of dormancy.

Brain Glycogen: Macroscopic Issues

Regional Variations in Glycogen Content

Glycogen content displays regional variability, with gray matter structures having higher levels than white matter structures. Caudal, primitive, gray matter structures have the highest glycogen content (e.g., pons/medulla, cerebellum), more than twice as much as rostral areas (e.g., cerebral cortex and striatum). Even at the level of individual brain structures there is variation in content, which may be related to the density of glycogen-containing cells within the structure. For example, the dentate gyrus possesses twice the glycogen content of the rest of the hippocampus; in mouse, cerebral cortex glycogen content is higher in the superficial layers than in the deeper layers; and in four areas of medulla oblongata glycogen levels vary significantly.

Cellular Localization of Brain Glycogen

Glycogen is located predominantly in the cytoplasm of astrocytes. During development, it appears in both neurons and glial cells, but thereafter only a few neurons in the brain stem express glycogen. Some glycogen is also found in ependymal cells, including the specialized ependyma that help form the choroid plexus; ependymal cells are considered to be a specialized type of astrocyte. The expression of the enzymes that control glycogen synthesis and breakdown correlates with the astrocytic localization of glycogen. The brain isozyme of glycogen phosphorylase, the enzyme involved in glycogen breakdown, is located in astrocytes. Glycogen synthase, the enzyme that controls glycogen synthesis, is also present in astrocytes (Figure 1). This enzyme is also found in neurons but its function is not well understood and appears not to involve glycogen metabolism. Since astrocytes are found in all brain regions, this cellular localization does not dictate regional distribution; rather, it may explain the variation in glycogen content within distinct brain areas. The highest concentration of glycogen occurs in areas of high synaptic density, which immediately suggests a role in neuronal (synaptic) activity.

Measurement of Brain Glycogen

As mentioned, central nervous system (CNS) glycogen is present in much lower concentrations than liver or skeletal muscle. The concentration of glycogen in the rodent brain is 2–12 μmol g^{-1} of wet tissue. The presence of glycogen in tissue can be ascertained using techniques that visually identify the presence of glycogen, and quantitative techniques that estimate or measure absolute glycogen content. The most common staining method relies on the interaction of glycogen and osmium tetroxide, resulting in glycogen appearing as electron dense particles, 10–40 nm in diameter. This technique is used to confirm the

Figure 1 Glucose entry and glycogen synthesis in the brain. Glucose is transported via the insulin-insensitive GLUT1 transporter (GLUT1) and converted to glucose-6-phosphate (G-6-P) by hexokinase (HK), then to glucose-1-phosphate (G-1-P) phosphoglucomutase (PGM). G-1-P is converted to uridine diphosphate (UDP)-glucose by UDP glucose pyrophosphate (UDPGPP). UDP-glucose is then converted by glycogen synthase (GS) to glycogen. Protein phosphatase 1 (PP1) converts the inactive GSb to the active GSa, promoting glycogen accumulation. Glycogen is broken down by glycogen phosphorylase (GP), which exists in the active phosphorylated form (GPa) or the inactive dephosphorylated form (GPb). Phosphorylase kinase (PK) dephosphorylates GPb to the active form.

presence of glycogen and cannot yield quantitative information.

Quantitative measurements of glycogen can be performed in live or postmortem tissue. The majority of reported measurements of glycogen were obtained using biochemical assays on postmortem tissue. Sacrifice using very high-intensity microwave radiation denatures enzymes responsible for glycogen metabolism, thus preserving glycogen content. Alternatively, tissue can be rapidly frozen to minimize glycogen breakdown. The most accurate and common assay technique for measuring glycogen in postmortem tissue is to use enzymes that metabolize glycogen to glucose, which is subsequently metabolized via the use of enzymes whose ultimate reaction yields the reduced form of nicotinamide adenine dinucleotide (NADH), which can be measured fluorometrically. Comparison with glucose standards is used to yield estimates of glycogen content. Glycogen is usually expressed as glucosyl units, as the debranching enzymes yield one glucose molecule per glucosyl unit of the glycogen molecule.

Nuclear magnetic resonance (NMR) spectroscopic detection of labeled glucose (^{13}C) incorporation into the glycogen can be used to estimate glycogen content *in vivo* in both laboratory animals and humans. ^{13}C-labeled glucose is systemically injected, resulting in slow incorporation of the labeled glucose into the brain glycogen pool, which produces a detectable glycogen signal that can be continuously monitored. Although used for investigational purposes at present, this technology could be used clinically to measure brain glycogen levels under both pathological and physiological conditions.

Roles of Brain Glycogen in Neural Function

Glycogen Function in Liver and Skeletal Muscle

The two main stores of glycogen in the body are contained in the liver (~100 g of glycogen in the well-fed liver) and skeletal muscle (400 g in resting skeletal muscle), and it is from these two tissues that the majority of our knowledge about glycogen derives. Excess systemic glucose is stored in the liver to act as a buffer against systemic hypoglycemia. During periods of hypoglycemia, liver glycogen is metabolized to glucose, which is released into the blood to maintain euglycemia. The liver glycogen can support euglycemia for about a day during starvation, after which fat stores are used. The liver glycogen can be viewed as an egalitarian molecule ensuring that euglycemia is maintained for the benefit of the entire body. In reality, liver glycogen is used to support brain function, which is far more sensitive to hypoglycemia than other organs; that is, brain function deteriorates during hypoglycemia, whereas organs such as the heart are unaffected. Skeletal muscle also contains significant reserves of glycogen, although at a concentration less than liver (30–100 μmol g^{-1} vs. 100–500 μmol g^{-1}; glycogen accounts for 1–2% of skeletal muscle weight and 6–8% of liver weight). However, given the much greater total body weight of skeletal muscle compared to liver, there is more glycogen contained in skeletal muscle than liver. Skeletal muscle glycogen is used to fuel muscle cells during exercise. The glycogen is metabolized to lactate, which is disposed of by the systemic circulation. This seems rather wasteful, as the relative energy yield of glycolysis to oxidative phosphorylation is low; however, oxygen uptake cannot keep up with the rate of lactate production. Thus, the dogmatic view is that skeletal muscle glycogen is used solely to fuel skeletal muscle cells.

Recent data, however, have indicated that lactate produced in skeletal muscle can by extracted from the systemic circulation and metabolized by the brain.

Review of Glycogen Dynamics

Fate of lactate, a glycogen breakdown product Because glycogen is located predominantly in astrocytes and is too big to be transferred across cell boundaries, a glycogen-derived intermediary must be employed as an energy conduit. It is widely agreed that the ultimate breakdown product of astrocytic glycogen is lactate, since astrocytes do not express glucose-6-phosphatase and are therefore incapable of releasing glucose. When astrocytes are deprived of glucose, glycogen rapidly disappears and nearly all of the glycogen-derived carbon fragments found in extracellular fluid are in the form of lactate.

It was realized over 100 years ago that the anatomical arrangement of astrocytes, capillaries, and neurons suggested that astrocytes mediated the transfer of metabolic substrate from capillary to neuron. The endothelial cells and astrocytic endfeet express the GLUT1 glucose transporter facilitating glucose uptake from capillaries into astrocytes. Astrocytes possess the isoform of the lactate dehydrogenase enzyme (LDH5) that preferentially converts pyruvate to lactate. Neurons stain exclusively for the LDH1 enzyme that preferentially oxidizes lactate to pyruvate. Consequently, astrocytes readily convert pyruvate to lactate, and neurons oxidize lactate to pyruvate. Monocarboxylate transporters (MCTs) transport lactate across cell membranes using proton symport. There are several isoforms of MCT, which vary in their lactate binding affinities. The form expressed by astrocytes, MCT1, excels at lactate export. The MCT isoform expressed in neurons, MCT2, is a preferential lactate importer. Studies on the rodent optic nerve provided proof of principle that a glycogen-derived monocarboxylate, most probably lactate (although pyruvate is also remotely possible) is transported from astrocytes to axons during both aglycemia and increased tissue energy demand.

Turnover Glycogen turnover in the brain can be activated selectively. For example, glycogen breakdown is increased in 'barrel fields' in rat somatosensory cortex when the facial whiskers that project to this area are manually stimulated. Glycogen turnover is reported as rapid or relatively slow, depending on the methods employed. Irrespective of turnover rates, during quiescence it is obvious that glycogen metabolism can be rapidly activated. Once glycogen has been depleted it can be replenished, depending upon the rates of synthesis and degradation. The resynthesis of glycogen depends on protein synthesis, and it appears that neurotransmitters modify this interaction. *In vivo* rat studies demonstrated decreases in brain glycogen content by insulin-induced hypoglycemia followed by increased glycogen content above baseline levels on restoration of normoglycemia. This increase in glycogen content above baseline has been termed supercompensation and appears to be a standard compensatory mechanism, possibly to prepare the tissue for anticipated future metabolic challenges.

Physiological conditions that modify glycogen content
Sleep The effects of sleep, an index of brain activity, may provide clues to glycogen's role during physiological activity. Early studies demonstrated that brain glycogen accumulates during sleep, is depleted by sleep deprivation, and is mobilized on waking. In rodents, glycogen increased by 70% above waking levels within a few minutes of induction of slow-wave sleep. There is a correlation between glycogen phosphorylase activity and levels of noradrenaline and serotonin (5-HT), which stimulate glycogenolysis. Thus, it is hypothesized that sleep is a state in which activity is decreased and glycogen is replenished, and that glycogen depletion slowly occurs during the increased activity associated with waking. The expression of glycogen synthase and glycogen phosphorylase varies with sleep, with maximal activity occurring in the middle of the light period and minimal activity occurring in the middle of the dark period.

General anesthesia General anesthesia resulted in elevations of glycogen dependent on the depth and duration of anesthesia. Electron microscopic studies demonstrated increases in glycogen levels in the hippocampus, cortex, and molecular layer of the cerebellum, areas of high synaptic density. This immediately suggests a correlation between the ability of anesthetics to reduce neuronal activity and to elevate glycogen content. The effect of anesthetics on brain glycogen is related to neuronal activity since anesthetics added to astrocytes in culture did not affect glycogen content. This ability of anesthetics to elevate *in vivo* glycogen content indicates that in the fully conscious state neurons utilize glycogen, but during quiescence the neurons reduce their utilization, allowing glycogen accumulation.

Can Glycogen Serve as an Energy Substrate for Adjacent Neural Elements?

Hypoglycemia The introduction of insulin-induced hypoglycemia to treat schizophrenia prompted some of the earliest studies on brain glycogen, which attempted to study the effect of limiting glucose delivery on brain biochemistry. Measurements of glycogen

in the adult dog subjected to varying degrees of hypoglycemia indicated that glycogen content fell first in areas of the brain with the highest metabolic rates, demonstrating a connection between glycogen and brain function. During insulin-induced hypoglycemia, when the brain's demand for energy exceeds blood-borne glucose supply, glycogen is degraded to support brain function. However, once glycogen content is depleted during constant hypoglycemia brain function fails. More recent data using NMR spectroscopy to measure ^{13}C glucose incorporation into brain glycogen have demonstrated similar results; insulin-induced hypoglycemia depleted brain glycogen levels in anaesthetized rats, but only after the brain glucose concentration had fallen to zero. Thus, for the first time a link was established between glycogen metabolism and brain function, albeit under pathological conditions.

A more direct clue emerged from tissue culture studies on hypothalamic neurons, which were cultured in the absence or presence of glial cells. Neurons grown with glia survived for longer periods than neurons grown in the absence of glial cells, implying that neuronal survival in glia-confluent conditions was due to a metabolic coupling of unknown mechanism between the cell types. A similar study showed that it was the glycogen content of astrocytes that was the determining factor in neuronal survival in mixed glial–neuronal cultures. The benefit of glycogen remained unclear. Was it promoting neuronal survival by allowing more robust astrocyte metabolism, perhaps assisting glutamate uptake, or was this energy supply somehow 'shared' with neighboring neurons?

Studies using intact preparations yielded more evidence of a link between glycogen content with brain function. Stimulus-evoked excitatory postsynaptic potentials (EPSPs) in the CA1 region of the hippocampus were sustained in artificial cerebrospinal fluid (aCSF) containing 10 mM glucose. Removal of glucose from the aCSF resulted in a delayed decrease in the EPSP slope. This limited duration of function in aglycemia may be due to metabolism of the glycogen stores to support function. Supporting this theory, experimental maneuvers that deplete glycogen result in accelerated EPSP decrease during aglycemia.

Studies on the rodent optic nerve established a relationship between glycogen content and axon function (Figure 2). In the presence of astrocyte glycogen, axon function loss was delayed during aglycemia. Axon function remained stable for 20–30 min. Increasing tissue metabolic demand resulted in accelerated axon function loss, verifying that the metabolic rate determines the rate of glycogen breakdown. Upregulation or downregulation of glycogen content modified latency to functional loss accordingly. Furthermore,

Figure 2 Glycogen content determines latency to axon function failure during aglycemia in mouse optic nerve (MON). (a) In MON, aglycemia results in delayed axon function loss. Axon function is quantitatively monitored as the area under the stimulus-evoked compound action potentials (CAPs). On exposure to aglycemia, glycogen content falls until it reaches its lowest point in 20 min, which coincides with CAP failure. The left axis indicates normalized CAP area (open squares) and the right axis indicates the glycogen content of the MONs (open columns ± S.E.M.) (b) The straight line is a best fit of data points and indicates the relationship between glycogen content and latency to CAP failure after aglycemia onset. (a, b) From Brown AM (2004) Brain glycogen re-awakened. *Journal of Neurochemistry* 89(3): 537–552, with permission from Blackwell Publishing.

blocking lactate uptake into axons using D-lactate, a competitive blocker of L-lactate uptake, accelerated axon function loss during aglycemia. Taken together, these data indicate that it is the product of glycogen metabolism, lactate, and its subsequent transfer to axons that sustain function. Therefore, it is the glycogen content of the tissue at the onset of aglycemia that determines the latency to functional loss. These results may have profound implications in understanding brain energy metabolism in patients suffering from type 1 diabetes mellitus.

Intense neural activity During high-frequency stimulation of a CNS axon pathway, glycogen content falls but axonal discharge is well maintained. When lactate transport is blocked by D-lactate during this high-frequency discharge, the axon function fails, supporting the idea that lactate is being transported

Figure 3 The role of brain glycogen. Glucose is transported into astrocytes then is phosphorylated to glucose-6-phosphate (G-6-P), which is the substrate for both glycogenesis and glycolysis. Glycogen can be rapidly degraded to G-1-P by glycogen phosphorylase (GP) in response to increased demand. G-6-P is then glycolytically metabolized ultimately to lactate, which is transported to neuronal element where it is oxidatively metabolized. TCA, tricarboxylic acid.

from astrocytes to axons under these conditions to assist axon ATP production (recall that the two molecules of lactate generated from one glucose molecule yield more than 90% of the ATP that would be generated if glucose itself were oxidized; Figure 3). Additionally, blocking glycogen phosphorylase during increased tissue energy demand causes axon function failure. Thus, glycogen appears to play a role in both pathological and physiological conditions, and astrocytes can share fuel with their neural neighbors. A possible advantage of this arrangement is that lactate taken up by neurons is metabolized without the initial expense of the ATP necessary to phosphorylate glucose. Since nearly every neuron/axon has astrocyte neighbors, the delivery of lactate may be more rapid, efficient, and reliable than diffusion of glucose from more distant capillaries.

A Physiological Role for Brain Glycogen

In summary, a role for brain glycogen is suggested based on the following: (1) glycogen can act as an energy substrate to support neural function during aglycemia; (2) glycogen content increases in the brain during quiescence are consistent with the conscious, awake brain utilizing glycogen; (3) glycogen metabolism is controlled by neurotransmitters and hormones, whose levels fluctuate, as well as local energy status; and (4) excess glucose uptake into the brain is disposed of by the venous circulation, implying that brain glycogen does serve a specific function. Stimulation of the rat face resulted in focal decreases in glycogen, implying local glycogenolysis, linking physiological neuronal activity with glycogen utilization. Handling of rats, which equates to elevated sensory activation, reduced brain glycogen compared to control unhandled animals. These studies demonstrate that sudden increases in local energy demand may be met by increased glycogenolysis in the brain.

In addition, studies on CNS white matter establish that astrocyte glycogen can support high-frequency axonal discharge by transferring glycogen-derived lactate to the intensely discharging axons. This 'physiological' role of glycogen was supported by the following observations: (1) inhibition of lactate transport out of astrocytes or into axons reduced function; (2) downregulation of glycogen content impaired high-frequency firing during normoglycemia; and (3) inhibition of glycogen phosphorylase activity by isofagomine reduced function. Thus, a role for glycogen as an energy buffer, rather than an energy reserve, has been proposed. In this role, brain glycogen provides energy substrate in the form of glycogen-derived lactate even in the presence of normoglycemic concentrations of glucose to support function when ambient glucose alone is insufficient to meet immediate tissue energy demands. Providing tissue with unlimited energy substrate allowed indefinite maintenance of function during high-intensity stimulus, indicating that the ability to support function during increased tissue energy demand is dependent on the availability of suitable energy substrate.

Protein Glycosylation

Congenital disorders of glycosylation (CDG) are a rapidly growing family of genetic diseases due to defects in the synthesis of the glycan moiety of glycoconjugates. This article is limited to genetic defects of protein glycosylation.

There are two main types of protein glycosylation: N-glycosylation and O-glycosylation. N-glycosylation (N-glycans attached to an aminogroup of asparagine of proteins) comprises an assembly part and a processing part, and extends over three cellular compartments: the cytosol, the endoplasmic reticulum (ER), and the Golgi. The assembly part of the N-glycosylation starts on the cytosolic side of the ER with the transfer of *N*-acetylglucosamine (GlcNAc) phosphate from Uridine diphosphate (UDP)–GlcNAc to membrane-bound dolichyl monophosphate (Dol-P), forming GlcNAc-pyrophosphatedolichol (GlcNAc-PP-Dol). One GlcNAc and five mannose (Man) residues are subsequently attached to this lipid-linked monosaccharide in a stepwise manner. The donor of these mannoses is a nucleotide-activated sugar, guanosine diphosphate (GDP)-Man, which is synthesized from fructose 6-phosphate, an intermediate of the glycolytic pathway. The lipid-linked heptasaccharide $Man_5GlcNAc_2$ is translocated by a flippase across the ER membrane and is elongated at the lumenal side by the attachment of four further mannose residues and, subsequently, three glucose residues. The four mannosyltransferases and three glucosyltransferases involved require dolichyl phosphate-bound monosaccharides (Dol-P-Man and Dol-P-Glc). The completed $Glc_3Man_9GlcNAc_2$ oligosaccharide is then transferred to selected asparagine residues of the nascent proteins by the oligosaccharyltransferase complex.

The processing part of the N-glycosylation starts in the ER by trimming the glucoses (catalyzed by glucosidases I and II) and one mannose (catalyzed by α-mannosidase I). The residual glycoprotein intermediate is directed to the *cis*-Golgi where the processing pathway branches. A minor branch targets glycoproteins to the lysosomes (after the action of a GlcNAc-phosphotransferase and removal of the GlcNAc residues, leaving high-mannose glycoproteins capped with Man 6-P). The main branch leads to further trimming of mannoses (leaving a trimannosyl core) and addition of, respectively, GlcNAc, galactose, and eventually, sialic acid in the medial- and *trans*-Golgi. Another modification of many N-glycoproteins in the Golgi is the attachment of fucose to the GlcNAc residue that is linked to asparagine. O-glycosylation (O-glycans attached to the hydroxylgroup of threonine or serine of proteins) has no processing part and thus only consists of assembly. Contrary to N-glycosylation, this assembly mainly occurs in the Golgi (Figure 1). O-glycan structures show a greater diversity than N-glycans. Examples of important O-glycans are *O*-*N*-acetylgalactosaminylglycans (mucin-type glycans), *O*-xylosylglycans (glycosaminylglycans), *O*-mannosylglycans, and *O*-fucosylglycans.

Genetic Diseases of Protein N-Glycosylation

Eighteen diseases are known in protein N-glycosylation: 12 assembly defects (CDG-I group) designated CDG-Ia to CDG-Il, and six processing defects (CDG-II group) designated CDG-IIa to CDG-IIf (Table 1).

Phosphomannomutase2 Deficiency (CDG-Ia)

Phosphomannomutase (PMM)2 deficiency is a (cytosolic) defect in the second step of the mannose pathway (transforming mannose-6-phosphate into mannose-1-phosphate), which normally leads to the synthesis of GDP-Man. This nucleotide sugar is the donor of the mannose used in the ER to assemble the dolichol-pyrophosphate oligosaccharide precursor. Deficiency of GDP-Man causes hypoglycosylation of numerous glycoproteins, including serum proteins, lysosomal enzymes, and membranous glycoproteins.

The diagnosis of CDG-Ia (and of congenital disorders of N-glycosylation in general) is usually made by isoelectrofocusing (IEF) and immunofixation of serum transferrin (Figure 2). Normal serum transferrin is mainly composed of tetrasialotransferrin and small amounts of mono-, di-, tri-, penta-, and hexasialotransferrins. The partial deficiency of sialic acid (a negatively charged and end-standing sugar) in CDG causes a cathodal shift. Two main types of cathodal shift can be recognized: type 1 is characterized by an increase of both disialo- and asialotransferrin and a decrease of tetrasialotransferrin; in type 2 there is also an increase of the tri- and/or monosialotransferrin bands. In PMM2 deficiency, a type 1 pattern is found. Capillary zone electrophoresis of total serum was introduced in the mid-2000s for the diagnosis of CDG (Figure 2). In addition to the above-mentioned serum glycoprotein abnormalities, laboratory findings

Table 1 Human hereditary N-glycosylation disorders

Name	*Defective gene*	*Defective protein*
CDG-I		
CDG-Ia	PMM2	Phosphomannomutase 2
CDG-Ib	*MPI*	Phosphomannose isomerase
CDG-Ic	*hALG6*	Glucosyltransferase I
CDG-Id	*hALG3*	Mannosyltransferase VI
CDG-Ie	*DPMI*	Dolichol-P-Man synthase I
CDG-If	*Lec35*	Lec35
CDG-Ig	*hALG12*	Mannosyltransferase VIII
CDG-Ih	*hALG8*	Glucosyltransferase II
CDG-Ii	*hALG2*	Mannosyltransferase II
CDG-Ij	*DPAGT1*	UDP-GlcNAc: dolichol phosphate *N*-acetylglucosamine 1-phosphate transferase
CDG-Ik	*hALG1*	Mannosyltransferase I
CDG-Il	*hALG9*	Mannosyltransferase VII/IX
CDG-II		
CDG-IIa	*MGAT2*	*N*-Acetylglucosaminyltransferase II
CDG-IIb	*GLS1*	Glucosidase I
CDG-IIc	*FUCT1*	GDP-fucose transporter I
CDG-IId	*B4GALT1*	β-1,4-Galactosyltransferase 1
CDG-IIe[a]	*COG7*	Conserved oligomeric Golgi complex, subunit 7
CDG-IIf	*SLC35A1*	CMP-sialic acid transporter

[a]Preliminary assignment, combined N- and O-glycosylation disorder.

include elevation of serum transaminase levels, hypoalbuminemia, hypocholesterolemia, and tubular proteinuria. To confirm the diagnosis, the activity of PMM2 should be measured in leukocytes or fibroblasts. Prenatal diagnosis is possible by enzymatic analysis of amniocytes and chorionic villus cells; this should be combined with mutation analysis of the PMM2 gene.

CDG-Ia is by far the most frequent protein N-glycosylation disorder (some 600 patients known). The clinical spectrum is very broad: the nervous system is affected in all patients, and most other organs are involved in a variable way. The neurologic picture comprises alternating internal strabism and other abnormal eye movements, axial hypotonia, psychomotor retardation, ataxia, and hyporeflexia. After infancy, symptoms include retinitis pigmentosa, often stroke-like episodes, and sometimes epilepsy. During the first year(s) of life, there are variable feeding problems (anorexia, vomiting, diarrhea) that can result in severe failure to thrive. Other features are a variable dysmorphy (large, hypoplastic/dysplastic ears), abnormal subcutaneous adipose-tissue distribution (fat pads, inverted nipples), mild to moderate hepatomegaly, H skeletal abnormalities (including atlantoaxial subluxation), and hypogonadism. Some infants develop pericardial effusion and/or cardiomyopathy. At the other end of the clinical spectrum are patients with a very mild phenotype (no dysmorphy, slight psychomotor retardation). Patients often have an extroverted and happy appearance. There is a substantially increased mortality in the first years of life due to vital organ involvement or severe infection.

CDG-Ia is an autosomal-recessive disease due to mutations of *PMM2* on chromosome 16p13. At least 60 mutations have been identified (mainly missense mutations), the most frequent being the R141H mutation.

Phosphomannose-Isomerase Deficiency (CDG-Ib)

The defect in phosphomannose-isomerase (PMI) deficiency is in the first step in the biosynthesis of the nucleotide sugar GDP-Man. The substrate of the enzyme, fructose 6-phosphate, does not accumulate since it is an intermediate of the glycolytic pathway. The blood biochemical abnormalities are indistinguishable from those found in CDG-Ia. The diagnosis is confirmed by finding a decreased activity of phosphomannose isomerase in leukocytes or fibroblasts and/or mutation(s) in *PMI*.

Some 20 patients have been reported with this mainly hepatic–intestinal disease. Together with CDG-Ih, it is the only known N-linked CDG without or with only minor neurological involvement. Symptoms started at ages between 1 month and 11 months and consisted of various combinations of

Figure 2 CE and IEF analysis of different types of serum transferrin profiles. (a) demonstrates a normal Tf profile, whereas (b–d) show the Tf profile corresponding to a CDG-Ia, CDG-IIa, and CDG-IIx, respectively. (e, f) both represent Tf protein variants, as the same profile was observed in one of the healthy parents and two major protein peaks remained after neuraminidase action.

recurrent vomiting, abdominal pain, protein-losing enteropathy, recurrent thromboses, gastrointestinal bleeding, liver disease, and symptoms of hypoglycemia. Several patients died.

This is the only known CDG that is efficiently treatable. The treatment is simple and consists of oral mannose (1 g kg^{-1} body weight per day, divided in 4–6 doses). The rationale for this treatment is that hexokinases phosphorylate mannose to mannose 6-phosphate, thus bypassing the defect.

Inheritance of CDG-Ib is autosomal recessive. The gene (*PMI*) has been localized to chromosome 15q22 and several (missense) mutations have been identified.

Glucosyltransferase I Deficiency (CDG-Ic)

Glucosyltransferase I deficiency is a defect in the attachment of the first glucose (of three) to the dolichol-linked $mannose_9$-*N*-$acetylglucosamine_2$ ER intermediate. It causes hypoglycosylation of serum glycoproteins, because nonglucosylated oligosaccharides are a suboptimal substrate for oligosaccharyltransferase.

This is the second most common protein N-glycosylation disease (some 30 patients identified). As in CDG-Ia, patients show hypotonia, strabismus, and seizures but psychomotor development is less retarded, there is less dysmorphy, and usually no retinitis pigmentosa or cerebellar hypoplasia. In one

patient, idiopathic intracranial hypertension and optic atrophy have been reported.

For unknown reasons, some of the glycoproteins have unusually low blood levels (particularly factor XI, and coagulation inhibitors such as antithrombin and protein C). The reason why the clinical picture in these patients is much milder than that of PMM-deficient patients may be because a deficiency in glucosylation of the dolichol-linked oligosaccharides does not affect the biosynthesis of GDP-Man and, hence, does not affect the biosynthesis of GDP-fucose or the biosynthesis of glycosylphosphatidylinositol-anchored glycoproteins. Long-term outcome is unknown since all reported patients have been children.

This disease illustrates that even in cases of mild psychomotor retardation without any specific dysmorphy, IEF of serum sialotransferrins has to be performed. When a type 1 pattern is found, PMM2 and PMI deficiency have to be considered first. If these enzymes show normal activities, the next step is analysis of the dolichol-linked oligosaccharides in fibroblasts. In CDG-I the major fraction of these oligosaccharides consists of nine mannose and two *N*-acetylglucosamine residues without the normally present three glucose residues. Glucosyltransferase I activity has to be measured in fibroblasts and/or mutation analysis performed.

Mannosyltransferase VI Deficiency (CDG-Id)

Three patients and a fetus have been reported affected with this deficiency. Also of the subsequently mentioned N-glycosylation disorders, only one or a few patients are known. Two patients showed a severe neurological syndrome with nearly absent psychomotor development, hypsarrhytmia, postnatal microcephaly, optic atrophy, iris coloboma, and brain and corpus callosum atrophy. In the third patient, there was hyperinsulinemic hypoglycemia with islet cell hyperplasia (also reported in CDG-Ia and CDG-Ib). IEF of serum transferrin showed a variant type 1 pattern without increase of asialotransferrin. The hallmark biochemical feature of this CDG (and of CDG-Ie) is an accumulation of dolichyl pyrophosphate-$Man_2GlcNAc_2$ in fibroblasts.

Dolichyl Phosphate-Mannose Synthase 1 Deficiency (CDG-Ie)

Five children have been reported with this defect in the synthesis of the mannose donor Dol-P-Man. These patients showed a severe neurological involvement as in CDG-Id, and a similar serum sialotransferrin pattern and accumulation of dolichyl pyrophosphate-Man_2 $GlcNAc_2$ in fibroblasts.

Lec35 deficiency (CDG-If) The deficient protein, Lec35, seems to be a chaperone involved in the utilization of both Dol-P-Man and Dol-P-Glc. The four reported patients showed severe encephalopathy and three of them had a scaly, erythematous skin disorder. The oldest patient (actually 20 years) had dwarfism with transient growth-hormone deficiency. Fibroblasts accumulated dolichyl pyrophosphate-$Man_5GlcNAc_2$ as well as dolichyl pyrophosphate-$Man_9GlcNAc_2$.

Mannosyltransferase VIII Deficiency (CDG-Ig)

In the five reported patients the clinical picture comprised facial dysmorphy, psychomotor retardation, and hypotonia. The three boys showed hypogenitalism and in two patients there were inverted nipples and subcutaneous fat pads. In the three patients tested, serum IgG was found to be decreased. The typical biochemical feature of this disorder is an accumulation of dolichyl pyrophosphate-$Man_5GlcNAc_2$ in fibroblasts. Eight different mutations were found in this small patient group.

Glucosyltransferase II Deficiency (CDG-Ih)

Five patients have been reported from four families. In four, there was no neurological involvement. Three showed a severe disease with dysmorphy and multiorgan failure resulting in death between three days and three months. The fourth patient had a milder presentation with hepatomegaly, protein-losing enteropathy, severe hypoalbuminemia, edema, and ascites. The fifth patient showed prominent central nervous system involvement (severe microcephaly, epilepsy, leukoencephalopathy) in addition to protein-losing enteropathy, and hepatic and renal disease.

Dolichyl pyrophosphate-$Glc_1Man_9GlcNAc_2$ was the accumulating lipid-linked oligosaccharide in fibroblasts.

Mannosyltransferase II Deficiency (CDG-Ii)

The clinical picture in the one reported patient was characterized by severe psychomotor retardation, infantile spasms, bilateral iris coloboma, and unilateral cataract. Brain magnetic resonance imaging showed severe dysmyelination. This is the first reported CDG in one of the early steps of dolichol-linked oligosaccharide biosynthesis at the cytosolic side of the endoplasmic reticulum. Accumulation of $Man_1GlcNAc_2$-PP-dolichol and $Man_2GlcNAc_2$-PP-dolichol, and severely reduced activity of the mannosyltransferase elongating $Man_1GlcNAc_2$-PP-dolichol were found in fibroblasts.

Deficiency of UDP–GlcNAc:Dolichol Phosphate *N*-Acetylglucosamine 1-Phosphate Transferase (CDG-Ij)

This is a defect in the very first step of dolichol-linked oligosaccharide biosynthesis. It was identified in a girl with intractable infantile spasms, severe psychomotor retardation, hypotonia, and microcephaly. Due to the nature of the defect there is no accumulation of lipid-linked oligosaccharides in fibroblasts.

Mannosyltransferase I Deficiency (CDG-Ik)

The four reported patients were boys showing epilepsy, severe psychomotor retardation, and variable features such as dysmorphy, liver dysfunction, cardiomyopathy, nephrotic syndrome, hypogonadism, and depletion of β-cells. Lipid-linked oligosaccharide analysis showed an accumulation of $GlcNAc_2$-PP-dolichol in the patients' fibroblasts.

Mannosyltransferase VII/IX deficiency (CDG-Il)

This is a defect in the only mannosyltransferase with a dual function. The reported patient presented with psychomotor retardation, microcephaly, seizures, axial hypotonia, and hepatomegaly. The lipid-linked oligosaccharide profile revealed an accumulation of the precursors $Man_6GlcNAc_2$-PP-dolichol and Man_8-$GlcNAc_2$-PP-dolichol.

N-Acetylglucosaminyltransferase II Deficiency (CDG-IIa)

Four patients have been reported with this first identified N-glycan processing defect. Besides neurological involvement (psychomotor retardation, epilepsy, behavioral disturbances) they presented with craniofacial dysmorphy, skeletal abnormalities, gastrointestinal disturbances, and growth retardation. Laboratory investigation showed increased glutamic oxaloacetic transaminase and normal glutamic pyruvic transaminase, a feature which is also seen in other CDG-II group patients. Isoelectrofocusing of serum transferrin showed a type 2 pattern (with nearly absent tetrasialotransferrin) and structural analysis of the transferrin oligosaccharides indicated a monoantennary *N*-acetyllactosamine type glycan. Thus, contrary to the structurally normal sialotransferrins in the CDG-I group or assembly disorders, the sialotransferrins of this and some other CDG-II diseases have abnormal glycan structures.

Glucosidase I Deficiency (CDG-IIb)

This CDG was discovered in an infant with dysmorphy, hypotonia, and epilepsy. The urine showed an abnormal oligosaccharide identified as the tetrasaccharide [Glc(α1-2) Glc(α1-3) Glc(α 1-3) Man]. This suggested a defect in glucosidase I, the first step in the N-glycan processing. Remarkably, IEF of serum transferrin was normal, probably due to a proven upregulation of ER mannosidase.

Golgi GDP-Fucose Transporter Deficiency (CDG-IIc)

This is the first reported CDG due to a nucleotide sugar transporter defect, specifically in a Golgi-localized, GDP-fucose transporter. The few reported patients suffered from leukocyte adhesion deficiency type II syndrome (LAD II) comprising craniofacial dysmorphy, severe psychomotor, and growth retardation as well as recurrent bacterial infections with persistent highly elevated leukocytosis. Due to hypofucosylation, neutrophils of these patients lack sialyl-Lewis X, a fucose-containing carbohydrate ligand of the selectin family of cell adhesion molecules that is required for the recruitment of neutrophils to infection sites. This hypofucosylation only affects N-glycans because GDP-fucose transport and O-fucosylation also occur in the ER. In one of the patients, fucose administration corrected the hypofucosylation and resulted in clinical improvement while other patients did not respond. Three kinds of molecular defects have been reported: mutations that affect the region for Golgi localization, mutations that affect the region necessary for the enzymatic function, and a truncation defect involving both regions.

β-1,4-Galactosyltransferase 1 Deficiency (CDG-IId)

Deficiency of this β-1,4-galactosyltransferase isoenzyme has been reported in a child with psychomotor retardation, Dandy–Walker malformation, and myopathy.

Golgi CMP–Sialic Acid Transporter Deficiency (CDG-IIf)

The one reported patient presented a very restricted and unusual phenotype with massive bleeding of the posterior chamber of the right eye and cutaneous bleeding as well as macrothrombocytopenia, neutropenia, and complete lack of the sialyl-Le antigen on polymorphonuclear cells. He also suffered from episodes of respiratory distress and opportunistic infections. Complications after bone marrow transplantation led to death at 37 months. Remarkably, plasma transferrin and other glycoproteins showed a normal glycosylation pattern possibly due to different degrees of altered splicing of the Golgi CMP–sialic acid transporter in different cells, but isoelectrofocusing of serum apolipoprotein CIII (containing only O-glycans) was abnormal.

Genetic Diseases of Protein O-Glycosylation

Defects have been identified in *O*-*N*-acetylgalactosaminylglycan synthesis (familial hyperphosphatemic tumoral calcinosis), in *O*-xylosylglycan synthesis (progeroid variant of Ehlers–Danlos syndrome and hereditary multiple exostoses), in *O*-mannosylglycan synthesis (Walker–Warburg syndrome and muscle–eye–brain disease), and in *O*-fucosylglycan synthesis (spondylocostal dysostosis type 3). They will be shortly summarized further.

Familial Hyperphosphatemic Tumoral Calcinosis

Patients suffer from recurrent, painful calcified subcutaneous masses that can be as large as 1 kg. This can be complicated by secondary infections and incapacitating mutilations. The hyperphosphatemia is due to increased renal phosphate retention. The physiopathology is not clear but is probably secondary to hypoglycosylation of a phosphatonin. The basic defect is in isoform 3 of the *N*-acetylgalactosaminyltransferase family comprising more than twenty members.

Progeroid Variant of Ehlers–Danlos Syndrome

This defect in β-1,4-galactosyltransferase 7 has been discovered in three patients from two families with a premature aging phenotype and hyperelastic skin in addition to microcephaly and joint hyperlaxity. The defect disrupts the trisaccharide linker region of glycosaminoglycans (O-linked xylose–galactose–galactose), specifically in the attachment of the first galactose to xylose.

Hereditary Multiple Exostoses

This is a long known disease and the only known CDG with autosomal dominant inheritance. It is characterized by osteochondromas of the ends of long bones. These tumors are often present at birth, their growth slows during adolescence, and stops in adulthood. Only a small percentage of these lesions show malignant degeneration. Compression of peripheral nerves and blood vessels may cause complications. The basic defect is in the Golgi-localized EXT1/EXT2 complex, which has both glucuronyltransferase and *N*-acetyl-D-hexosaminyltransferase activities involved in the polymerization of heparan sulphate.

Walker–Warburg Syndrome

This is a rare neuronal migration disorder characterized by brain and eye involvement associated with congenital muscular dystrophy. Male patients often have testicular defects. It is a very severe disease that usually runs a fatal course before the age of one year. Psychomotor development is absent. The brain lesions consist of cobblestone lissencephaly, agenesis of the corpus callosum, cerebellar hypoplasia, hydrocephaly, and sometimes an encephalocoele. In this disorder there is an aberrant glycosylation of α-dystroglycan, an external membrane protein expressed in muscle, brain, and other tissues. Most glycans of this heavily glycosylated protein seem to be O-linked via mannose and they control the interaction with extracellular matrix proteins. Disrupted glycosylation of α-dystroglycan (and probably other glycoproteins) results in loss of this interaction and hence in progressive muscle degeneration and abnormal neuronal migration (overmigration) in the brain. A minority of patients with this syndrome show mutations in the *POMT1* gene coding for protein *O*-mannosyltransferase 1. This enzyme catalyzes the first step in the synthesis of the *O*-mannose-linked core Galβ1-4GlcNAcβ1-2Man-*O*-Ser/Thr.

In some patients with this disorder, mutations have been found in the gene for protein *O*-mannosyltransferase 2, and in others mutations in the fukutin and the fukutin-related protein genes. Together these four defects explain only about 30% of patients with Walker–Warburg syndrome. On the other hand it should be noted that *POMT1* mutations not only cause Walker–Warburg syndrome but also limb girdle muscular dystrophy with mild mental retardation.

Muscle–Eye–Brain Disease

This is a neuronal migration/congenital muscular dystrophy syndrome similar to Walker–Warburg syndrome but less severe. As in Walker–Warburg syndrome, skeletal muscle shows almost no α-dystroglycan by western blotting and immunohistochemical analysis with an antibody that recognizes a glycosylated epitope. These patients show mutations in the gene encoding protein *O*-mannosyl-β1,2-*N*-acetylglucosaminyltransferase I, catalyzing the second step in the synthesis of the *O*-mannosylglycan core.

Spondylocostal Dysostosis Type 3

This type of spondylocostal dysostosis has very recently been identified as a notch pathway defect more specifically in Lunatic Fringe, an *O*-fucose-specific β-1-3-N-acetylglucosaminyltransferase. Patients show a severe vertebral phenotype with malsegmentation due to disruption of somitogenesis. Somites are precursors of the axial skeleton and associated musculature. Spondylocostal dystosis type 1 and 2 are due to mutations in other members of the notch pathway (*DLL3* and *MESP2*) indicating that this pathway is absolutely required for correct patterning of the axial skeleton.

Table 2 Human hereditary O-glycosylation disorders

Name	*Defective gene*	*Defective protein*
Defect in O-N-acetylgalactosaminylglycan synthesis	*GALNT3*	ppGaNTase-T3[a]
Familial tumoral calcinosis		
Defects in O-xylosylglycan synthesis	*B4GALT7*	β-1,4-Galactosyltransferase 7
Progeroid variant of Ehlers–Danlos syndrome	*EXT1/EXT2*	Glucuronyltransferase/*N*-acetyl-D-hexosaminyltransferase
Hereditary multiple exostoses		
Defects in O-mannosylglycan synthesis	*POMT1*	*O*-Mannosyltransferase 1
Walker–Warburg syndrome	*POMGnT1*	*O*-Mannosyl-β-1,2-*N*-acetylglucosaminyltransferase 1
Muscle–eye–brain disease		
Defects in O-fucosylglycan synthesis	*LFNG*	*O*-Fucose-specific β-1,3-*N*-acetylglucosaminyltransferase
Spondylocostal dysostosis type 3		

[a]UDP-*N*-acetyl-α-D-galactosamine: polypeptide *N*-acetylgalactosaminyltransferase 3.

Genetic Diseases of Protein N- and O-Glycosylation

Conserved Oligomeric Golgi Complex Subunit 7 Deficiency (CDG-IIe)

COG7 deficiency was identified in two siblings with dysmorphy (particularly of the face), encephalopathy, and cholestatic liver disease. They died at 5 and 10 weeks, respectively. Serum transferrin isoelectrofocusing showed a type 2 pattern.

The discovery of this disease opens a new avenue in the CDG field because it affects a protein complex (COG: conserved oligomeric Golgi complex, containing 8 subunits) involved in trafficking and function of the glycosylation machinery. Studies of fibroblast glycoproteins showed a partial N- and O-glycosylation defect caused by a decreased transport of CMP–sialic acid and UDP–galactose into the Golgi as well as a reduced activity of two glycosyltransferases involved in the galactosylation and sialylation of O-glycans. Localization of the COG subunits was investigated by indirect immunofluorescence and an abnormal distribution of COG5, COG6, and COG8 (diffuse cytoplasmic staining instead of Golgi localization) was found. The basic defect was eventually localized to the COG7 subunit (Figure 2 and Table 2).

Conserved Oligomeric Golgi Complex Subunit 1 Deficiency

The one reported patient, a girl, had a mild phenotype compared to the severe neurological and hepatic involvement in the COG7-deficient siblings (mild psychomotor retardation, slight brain hypotrophy, and minor dysmorphy). As the latter, this patient showed hyposialylation as well as hypogalactosylation.

Goal-Directed Behavior Theories

S B Ostlund and B W Balleine, University of California at Los Angeles, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The capacity for goal-directed action allows us and other animals to develop new behavioral strategies to control events in our environment so as to gain access to valued goals and avoid those we no longer value or that we find aversive. The adaptive significance of this capacity becomes most clear when these processes break down, as they do in disorders of 'voluntary' movement (e.g., Parkinson's disease) and in disorders involving intrusive involuntary movement (e.g., Tourette's syndrome, obsessive compulsive disorder, Huntington's disease, and in the behavioral stereotypes associated with clinical syndromes such as schizophrenia). In spite of the obvious importance of this capacity, the determinants of goal-directed action in humans are not fully understood. Many contemporary theorists have adopted a cognitive approach and developed accounts in terms of agents planning various behavioral strategies on the basis of their knowledge of action–outcome relationships, and selecting courses of action by some rational criterion after an evaluation of various alternatives. In fact, there is very little objective evidence that these kinds of factors play a direct role in human action. The main source of data regarding the fundamental determinants of goal-directed action is studies of animal models, perhaps the best known of which is the instrumental conditioning paradigm.

Goal-Directed, Instrumental Actions

The Contingency Criterion

In instrumental conditioning, animals are taught to perform arbitrary actions in order to gain access to some or other valued goal. In the paradigm case, hungry rats are taught to press a freely available lever to gain access to a food reward. But what is learned in instrumental conditioning? Is lever pressing by rats truly determined by the animals' knowledge of the relationship between the action and its consequences? Is it truly goal directed or is it merely a stimulus-elicited reflex? What tests should we apply to lever pressing – indeed, to any putative goal-directed action – in order to answer this question?

Such questions have been addressed in recent years using a variety of experimental approaches. For example, if the performance of an action is determined by the belief that a specific action is required in order to gain access to some goal or other, then the action should never be acquired or should be completely withheld in a situation in which performing the action actually precludes access to the goal; that is, performance should adjust appropriately to the imposition of an omission schedule. Similarly, to be regarded as goal directed, actions should surely respect the causal relation between the action and its consequences: any action acquired and/or maintained in a situation in which the occurrence of its particular outcome is equally likely whether the action is performed or not should not be considered goal directed.

There is, in fact, considerable evidence that free operant lever pressing in rats is sensitive to the causal relation between the action and its consequences. Not only will rats stop responding if lever pressing no longer delivers a valued food, they will stop responding even faster if their performance cancels otherwise freely available food (i.e., leads to the omission of the outcome). Assessing the ability of rats to encode the causal relationship between an action and its consequences has been difficult to achieve because research on causal judgment has been developed in humans often using verbal measures of causality rating. Nevertheless, causal relationships have been argued to approximate the contingency between a cause and an effect derived from the interaction of two probabilities: the probability of the effect given that the cause has been presented, and the probability of the effect given the absence of the cause. In instrumental conditioning these probabilities become (1) the probability of an outcome (O) given that an action (A) is performed, or $p(\mathrm{O/A})$, and (2) the probability of an outcome given that an action has not been performed, or $p(\mathrm{O/noA})$ (see Figure 1). In this situation, the net positive contingency between an action and an outcome ($V_{\mathrm{A-O}}$) is given by

$$V_{\mathrm{A-O}} = p(\mathrm{O/A}) - p(\mathrm{O/noA})$$

Using this approach, numerous experiments have demonstrated both that lever press performance is increased as $p(\mathrm{O/A})$ is increased and, conversely, that lever pressing is reduced as $p(\mathrm{O/noA})$ is increased. Furthermore, a number of studies have confirmed that rats are sensitive to a selective change in one action–outcome contingency in a situation in which another contingency is maintained intact. For example, in one experiment, hungry rats were trained to perform two actions, lever pressing and chain pulling, with one action earning food pellets and the other earning a starch solution, with a fixed probability in

Figure 1 Contingency degradation. Studies in animals examining the sensitivity of an action to changes in the causal relation to its consequences typically modify the contingency between an action (A) and its outcome (O). Although not strictly identical, contingency degradation approximates changes in the causal relationship. Rats are typically trained (panel 1) on two actions (e.g., two levers), each earning a different outcome (grain pellets and sugar), with each action delivering its appropriate outcome at a fixed probability, $p(O_1/A_1)$. The contingency between one action and its outcome is then degraded (panel 2) by delivering that outcome at a fixed probability when the action is not performed, $p(O_1/noA_1)$. Finally, the effect of the degradation is assessed in a choice test (panel 3) in which neither the earned nor the free outcome is delivered.

each second in which a response was performed. After this training, in addition to being earned by performing its associated action, one of the two outcomes was also delivered in the absence of its associated action and at the same probability. As a consequence, the delivery of that outcome was equally probable in each second of the session, regardless of whether its associated action had been performed. If, in this situation, lever pressing and chain pulling were determined by the causal relationship between the actions and their consequences, then degrading one of the action–outcome contingencies in this way should result in a reduction in the performance of that specific action relative to performance of the other action. In fact, this result has been reported on many occasions.

Reward Value

The Goal Criterion

The foregoing discussion suggests that, in instrumental conditioning, animals encode the relationship between specific actions and their outcomes and remain sensitive to changes in this causal relationship. It has long been recognized, however, that encoding an action–outcome relationship is not sufficient to determine the performance of an action. Any learning that takes the form 'action A leads to outcome O' can be used both to perform A and to avoid performing A. It is now well established that the rats' evaluation of the reward value of the outcome – that is, its affective and motivationally relevant properties – can influence the performance of actions instrumental to outcome delivery. This has been referred to as the 'goal criterion of goal-directed action'; surely, if an action were to be maintained despite a significant reduction in the value of the goal, then we should doubt that the action was goal directed.

There is considerable evidence from studies of instrumental conditioning that actions such as lever pressing satisfy the goal criterion. This evidence comes largely from studies assessing posttraining devaluation of the instrumental outcome. For example, in a number of studies of this kind, hungry rats have been trained to press a lever and pull a chain, with one response earning, say, food pellets and the other, say, a starch solution. After this training, the reward value of one of the two outcomes is then reduced – typically by specific satiety, in which the rats are allowed to eat a large quantity of one or other outcome, but also by taste aversion learning, in which consumption of one or other outcome is followed by the induction of illness using an injection of lithium chloride. Both of these treatments are well known to reduce the consumption of a specific food relative to other, non-pre-fed, or unpoisoned, foods. After the devaluation treatment, the rats are then given a choice test on the levers and chains conducted in extinction (i.e., in the absence of the delivery of either food

outcome; see Figure 2). If performance of the actions during training is maintained by the motivational value of their respective outcomes, then devaluation of one outcome should reduce subsequent performance of its associated action in the extinction test relative to the other action. This is exactly the result that is commonly reported; devaluing one of the food rewards by specific satiety or taste aversion learning selectively and profoundly reduces the performance of the action that, in training, delivered that outcome, compared to the action trained with the nondevalued outcome.

Evidence for this claim has also come from studies assessing the effect of shifts in primary motivation on instrumental performance. Posttraining shifts, such as from hunger to satiety or from hunger to thirst, often

Figure 2 Outcome devaluation. Studies assessing effects of changes in the value of the goal on the performance of goal-directed actions typically use some form of outcome devaluation procedure. Rats are trained on two actions, each earning a different outcome (panel 1). After this phase, one or other outcome is devalued either by specific satiety (panel 2a) or taste aversion learning (panel 2b). When the outcome is no longer consumed, the tendency of the rats to perform the two actions is tested back in the training situation, except that now responding on the lever does not deliver the food. Hence, changes in the tendency to perform one or other action must reflect the integration of the training and devaluation phases.

have very little direct impact on the performance of goal-directed actions until the effect of the motivational shift on the reward value of goal has been made explicit through direct consummatory contact in the new motivational state (i.e., by allowing animals to engage in what is referred to as incentive learning). Satiety, for example, appears to reduce the performance of goal-directed actions that gain access to specific food rewards, not because it reduces general drive or arousal, but rather because it makes that food less palatable when it is contacted in the sated state (i.e., it reduces the reward value of that food). Likewise, a dry food reward appears to become aversive when it is contacted by animals that are thirsty, whereas a nutritive fluid reward, such as a starch solution or a sugar solution, becomes more highly valued, and the performance of actions trained with either the dry or liquid nutrients has been found to reflect this experienced value, even when assessed in a choice extinction test.

The general nature of the role of incentive learning in instrumental performance has been confirmed for a number of different motivational systems and in a number of devaluation paradigms. For example, in addition to the effects of satiety on the value of nutritive outcomes, incentive learning has been found to play a role in changes in the value of specific outcomes produced by (1) conditioned taste aversion, (2) posttraining shifts in food deprivation, (3) posttraining shifts in water deprivation, (4) changes in outcome value mediated by drug states, and (5) changes in the value of thermoregulatory and sexual rewards. In all of these cases, evidence suggests that, after a shift in primary motivation, learning about the effect of that shift on the incentive value of an instrumental outcome through consummatory contact increases the influence of this shift on subsequent performance. With respect to the processes controlling performance, this analysis suggests that, in instrumental conditioning, rats encode the relationship between actions and goals, as well as the current incentive value of the goal, and, more importantly, that they are able to integrate these sources of information to select a course of action. Indeed, it is in the evidence for the control over performance exerted by the integration of these two sources of information that the fundamentally goal-directed quality of instrumental conditioning in rats is most forcefully revealed.

Goal-Directed Learning: Outcome Encoding and Action Selection

The contingency and goal criteria that, when met, justify the description of an action as goal directed, claim that such actions respect both their causal relation to the goal and the reward value of the goal. Hence they tend to imply that the critical learning process that mediates the acquisition of goal-directed actions involves the association of an action with the outcome. Beyond that, however, they do not constrain theories of this learning process, and, unsurprisingly, a number of different theories have been offered over the years to describe the goal-directed nature of instrumental performance. These theories can be divided into two broad categories based on the their assumptions about how the outcome is encoded.

The first category, derived from traditional stimulus–response theory, focuses on the outcome as a stimulus and assumes that stimuli signaling the training outcome can acquire the capacity to elicit an expectation composed solely of that outcome's sensory features (e.g., texture, shape, flavor, and so on). When reinforced by the delivery of food, or some other positive event, the instrumental response becomes associated with this outcome expectation and, as a consequence, anything that alters outcome expectancy should also produce a concomitant change in the performance of the action associated with this expectancy. A variant on this suggestion argues that, rather than an expectancy of some subsequent outcome, actions become associated with the sensory features of any outcome earned prior to their performance, something that allows that outcome itself, or any stimulus that activates the representation of that outcome, to exert control over the performance of the action. According to this account, therefore, it is the antecedent relationship between a previously earned outcome and the response performed next that is encoded during instrumental training (i.e., an outcome–response, or O–R, association; see **Figure 3**). Note, however, that, since this account assumes that the outcome is encoded purely as a sensory event, it also tends to predict that, unless it is agreed that a change in the incentive value of the outcome modifies the ability of an animal to process those sensory features, outcome devaluation will have no effect on the outcome's ability to influence subsequent response selection.

Alternatively, a distinct category of theory holds that it is the consequent relationship, between a response and the outcome that it earns, that is learned during instrumental conditioning, and that mediates the acquisition of goal-directed action (i.e., a response–outcome, or R–O, association; see **Figure 3**). In general, R–O theories emphasize the status of the outcome as a goal and so often make the explicit assumption that the influence of the outcome on response selection depends on its current incentive value. Although it is possible to imagine a version of the O–R theory that can account for outcome

Figure 3 The associative structure of goal-directed action. Associations that current evidence suggests are formed between environmental stimuli (S), actions (R), and outcomes or goals (O) and goal value (V) during the course of acquisition or performance of goal-directed action. (a) Current research provides evidence for both R–O and O–R associations in the control of performance. Whereas the O–R association appears not to engage or be influenced by changes in outcome value, the R–O association strongly engages these evaluative processes. (b) The joint reliance on R–O (pathway *a*) and O–R (pathway *b*) processes suggests that these processes interact to control response execution (R_e). (c) The impact of pathway *a* can be overcome by increasing the contribution of pathway *b* to performance either by presenting a stimulus separately trained with the outcome (i.e., S–O, as in Pavlovian-instrumental transfer experiments) or by strengthening the association itself by selective reinforcement through overtraining. R, response; R_i, initiated response; R_s, selected response; R_e, executed response; O, outcome; O_s, sensory properties of the outcome; O_m, motivational properties of the outcome; V, value.

devaluation, the well-established sensitivity of instrumental performance to outcome devaluation is clearly consistent with the R–O account. Indeed, experiments contrasting the relative contribution of O–R and R–O relationships to outcome devaluation have generally confirmed that this effect is dominated by the R–O component.

The outcome devaluation effect is not, however, the only means of evaluating the nature of outcome encoding. Other findings relevant to an assessment of theories of goal-directed learning have come from studies investigating the facilitation of instrumental performance resulting from the noncontingent presentation of either the training outcome itself (i.e., the reinstatement effect) or a stimulus that predicts that outcome (i.e., the Pavlovian-instrumental transfer effect). Generally, if it is assumed that the connections between action and response are bidirectional, both the O–R and the R–O account of outcome encoding predict that the noncontingent presentation of the training outcome, or a stimulus that predicts that outcome, will trigger the selection of its associated action.

More recently, attempts to differentiate the two accounts have been developed by explicitly training hungry rats to use stimuli (S1 or S2) paired with specific outcomes (O1 or O2) as discriminanda signaling which of two actions (R1 or R2) will be rewarded either with the same outcome anticipated by the stimulus (the congruent case) or with a different stimulus (the incongruent case):

$$\text{Congruent: S1} - \text{O1}, \text{S2} - \text{O2}$$

$$\text{S1: R1} - \text{O1}, \text{R2}-; \text{S2: R1}-, \text{R2} - \text{O2}$$

$$\text{Incongruent: S1} - \text{O1}, \text{S2} - \text{O2}$$

$$\text{S1: R1} - \text{O2}, \text{R2}-; \text{S2: R1}-, \text{R2} - \text{O1}$$

In line with predictions from O–R theory, discriminative control has been found to be greater in the former case – that is, when the outcome anticipated by the cue is also used to reward the performance of the correct action. Nevertheless, devaluation of one or other outcome (O1 or O2) has been found to affect the response with which it is associated as an outcome – that is, if, say, O1 is devalued, R1 is reduced relative to R2 in the congruent case but R2 is reduced relative to R1 in the incongruent case.

A similar approach using the outcome itself as the discriminative stimulus has been applied to this problem:

$$\frac{\text{Congruent: O1: R1} - \text{O1}; \text{O2: R2} - \text{O2}}{\text{Incongruent: O2: R1} - \text{O1}; \text{O1: R2} - \text{O2}}$$

Thus, during training, each action is either signaled and followed by the same outcome (congruent training) or signaled and followed by different outcomes (incongruent training). As in the previous study, the performance of the incongruent group can be used to contrast the relative contribution of O–R and R–O relationships to the control of instrumental performance. It has been shown that, after such training, the devaluation of one or other outcome (e.g., O1)

tends to reduce the performance of the action that had been followed by that outcome (i.e., R1) relative to the action that had been signaled by that outcome (R2). This approach has also been used to assess the associative structure underlying the outcome's ability to reinstate extinguished instrumental performance. For example, it has been shown that after incongruent training and subsequent extinction on both actions, the noncontingent delivery of one or other outcome (O1) preferentially reinstates the performance of the action that had been signaled by that outcome (R2) relative to the outcome that had been followed by that outcome (R1). Again, these studies provide further evidence for both R–O and O–R processes.

Further evidence of variation in outcome encoding is provided by the Pavlovian-instrumental transfer effect. A number of studies have shown that a stimulus paired with a particular outcome can exert a selective excitatory effect over the performance of an action that has also been trained with that outcome, relative both to baseline performance and to performance of an action trained with a different outcome. Although transfer effects are compatible with O–R theory, they can also be explained in terms of action–outcome associations again, if it is assumed that stimuli associated with the outcome retrieve the action through a bidirectional action–outcome association. However, a growing body of evidence suggests that transfer effects are mediated by an associative structure different from that mediating the influence of the reward value of the goal on instrumental performance. For instance, a number of experiments have now been conducted assessing the effects of outcome devaluation on Pavlovian-instrumental transfer and have found that, although outcome devaluation reliably suppresses the performance of actions that deliver the now devalued outcome, it has no detectable effect on the facilitation of performance produced by a stimulus that predicts that outcome (i.e., the transfer effect). Using a similar approach, we have recently observed that the outcome selectivity of instrumental reinstatement is similarly insensitive to outcome devaluation.

This pattern of results has largely resisted interpretation in terms of a single associative process. Rather, the kind of model suggested reflects a combination of R–O and O–R associative processes, the R–O process mediating the acquisition and selection of actions based on the value of their consequences, and a separate O–R process mediating the initiation and execution of the action. This view of the relationship between the action selection, outcome evaluation, and action initiation processes is illustrated in **Figure 3**. **Figure 3**(a) illustrates the general principle captured by this combined model; the forward R–O association engages an evaluative process supporting the subsequent initiation and execution of the response. In **Figures 3**(b) and **3**(c) the relationship between these processes is more clearly explicated. In this view, actions can only be executed when motor excitation increases above a threshold. In the usual case, this requires both the selection of a valued action (i.e., one that delivers a rewarding outcome) and the initiation of that action through the O–R process. These two processes summate to drive activity in the motor system above threshold. The situation is slightly different in cases in which a stimulus independently associated with the outcome is presented. In this case, and consistent with the observed failure of outcome devaluation to affect transfer effects, the stimulus can drive the activation of the motor system by the O–R association sufficiently strongly to execute the action without the need of the R–O association. In fact, under certain conditions, the O–R association can grow sufficiently strong in and of itself to produce action execution in the absence of the R–O association. These cases are described briefly in the next section.

Actions and Habits

As mentioned earlier, the outcome devaluation and instrumental contingency degradation procedures provide useful diagnostic tests for whether or not a particular learned response should be considered a goal-directed action. Generally, the very great majority of the evidence suggests that free operant performance in rats meets these two criteria. Reports of negative results have not been uncommon, however. Nevertheless, these negative results have proved useful in establishing the boundary conditions determining when an action is goal directed and when it is not (i.e., when it is automatic, inflexible, stimulus bound, and habitual). For example, prior to the early 1980s, mostly failures to find an effect of outcome devaluation had been reported in the animal literature. One reason for these early failures appears to have been the use of interval schedules of reinforcement during training; early successful attempts to demonstrate the devaluation effect used either continuous or ratio schedules of reinforcement. And, indeed, in experiments comparing the impact of ratio and interval schedules, reliable devaluation emerged only when rats were trained on ratio schedules. Even with the use of a ratio schedule, however, instrumental performance may be rendered insensitive to devaluation and contingency degradation through repeated, unchanging training at asymptote – referred to as overtraining.

Although instrumental conditioning very often possesses the characteristics of a goal-directed action,

certain training conditions can facilitate the development of those responses into habits, the performance of which is insensitive to the consequences. One interpretation of this complex pattern of data is that, although instrumental performance is initially dominated by action–outcome learning, extensive training or training on interval schedules of reinforcement, by constraining experienced changes in the relationship between response rate and reinforcement rate, supports the acquisition of stimulus–response (S–R) associations and, hence, weakening in the relative control of performance by the R–O association. According to the S–R view, the outcome is thought to serve merely as a catalyst for strengthening the association between situational cues and the instrumental response and, when dominated by S–R associations of this kind, the outcome is prevented from playing a role in response selection.

Multiple Learning Systems?

Inevitably, the evidence referred to in the preceding discussion leads to the general conclusion that goal-directed action is multiply determined; whereas goal-directed learning involves encoding the relation between an action and its consequences, the overall rate of performance can also reflect input from S–R or (more specific) O–R processes. These two influences on performance may be thought to reflect control by two distinct kinds of representational structure: one truly goal directed, based on the encoding of the relationship between an action and it consequences (often described as a declarative representation), and a second sensorimotor or S–R association (described as a procedural representation because it directly reflects the use to which the representation is put in controlling behavior). The interaction of these two representational systems in the control of performance is, as described in Figure 3, likely to reflect a complex interaction between distinct learning processes at a number of levels. One of these has already been described in the way that response execution can be seen as reflecting summation of both R–O and O–R processes. Yet another is the interaction of reward and reinforcement processes. The outcome of a goal-directed action provides both an associate of the action in the formation of the R–O process and also a reinforcement signal that strengthens S–R associations. On the one hand, the outcome is represented as a valuable goal in terms of its specific motivational and emotional properties that allow it to serve an incentive. On the other hand, the outcome provides a general positive (or negative) signal that strengthens (or weakens) sensorimotor connections monotonically whenever it occurs, making a specific motor act more (or less) probable in the presence of that sensory event. Generally, therefore, it may be argued that these distinct learning systems differ not only in terms of the representational content of the learning they support, but also in terms of the distinct learning rules they obey: action–outcome causality (or contingency) in the case of goal-directed actions and response–reinforcer contiguity in the case of habits.

Gonadal Steroid Actions on Brain

Introduction

Androgens and estrogens affect many structures in the brain and other areas of the nervous system. These gonadal steroids also undergo metabolism in several brain sites, and the interactions of the resulting array of steroids influence brain development, behavior, and neuroendocrine function. Since it consists of varied regions and cell types, which exhibit a spectrum of metabolic activities, the brain has been viewed as a second endocrine system in which steroid conversions and cellular actions occur. Many expressed proteins and molecular interactions in the nervous system resemble or are the same as those of classically defined endocrine tissues. These include enzymes that metabolize steroids, intracellular receptor proteins that are selective for different steroids, and regulatory proteins that help mediate steroid action.

Intracellular steroid receptors in neural tissues exhibit properties and characteristics similar to those in other tissues. In the absence of ligand, these proteins are soluble and are detectable in the cytosolic fractions of tissue homogenates following differential centrifugation. After binding to steroids, these receptors are less soluble and are more likely to be detectable in the pellets of sedimented tissue homogenates. Biochemical evidence indicates that both androgen and estrogen receptors have significant affinities for DNA, whether or not steroid is bound. However, when ligand bound, the equilibrium for the receptor to bind sites in cell nuclei is shifted toward higher affinity. Live cell imaging of chimeric receptor proteins that are tagged with fluorescent molecules shows that this change targets the receptors to specific sites in cell nuclei, correlating with selective gene expression. In general, many of these gonadal steroid receptors reside in cell nuclei even in the unoccupied state. However, steroid receptors are more and more frequently being found in additional cellular locations, particularly plasma membranes.

Experiments have revealed, in addition to actions in the nucleus, rapid electrical responses by neurons in the brain to specific steroids. There are also instances in which signal transduction cascades that begin at the cell surface are activated, leading to the phosphorylation of key intracellular proteins that regulate functions in cytoplasmic and nuclear compartments. Increased interest in finding receptors for steroids in neural membranes has led to a growing number of examples. In parallel with studies of these putative receptor sites is evidence for interactions of gonadal steroids with ion channel molecules. A class of steroid-related compounds called neurosteroids is produced in the brain, and these compounds interact with channel proteins, other neurotransmitter receptors, and possibly other classes of receptors. This continues to be an active and expanding area of investigation.

Investigators now know many details of the development, localization, and dynamics of interactions of the classical intracellular steroid receptors with physiologically circulating steroids. The proteins are products of a superfamily of nuclear receptors and related molecules. More than 300 sequences have now been attributed to this family of proteins, and a unifying system of nomenclature has been proposed. Public databases, the Nuclear Receptor Database and the Nuclear Receptor Signaling Atlas, have been created for cataloging and disseminating the rapidly expanding knowledge in this field. There are similarities in the gene sequences and protein structures for parts of these receptor molecules, and it is believed that androgen and estrogen receptors have evolved along a common phylogenetic path. Recent studies, however, indicate that they were first utilized as transcription factors and later evolved ligand dependence. Since estrogens are metabolized from androgens, it is reasonable to hypothesize that the hormonal system of agonist and receptor for one served as forerunner for the other, resulting in a more complex, interrelated system for regulation by androgens and estrogens. A major recent realization, and an expanding area of investigation, is the many forms of estrogen receptors. The original estrogen receptor is now termed alpha, as a beta form was discovered in 1996. Alternate forms of both of these have been described based on alternative splicing. Additional novel forms of estrogen receptors have been suggested, and estrogen binding by proteins not considered 'receptors' has also been reported.

In the brain, as elsewhere in the body, two primary synthetic routes metabolize androgens (**Figure 1**). These convert testosterone (T) to alternate, active androgen metabolites, including estrogens. The enzyme 5α-reductase catalyzes addition of two hydrogens across the delta^4 double bond in the A-ring of T, forming the major reduced form of androgen, 5α-dihydrotestosterone (DHT). Like T, DHT can bind to androgen receptors (ARs). The enzyme aromatase

Figure 1 Testosterone metabolism to estradiol (aromatization) and dihydrotestosterone (5α reduction). Letters A–D denote the rings comprising the steroid nucleus, while the numbers denote identified carbon atoms among the rings of testorterone.

converts the A-ring of T to a phenolic one – an aromatic ring with a hydroxyl forming the major aromatized product, estradiol (E). In mammalian brains, E can accumulate from the circulation or can be formed *in situ* from circulating androgen. Aromatase is a member of the cytochrome P-450 family of enzymes that share a highly conserved heme-binding region and require nicotinamide adenine dinucleotide phosphate as a cofactor. The location of aromatase in brain has been examined by biochemical, molecular, and anatomical methods that indicate its selective expression in particular brain regions associated with gonadal steroid actions. The location of 5α-reductase in brain has received less attention, but biochemical methods have suggested a significantly more widespread distribution throughout the brain relative to aromatase.

Popularly, androgens and estrogens have been referred to as male and female hormones, respectively, since they were found originally to be the primary gonadal steroid hormones of the male (testis) and female (ovary) gonads. The experiments elucidating the interrelationships of androgens and estrogens in brain inform us that both of these hormones are functionally important sex steroids in both sexes. Accordingly, it can be misleading to refer to them as the respective male or female gonadal steroids, since they are critical to normal physiology in both sexes. These classifications are likely to change further as we learn more about the functions of sex steroids and their roles in different species.

Levels of androgen metabolism and quantities of intracellular receptor proteins to which they bind vary among species and change with age within species. Steroids and their receptors are found widely throughout the phylogenetic spectrum. Though utilized differently in the highly variable reproductive schemes among species, these hormones function intracellularly by similar routes to partially determine the development of reproductive tissues and the neural components regulating behavioral and reproductive physiology. Androgens and estrogens and their receptors are important in reproductive physiology during development and adulthood.

Steroids have been shown to act epigenetically at critical times in development to cause stable or imprinted differences in adult neural functions. These include effects on gene expression, behaviors, neuroendocrine regulation, and formations of several morphological traits that typically differ between males and females. Usually these developmental effects persist for the life of the animal, without requiring continuous exposure to hormone, and are called organizational effects. Commonly, these are believed to be permanent changes, though in some cases they can be altered later in life. Other responses occur repeatedly in direct response to steroid hormone activation whenever in the life span the appropriate signal or signals are given, and these are called activational effects. An example of this is the neuroendocrine signals causing release of some pituitary hormones. They also include acute effects on gene expression in sets of neurons. For some responses, both organizational and activational actions of steroids are required. Among species, the details of reproductive anatomy and physiology vary to a high degree. Presumably, the strong selective pressure on reproduction during evolution results in the high level of heterogeneity of this vital system among species or organisms, although the same steroidal hormones continue to be used as signals.

Estrogen Action

Organizational Effects

In most male mammals, during perinatal development, estrogens help determine differentiation of certain brain nuclei at the same time that they affect the differentiation of male-typical functional characteristics. It is presumed that this structural differentiation leads to mature males' potential to display masculine neuroendocrine and behavioral regulation. Given artificially to female fetuses, estrogen induces many of the same structural and functional changes, supporting the presumption of cause and effect between affected brain structures and elicited behaviors. If agents are used to block the action of aromatase, most of the actions of androgen in developing male

brain are prevented, supporting the role of estrogen as an essential determinant. The optimal ages for these effects to occur under the influence of physiological hormone levels in normal males, or in response to exogenous hormones in females, are generally restricted to certain perinatal ages, termed the 'critical period' for sexual differentiation of brain.

The timing of the onset of these estrogenic effects correlates with the final development of the gonads and the appearance of neural receptors for estradiol (ERs) in subcortical brain regions, including preoptic area, hypothalamus, and amygdala, and in certain cortical regions. The nervous system itself is the primary source of estrogen that interacts with ERs in developing male brains. For each vertebrate species studied, the specific activity of neural aromatization of androgen to estrogen (**Figure 1**) is several fold higher during perinatal life than in adulthood, with the activity of aromatase in preoptic area and amygdala being higher in males than in females at certain times during perinatal development. Concentrations of circulating T, the major substrate for brain aromatase, also are higher in male than in female vertebrates during critical periods of brain sexual differentiation. These result in increased biosynthesis of estrogen at specific sites and times in the developing male brain. The availability of androgen influences estrogen biosynthesis in two ways: (1) as the substrate for the enzyme and (2) via its action during adulthood to increase levels of aromatase.

During sexual differentiation, male mammals normally acquire the capacity for displaying masculine sexual behavior (the process of coital masculinization) and, depending on the species, lose the capacity to display feminine patterns of sexual behavior (the process of coital defeminization). In nonprimate species perinatal exposure of the male to T defeminizes both the neural mechanism controlling feminine sexual behavior and the brain mechanism controlling the cyclic release of luteinizing hormone-releasing hormone (also called gonadotropin-releasing hormone (GnRH)) from the median eminence into the hypophyseal portal vessels, thereby controlling the release of luteinizing hormone (LH) from the pituitary. In rats, both of these defeminizing actions of T in the male are caused by estrogen, which is formed in the developing brain from circulating androgen of testicular origin. Likewise, in species such as rat and hamster, the process of coital masculinization also depends to a high degree on the action of estrogen formed in neural tissues directly from circulating T, although there is evidence for ARs playing a role in this process. Some evidence has demonstrated that estrogens can exert developmental effects in the brains of higher mammals, including carnivores and primates. Experimentation supports the notion that both estrogen and androgens are required for masculinization, perhaps in a sequential manner, with estrogen acting before androgen. Nonetheless, significant data from human studies, including those with gene disruptions in either the estrogen receptor (alpha) or aromatase, indicate that investigators are a long way from transferring their understanding of the contributions of estrogen in rodents to these processes in humans.

Neural aromatization of androgen to estrogen also contributes to the formation of typically masculine patterns of neuroanatomical organization in both rats and ferrets. In rats, the medial nucleus of the preoptic area/anterior hypothalamus (POA/AH) is several times greater in volume in males than in females, and prenatal administration of either T or E to females augments the size of this nucleus toward that of males. By contrast, ER antagonists block normal differentiation of this nucleus in male rats. Similarly, in male ferrets a discrete nucleus is present in the dorsal portion of the POA/AH and is not apparent in females. Prenatal administration of a drug that inhibits brain aromatase activity prevents the development of this dorsal nucleus in male ferrets, whereas prenatal treatment with an androgen receptor antagonist does not.

Estrogen formed directly in neurons via aromatization of circulating androgen is a crucial source of estrogen to developing brains in male mice and rats. In rats and mice, but not in all species, the circulating liver-secreted protein α-fetoprotein has the property of binding estrogen with moderate affinity and high capacity. In these two rodents, α-fetoprotein concentrations are high enough to reduce the availability of estrogen from the general circulation. The recent creation of α-fetoprotein knockout mice provided for the demonstration that one role of α-fetoprotein is to prevent masculinization and defeminization in normal females. Whether α-fetoprotein also has other functions during brain development in these and other animals continues to be investigated. In other mammalian species, α-fetoprotein does not bind estrogen, so levels of circulating estrogen must be low enough in fetal female brains of those species at ages of high sensitivity so that they do not cause defeminization.

As in their male counterparts, the developing brains of female mammals produce considerable estrogen locally. Although estrogen receptors are prevalent in numerous subcortical and cortical brain regions during female development, lower numbers of estrogen receptors appear to be occupied by estrogen in developing females compared with males. Some investigators have hypothesized that some of this estrogen is available for potential interaction with neural ERs

and direct organization of developing female brains. This is in contrast with the prevailing dogma that all morphological and functional aspects of female brain development occur normally in the absence of any active steroidal signal. In rats, for example, perinatal exposure to very low levels of estrogenic stimulation can augment the ability of females to display sexually receptive behavior in adulthood; similar findings have been obtained in female ferrets. However, in the latter instance, severe perinatal deprivation of estrogenic stimulation to the developing female central nervous system (CNS) did not eliminate the ability of females to copulate after adult exposure to estrogen. In female rats the volume of the medial nucleus of the POA/AH, which normally is smaller in females than in males, is reduced by perinatal treatment with an estrogen receptor antagonist. Thus, differences between adult males and females in neural and functional characteristics may depend, in part, on the relative amount of estrogenic stimulation occurring in particular neural sites during development.

Activational Effects

Acting via intraneuronal ERs, estrogen also affects the function of the adult male and female CNS. In a wide variety of mammalian species, rising levels of estrogen, secreted by granulosa cells of developing ovarian follicles, promote the cyclic secretion of GnRH from the median eminence of the hypothalamus into the hypophyseal portal vessels, which conduct it to gonadotrophs in the anterior pituitary, which in turn release LH in quantities sufficient to cause ovulation. At other times during the female reproductive cycle, circulating estrogen acts to restrain the pulsatile secretion of GnRH from nerve terminals abutting portal capillaries of the median eminence. Other effects of estrogen in adult female rodents involve the priming of hypothalamic mechanisms to later respond to progesterone (P) stimulation, which in turn activates feminine sexual behaviors, including proceptive (solicitation of male partners) and receptive (lordosis) responses. Each of these effects of estrogen depends on the stimulation of protein synthesis at the neural sites being affected by the steroid.

In male mammals, estrogens also affect neuroendocrine function. For example, the expression of masculine sexual behavior in male rats, hamsters, and ferrets depends in part on the neural aromatization of circulating T. Likewise, estrogens formed locally in the hypothalamus and preoptic area of adult male mammals contribute to the inhibitory regulation of GnRH secretion, which in turn leads to the regulation of LH. Finally, exposure of either the perinatal or adult brain to supraphysiological concentrations of estrogen, either in the form of the natural estrogens such as E or in the form of synthetic estrogens such as diethylstilbestrol, can lead to the death of neurons in the arcuate region of the hypothalamus. Because estrogen has potent effects on males and females during development and in adulthood, there is considerable and growing concern for exposure to environmental estrogens. Substances with estrogenic actions are plentiful in many plants, and consequently in food sources, and others including insecticides and herbicides are released into the environment for commercial reasons. As risk assessment for these effects becomes more sensitive and selective, investigators are finding examples of neurobiological effects of many environmental estrogens. Some of these effects may be subtle, affecting normal events such as masculinization and defeminization, and others may be profoundly destructive to particular brain structures.

Parallel to their effects on gonadotropin secretion, estrogens and androgens modulate the brain areas controlling secretion of other anterior pituitary hormones such as growth hormone (GH), thyroid stimulating hormone, and adrenocorticotropic hormones. But unlike effects on gonadotrophins, some of these may not necessarily require sexual differentiation of the brain during development. For example, male rats display a low-frequency, high-amplitude GH secretory pattern with bursts of GH occurring every 3–4 h and separated by prolonged GH trough periods during which GH levels are very low or undetectable. Females show a high-frequency, low-amplitude pattern of GH secretion, with pulses of GH occurring every 1–2 h. Individual peak amplitudes are lower, and GH trough values higher and of shorter duration than those of male rats. Depending on the endocrine state of the animal, these parameters can be altered and sex-reversed in adults by administration of estrogens and androgens.

Androgen Action

Genetics

For the brain, less is known about effects of androgens that are directly mediated by ARs than about effects involving androgen conversion to estrogen and subsequent mediation by ERs. However, since androgen actions are required for normal male development and reproduction, but not for individual viability, animals with occurrences of genetic defects in androgen action survive and can be studied. Naturally occurring mutations can affect either the synthesis of androgens or the receptor proteins that mediate their actions. It had been assumed that the paucity of

similar estrogen receptor mutations was attributable to the likelihood of their lethality to the fetus. Recently, however, examples have been detected in humans for receptors or for aromatase. Also, through molecular genetic manipulations to produce 'knock-out' animals lacking receptors, viable mice have been obtained without the normal complement of ER alpha and/or beta. Since these receptor proteins have many functions, the genes are pleiotropic, and compensatory changes may occur during development. Therefore, while they are very suggestive of testable mechanisms, it is still challenging to discern causal relationships between these mutations and altered functions.

AR mutations affect all tissues in the body, including neural, and cause the syndrome of testicular feminization (TFM). In humans, rats, and mice, TFM is X-linked. Although X/Y animals with TFM have testes, which produce androgens, these animals do not respond normally to androgen and therefore develop with deficiencies of masculinization. Highly affected animals, including many humans with TFM, are externally female in appearance; other particular androgen-resistant animals, including humans with incomplete TFM, are virilized to variable extents. These mutants aid in determining the roles ARs play during development and behavior. Male sexual behavior can be elicited with estrogen or androgens in adult TFM rats, which are partially responsive to androgens, as it can be in normal males. Presumably the normal ERs in these animals and the partial complement of ARs are sufficient for masculinization during differentiation and activation of behavior in adults. By contrast, the TFM^H allele in mice results in profound insensitivity to those actions of androgen that require ARs rather than conversion to estrogen and binding to ERs. When given estrogen or androgen, a few of these adults showed partial male copulatory behavior, but most did not respond. These results are consistent with the concept that ARs, along with ERs, are involved both in sexual differentiation of mouse brain and in eliciting behavior.

Mutations in the gene for the enzyme 5α-reductase (Figure 1) affect androgen action. Humans with deficits in this enzyme are externally undervirilized to varying extents, depending on the specific mutation and protein defect. Certain of these patients appear externally as females at birth, and though raised as girls, they undergo virtually complete virilization over a period of years at pubertal ages. These individuals can then assume typical male gender roles, including marriage. It has been assumed that this transformation occurs because high levels of T at puberty are able to mimic the normal action of dihydrotestosterone at earlier ages. The question that is raised regarding behavior is: Does androgen act prenatally to masculinize the brains of human males as it does for rodents? Or is sexual behavior in humans less dependent on hormonal than on experiential and other influences? The sequence in the patients mentioned earlier is consistent with either hypothesis. On one hand, T is active in the development of brains of other animals without its reduction to DHT, so it may function normally in the brains of these individuals. When their genitalia become virilized, they would already have masculine brains. On the other hand, gender identity in humans is dependent on the perception of gender, so a person eventually appearing male might acquire the potential to assume male gender behaviors without specific hormonal effects on the brain. This dichotomy illustrates how mutations can result in ambiguous hypotheses about mechanisms of development and behavior.

Additional steps in metabolism of sex steroids in the brain might be important and are being investigated. One of these provides a third hypothesis regarding sexual differentiation of the human brain: that it is capable of occurring years after birth under the influence of androgen. The enzyme 5α-reductase catalyzes the reduction of several $delta^4$ steroids, including P and T. Unlike most other steroid receptors that are highly selective for a particular ligand, ARs bind both T and DHT, but with higher affinity for DHT, and they have moderately high affinities for E and P. It has been suggested that during gestation, P concentrations are high enough that in some tissues they might potentially inhibit androgen binding to ARs. However, the 5α-reduced product, 5α-pregnane-3,20-dione (5α-dihydroprogesterone, DHP), is less inhibitory than P. Accordingly, 5α-reductase could normally reduce T and P to DHT and DHP, respectively, thus allowing greater binding of androgen to AR. In some patients with 5α-reductase deficiency, P would achieve its potential for blocking AR, thus inhibiting its normal action. The virilization that occurs in these 5α-reductase-deficient patients could occur when androgen levels rise during puberty but without high levels of P that occur during gestation. The brain may be one organ in which this role of 5α-reductase is important. This explanation is plausible if the human brain is susceptible to change by hormones at near-adult ages.

Analogs

Analogs of androgens and estrogens which are agonists or antagonists for specific receptors or specific steps in metabolism help evaluate the involvement

and mechanisms of action of these hormones in the brain. If an effect of T involves aromatization to E and binding to ERs, then inhibitors of aromatase activity can prevent the response, whereas synthetic estrogens may mimic T. DHT is unlikely to be active for responses where strong activation of ER-alpha is needed, since reduced androgens are not aromatized to estrogens. Increasing understanding of ER-beta (and possibly other ERs) will likely engender an increasing interest in how DHT metabolites such as androstenediols may have estrogenic actions. If the effect of T is mediated by ARs, then DHT may be as agonistic as T. Nonetheless, situations occur in which T is active, aromatization and ERs are not indicated as involved, and yet DHT is not effective. This can occur if administered DHT is very quickly metabolized to inactive products before reaching target cells. To avoid this complication, synthetic androgens like methylenetrienolone (R1881) can be used. In adult castrated male rats and hamsters, administration of this synthetic steroid duplicates the rather minimal stimulatory action on mating that occurs in response to a naturally occurring androgen, DHT. When given concurrently with estrogen, either R1881 or DHT causes essentially a complete restoration of sexual activity in castrated males, equivalent qualitatively and quantitatively to the behavior seen after T treatment. This suggests that some actions of T involve both ERs and ARs. It has also been hypothesized that some responses to androgen occur efficiently only if T, but not DHT, binds to ARs.

A growing number of substances are being characterized as endocrine disruptors on the basis of their influences on estrogenic or androgenic targets. Some of these compounds also might have protective actions against some hormone-dependent cancers, increase emotional well-being, and inhibit other pathologies. Interest in the use of some of these compounds, known as phytoestrogens, as dietary supplements is increasing, and the basis for this is their estrogen-like action. There are three main classifications of phytoestrogens: (1) isoflavones, derived principally from soybeans; (2) lignans, found in flaxseed; and (3) coumestans, derived from alfalfa. Of these, consumption of isoflavones has the largest impact on human health because of its availability in a variety of food products containing soy. Of the isoflavones, genistein and daidzein are considered the most potent estrogens and thus have historically attracted the most attention. However, phytoestrogens (e.g., equol, a metabolite of the isoflavone daidzein) can also have other mechanisms of action, including antiandrogenic effects.

Other steps in sex steroid metabolism that are possibly involved in brain function have been investigated. Much interest has been generated in a possible chemical relationship between steroids and neurotransmitters. E can be hydroxylated to catechol estradiol (2-hydroxyestradiol). While considerable data demonstrate that certain brain tissues can catalyze the formation of this and related products, and that they can be potent when administered, many investigators now are uncertain that these have a significant physiological role. Another product, 5β-dihydrotestosterone (the 5β-reduced product of T reduction, rather than the more common 5α isomer), has been observed in avian species. Whether it is part of an alternative degradative, and perhaps regulatory, catabolic step or is another active steroid, as has been suggested for steps in blood production, is unknown. As methods for steroid and receptor biochemistry become increasingly refined and are applied toward the level of single cells, further steroid products may be discovered that play specific roles in brains of different species. Much has been learned in recent decades about the dynamics of androgens, estrogens, and their receptors in the brain and the effects these have on development and mature CNS. Current and future studies are revealing the changes in cellular and molecular biology that underlie these influences.

Gonadotropin, Neural and Hormonal Control

Introduction

Reproduction is vital to the survival of species, and highly tuned systems have evolved to ensure success. The process is totally dependent on the function of gonadotropin-releasing hormone (GnRH) neurons, which provide the necessary drive to the gonadotropes of the pituitary gland, through neurosecretion. In turn, the secretion of gonadotropins maintains the function of the gonads. Although various factors may influence the function of the gonadotropes and the gonads, normal function is dictated by the function of GnRH neurons. Thus, pulsatile secretion of GnRH into the hypophysial portal system maintains synthesis and secretion of gonadotropins. Without GnRH function, the gonadotropes cease to function, and reproduction is not possible.

The phasic pattern of GnRH secretion is a fundamental property that allows high-fidelity control of downstream processes. Whereas the notion of a 'pulse generator' in the brain to control the phasic pattern of secretion has been proposed, such a center has not been identified, nor has any type of cell in the brain been ascribed such a function. On the other hand, it has been proposed that GnRH neurons possess an inherent ability to operate in a phasic manner; this allows modulation of secretion by various factors, including feedback of gonadal hormones. If one allows that GnRH neurons have inherent oscillatory function, then one can invoke control mechanisms that involve changes in phase (pulse frequency) and strength (pulse amplitude). There is a direct inverse relationship between the frequency and amplitude of GnRH and luteinizing hormone (LH) pulses such that a slow rate of pulses tends to increase the amplitude of the pulses and vice versa. Whereas this has been modeled for the release of LH, showing that the relationship reflects a releasable pool of hormone in the gonadotropes, there is no good understanding of whether such a relationship prevails in the neurosecretory terminals of GnRH neurons. Such changes are seen in the patterns of secretion that prevail across the female estrous/menstrual cycle and with changing function of reproduction in males, especially in seasonal breeders.

The GnRH neurons integrate information from other neuronal systems, which define the pattern of GnRH secretion from the brain. This hierarchical system allows various points of control. Figure 1 emphasizes the point that the function of GnRH neurons is affected by gonadal hormone feedback, stress, nutritional status, and mood in humans, as well as season in subhuman species. GnRH neurons receive information from a range of neuronal systems. These arise from the vegetative regions, such as the lateroventral medulla, the serotoninergic system, and various regions of the limbic system. These brain regions probably provide 'drive' to the GnRH neurons and process information from environmental cues (season and stressors) as well as intrinsic feedback. In particular, the GnRH system is regulated by the feedback effects of sex steroids from the gonads. The final common output of the brain that controls the reproductive system is GnRH secretion, which represents the integration of all this information from various brain regions.

GnRH Control of the Gonadotropes via the Hypophysial Portal

The neuroendocrine, hypothalamopituitary axis has special anatomical and functional features that optimize function and fine control. GnRH neuronal cell bodies are found in the preoptic area of most species but are predominantly located in the basal hypothalamus of primates. The cells are not as closely grouped as other neuroendocrine systems, such as the corticotrophin-releasing hormone neurons of the paraventricular nucleus. Nevertheless, the GnRH cells operate in a coordinated manner, possibly due to cell–cell communication. This synchronized pattern of activity of GnRH neurons may be due to coordinate function of afferents that arise from elsewhere in the brain, providing 'drive' to the system.

The GnRH cells project to the median eminence to provide a dense plexus of neurosecretory terminals in the external zone of this structure. Secretion into the hypophysial portal system reflects the phasic activity of the neurons and represents conversion from neural transmission to an endocrine signal. Since the hypophysial portal system is a relatively short one (<1 cm) and relatively low in volume, the secretion of femtomolar quantities of releasing factors (such as GnRH) from neuronal terminals can present physiologically relevant concentrations (picograms per milliliter) of the hormone to the relevant cells (gonadotropes) of the pituitary gland. The portal provides optimal economy of delivery to the pituitary gland since different releasing factors are carried in the same milieu, but selectivity of function is achieved because each relevant cell type of the pituitary gland possesses receptors specific

Figure 1 Schematic representation of the integration of information from various neural systems to regulate the function of gonadotropin-releasing hormone (GnRH) neurons. The GnRH cells are influenced by neurons that receive steroidal feedback signals from the gonads, centers that process information on energy balance, season, and stress. Thus, the secretion of GnRH and the gonadotropins provides drive to the reproductive system, in relation to environmental and internal homeostatic systems. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

for a particular function. Thus, gonadotropes possess GnRH receptors, but corticotropes, lactotropes, and so forth, do not. Another special feature of this neuroendocrine architecture is that responses of the relevant pituitary cells may amplify the neuroendocrine signal manifold. Thus, the GnRH signal, which is at a concentration of picograms per milliliter in a few milliliters of hypophysial blood, acts on gonadotropes, which amplify the signal and secrete sufficient gonadotropin to achieve peripheral circulating concentrations of the order of nanograms per milliliter.

Relationship between GnRH, LH, and FSH Secretion

Of all the neuroendocrine systems studied, the relationship between GnRH and LH provides the best example of a one-to-one relationship. It was originally proposed by GW Harris that endocrine function of the anterior pituitary cells was a direct reflection of neurosecretion of relevant factors from the hypothalamus, and this hypothesis has been tested for all systems (reproductive axis, stress axis, thyroid axis, etc.). In particular, the pulsatile secretion of LH is a direct function of GnRH secretion, although some modulation of the output (LH) may occur by modulation of gonadotrope function. On the other hand, the secretion of follicle-stimulating hormone (FSH) from the same gonadotropes is not such a simple reflection of GnRH secretion. This is because the secretion of LH in a pulsatile manner is entirely dependent on GnRH action, whereas FSH secretion can occur without the secretory stimulus of GnRH. The difference in the means by which the secretion of the two gonadotropins is supported may be explained by the fact that secretion *per se* of LH requires a stimulus, whereas secretion of FSH may be passive. Regarding the latter, GnRH supports FSH synthesis, and by virtue of this, secretion occurs; secretion of this gonadotropin does not have the absolute requirement for acute stimulus. In this context, it may be considered that the pulsatile secretion of LH is the primary driver of endocrine function of the gonads, which is reflected in pulsatile secretion of estrogen from the ovary and testosterone from the testis. The function of FSH primarily supports gamete development, although this gonadotropin also stimulates inhibin production.

Feedback Control of GnRH Secretion

The arrangement of the GnRH system provides various control points, as outlined in Figure 2 for the feedback effects of estrogen. Similar 'wiring diagrams' may be constructed for other feedback regulators, and for purposes of simplification, the figure does not integrate all neuronal systems involved in the feedback regulation of estrogen.

Figure 2 Estrogen (E) is able to negatively and positively regulate the secretion of gonadotropin-releasing hormone (GnRH) and the gonadotropins. These feedback effects are mediated via neurons in the brain that possess estrogen receptor-α, which may provide either direct input to GnRH neurons or interneuronal input via relay neurons. Positive feedback may also be assisted by disinhibition of neurons that are inhibitory to GnRH function. Various centers of the brain contain concentrations of neurons that are estrogen-responsive and have been shown to project to the preoptic area (POA) or the GnRH neurons. Main subgroups that provide input to the POA and GnRH neurons are (1) brain stem (especially the A1 cell group of the ventrolateral medulla; (2) the arcuate nucleus (ARC) and the ventromedial nucleus (VMN); and (3) the bed nucleus of the stria terminalis (BnST) and subgroups of the POA, including an area (the anteroventral periventricular nucleus) that displays sexual dimorphism and is known to be important in the generation of the positive feedback effect of estrogen that causes the preovulatory surge in rodent species. Stimulation and/or disinhibition may also regulate GnRH secretion by action at the level of the GnRH terminals in the neurosecretory zone of the median eminence. Estrogen may also act on hypothalamic cells that project to the brain stem, thus modulating the function of noradrenergic neurons that then project to the POA. Estrogen also acts on the pituitary gonadotropes so that there is coordinated action. For example, to generate the preovulatory surge in GnRH/luteinizing hormone (LH), estrogen acts to increase the secretion as well as the action of GnRH in a coordinated manner. This positive feedback action may involve similar time-delayed signaling processes in neurons and in gonadotropes. FSH, follicle-stimulating hormone.

These points of control are at various levels of the brain and allow the integration of information from environmental factors as well as intrinsic systems. There is significant experimental evidence to support the notion of a serial and converging 'wiring pattern' to GnRH neurons (Figure 3). Synaptic input to GnRH neurons has been described for a wide range of systems, but the extent to which each of these may be important and how they interact require further study. Whereas such synaptic input of a given element to GnRH cells may be demonstrable, the magnitude of influence of any one system is more difficult to ascertain. Nevertheless, evidence is emerging for a highly organized network of neuronal control that may involve direct input from 'major' control systems and 'modulatory' input from other systems. One potential model is an 'on–off' system, which is outlined in Figure 4; this is a model of multiple integration at a point upstream of the GnRH neuron (an on–off switch) and presumes that glutamate is the main stimulatory neurotransmitter and γ-aminobutyric acid is the main inhibitory neurotransmitter in the neuroendocrine system. Certainly this notion of primary stimulator/inhibitor has been proposed by various investigators, and GnRH cells receive inputs from both glutamate and γ-aminobutyric acid systems, but there is also strong evidence for other systems that exert major control. For example, the noradrenergic system of the brain stem provides input to GnRH cells, and this may provide a mechanism of primary drive. The proposed model is attractive because it allows the serial and converging input to GnRH neurons to be integrated into simple stimulatory or inhibitory signals, prior to final 'instruction' to the GnRH neurons. The integrated information from all afferent systems is reflected in output (GnRH secretion).

Neuronal afferents may regulate the function of the GnRH system by pre- or postsynaptic communication of afferent input, and there is also significant support for the notion that GnRH may be influenced by action of neurotransmitters at the level of the cell bodies or at the level of the terminals in the median eminence (Figure 5).

Steroid Feedback to the GnRH Cells

The function of GnRH cells is strongly influenced by the feedback of gonadal steroids on the brain. This dictates the cyclic pattern of reproductive function in the female and also maintains a closed-loop system in the male. Such a system allows for constant maintenance of finely tuned feed-forward (GnRH secretion) by feedback regulation. Although the gonads also secrete protein hormones, such as inhibin, the feedback action of these factors appears to be at the level of the pituitary gonadotropes, influencing GnRH action rather than secretion. Although powerfully influenced by the feedback effects of gonadal steroids, the GnRH cells do not express the relevant steroid receptors at a level that is of major functional relevance. Thus, GnRH cells do not express estrogen receptor-α (ER-α), androgen (AR), or progesterone receptors, but do express estrogen receptor-β (ER-β). Since the major feedback effects of estrogen are transmitted via ER-α, the expression of ER-β in GnRH cells is probably of minor consequence. Various cell types express the relevant steroid receptors and transmit information to GnRH cells; a good example of such a system is the recently discovered kisspeptin cells of the hypothalamus and preoptic area, which express ER-α and powerfully regulate

Figure 3 The gonadotropin-releasing hormone (GnRH) neuron is influenced by serial and converging series of inputs from various brain regions that support and modulate function. The figure indicates major centers in the brain from which cells project to the GnRH cell bodies. These may be involved in steroid feedback, and the figure indicates centers that contain estrogen receptor-α (ER+) and respond to estrogen, as well as centers where afferents do not express ER. The latter probably convey information other than steroid feedback to GnRH cells. For example the orexin (ORX) and melanin concentrating hormone (MCH) cells of the lateral hypothalamus may transmit information on metabolic state to the GnRH cells. These centers of the brain may also intercommunicate, as indicated. The 'wiring' may be directly to the GnRH neurons or may involve interneurons in the bed nucleus of the stria terminalis (BnST) or the preoptic area (POA). Serial input via chains of ER+ neurons may allow amplification of estrogen signaling. NA, noradrenaline; A1, noradrenergic cells of the caudal ventrolateral medulla; ARC, arcuate nucleus of the hypothalamus; VMN, ventromedial nucleus; DA, dopamine; ENK, enkephalin; NPY, neuropeptide Y; GLU, glutamate; MSH, melanocyte stimulating hormone; GABA, γ-aminobutyric acid; βEND, β-endorphin; GAL, galanin. For simplification, this figure represents a few pathways in order to indicate a general organization, but other pathways have also been described.

GnRH cells. Nevertheless, electrophysiological, single-cell studies have shown some direct effects of steroids in GnRH cells, so it remains possible that some level of direct control occurs. In spite of this, overwhelming evidence shows that the feedback effects of gonadal steroids are transmitted by neurons that express the relevant receptors at high levels and transmit information to GnRH cells. This pattern can be demonstrated by implantation of steroids in discrete regions of the brain and subsequent measurement of GnRH or gonadotropin secretion. In this way, various brain regions have been shown to participate in the steroid feedback regulation of GnRH cells.

Steroidal feedback regulation of GnRH cells may be negative or positive, although the latter is only seen in the female. This is due to sexually dimorphic patterns of brain development. The sexually dimorphic anteroventral periventricular nucleus of the female rodent brain is the center which appears responsible for generation of positive feedback signals of estrogen that produce the preovulatory surge in GnRH and LH. In other species, the relevant 'surge center' is found elsewhere; in sheep it resides within the mediobasal hypothalamus.

The means by which steroids such as estrogen may exert both negative and positive feedback actions on GnRH secretion is not well deciphered. Further work is required to examine the subcellular functions of estrogen within particular cell types. Another feature of the feedback systems is that different temporal patterns of response (in terms of GnRH secretion) may be observed. Thus, in a gonadectomized animal that is deprived of steroids, challenge by estrogen first causes a short-term negative feedback response, followed by a positive feedback response, followed by a prolonged negative feedback response. Active research is in progress to understand this time-related response.

Feedback Control of the Female Reproductive Cycle

Females undergo cyclic patterns of ovarian function that reflect cyclic patterns of GnRH and gonadotropin secretion. Ovulation is caused by a positive feedback action of estrogen, which causes a surge in secretion of GnRH. This involves the time-delayed response of neural systems mentioned above. Once ovulation has occurred, a corpus luteum forms on the

Figure 4 A proposed model for control of gonadotropin-releasing hormone (GnRH) neurons that involves simple on–off regulation via the glutamate (GLU) and γ-aminobutyric acid (GABA) systems, respectively, of the bed nucleus of the stria terminalis (BnST) or the preoptic area (POA). This model also incorporates input to the GnRH terminals that may modulate GnRH secretion. The evidence for direct 'axo-axonic' input to GnRH terminals is not strong, but various systems provide input to the neurosecretory zone of the median eminence and modulate secretion by 'volume control,' which does not require synaptic contact. The simplified 'on–off' model also incorporates direct input to GnRH cell bodies and dendrites, which is well described.

Figure 5 The female estrous/menstrual cycle is characterized by changing patterns of gonadotropin-releasing hormone (GnRH) and luteinizing hormone (LH) pulse frequency and amplitude, which reflect the feedback actions of progesterone (P) and estrogen (E). During the luteal phase, combined action of both steroids causes low-frequency, high-amplitude GnRH and LH pulses. With the decline in P at the end of the luteal phase, the frequency of GnRH and LH pulses increases, and the response of the ovarian follicles in terms of E secretion increases. At a critical level of E, a positive feedback effect on GnRH and LH secretion is initiated, culminating in the preovulatory surge. Note that the surge in GnRH secretion is more prolonged than the surge in LH secretion.

ovary, and plasma levels of progesterone rise. Progesterone acts on the brain to slow the rate of pulsatile release of GnRH, with an associated increase in pulse amplitude. Since estrogen (and androgens) is released by the ovary during the luteal phase of the cycle, the negative feedback control of GnRH neurons probably represents a combination of signaling from cells in the brain that are receptive to both steroids. In fact, work in various species has shown that all cells that express progesterone receptors also express estrogen receptors, so combined action of both steroids may be transmitted by the same cells. As the cycle progresses and if pregnancy does not ensue, the corpus luteum regresses, and progesterone levels fall. Associated with the demise of the corpus luteum, progesterone feedback is lost, and the restraint on GnRH cells is lifted. This leads to increased frequency of pulsatile secretion of GnRH and LH, with associated reduction in amplitude. The frequency of GnRH pulses increases throughout the follicular phase of the cycle, and a GnRH surge ensues that causes another reproductive cycle.

At some point in the follicular phase of the female cycle, the positive feedback mechanism is activated, probably in response to a critical circulating level of estrogen. Recent studies indicate that this phenomenon requires a minimum duration of estrogen action, but the cellular mechanisms involved are not defined. This is not an easy task, since it appears that the positive feedback stimulus occurs at a time when some degree of negative feedback prevails, that is, during the midfollicular phase of the ovarian cycle. It is possible that the effect of estrogen in this particular phase of the cycle is to set in train a sequence of events that is manifest as negative response followed by positive response, involving the same subcellular mechanisms. It is important to note that the negative effect of estrogen in the follicular phase of the cycle involves reduction in pulse amplitude but not frequency. Indeed, there is evidence that GnRH/LH pulse frequency increases during the follicular phase of the cycle, and this may be the primary determinant of rising estrogen levels.

Feedback Control of the Male Reproductive Process

Neural control of male reproductive function is subject to the feedback actions of testicular steroids. As in the female, the gonadal protein hormone inhibin acts on pituitary gonadotropes and not the brain. In particular, testosterone acts to negatively regulate the secretion of GnRH. The sites of negative feedback action of testicular steroids have been most extensively studied in

sheep and primates, indicating that the major effects are at the level of the brain, with minimal effects on pituitary gonadotropes. Control of GnRH function in males differs from control in females in that it is a closed system, with no cyclic changes and no positive feedback system. The mechanisms of negative feedback actions of sex steroids have not been as well researched in males, but as in females, the GnRH neurons do not possess steroid receptors.

In most species the predominant steroid produced by the testes is testosterone. In many tissues, including the brain, testosterone can be converted via 5α-reduction to the more potent androgen dihydrotestosterone, or via aromatization to estrogen (Figure 6). Thus, the negative-feedback actions of testosterone to regulate GnRH cells could be due to direct actions or via its primary metabolites. Both AR and ER exist in the male brain regions that control GnRH neurons. Progesterone receptors exist in the same regions, but the significance of this steroid in the control of GnRH neurons in males is not clear. The relative roles of testosterone and its metabolites in the regulation of GnRH neurons are not well understood, but it seems most likely that conversion of testosterone to estradiol accounts for at least some of the negative feedback effects on the secretion of GnRH. In male sheep, a key region of action of estradiol is the arcuate nucleus–ventromedial region. In male rats, androgens stimulate aromatase activity in the preoptic area and hypothalamus, which would stimulate conversion of testosterone to estradiol-17β. The importance of conversion of testosterone to dihydrotestosterone with respect to negative feedback regulation of GnRH is essentially unknown. If this conversion is important, the action would be mediated by AR. The locations of AR-containing cells involved in this action have not been identified, but evidence suggests that they are not in the arcuate nucleus–ventromedial region.

The neuronal systems relevant to the negative feedback actions of testicular steroids are largely unidentified. In male sheep, GnRH neurons receive input from various parts of the hypothalamus, with the major contribution from the medial or periventricular region, which is a region containing AR and ERα.

Figure 6 Schematic representation of the hypothalamopituitary-testicular axis. Luteinizing hormone (LH) acts on Leydig cells in the testes to stimulate the synthesis of testosterone (T), and follicle-stimulating hormone (FSH) acts on Sertoli cells to stimulate the secretion of inhibin. Testosterone has negative feedback actions in the central nervous system to suppress gonadotropin-releasing hormone (GnRH) secretion, but the specific sites of action have not been determined. Direct pituitary actions of testosterone are negligible. Testosterone may exert negative-feedback actions on GnRH neurons after conversion to either or both of its primary metabolites, dihydrotestosterone (DHT) or estradiol-17β (E). The neural pathways that mediate the negative-feedback effects of steroids in males have not been determined with certainty but may include γ-aminobutyric acid, opioids, and cathecholamines. Inhibin has negative feedback actions directly at the anterior pituitary (not the brain) to regulate FSH secretion. BnST, bed nucleus of the stria terminalis; POA, preoptic area.

Various hypothalamic nuclei also appear to transmit the feedback effects of steroids to the GnRH neurons. Nevertheless, the identity of most of these cells and the extent to which particular inputs relay the negative feedback effects of steroids are unknown. The brain stem also provides input to GnRH neurons in the male brain, mostly arising from noradrenergic fields. In essence, the effects of sex steroids on the male brain are not well understood.

Summary

GnRH neurons control reproduction, but synthesis of the peptide and secretion is regulated by feedback effects of gonadal steroids acting in specific regions of the brain. Since GnRH cells do not possess the relevant receptors, the feedback signals are relayed to GnRH cells via cells that are steroid-responsive. These steroid-receptive cells provide serial and converging pathways to GnRH neurons. In females, both negative and positive feedback systems operate, but the male system is controlled only by negative feedback. Reproduction is also modulated by stress, energy balance, and season, via neuronal systems in the brain that transmit information to the GnRH neurons. Thus, GnRH secretion represents the output of neurons that integrate information from a variety of control systems.

Introduction

The neuroendocrine gonadotropin-releasing hormone (GnRH) system (also known as the luteinizing hormone-releasing system) is essential for vertebrate reproductive function. In mammals, cells within this system usually express the 'mammalian form' of the GnRH transcript. These cells undergo an unusual developmental journey, migrating from the nasal placode into the central nervous system (CNS), where they then become integral members of the hypothalamic–pituitary–gonadal axis (Figure 1). Throughout this article, these cells will be referred to as GnRH-1 cells. There are between 800 and 2000 neuroendocrine GnRH-1 cells in mammals. Within the rodent forebrain, the neuroendocrine GnRH-1 neurons are distributed in a bilateral continuum extending from the olfactory bulbs to the hypothalamus, with a large number of cells located in the diagonal band of Broca/preoptic area (Figure 1). Rostrally, the GnRH-1 cells are located on either side of the midline, in the dorsal half of the forebrain and close to the midline pial surface. Caudally, the GnRH-1 cells are found in the ventral half of the forebrain in more-lateral areas (approaching the hypothalamic sulcus). Independent of location, the majority of GnRH-1 cells send their axons to the median eminence, where they access (via fenestrated capillaries) the pituitary portal capillary system (Figure 1). Release of GnRH-1 at this site is pulsatile and activates the GnRH receptor (GnRHR) that is expressed on the surface of pituitary gonadotrope cells and subsequently affects the synthesis and secretion of gonadotropins (luteinizing hormone (LH) and follicle-stimulating hormone (FSH)) and consequently gonadal function. Genetic evidence from the hypogonadal mouse, which is sterile, established that the GnRH-1 system is essential for reproduction. The hypogonadal mouse has a mutation in only the mammalian GnRH-1 gene, and reproduction can be rescued by GnRH-1 gene therapy.

Although located within the CNS postnatally, neuroendocrine GnRH-1 cells in mammals are first detected in the nasal placode (Figure 2). To date it is still unclear whether GnRH-1 cells differentiate from precursors in the nasal placode or are derived from a stage in development prior to placode formation. It should also be noted that in mammals, GnRH-1 expression appears in the embryo preimplantation, and immunoreactive GnRH-1 is present in the morula and blastocyst stages. In chicken, GnRH-1 expression was found at gastrulation, when expression was detected in cells along the primitive streak. The role of GnRH-1 in early development is not completely understood and, in some cases, may represent transitory expression or a role in nonneuronal cell types.

The migration of neuroendocrine GnRH-1 into the forebrain during prenatal development is universal (Figure 2). GnRH-1 cells migrate on a subset of olfactory/vomeronasal axons, that is, they are neurophilic (also termed axonophilic) in nature and not gliophilic (Figure 3). The developmental relationship of the GnRH-1 system to the olfactory system is illustrated by Kallmann syndrome. Humans with the X-linked form of this disease have a monogenetic mutation that results in anosmia (lack of smell) and hypogonadism (failure to undergo pubertal development). Examination of Kallmann fetal material revealed lack of olfactory axon ingrowth into the developing forebrain and GnRH-1 cells 'stuck' on the CNS–side of the cribriform plate in a tangle of olfactory axons in one case and GnRH-1 cells in only nasal regions in a second case. Although the migration of GnRH-1 cells from nose to brain constitutes the best-characterized example of neurophilic migration in the forebrain, many questions still remain concerning the molecules and cues directing GnRH-1 cells to their final CNS location. But it is clear that disruption of either the development or the regulation of the GnRH-1 system results in reproductive dysfunction.

GnRH-Expressing Cell Groups within the CNS

A total of 24 distinct 'GnRH' forms have been described. Discussion of GnRH cell groups has been confounded by the classification of GnRH genes because of variants in specific species, developmental origin, cell location, and function of the gene products. Certainly, as complete sequence information becomes available for more species, classification may be revised, but several generalizations can be made. In vertebrates, a maximum of three GnRH forms have been detected in any given species, each encoded by a separate GnRH gene: GnRH-1 (human chromosome 8), GnRH-2 (human chromosome 20), and GnRH-3 (primarily in teleosts). Duplication of the genome has been proposed to account for the emergence of multiple GnRH genes. All the genes possess four exons and three introns, and the products

Figure 1 Overview of gonadotropin-releasing hormone-1 (GnRH-1) neuroendocrine system. (a) Hypothalamic–pituitary–gonadal axis. The majority of GnRH-1 cells send axons to the median eminence (me), where GnRH-1 is secreted into the portal capillary system. It is via this system that GnRH-1 cells affect gonadotropes of the anterior pituitary and subsequently gonadal function. POA/AH, preoptic area/anterior hypothalamus; vmh, ventromedial hypothalamus; Arc, arcuate nucleus; LH, luteinizing hormone; FSH, follicle-stimulating hormone. (b) Schematic of a parasagittal section of a rodent brain indicating the location of GnRH-1 cells (blue dots). GnRH-1 cells are distributed bilaterally in a continuum from the olfactory bulbs to the caudal hypothalamus; h, hippocampus; f, fornix; ob, olfactory bulb; mot, medial olfactory tract; ms, medial septum; dbb, diagonal band of Broca; mpoa, medial preoptic area; dh, dorsomedial hypothalamus; ot, optic tract; vh, ventromedial hypothalamus; a, arcuate nucleus; me, median eminence. (c, d) Photomicrographs of sections ((c) = DBB; (d) = ME); immunocytochemically stained for GnRH-1 (at levels indicated in (b)). Scale bar = 50 μm (c) and 330 μm (d).

Camera lucida drawing from embryonic day (E) 10.5–E12.5 mouse embryos showing invagination of the nasal placode and the development of the respiratory epithelium (re), olfactory epithelium (oe), and -nasal pit (np). tv, telencephalon; III, third ventricle; IV, fourth ventricle; t, tongue; fb, forebrain; ob, olfactory bulb. Parasagittal section immunocytochemically stained for GnRH-1 shows cells migrating from the nasal pit/vomeronasal organ, apposed to axons, through the nasal forebrain junction into the forebrain. Scale bar = 100 μm.

from these genes show a similar tripartite structure. Exon 1 encodes the 5′UTR, and exon 2 encodes a signal sequence, the GnRH decapeptide and the N-terminal region of gonadotropin-associated peptide (GAP, usually 50–60 amino acids in length). Exon 3 encodes the majority of GAP residues, and exon 4 encodes the C-terminal GAP residues and the entire 3′UTR. The function of GAP is unknown in any species. All known GnRH forms are ten amino acids in length, and the most common variation between forms occurs in amino acid positions 5–8.

GnRH-1 is in most vertebrates and clearly is the form in mammals that controls reproductive function. GnRH-1 is present in axons in the median eminence, where GnRH-1 is secreted into the portal capillary blood and thus affects pituitary function (Figure 1). Although the location of the GnRH-1 cells postnatally is species-dependent, they are often referred to as preoptic area/hypothalamic GnRH cells. The peptides encoded by the GnRH-1 gene can vary by as much as 50% among species.

GnRH-2 is highly conserved (this decapeptide is the most ancient and conserved form of GnRH) and, when present, is consistently found in cells in the midbrain. The function of GnRH-2 is unclear, but roles for GnRH-2 in regulation of puberty, reproductive behavior, feeding, and energy balance have been proposed in mammals. In some species, immunocytochemical and biochemical data suggested widespread expression of GnRH-2, with GnRH-2-expressing cell bodies within

Figure 3 Migration of gonadotropin-releasing hormone-1 (GnRH-1) cells is neurophilic. GnRH-1 cells migrate along olfactory axons (a–c) and are exposed to multiple regulatory domains along the migratory route (d). (c) Cells expressing GnRH-1 transcript (black grains, arrow) apposed to cell poor areas (olfactory axons, oa). (d) Schematic highlighting domains which may produce factors that regulate GnRH-1 neuronal movement (light green; nasal pit, blue; olfactory epitelium, pink; nasal mesenchyme, white; nasal forebrain junction, blue line; transient pathway, red; basal forebrain, dark green; GnRH-1 cells themselves or other migrating cells along pathway). fb, forebrain; OB, olfactory bulb; N/FJ, nasal forebrain junction; VNO, vorneronasal organ; 3, third ventricle.

the hippocampus, thalamus, and hypothalamus. However, recent data indicate that the preproGnRH-2 gene has, during evolution, been deleted from the genome of rats and mice and inactivated in chimpanzee, sheep, and bovine. In humans, GnRH-2 messenger RNA (mRNA) may have stability and/or translation changes due to modifications. Thus, a physiological role for GnRH-2 remains controversial, especially as more information on the receptor becomes available.

GnRH-3, prevalent in fish, exhibits functional, anatomical, and developmental similarities to GnRH-1, depending on the species studied, and in some fish, it has the strongest projection to the pituitary, suggesting a primary function in reproduction. Many fish express all three forms of GnRH (GnRH-1, -2, and -3). In teleosts, when two forms of GnRH are expressed, one is GnRH-2 and the other is (1) GnRH-1 in ancient teleosts but (2) GnRH-3 in modern teleosts (zebra fish), with these fish appearing to have lost the mammalian GnRH-1 ortholog. Usually GnRH-3 is found in the terminal nerve/ganglia and rostral telencephalon. If GnRH-1 is absent, then GnRH-3 can also be found in areas normally populated with GnRH-1 cells.

Multiple GnRHRs have also been identified, with mammals exhibiting primarily two GnRHRs (GnRHR, human chromosome 4, and GnRHR2, human chromosome 1). Both genes encode a seven-transmembrane G-protein-coupled receptor. GnRHR is found on cells in the pituitary and is 'tailless' compared with GnRHR2. In many species that exhibit multiple forms of GnRH and GnRHRs, specificity of receptor to a specific GnRH ligand is often not observed. In general, though, GnRHR has a higher affinity for GnRH-1, and GnRHR2 has a higher affinity for GnRH-2. Evidence that GnRHR2 has been inactivated or deleted from the genome during evolution exists for rats, mice, cow, sheep, chimpanzee, and humans. Thus, even if GnRH-2 is present in mammals, functional analysis of GnRHR2 needs to be evaluated at the species level. The mammalian GnRHR appears to be unique to mammals and cannot be found in amphibians and fish.

Although in the past, GnRH-1 cells and GnRH-2 cells in mammals were easily discernible based on anatomical location and developmental origin, the scenario has become more complex as (1) populations of forebrain cells that transiently express GnRH-1 transcript have been identified, (2) cells expressing GnRH-1 transcript but truncated peptide (amino acids 1–5) have been found in extrahypothalamic areas, (3) GnRH-1-expressing cells have been characterized in the developing tooth 'placode,' (4) an early group of GnRH-1 cells was identified that populated forebrain areas but also appeared to arise from the nasal placode area (reminiscent of GnRH-1 and

GnRH-3 in some fish), and (5) GnRH-2-expressing cells have expanded to nonmidbrain regions. One can initially separate and identify GnRH-1 cells by referring to the neuroendocrine GnRH-1 cells. These cells project to the median eminence, alter pituitary function, and are essential for reproduction. Thus, there are three forebrain populations of 'nonneuroendocrine' GnRH-1-expressing neurons that originate in the brain and express GnRH-1 transiently during development and are not 'related' to neuroendocrine GnRH-1 cells *per se*, although they clearly express the correct combination of transcription factors for GnRH-1 production. The function, if any, of GnRH-1 in these nonneuroendocrine brain cells is unknown. Nonneuroendocrine GnRH-1-expressing cells in rodent teeth may provide developmental information relevant to the neuroendocrine GnRH-1 population since development of the tooth is a dynamic process that involves the interaction of ectoderm-derived dental epithelial cells and underlying neural crest-derived mesenchymal cells – an event that has similarities to invagination of the olfactory and respiratory epithelia in the nasal placode. In the tooth, the GnRH-1 cells are in epithelial-derived structures and not in neural crest-derived structures (see the section titled 'Development of GnRH-1, GnRH-2, and GnRH-3 cell groups'). Also noteworthy are several independent reports documenting dental agenesis in patients with Kallmann syndrome. Whether these occurrences are due to overlaps in craniofacial factors and/or GnRH-1 factors is not known. The occurrence and function of GnRH-2 cells outside mesencephalic areas in mammals awaits further research. Although certainly more complicated, the GnRH-1 and GnRH-2 systems are clearly discernible on the basis of sequence differences, postnatal anatomical distribution, different receptor specificity, and developmental history.

Development of GnRH-1, GnRH-2, and GnRH-3 Cell Groups

This section discusses only cells expressing both transcript and peptide for GnRH-1, -2, or -3, pre- and postnatally.

In 1989, two groups independently showed that neuroendocrine GnRH-1 neurons in mice arise from an extra-CNS origin and suggested the olfactory placode (now referred to as nasal placode) as the source since the GnRH-1 cells were first detected in the evaginating vomeronasal organ/nasal pit (Figure 2). Classically, it was thought that the olfactory placode gives rise to nonsensory respiratory and sensory olfactory epithelium (OE; Figure 2). The OE produces the main olfactory (chemosensory) epithelia, as well as the vomeronasal organ epithelia (pheromone reception). The location of the GnRH-1 cells led to the hypothesis that GnRH-1 cells originate in an area of the olfactory placode associated with OE-derived structures. However, ablation experiments in the chick, subdividing the presumptive olfactory and respiratory areas prior to placode formation, suggested that the GnRH-1 progenitors were more closely related to respiratory areas. Removal of the posterior area eliminated olfactory epithelial structures but spared the GnRH-1 nasal population. Conversely, removal of the anterior area eliminated GnRH-1 cells and respiratory epithelial cells but spared olfactory epithelial structures. Subsequent studies in chicken and mouse argued that OE progenitors were distinct from GnRH-1 progenitors. These studies included (1) screening of early-expressing mouse GnRH-1 cells for the olfactory epithelial lineage markers Mash-1, Math4A, Math4C/neurogenin1, and NeuroD (the markers were not detected in GnRH-1 cells) and (2) identification of 'ectopic' GnRH-1 cells emerging from the respiratory epithelium in a mutant mouse and in the respiratory epithelium of normal chick. These studies argue that GnRH-1 progenitors are closely associated with anterior or respiratory regions rather than with olfactory regions and that GnRH-1 neurons diverge from olfactory sensory cells during early stages of nasal placode differentiation. Therefore the more generic name, nasal placode, was used in mouse to delineate the structure from which neuroendocrine GnRH-1 cells arose. In addition, in mouse nasal placode (Figure 2), an intermediate area was identified between respiratory cells and sensory cells, and it has been suggested that this intermediate region normally gives rise to GnRH-1 cells and hence is the location of GnRH-1 progenitor cells. However, the lineage and location of the precursors of neuroendocrine GnRH-1 cells still remain to be determined, but experiments in most species document expression of neuroendocrine GnRH-1 cells first in the nasal placode area.

The embryonic origin of forebrain GnRH-1 neurons is perhaps more 'controversial' in nonmammalian taxa, with most work being performed in fish. Many different species have been examined, and different sites of origin have been reported for GnRH-1 and-3. By the use of molecular techniques in fish with one rostral forebrain population (either GnRH-1 or GnRH-3), the cells are first detected in the nasal epithelium, similar to mammals. If the fish has two rostral GnRH forebrain populations (both 1 and 3), then the neurons can share a nasal placode developmental origin or exhibit different developmental origins, nasal placode and telencephalon. These studies are based on the expression of appropriate GnRH mRNAs and/or green fluorescent proteins driven by specific GnRH promoters. As in mammals, it is still unclear whether

the precursors are located within the area of first detection or end up in this region as the placode fields form.

In zebra fish, after exhaustive searches, only GnRH-2 and GnRH-3 have been molecularly cloned, and it has been shown that all the rostral forebrain cells in zebra fish express GnRH-3 transcript. However, studies using lineage tracer dyes and immunocytochemistry or gene knockdown fish and immunocytochemistry have proposed that in zebra fish, GnRH-1 and GnRH-3 cell populations arise from two separate regions of the neural plate: the adenohypophysis (anterior pituitary) region of the anterior neural plate and cranial neural crest, respectively, and that GnRH-2 cells of the midbrain share a common neural crest origin with GnRH-3 cells (terminal nerve). Here, the terms GnRH-1 and GnRH-3 refer to the location of the cell population, with GnRH-1 cells eventually residing within the hypothalamus and GnRH-3 cells being associated with the terminal nerve and rostral telencephalon. Although these results have raised new questions about the origin of GnRH cell groups, the results are hard to reconcile with molecular work showing only GnRH-2 and one forebrain GnRH gene in zebra fish (GnRH-3, but not GnRH-1), and GnRH-3 cells' (both those of the terminal nerve and hypothalamus) sharing a common origin: nasal epithelium. The differences observed in fish, and often the same species of fish, remain to be resolved.

Thus, while the exact precursors of GnRH-1, -2, and -3 are still elusive, the consensus is that GnRH-1 and GnRH-3 cells are associated with the nasal placode as they turn on GnRH expression. Both GnRH-1- and GnRH-3-expressing cells thereafter migrate, to various extents, within the olfactory system and into rostral forebrain areas. Again, in most mammals, GnRH-3 has been lost, and the function of these cells may have been incorporated into the GnRH-1 group. The cells discussed, for the most part, in the remainder of this article express the GnRH-1 transcript, originate in placodal regions, migrate into the CNS, synthesize and process the decapeptide GnRH, and are essential for reproduction.

Migration of GnRH-1 Cells into the CNS

Nasal Regions

It is clear from studies examining GnRH-1 cell movement in nasal regions that the development of the olfactory system and the development of the GnRH-1 neuroendocrine system are intimately entwined (Figure 3). In all species examined to date, GnRH-1 cells migrate across the nasal region on axons originating from cells in the olfactory pit/vomeronasal organ (Figure 3). Several of the other phenotypes localized to the nasal placode (γ-aminobutyricacidergic (GABAergic), somatostatin-, neuropeptide Y-, tyrosine hydroxylase-, and calbindin D-28k-expressing cells) have also been shown to migrate along these same axonal pathways in nasal regions. A variety of molecules expressed on olfactory/vomeronasal axons mark these pathways, but to date none has exclusively been limited to the route on which GnRH-1 cells move in nasal regions. However, what is clear is that when the course of the olfactory/vomeronasal axons is altered, so is the migration of the GnRH-1 cells (or GnRH-3 in the case of zebra fish).

Prior to GnRH-1 migration, a group of 'pioneer' olfactory axons crosses the nasal region and targets the base of the developing telencephalon. The cues that direct this group of pioneer axons may be critical for the guidance and targeting of all future olfactory/vomeronasal axons and subsequently the appropriate migration of GnRH-1 cells to the developing forebrain. In addition, migratory neuronal progenitor cells and neuronal precursors have been identified leaving the nasal placode prior to pioneer axonal outgrowth in nasal regions. Thus, exactly how guidance cues are established in the developing olfactory system is still unclear. Once guidance cues are in place, however, it is apparent that the GnRH-1 cells use a subset of olfactory/vomeronasal axons as their pathway across the nasal region. At the light microscopic level, GnRH-1 cells have been shown to be associated with axons expressing the intermediate filament peripherin, which is a marker for all olfactory/vomeronasal axons. When examined at the electron microscopic level, GnRH-1 cells in the submucosa of the nasal septum were always found within axonal fascicles and never appeared in direct contact with the nasal mesenchymal cells. The association of GnRH-1 cells with peripherin-positive nasal axons, and not mesenchymal cells, led to the hypothesis that a cell-adhesion molecule or molecules may be involved in the movement of GnRH-1 cells in this region.

Kallmann Syndrome

Although a variety of molecules are expressed on olfactory/vomeronasal axons, none has been limited exclusively to the GnRH-1 cell route, and thus the molecular guides that lead to this pathway choice are unknown. Recently, genetic work (by several groups) on Kallmann (anosmic) and normosmic hypogonadotropic hypogonadism patients has yielded molecules that influence GnRH-1 development, including anosmin-1, FGFR1, GPR54, NELF, and prokineticin. All but GPR54 appear to act prenatally and indirectly via olfactory axon outgrowth. The *Kal* gene has been lost from the mouse/rat genome. In medaka, a fish with both GnRH-1 and GnRH-3, knockdown

of the Kal ortholog (Kal 1.1) disrupted migration of both GnRH cell populations, while in zebra fish, with only GnRH-3, knockdown of this same gene (*Kal1.1*) disrupted cell migration into the hypothalamus but did not affect those remaining in the terminal nerve. The *C. elegans* Kal-1 has also been cloned and shown to interact with multiple heparan sulfate proteoglycans to promote neuroblast migration. Where examined, Anosmin-1, FGFR1, NELF, and Prokinectin are not limited to nasal regions during development, often being found in areas actively showing cell/neuronal migration. In patients with Kallmann syndrome, other deficits occur, both within the CNS and in other organs. Whether deficits occur in other regions in vertebrates in general, after knockdown on these genes, remains to be determined. As genetic details emerge from work in human patients who come to the clinic because of pubertal delay, one can expect other genes involved in the development or migration of GnRH-1 neurons to be discovered.

Nasal–Forebrain Junction

The crossover from nasal region to CNS is a dramatic change in environment. At this region, GnRH-1 cells appear to pause, and this pause appears to be regulated, in part, by GABA via $GABA_A$ receptors. The reason for this pause is unclear, but it may ensure (1) maturation of GnRH-1 neurons, (2) establishment and/or targeting of the migratory pathway to appropriate brain regions, and/or (3) changes in the extracellular milieu composition. Chemokines, growth factors, and neurotransmitters localized to, or forming gradients at, the nasal forebrain junction have been shown to alter movement of GnRH-1 cells into the forebrain or out of nasal regions.

Pathway in CNS

It appears that a single pathway is used by GnRH-1 cells through nasal regions into the developing hypothalamus in mammals. The majority of peripherin-positive olfactory axons project to the main and accessory olfactory bulbs. However, in the embryonic mouse, peripherin has been shown to highlight a pathway that enters the CNS and turns caudally toward the developing hypothalamus. GnRH-1 cells have been shown to be associated with this caudally projecting peripherin-positive axonal pathway. This pathway (often termed the nervus terminalis or the caudal branch of the vomeronasal nerve) has also been identified by the markers TAG-1 (an axonal surface glycoprotein that is transiently expressed) and deleted in colorectal cancer (DCC; a receptor for the guidance molecule netrin-1). These two markers are expressed on olfactory/vomeronasal axons in the nasal region but are low, or not expressed, on the branches of these nerves that enter the forebrain and proceed rostrally toward the olfactory bulb/accessory regions. Certainly, guidance of this caudal axonal pathway is an important prerequisite for the establishment of the adultlike GnRH-1 cell distribution. In DCC knockout mice, the trajectory of the caudal branch of the vomeronasal nerve is abnormal, turning toward the cerebral cortex instead of the hypothalamus. GnRH-1 cells follow this pathway and therefore do not reach the hypothalamus but migrate into the cortex. GnRH-1 cells must differentiate between axons ending within olfactory regions and those reaching the hypothalamus. Some molecules appear to be expressed on the rostral olfactory/vomeronasal axons and to be absent from the caudal hypothalamic projection. In addition, some molecules are downregulated on GnRH-1 neurons as they enter the forebrain. This raises the possibility that a combination of molecules, some turning on while others turn off, play an important role in establishing the appropriate GnRH-1 adultlike distribution by ensuring that most GnRH-1 cells do not end up in forebrain olfactory regions. Clearly multiple regulatory domains exist as GnRH-1 (and GnRH-3) neurons migrate from their origin to their final destination within the CNS (**Figure 3**).

Gravitational Effects on Brain and Behavior

Balance on Earth

Our sense of the direction of the vertical is vital to avoid falling. On earth, the vertical is sensed by a combination of many different sensory organs. Visual, vestibular, haptic, proprioceptive, and auditory cues are combined with knowledge of voluntary movement and the sense of body axis to produce a single, usually consistent, perception of body orientation and motion. Similar processes are involved in the stabilization of the head and the eye, in order to avoid slip of the retinal image of the seen world with every step. Consider the simple act of tilting one's head to the shoulder. The voluntary movement is confirmed by the muscle and joint receptors at the neck, by the tilted visual scene imaged on the retina, by the increased pressure on one foot, and by two sets of signals from the balance organ in the inner ear. The semicircular canals sense the angular motion. The otolith organs, which are sensitive to gravity and linear acceleration, sense that the head is tilted relative to the vertical.

Orientation in Weightlessness

In the weightless free-fall condition of orbital space flight, the synergy among the sensors is drastically altered. The otolith organs no longer indicate anything meaningful concerning the static orientation of the head, since the dense otoconia on the otolithic membrane no longer pull the membrane toward the vertical, thus bending the hair cells of the maculae when the head is tilted. In weightlessness, the otolith organs act like any other accelerometer, or a pendulum for that matter, and only respond to linear acceleration as the astronaut moves about. Once deprived of the usual static orientation information from the otolith organs, the brain must turn to other sources to erect a reference frame with respect to which an astronaut can judge his or her orientation. According to the otolith–tilt-translation–reinterpretation (OTTR) theory, the brain learns to reinterpret novel otolith quasi-static signals to represent linear acceleration in space, rather than the usual interpretation of tilt relative to the earth vertical. As a consequence astronauts may feel themselves moving linearly to the side when tilting their head shortly after return to earth, and they may also have difficulty walking around corners.

Weightlessness and Space Motion Sickness

Motion sickness, whether it is sea sickness, car sickness, or even 'space sickness,' is generally associated with a sensorimotor conflict. When the nervous system is presented with orientation signals that are inconsistent with one another or with the motor commands associated with motion, the conflict stimulates the autonomic nervous system to produce a pattern of responses, from nausea to vomiting.

In space, upon initial head movements in weightlessness, the conflict between the unexpected otolith signals and the remaining senses at first can produce such a malady, known as 'space motion sickness,' which occurs in about two-thirds of all space travelers and can last from hours to a few days. It is not evident how to predict who will be sick, although repeat travelers are less likely to have difficulty. In space, the presence of unusual visual orientations, such as seeing a fellow crew member upside down (relative to the viewer and the spacecraft) or seeing the earth at the top of a window, can suddenly bring on vomiting. Space motion sickness is often treated by an intramuscular injection of promethazine, which seems to produce fewer side effects of drowsiness in space than on the ground.

Posture in Space

When a new astronaut is first exposed to space, the postural reactions are inappropriate. Legs keep getting in the way and there is a tendency to stand against the floor, which, in turn, propels the astronaut headward toward the ceiling. After a few hours, however, space locomotion is learned, and after several days most astronauts comfortably and efficiently move about, using hand-holds or precise forces against the walls. Many enjoy working 'inverted,' although their preflight training may be of limited use to them.

Visual Reorientation Illusions

Early in a space mission most astronauts tend to substitute visual orientation cues for the misleading otolith signals, and become more sensitive to self-motion created by moving visual fields. As described by Charles Oman (director of the Man/Vehicle Laboratory at the Massachusetts Institute of Technology), visual reorientation illusions are commonly reported, in which the spacecraft surface closest to being beneath the astronaut's feet suddenly becomes the

apparent 'floor,' even if it is a ceiling or wall. The subjective frame may suddenly shift, analogous to a figure reversal illusion such as the Necker cube, without any sense of being rotated. Entering a part of the spacecraft in an unexpected orientation, or seeing a crewmate 'upside down,' may trigger a sudden visual reorientation illusion. Localized tactile cues, such as foot pressure applied by standing against stretched elastic cords, may accelerate the switch of reference frame and then stabilize the sense of orientation, and may enhance the illusion that the surface beneath the floor feet is 'down.' Outside the spacecraft, during extravehicular activity, the visual reorientation illusion is even more striking (see Figure 1). When working close to some surface, such as the outside of a space station or the open cargo bay of the Space Shuttle, astronauts will normally adopt the local surface beneath their feet as the 'down' reference. When looking off into space with the earth in view, however, our home planet becomes the vertical reference, and astronauts frequently report height vertigo and a fear of falling, causing them to clutch their hand-hold strenuously.

Another common phenomenon, distinct from the visual reorientation, is the 'inversion illusion,' typically occurring shortly after entry into weightlessness and persisting even with eyes closed. The usual description of the inversion illusion includes a momentary sensation of tumbling immediately upon entering weightlessness, followed by a sensation of being upside down, which generally lasts from seconds to minutes but which can, in some cases, remain for days. It is not influenced by visual inputs. After 4–7 days, however, some astronauts seem to adopt an internal reference system, relying upon their own body axis rather than any external cues, and their orientation illusions are either eliminated or cease to be disturbing. Many others adopt a local reference frame whereby the floor of the module in which they are working represents a universal 'down' direction – at least until they move into another module.

Figure 1 NASA photo of an astronaut performing extravehicular activity, hanging from the International Space Station (ISS), with earth below.

Orientation to Gravity and to Free Fall

The role of gravity in the interpretation of a visual upright is well known and appears in the Aubert illusion, whereby a sole vertical line appears tilted when the head is tilted sideways. For most stationary subjects, on Earth, the subjective visual vertical lies between the direction of the true vertical, as measured by the graviceptors, and that defined by familiar objects in the visual scene. The tendency toward visual dominance is often measured by the rod-and-frame test, in which the surrounding lighted frame influences the perceived visual vertical. In weightlessness, absent any orientation information from the graviceptors, the subjective visual vertical normally aligns with either the visual vertical or the body axis.

Vection

When a large visual scene is moved in front of a stationary subject on earth, it generally causes a sensation of self-motion, or 'vection,' after several seconds. In space, absent the expected motion cues from the semicircular canals or otolith organs, which might otherwise inhibit or eliminate such illusions, the vection is strengthened and occurs more rapidly (see Figure 2). This can, however, be reduced by the provision of static tactile cues to the feet, when the individual stands upright against the force of stretched elastic cords.

Proprioception

Proprioception is altered in space because of the absence of static muscle tension required to support the weight of a limb, but accurate pointing is quickly learned. The proprioceptive feedback signaling ankle, knee, and hip flexion is disturbed during extended weightlessness and is likely a significant source of the inability of some astronauts to walk and run normally following return to earth. The ability to

Figure 2 (a) On earth, the typical individual points upward, based largely on otolith cues measuring the direction of **f**, the specific force vector **g–a**. The direction is influenced also by the visual orientation **v** of apparently vertical surfaces, such as the panels of a work station, by the tactile cues **t,** coming from forces on the feet, and by an internal ideotropic vector **m,** aligned with the body axis. A ball held by the individual would hang straight down. (b) In weightlessness, however, the otolith measure of **f** indicates only acceleration and is largely ignored, in favor of increased weighting of the visual, tactile, and body vector signals. The indicated direction of 'up' now aligns more nearly with the direction of the visual ceiling.

estimate the mass of objects, in the absence of their weight, is also reduced. The otolith–spinal reflex, which normally prepares one for a landing from a fall, is also reduced in space, as well as is the Hoffman reflex measurement of spinal cord excitability during transient acceleration.

Vestibuloocular Reflex

Ocular stabilization during head movements, the vestibuloocular reflex, is disturbed in some individuals during space flight. Vertical and horizontal vestibuloocular reflex gains to head turns vary with duration in weightlessness. The time constant characterizing the decay of postrotatory nystagmus (oscillatory eye movements following prolonged turning) is thought to consist of a shorter time, about 5 s, characterizing the mechanical return of the displaced cupula, and a longer period, sometimes referred to as 'velocity storage,' which involves the vestibulocerebellum. Early on during space flight the time constant is shortened, representing a loss of the higher-order velocity storage mechanism. During prolonged flight, however, the time constants return to close to their preflight levels. An interesting gravity-related phenomenon is the sudden decrease in postrotatory nystagmus, known as 'nystagmus dumping,' normally produced by pitching the head forward. This dumping is absent in weightlessness and therefore is attributed to the effect of gravity on the otolith organs. The 'caloric response,' a nystagmus induced by applying hot or cold fluid in one ear, is a common clinical procedure for diagnosing peripheral vestibular loss. It is still present, to a lesser extent, in space, indicating that it is partially caused by some direct thermal effect rather than entirely by gravity-driven convection. Ocular counter-rolling of the eyes, in a direction toward stabilizing the eye relative to the vertical, is a sensitive measure of the response of the utricular otoliths to gravitational stimulation. Most measurements of this response postflight show a decrease in gain for astronauts, and frequently the appearance of some directional asymmetry not seen preflight. This may be interpreted as the emergence of an underlying uncompensated reflex. (No such preflight/postflight difference was found for the four astronauts tested on the 16-day National Aeronautics and Space Administration Neurolab mission, however, nor did these astronauts show any inflight changes in ocular counter-rolling, as tested on a short-radius centrifuge.)

Reentry and Earth Sickness

Although the adaptive behavior of the neurovestibular system is appropriate to living in weightlessness, it introduces problems during reentry and when back

on the ground. Head movements during entry can cause the visual scene to swim around (oscillopsia) and may produce significant spatial disorientation. Such head movements are therefore avoided by reentering pilots. Once back on the ground, many astronauts experience a period of 'earth sickness,' especially when making head movements in a limited visual field. Unlike space motion sickness, however, earth sickness generally disappears in less than a day. Locomotion takes a longer time to readapt. Returning space travelers will usually exhibit a wide stance and unsteady gait after landing. Their ability to maintain balance is impaired, especially when visual and ankle proprioceptive cues are eliminated, forcing them to rely on their vestibular system to remain steady. The ability to stand quietly for 10 min is severely challenged, presumably because of orthostatic hypotension associated with cardiovascular regulation, loss of venous tone, and fluid loss, but also possibly due to altered vestibular inputs to the sympathetic nervous system. (Reduced blood supply to the brain, associated with cardiovascular deconditioning, may contribute to the unsteadiness.) Return to normal spatial orientation, eye movements, and posture may take several days or even weeks following long space flights.

End Organ, Peripheral, and Cerebellar Changes

The end organs may show some dramatic changes in weightlessness. Although the otoconia appear unchanged, the peripheral synaptic connections apparently are altered significantly in space, at least in rats. Monkey eye movements show normal responses in space despite some apparent alterations in the gain or time constants of the basic semicircular afferent responses to rotation. Fish, when deprived of normal gravity cues, will perform looping swimming motions which may serve a postural reaction to remain level. Fish eye movements and cerebellar activity also support a shift toward visual dominance over vestibular in space.

The Neurolab space mission included a number of experiments aimed at uncovering the underlying neurophysiological sources of neurovestibular adaptation to weightlessness. Purkinje cells in the nodulus regions of the cerebellar cortex, receiving input from the otolith organs, showed significant changes in space, suggesting their role in the short-term plasticity seen in response to weightlessness. In an attempt to identify the areas of the brain involved in the plasticity of balance, the rat brain was studied for changes in Fos and fos-related antigens (FRAs) indicating change in immediate-early genes. Such gene expression was found in the vestibular nuclei, the nucleus of the tractus solitarius, the area postrema, and the central nucleus of the amygdala, as well as in certain cortical and subcortical areas and regions of the hypothalamus and brain stem. The peripheral nerve connections to the hair cells which detect movements of the otolithic membrane are subject to extensive changes during exposure to weightlessness. In rats examined early during space flight and again after 2 weeks, the number of cross-links between adjacent hair cells was extensively increased, relative to ground controls. This suggests that at least some of the sensory adaptation to weightlessness occurs at the periphery, changing the sensitivity and even the function of the otolith organs, rather than occurring entirely centrally.

Orientation

Three-dimensional navigation in weightlessness is challenging for humans, and may be related to our inability to maintain a vertical reference frame. Astronauts frequently experience disorientation when moving from one module of a space station to another one with a different orientation of floor and ceiling. Limited investigation of rat place cells during space flight, and head direction cells during short-duration parabolic flights, support the conclusion that two-dimensional navigation, as carried out on earth, requires the existence of an assumed vertical reference. In its absence, the well-known directional tuning could either disappear or show evidence of a shifted reference frame.

Development

The role of gravity in the normal development of the vestibular system and in the development of balance and locomotion remains a subject of importance, still lacking in significant experimental data in higher animals. Chicks developed in space show head stability problems on return to earth, and the postural reactions of rats after 2 weeks in space show marked deficit, from which they generally recover. However, the question remains open as to the existence of a critical period for exposure to gravity in the development of postural stability and spatial orientation.

Growth Cones

J A Raper, University of Pennsylvania, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neurons communicate with one another through synaptic connections on their dendritic and axonal processes. These processes can be highly elaborate, and axons in particular can grow long distances along highly precise routes to acquire their appropriate targets. At the tip of each growing process is a specialized motile structure called the growth cone. The growth cone contains the cellular machinery that drives process extension. This extension is not random but is guided by signals in the surrounding cellular and extracellular environment. These signals are called guidance cues. Guidance cues are recognized by receptors whose activation controls the direction of growth cone advance through a complex network of signaling pathways that is still being elucidated.

Growth Cone Structure

A growth cone's shape varies greatly depending on its rate of advance, the physical properties of the substratum on which it is growing, and its responses to guidance cues in the outside environment (Figure 1). A growth cone extending on a flat, featureless, and adhesive surface *in vitro* has a characteristic shape (Figure 2). At the tip of a growing axon is a fan-shaped structure which can be divided into three regions: the central, transitional, and peripheral domains. The central domain is closest to the axon and set back from the leading edge. It is rich in microtubules that splay out from the axon as they enter the growth cone. The peripheral domain is at the leading edge of the growth cone. It is composed of thin lamellar sheets and long thin protrusions called filopodia. The predominant cytoskeletal component of lamellae and filopodia is fibrillar actin. Actin is tightly bundled into a rodlike arrangement that fills each filopodium. Actin is organized into a highly cross-linked and branched network with the growing ends pointed predominantly toward the growth cone's leading edge in lamellipodia. The transition zone, as its name implies, is the region between the microtubule-rich central domain and the actin-rich peripheral domain.

Growth Cone Motility

Axonal extension is driven by the motile force generated by the cytoskeletal machinery within the growth cone. Growth cone motility is thought to be the result of force that is generated by a cycle of actin polymerization at its leading edge, myosin-driven retrograde flow of actin polymers through the peripheral domain, depolymerization of actin as it approaches the transition zone, diffusion of the released actin monomers back to the leading edge, and their repolymerization there (Figure 3). The resulting actin cycle generates a tank-tread-like flow of polymerized actin from the front to the back of the growth cone. When the actin-based tank tread gets a grip on the substratum, it can advance the leading edge and draw the growth cone forward. Coupling of the cytoskeleton to the substratum is accomplished by specialized receptors on the surface of the growth cone that recognize and bind to specific molecules in the outside environment. These receptors are indirectly linked to the actin cytoskeleton within the growth cone by cross-linking proteins. Receptors that provide this motility-enhancing function include integrins that recognize extracellular matrix components like laminin, and cadherins or immunoglobulin (Ig) superfamily members that recognize homophilic or heterophilic cadherins or Ig superfamily members expressed on adjacent cell surfaces.

Growth Cone Steering

Time-lapse observations of growth cones *in vitro* and *in vivo* demonstrate that both filopodia and lamellipodia are highly motile structures. Individual lamellae or filopodia appear to advance stochastically, at times and directions that are difficult to predict. Those that do not establish a secure contact with the substratum are soon withdrawn and resorbed, whereas those that establish a secure contact are more likely to become stabilized and persist. Growth cones facing a sharp boundary between a more permissive and a less permissive substratum tend to consolidate advances on the more permissive area while withdrawing more often from the nonpermissive area. In this way, differential adhesion experienced by spatially distinct lamellar and filopodial processes can steer growth cones onto a more permissive area of the substratum.

The growth cone is a highly polarized structure and advances only at its leading edge. Its ability to make sharp turns is limited by this extreme polarization, and it is relatively difficult to induce a turn, by any means, that is greater than about 90°. Growth cones are sensitive to the topology of the surface on which they extend. They tend to orient in the same direction as a grooved or filamentous substratum on which they are growing. A growth cone generates tension on the axon as it advances, and this tension reorients and stimulates additional growth in the

Figure 1 Growth cones were originally described by the famous neuroanatomist Ramón Y Cajal more than a century ago. This is a drawing he made to show the many different shapes they assume (grouped as A, B, and C by Ramón Y Cajal). Some of the variability comes from the stochastic manner in which individual filopodial and lamellar processes advance and withdraw, some is the result of growing in very different environments, and some is due to inherent differences in the overall motile state of the growth cone. From Ramón Y Cajal S (1890) Sur l'origine et les ramifications des fibres nerveuses de la moelle embryonaire. *Anatomischer Anzeiger* 5: 609–613. In Ramón Y Cajal S (ed.) (1995) *Histology of the Nervous System* (Swanson N and Swanson LW, trans.). New York: Oxford University Press. Originally published 1909.

Figure 2 A scanning electron micrograph of a cultured growth cone. Note the thin lamellae and long, thin filopodia (M) projecting radially away from the leading edge and sides of the growth cone. In contrast, few filopodia originate from the traiting edges (T) of the growth cone. This growth cone is approximately 20 μm across. From Wessells NK and Nuttall RP (1978) Normal branching, induced branching, and steering of cultured parasympathetic motor neurons. *Experimental Cell Research* 115(1): 111–122.

Figure 3 A schematic of the motile machinery at the leading edge of a growth cone that is advancing toward the right. Microtubles (olive) are confined to the proximal portion of the growth cone while fibrilar actin (rose) reaches into the distal most leading edge where it extends by polymerization (red). The resulting actin fibrils are contracted and moved backward by myosins (blue). A continuous cycle of actin polymerization at the leading edge, retrograde flow, and depolymerization at the rear is established. This cycle drives the growth cone forward over a substratum (black) decorated with specific permissive molecules (green) that are recognized by complementary cell surface receptors (light blue) which are linked to fibrilar actin (purples).

same orientation. This is likely to represent a reinforcing mechanism by which growth cones are steered toward more-permissive substrata as processes better stabilized against the substratum are likely to generate more tensile force than poorly stabilized processes. This differential tensile force would be expected to stimulate further additional advance toward a point of contact.

The consolidation of adhesive gains or responses to tensile force can be related to changes in the

organization of the growth cone cytoskeleton. Microtubules and fibrillar actin are in a kind of dynamic equilibrium that maintains their relatively high respective concentrations in the central and peripheral domains of the growth cone. The retrograde flow of actin in the peripheral domain tends to carry or push microtubules away from the leading edge. Some individual microtubules polymerize more rapidly than the retrograde flow of actin for brief periods and advance into the peripheral domain, but they cannot sustain high rates of polymerization long enough to remain there, and they get pushed or carried back to the central domain. In this way, a small subset of microtubules constantly probe the more peripheral regions of the growth cone. When filopodia or lamellae make contact with a highly permissive substratum, for example a preferred cell surface, the retrograde flow of actin is slowed by strong coupling to the substratum. Microtubules are then able to advance toward the site of contact (Figure 4). This invasion of microtubules stabilizes the advanced process and appears to bias further extension in the same direction. Treatments that prevent microtubules from polymerizing quickly make growth cones largely insensitive to external guidance cues. This suggests that stabilization of advancing microtubules as they probe the peripheral domain may help lock in actin-based advances at the leading edge.

A second method by which growth cones can be steered is by modulating the propensity of the leading edge to advance. Any localized change that promotes actin polymerization at the leading edge should tend to advance that region of a growth cone, while conversely, localized signals that inhibit actin polymerization or accelerate retrograde transport should induce retreat. Repellent guidance cues like semaphorin 3A can shut down actin polymerization at the leading edge, halting forward advance. When applied locally, semaphorin 3A discourages the advance of nearby lamellae more effectively than those at a distance. Lamellae that are less subject to the repellent signal advance more successfully than those that are close to the repellent stimulus. The growth cone consequently turns away from the localized source of repellent. Many attractants can be expected to work in a converse manner, locally promoting actin polymerization and the local advance of the leading edge of the growth cone.

Guidance Cues and Their Receptors

Growth cone advance in the developing nervous system is not random but highly stereotyped and organized. Axons generally follow reproducible routes to their appropriate targets, indicating that they are guided there by information in their surrounding environment. To be useful, this information must be distributed in a reproducible and spatially heterogeneous pattern. In consideration of what is known about growth cone motility and steering, this information is likely to fall into at least three general categories. The first is physical features that make advance easier in one

Figure 4 Microtubules within a growth cone are reoriented by contact with another cell surface. A sequence of differential interference contrast photographs of cultured snail neurons begins at 0′ with the initial contact between two growth cones. At 2′, the actin-rich leading edge has advanced markedly at the point of contact. Microtubules in the central domain already appear to be turning toward the point of contact. By 4′, microtubules in the left-most growth cone have advanced dramatically toward the portion of the leading edge that is growing rapidly onto the other cell surface. Black arrowheads mark a filopodium from the left-most growth cone extending on the second growth cone, white arrowheads mark a growing lamellum extending from the left-most growth cone onto the other growth cone. From Lin CH and Forscher P (1993) Cytoskeletal remodeling during growth cone-target interactions. *Journal of Cell Biology* 121(6): 1369–1383.

direction than another. For example, axons are sometimes canalized into a specific route by dense tissues on either side of their path. The second is permissive molecules whose distribution can guide axons by making some pathways better for outgrowth than others. This would in principle be a powerful method of determining where nerve tracts form; however, permissive molecules have rarely been found to be expressed in a prepattern that correlates well with axonal outgrowth. Permissive molecules are often more broadly distributed than the trajectories of forming axonal tracts. Finally, signaling molecules can steer growth cones by locally altering cytoskeletal dynamics. Thus far, it is these signaling cues that seem to play the most important role in guiding axons *in vivo*.

A wide range of disparate signaling molecules have been shown to help guide axons *in vivo*. Some of the first to be characterized include members of the semaphorin, netrin, ephrin, and slit families. A large proportion of these family members can act as guidance molecules, although it would be wrong to think of them as being dedicated to this function alone since many contribute to other developmental and signaling events. In addition to these well-recognized guidance families, signaling molecules that were originally identified as morphogens have been strongly implicated as guidance cues, including members of the Wnt, BMP, and hedgehog families. Additional guidance cues have been identified in the cadherin and Ig superfamilies, among others.

For the most part, each guidance cue has a well-defined receptor or receptor complex which must be expressed by a growth cone for it to be sensitive to that particular cue. For example, each semaphorin is recognized by specific members of the plexin family, ephrins by the members of the eph family of transmembrane tyrosine kinases, and slits and netrins by select members of the Ig superfamily. Most often a traditional ligand–receptor pairing triggers a signaling event within the growth cone that alters its direction, but in some cases, homophilic interactions underlie important guidance events, for example between Down syndrome cell adhesion molecule Ig superfamily members in invertebrates. It is interesting that many of the ligands that act as guidance molecules have some of the same general characteristics as receptors, and in some instances it can be shown that 'reverse signaling' occurs where the presumptive ligand acts as a receptor and the presumptive receptor acts as its ligand. Since a growth cone's response to a particular cue in its environment depends on its ability to recognize the cue, some guidance decisions depend critically on the expression of accessory proteins that control receptor expression. For example, whether an axon chooses to cross the midline of the fly central nervous system can be determined by the expression of a protein called commissureless which in turn controls the axonal expression of a receptor for midline repellents.

Signaling molecules that guide growth cones can be further subdivided into those that serve as attractants or repellents. Attractive interactions can be detected in several different ways. *In vitro*, attractants can sometimes promote axonal outgrowth. A surer test for attractant activity is to demonstrate that a localized source of signal turns or attracts axons (Figure 5). Similarly, *in vivo*, ectopic expression of an attractant will orient sensitive axons toward higher levels of expression, while knockdowns of an attractant are expected to reduce axonal trajectories toward the normal source of signal. Repellents are easily detected *in vitro* by their ability to quickly paralyze growth cone motility. A localized source of soluble or surface-bound repellent can redirect growth cones away from a localized source of signal. *In vivo*, misexpression of a repellent will exclude axons from an area they would normally enter or when knocked down and will encourage sensitive axons to invade an area they would normally avoid. It is interesting that the same guidance cue can act as either an attractant or a repellent. This is observed in

Figure 5 The conversion of an attractant into a repellent induced by a cyclic adenosine monophosphate (cAMP) antagonist (a, b). A cultured frog growth cone is induced to turn toward a source of brain-derived neurotrophic factor (BDNF) ejected from a pipette (p). (c, d) After treatment with the cAMP antagonist Rp-cAMPs, growth cones turn away from a source of BDNF. Scale bar = 20 μm (d). From Song HJ, Ming GL, and Poo MM (1997) cAMP-induced switching in turning direction of nerve growth cones. *Nature* 388(6639): 275–279.

the case of netrin-1. Attraction to netrin-1 is mediated by the expression of the DCC receptor, and repulsion is mediated by expression of the unc-5 receptor.

Guidance cues may act either on contact or at a modest distance. Many guidance cues are transmembrane proteins or are coupled directly to lipids on the cell surface. Unless cleaved by a protease, these cues cannot diffuse away from the cell that produces them and are recognized only by growth cones that touch them. Other guidance cues are secreted and can act at a distance. Thus far it appears that this distance is relatively small, perhaps only a few hundred micrometers or so. This relatively limited range may be partially determined by the required steepness of the concentration gradient required to orient growth cones. An additional limiting factor is that some secreted guidance cues are charged and diffuse poorly through the extracellular matrix. Thus, most growth cone guidance decisions are largely local in nature and are determined by the expression of guidance cues on immediately adjacent surfaces or nearby tissues.

Receptor Signaling

Since many of the receptors for guidance cues discovered over the past decade are novel, the signaling pathways through which they control growth cone motility and orientation are only now being determined. Presumably, their signaling must converge on common pathways that control actin polymerization, retrograde flow, and microtubule dynamics. Among the key downstream signaling intermediaries are the Rho family of small guanosine triphosphatases, RhoA, Rac, and CDC42, which are well known to affect actin polymerization and organization in non-neuronal cells. Activation of many of the known guidance receptors stimulates or inhibits the activity of one or more Rho family members. These in turn modulate the activity of a complex circuit of downstream effector proteins which reorganize the cytoskeleton. A second signaling intermediary of some importance is the divalent cation calcium. Its overall intracellular concentration has been shown to affect growth cone motility, while localized intracellular perturbations in calcium levels can induce localized changes in the cytoskeleton and steering of the growth cone. The activation of some but not all guidance receptors induces significant changes in intracellular calcium that are important in the growth cone's response. A third key signaling component appears to be cyclic nucleotides such as cyclic adenosine monophosphate (cAMP). Altering their internal concentrations can alter how growth cones respond to a given guidance cue. In the most dramatic examples, altering cAMP levels can convert an attractant into a repellent or a repellent into an attractant (Figure 5). From these observations it is evident that the internal state of the growth cone affects how it responds to outside guidance cues.

The growth cone has been a source of fascination ever since it was first described by the famous neuroanatomist Ramón Y Cajal more than a century ago. During the intervening years, great progress has been made in elucidating the basic mechanism through which growth cones advance and identifying many of the guidance cues that steer growth cones. Even so, much remains to be discovered. The signaling pathways through which guidance receptors control the cytoskeleton are only partly known, and a fuller understanding of this signaling circuitry will be essential in understanding how growth cones integrate and respond to multiple competing guidance cues. From a developmental perspective, much of the information about where and when guidance cues affect axon trajectories is fragmentary and incomplete. A more systematic, systems-based examination of all the guidance cues involved in determining any given axonal trajectory will be required to fully explain how growth cones are guided to their correct targets.

Growth Factors: Neuronal Atrophy

M von dem Bussche and M H Tuszynski, University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Growth factors are proteins that bind to specific receptors on the cell surface, with the primary effect during nervous system development of stimulating cell proliferation, neuronal differentiation, or neurite outgrowth. Expression of growth factors and their receptors continues in the nervous system throughout adulthood, where the growth factors act to modulate the functional state of neurons, influence synaptic efficacy, and potentially modify neuronal structure. Growth factors also exert potent effects on cell survival and axonal outgrowth in animal models of nervous system disease or age-related atrophy. This article focuses on the roles of growth factors in affecting neurons in a state of atrophy arising from either aging or disease.

Classification

More than 50 proteins with growth factor-like properties have been identified in the nervous system. Many of these are grouped into related families of molecules, including the neurotrophins, the glial cell line-derived neurotrophic factor (GDNF) family of ligands (GFLs), the cytokine growth factors, the insulin-like growth factors (IGFs), the fibroblast growth factors, and the hepatocyte growth factor family. These are summarized in Table 1. Effects of individual growth factors, with specific reference to models of aging and neuronal injury, are described in greater detail in the following sections.

The Neurotrophin Family

Nerve growth factor (NGF) The first growth factor to be identified was nerve growth factor (NGF), originally described by Rita Levi-Montalcini and Viktor Hamburger more than 50 years ago. NGF supports the survival of sensory and sympathetic neurons of the peripheral nervous system and establishes the patterning and timing of cholinergic innervation of the hippocampus during development. Of particular interest in the context of neuronal atrophy and aging, NGF promotes the survival and function of cholinergic neurons of the central nervous system (CNS).

Degeneration of basal forebrain cholinergic neurons (BFCNs) occurs in the aged brain and is an early and prominent feature of several age-related disorders of the nervous system, including Alzheimer's disease (AD) and such 'system degenerations' as progressive supranuclear palsy. Considerable evidence from animal studies suggests that NGF ameliorates basal forebrain cholinergic atrophy in models of both aging (Figure 1) and disease, with further evidence that NGF attenuates cognitive deficits. This evidence has emerged from both rodent and primate models. Further, elimination of NGF-producing cells in the hippocampus of intact adult rats by excitotoxic lesions induces atrophy of BFCNs, indicating an ongoing requirement for NGF to support cholinergic neuronal function in the intact brain.

Aging and NGF. With normal aging, cholinergic neurons of the rat and primate brain become atrophic, exhibiting reductions in neuronal size and function. However, there is little if any detectable death of cholinergic neurons as a function of aging, based on 'stereological' methods of quantification that correct for variations in cell size, brain volume, and sampling error when calculating total neuronal number. Yet aged cholinergic neurons are clearly hypofunctional, reflected by shrinkage in cell size and reduction in a variety of biochemical measures, including but not limited to choline acetyltransferase, high-affinity choline uptake, acetylcholine release, and expression of neurotrophin receptors. There is also evidence that age-related alterations in the electrophysiological properties of cholinergic systems occur, including perturbations in the ability of cholinergic systems to synchronize theta activity with activity generated in hippocampal targets. Collectively, there is evidence suggesting that hypofunctionality of the cholinergic system contributes to the extent and severity of cognitive decline with aging.

One of the earliest-described and most striking effects of growth factors in the adult nervous system came with the report of Fischer et al. in 1987 that NGF administration to aged rats reversed cognitive deficits and restored morphological features of cholinergic neurons. NGF was infused intracerebroventricularly into aged rats, and within a 2-week time period the animals exhibited significant improvement in spatial memory, functioning at the level of young rats in the Morris water maze (Figure 2). Anatomical analysis demonstrated a reversal of cholinergic neuronal atrophy and restoration of labeling for choline acetyltransferase to levels equaling those in young animals. This, together with earlier evidence that NGF prevents cholinergic neuronal death in a fimbria-fornix lesion model in young animals, ushered in an era of intense interest in and research on the effects of

Table 1 A partial list of identified growth factors

Family	*Growth factor*	*Preferred receptor(s)*
Classic neurotrophins	Nerve growth factor (NGF)	TrkA, $p75^{NTR}$
	Brain-derived neurotrophic factor (BDNF)	TrkB, $p75^{NTR}$
	Neurotrophin-3 (NT-3)	TrkC, $p75^{NTR}$
	Neurotrophin-4 (NT-4)	TrkB, $p75^{NTR}$
Glial cell-derived	GDNF	Ret, GFRα-1
neurotrophic factor (GDNF)	Neurturin	Ret, GFRα-2
family of ligands (GFLs)	Artemin	Ret, GFRα-3
	Persephin	Ret, GFRα-4
Cytokine family	Ciliary neurotrophic factor (CNTF)	gp130, LIFRβ, CNTFRα
	Leukemia inhibitory factor (LIF)	gp130, LIFRβ
	Cardiotrophin-1 (CT-1)	gp130, LIFRβ, CT1R
	Oncostatin-M (OSM)	gp130, OM1Rα, β
	Interleukin (IL)-6	gp130, IL-6Rα
	Interleukin (IL)-2–7,-9,-11,-12,-15	gp130, ILRs
	Granulocyte-colony stimulating factor (G-CSF)	G-CSFR
	Granulocyte-macrophage colony-stimulating factor (GM-CSF)	GM-CSFRα, β_C
	Leptin	Leptin receptor
Insulin-like growth factor	IGF-1	IGFR-1
(IGF) family	IGF-2	IGFR-1,2
Fibroblast growth factor	FGF 1 (aFGF)	FGFR1–4
(FGF) family	FGF 2 (bFGF)	FGFR1–3
Hepatocye growth factor	HGF	Met
(HGF) family	Macrophage-stimulating protein (MSP)	Ron
Epidermal growth factors (EGFs)	Neuregulin (ARIA)	NEU/ERBB2,3 RTK
	Neuregulin 3	ERBB4 RTK
	Netrin 1,2	Unc/DCC families
	TGF-α	EGFR
	Amphiregulin	EGFR
Others	Bone morphogenic proteins (BMPs)	BMPRs
	Midkine (NEGF2)	Syndecan-1
	Stem cell factor	c-kit
	Platelet-derived growth factor (PDGF)	PDGFR α, β
	Saposin C	?
	Semaphorins	Neuropilin, plexins

growth factors in the adult nervous system. The initial report of Fischer and colleagues was confirmed by several subsequent reports.

Following these findings in aged rodents, Smith et al. in 1999 and Conner et al. in 2001 reported that aged rhesus monkeys also exhibit atrophy in morphological features of cholinergic neurons and that NGF administration restores these markers to levels of young primates. Stereological quantification indicated that, as a function of normal aging, rhesus monkeys exhibit a 40% reduction in the number of cells expressing cholinergic markers and a 10% shrinkage in the remaining cholinergic neurons. Quantification of Nissl-stained sections in the same subjects indicated that cholinergic neurons were atrophic but not dead, paralleling observations of age-related atrophy rather than death of cholinergic neurons in rodent studies. NGF gene delivery to the brains of aged monkeys restored the morphological parameters of cholinergic neurons to levels of young monkeys, including the number of neurons labeled for choline acetyltransferase and the low-affinity neurotrophin receptor p75, and the size of neurons. Conner and colleagues subsequently reported that aged rhesus monkeys also exhibit a 25% reduction in cholinergic terminals innervating cortical target regions, including frontal, temporal, and parietal cortices. NGF gene delivery to the cholinergic somata restored the density of cortical cholinergic axons in the cortex to levels of young monkeys.

Thus, a variety of age-related neurodegenerative effects are sensitive to growth factors in rodent and primate models. However, age-related atrophy of these systems does not appear to be caused by deficient growth factor production, because NGF protein and mRNA levels do not decline in aging.

Other studies provide further support for the trophic effects of NGF on cholinergic systems of the basal forebrain. Hefti, Kromer, Williams, and their colleagues in the mid-1980s separately reported that NGF administered to the brains of adult rats prevented the death of basal forebrain cholinergic neurons after

Figure 1 NGF ameliorates age related neuronal atrophy. (a–c) Immunolabling for p75, a marker of cholinergic neurons, in aged-control, aged-NGF-treated, and young rats, respectively. Aged rats show a reduction in functional cholinergic markers, and reversal of age-related atrophy with lentiviral NGF gene transfer. Insets, higher magnification. (d) Quantification of labeled neuron number using stereological methods. Scale bar = 35 μm. Reproduced by permission of A Blesch, Department of Neurosciences, UCSD.

Figure 2 Behavioral performance on the Morris water maze of young, aged-impaired, aged non-impaired, and NGF-treated aged impaired rats (mean +/− s.e.m.). Performance is measured as swim distance to reach the hidden platform. The NGF-treated group alone improved significantly in week 2 compared to week 1 (cross). For week 2, the NGF-treated aged impaired group differed significantly from the control aged impaired group (asterisk). fimbria-fornix lesions. Whereas this lesion model ordinarily results in the death of 75–90% of cholinergic neurons over a 1-month period, NGF infusions rescue 90–100% of the cells. Tuszynski et al., Koliatosis et al., and Kordower et al., in separate studies, confirmed the neuroprotective effects of NGF after fornix lesions in the brains of adult primates. Excitotoxic mechanisms of injury to cholinergic neurons of the nucleus basalis of Meynert in rats were also prevented by NGF administration. Mobley and colleagues further reported that trisomy 16 mice, a model of Down syndrome in which an extra copy of the amyloid precursor protein (APP) gene is expressed, exhibit spontaneous atrophy of cholinergic neurons. NGF administration reversed cholinergic atrophy in these mice and improved learning and memory. Potential NGF effects have also been explored in transgenic mice either overexpressing APP or expressing mutant forms of APP; however, stereological quantification to date has disclosed no loss of cholinergic neurons in the brains of APP transgenic mice (reflecting the imperfect nature of APP overexpression as a complete model of AD).

Thus, NGF exerts potent effects on the survival and functional state of BFCNs. In AD, the most common human neurodegenerative disorder, basal forebrain cholinergic neuronal degeneration is an early and

prominent feature, likely contributing to cognitive impairment. Although NGF levels do not decline in either the aged or the AD brain, NGF transport from the cortex to the cholinergic basal forebrain is impaired. These findings collectively constitute a rationale for testing the hypothesis that NGF delivery in AD might improve cognition or cognitive decline. This hypothesis has undergone preliminary testing in human clinical trials.

Brain-derived neurotrophic factor (BDNF) and neurotrophin-4 (NT-4) Brain-derived neurotrophic factor (BDNF) and neurotrophin-4 (NT-4) are related growth factors sharing more than 50% amino acid homology that exhibit preferential binding to the tyrosine kinase receptor B (trkB) neurotrophin receptor. During nervous system development, BDNF and NT-4 influence the survival and patterning of several neuronal projections, and homozygous BDNF gene deletion in mice leads to early postnatal death. Notably, BDNF, NT-4, and trkB are extensively expressed in the adult and aged brain, suggesting ongoing roles throughout life in modulating neuronal function. Indeed, the existing evidence supports a direct and important role for these growth factors in modulating neuronal plasticity and function throughout life.

Several studies have examined the role of BDNF in the adult brain. BDNF is produced in most cortical regions and the hippocampus at all stages of life, and is actively trafficked along neuronal circuits in both anterograde and retrograde directions. Thus, BDNF may act as a molecular signal to support neuronal activity. Further, mRNA for BDNF is trafficked to dendrites, suggesting that its short-term availability in regions of synaptic activity may influence brain function. Notably, BDNF application to hippocampal slices can induce long-term potentiation and facilitate neurotransmitter release, confirming a role in modulating synaptic activity. Indeed, recent studies have indicated that BDNF availability is essential in at least two brain circuits to establish learning or experience: the amygdala and dopaminergic projections to cortex that influence addiction.

There are contradictory reports regarding the fate of BDNF in the aged brain. Some studies indicate that BDNF mRNA and protein levels are stable with aging, arguing against a direct role of this growth factor in events leading to age-related neuronal decline. Other studies suggest modest reductions of BDNF levels in the hippocampus or temporal cortex with aging. The question awaits resolution. It is clear, however, that BDNF levels decline in the temporal cortex in AD, potentially contributing to neuronal degeneration. Experiments in progress are exploring the potential protective effects of BDNF in animal models related to AD.

A number of experimental models have also reported neuroprotective effects of BDNF on cell degeneration in the striatum, substantia nigra, and motor neurons. BDNF has also been reported to induce neurogenesis in the adult brain. The possibility exists, therefore, that BDNF augmentation could be of therapeutic benefit in human disease.

Glial Cell-Derived Neurotrophic Factor Family

GDNF and neurturin A second major family of growth factors in the adult CNS is the GDNF family of ligands, or GFLs. This family consists at present of GDNF, neurturin (NTN), artemin, and persephin. GDNF and NTN have been the most extensively studied. Among the populations of neurons influenced by these growth factors are nigral and motor neurons and neurons comprising the parasympathetic nervous system.

The effects of GDNF and NTN on nigral neurons have generated much interest in their potential use as therapeutic agents in the treatment of Parkinson's disease. Following 6-OH-dopamine lesions in rats and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) lesions in primates, both GDNF and NTN potently prevent nigral neuronal degeneration and promote striatal reinnervation, leading to significant improvement on behavioral assays that assess motor function.

GDNF and NTN also reverse age-related morphological and functional decline of nigrostriatal function. Aged rhesus monkeys exhibit a reduction in cellular and biochemical indices of striatal function, including reductions in levels of dopaminergic transmitters and their metabolites. These age-related atrophic events are paralleled by losses of striatal fluoro-dopa uptake on positron emission tomography (PET) scans. There are varying reports in the literature regarding the functional consequences of age-related nigrostriatal degeneration in primates, with some claims of functional integrity in motor tasks reflecting nigrostriatal functions in aged primates, and other reports of age-related decrements in motor function. Notably, provision of GDNF or NTN to the nigrostriatal system in aged primates enhances biochemical, anatomical, and PET-related measures. These effects are observed whether growth factors are administered by direct protein delivery or via gene therapy methods. Some studies also report benefits of growth factors

on motor performance in aged monkeys. Thus, paralleling observations of NGF on cholinergic systems, GDNF and NTN exhibit a capacity to directly amelioriate atrophic changes in nigrostriatal systems.

Clinical trials of GDNF, NTN, and other growth factors have been performed in Parkinson's disease. Early trials likely failed to deliver growth factors to the nigrostriatal system in sufficient doses to allow detection of potential beneficial effects. More recent trials, currently in progress, will provide the first true test of the hypothesis that growth factor delivery to the striatum will influence the clinical course of Parkinson's disease.

Insulin-Like Growth Factor-1

In the developing nervous system, IGF-1 promotes neurite outgrowth and can influence the survival of several neuronal populations, including primary motor neurons. The receptor for IGF-1 continues to be broadly expressed in the adult nervous system, and neuroprotective effects of IGF-1 have been reported in a variety of neuronal systems in the brain, including the cortex and hippocampus.

There has been a particular focus, however, on the possible use of IGF-1 as a treatment for motor neuronal degeneration that occurs in amyotrophic lateral sclerosis (ALS). In several models of motor neuron atrophy and degeneration, IGF-1 has been reported to protect motor neurons. These models include *in vitro* motor neuronal survival assays, motor nerve transection lesions that induce neuronal atrophy, and motor root avulsion lesions that lead to neuronal death. In all of these models, IGF-1 protects motor neurons. More recently, IGF-1 was reported to promote the survival of spinal cord motor neurons in transgenic mice expressing forms of superoxide dismutase mutation that occur in familial ALS.

A clinical program tested the ability of peripherally administered IGF-1 to alter the course of ALS. This program was in fact carried through two large phase three clinical trials: one trial showed efficacy, but the other did not, and the growth factor was not approved for human use. However, another National Institutes of Health (NIH)-sponsored multicenter controlled trial of IGF-1 in ALS is currently under way to establish definitively whether in fact IGF-1 will benefit the sporadic form of ALS. It was recently reported that gene delivery of IGF-1 to motor neurons utilizing retrograde transport of viral vectors may be a superior means of delivering the growth factor to necessary targets in the spinal cord. Additional preclinical studies are testing this possibility.

Summary

Neuronal atrophy is a feature of aging and a component of progressive neurodegenerative disorders and nervous system trauma. Many growth factors have been demonstrated to ameliorate neuronal atrophy, prevent cell death, and enhance the functional state of the neuron in models of disease. Indeed, neutralization of growth factor production or signaling in the normal brain appears to cause neuronal atrophy. Success in capturing the biological properties of the growth factors to treat human disease has been elusive, however, due to challenges in delivering growth factors into the CNS in a sustainable and safe manner. Nonetheless, such efforts are continuing. For the present, the study of growth factors remains an informative route to further our understanding of the signaling, structure, and function of the nervous system.

Introduction

Growth hormone (GH) is a single-chain protein of 191 amino acids with a molecular size of approximately 22 kDa that is synthesized by and secreted from the somatotroph cells of the anterior pituitary gland. GH exerts a broad spectrum of effects, leading to the promotion of growth and the regulation of carbohydrate, lipid, protein, and mineral metabolism. GH synthesis and secretion are regulated in a complex manner, primarily through the actions of hypothalamic neuropeptides that integrate hormonal, metabolic, and neurogenic signals. Alterations in GH secretion lead to disorders of growth and metabolism. This article addresses the identification and structure of this critical hormone, its expression and regulation in the pituitary gland, its mechanisms of action, both peripherally and within the central nervous system, diseases of GH secretion, and the therapeutic use of GH.

Identification and Structure of Growth Hormone

The first suggestion that the pituitary was a site of synthesis of a growth-promoting substance resulted from the observations of Marie in 1886 of pituitary gland tumors associated with acromegaly. Following this lead, Evans and Long directly demonstrated the ability of pituitary extracts to augment growth in the dog and rat, leading to the development of a rat tibial bioassay used to purify GH from the bovine pituitary. Determination of the primary structure of human GH revealed a protein that is similar in sequence to human chorionic somatomammotropin, also known as placental lactogen (Figure 1).

The primary structure of GH from numerous species was rapidly deduced through complementary deoxyribonucleic acid (cDNA) cloning techniques, beginning with the characterization of rat pituitary GH cDNA. The subsequent sequencing of human GH led to the production of recombinant hormone used for treating GH deficiency, and the sequencing of bovine GH has led to its use for enhancing milk production in cattle. Molecular cloning also led to the identification of the structure of the GH gene, which contains five exons separated by four introns. The human GH gene transcript undergoes alternative ribonucleic acid (RNA) processing to encode either the 22 kDa polypeptide or a shorter 20 kDa species, referred to as variant GH, which constitutes up to 20% of pituitary GH and may have altered biologic properties. The human GH gene, designated GH1 and which encodes growth hormone normal (GH-N), is part of a cluster of five related genes found in a 50 kb locus on chromosome 17. The locus also includes the genes for the chorionic somatomammotropins (CSH1, CSH2, and CSHP1) and for growth hormone variant (GH-V) (the GH2 gene), a form of GH expressed only in the placenta that becomes the predominant GH form during the latter half of pregnancy. GH-V differs from GH-N at 13 amino acid positions and exhibits most or all the biologic effects of GH-N, though its significance in fetal development is not well understood.

The crystallographic structure of GH was determined by radiographic diffraction techniques using genetically engineered porcine GH. The molecule consists of four antiparallel alpha helices with a unique connectivity, arranged in a left-twisted bundle. The other GH-related proteins are believed to share this same basic structure.

Expression and Regulation of GH

The GH gene is expressed in the pituitary gland during fetal development. Although GH gene expression in the rat is not detected until day 18 of gestation, in the human, serum GH is measurable by the end of the first trimester. GH is expressed exclusively in somatotrophs and, together with prolactin, in mammosomatotrophs. These cell populations vary depending on the species and the physiologic state and have been proposed to interconvert in the adult pituitary by transdifferentiation. The specific expression of GH in somatotrophs or mammosomatotrophs derives, in part, from the selective expression of the transcription factor Pit-1, a POU–domain protein found in somatotrophs, lactotrophs, and thyrotrophs. Pit-1 is required for transcription of the GH gene, where it appears to act together with a zinc finger protein, Zn-15. Mutations that disrupt the Pit-1 gene in the Snell or Jackson dwarf strains of mice and in some human patients with combined pituitary hormone deficiency result not only in a loss of GH expression but also in a failure of pituitary cells expressing Pit-1 to differentiate appropriately, resulting in pituitary hypoplasia. Another nuclear transcription factor, Prop1, is required to activate Pit-1 expression. Whereas Pit-1 mutations are rare, Prop1 mutations are the most common cause of multiple pituitary hormone deficiency in humans. The phenotype shows considerable variability but usually includes severe hypopituitarism owing to the lack of cells synthesizing

Figure 1 Structure of human growth hormone (GH) and its gene. Panel (a) shows the structure of the human GH gene, which includes five exons (I–V) and four introns. Alternative RNA processing generates the messenger RNA encoding the variant 20 kDa GH, as indicated. Panel (b) shows the primary sequence of human GH. The boxed residues are deleted from the 20 kDa variant GH. Panel (c) is a schematic representation of the crystallographic structure of porcine GH, a four-helix-bundle protein. Adapted from Abdel-Meguid SS, Shieh HS, Smith WW, et al. (1987) Three-dimensional structure of a genetically engineered variant of porcine growth hormone. *Proteomics* 84: 6434–6437.

GH, prolactin, and thyroid-stimulating hormone. Patients with Prop1 mutations may exhibit, in addition, gonadotropin deficiency. An animal model of Prop1 deficiency, the Ames dwarf mouse, has also been described. Other transcription factor mutations also cause GH and/or combined pituitary hormone deficiencies as a result of impaired pituitary gland development during fetal development.

Regulation of GH synthesis and secretion occurs through the integrated action of numerous peptide and nonpeptide hormones. The neuroendocrine control of GH is mediated predominantly by the hypophysiotropic hormones: GH-releasing hormone (GHRH) and somatostatin (Figure 2). These neuropeptides interact with specific G-protein-coupled receptors expressed by the somatotrophs, leading to activation

Figure 2 Neuroendocrine regulation of growth hormone (GH) secretion. GH-releasing hormone (GHRH) and somatostatin effects on GH synthesis and secretion are indicated. In addition to modulating proliferation, differentiation, and metabolic events in target cells, GH induces synthesis of insulin-like growth factor 1 (IGF-1), important for mediating many effects of GH on body growth and for negative feedback regulation, indicated by the arrows. Ghrelin also stimulates GH secretion at both pituitary and hypothalamic levels, though its role in physiologic regulation of the hormone is unclear.

(GHRH) or suppression (somatostatin) of adenylate cyclase and a corresponding change in intracellular cyclic adenosine monophosphate (cAMP) levels and an alteration in intracellular Ca^{2+}. GHRH stimulates GH synthesis and GH secretion, and chronic GHRH exposure results in somatotroph proliferation. Somatostatin exerts its effects predominantly at the level of GH secretion but also attenuates GHRH-induced GH gene expression and somatotroph proliferation. Many additional peptide hormones are reported to have modulatory effects on GH synthesis or secretion, including galanin, neuropeptide Y, and thyrotropin-releasing hormone, though their physiologic relevance is quite limited.

Potent synthetic GH secretagogues (GHSs) have been designed, initially based on a synthetic enkephalin-related hexapeptide (GHRP) and more recently on nonpeptide mimetics of GHRP. The GHRPs bind to the GHS receptor and appear to act at both the hypothalamic and the pituitary level. The endogenous ligand of the GHS receptor, ghrelin, has recently been identified and, like the GHRPs, potently stimulates acute GH release through both hypothalamic and pituitary actions. The stomach is the major site of ghrelin production, and its secretion is regulated by food intake. It may have a role in mediating the nutrient regulation of GH secretion although it does not appear to exert a role in other neuroendocrine control mechanisms for GH.

Nonpeptide hormones that modulate GH synthesis include glucocorticoids, which increase both GH gene transcription and messenger RNA (mRNA) stability, and thyroid hormones, which exert principally stimulatory actions on GH expression, although suppressive effects of thyroid hormones have been observed in experiments with the human GH gene.

GH secretion from the pituitary is pulsatile, with 8–12 peaks during a 24 h period, and the pulsatility is believed to be important for the physiologic actions of the hormone. GH secretion is augmented during sleep, by exercise, and during puberty, whereas it progressively decreases with aging. Negative feedback effects constitute a major component of GH secretory regulation. GH, GHRH, and somatostatin are all subject to feedback regulation, as is insulin-like growth factor 1 (IGF-1), the synthesis of which is induced in numerous target tissues in response to GH. IGF-1 exerts feedback effects at both the pituitary and the hypothalamic levels by suppressing GH and GHRH secretion and stimulating somatostatin secretion while GH feedback effects occur in the hypothalamus by stimulating somatostatin and inhibiting GHRH secretion.

Mechanism of Action of GH

GH exhibits a broad range of biologic actions which promote cellular differentiation and proliferation leading to increased growth and also exert non-growth-related metabolic effects. Many of the rapid actions of GH are believed to be direct, but a significant portion of its effects on body growth are mediated by IGF-1. GH induces IGF-1 generation in response to GH in numerous tissues including the liver, which is a major target of GH action. Circulating IGF-1 is derived primarily from hepatic secretion and, together with locally produced IGF-1 acting in a paracrine or autocrine manner, exerts a role in body growth.

Most GH in circulation is bound to a GH-binding protein (GH-BP), the N-terminus of which is identical to the cell surface GH receptor (GH-R), through which GH exerts its actions. Cloning of the common cDNA for GH-BP and GH-R revealed the receptor to be a protein of 638 amino acids that spans the plasma membrane, whereas the binding protein represents the extracellular domain of this receptor. The soluble binding protein is released from the mature receptor by proteolysis in some species (rabbit and human) and is encoded by a distinct mRNA

generated through alternative RNA splicing of the GH-R transcript in other species (rat and mouse). The radiographic crystallographic structure of the extracellular domain of the GH-R bound to GH consists of one molecule of GH interacting with two receptor molecules. Distinct domains within the GH molecule interact with unique sites in the two receptor molecules to form this complex.

The GH-R is a member of the cytokine receptor superfamily. The extracellular domains of these receptors include two pairs of conserved cysteine residues. The cytoplasmic domains are quite divergent but do share a proline-rich motif near the transmembrane domain. The initial step in GH signal transduction involves the binding of GH to its receptor followed by receptor dimerization. Janus kinase 2 (JAK2), a cellular protein tyrosine kinase that binds to the dimerized GH-R via the receptor's proline-rich motif, is activated in response to GH treatment. The activated JAK2 undergoes autophosphorylation and also phosphorylates the associated GH receptor on tyrosines which, in turn, recruit a variety of signaling proteins, many of which are then phosphorylated by JAK2. These signaling proteins include a group of cytoplasmic proteins – signal transducers and activators of transcription (STATs) – which translocate to the nucleus and regulate transcription, thereby mediating the actions of GH on gene expression. Among these, STAT5-b appears to exert a critical mediating role. The mitogen-activated protein kinases are also activated in response to GH, and roles for phospholipase C, protein kinase C, insulin receptor substrate/phosphatidyl inositol 3′ kinase/AKT pathways in GH signaling have been suggested (Figure 3). Additional adapter proteins (e.g., grb10, SH2-B), proteins that regulate the actin cytoskeleton and cell motility, and proteins in the JNK pathway have also been implicated in GH signaling.

Mutations of the GH receptor gene (Laron syndrome) or in genes encoding downstream signal transduction proteins (e.g., STAT5-b) lead to a GH insensitivity syndrome that consists of elevated GH levels, reduced IGF-1 concentrations, and impaired linear growth.

In addition to its growth-promoting effects, GH exhibits many effects on metabolic processes. Effects

Figure 3 Signal transduction by growth hormone (GH) and its receptor. A single GH molecule binds through distinct sites on the hormone to two receptor molecules. The Janus kinase family member Janus kinase 2 (JAK2) that associates with the dimerized GH receptor is activated by GH binding, resulting in tyrosine phosphorylation of both JAK2 and the GH receptor. Activated JAK2 phosphorylates members of the signal transducers and activators of transcription (STAT) family of proteins, which then move to the nucleus and regulate the transcription of target genes. GH activates the mitogen-activated protein kinase (MAPK) pathway, perhaps through interaction of the phosphorylated receptorJAK2 complex with Shc. Insulin receptor substrates (IRS) and downstream signaling proteins including phosphatidyl inositol 3′kinase (PI3K) are also recruited into GH signaling pathways, as are a variety of other proteins, including adapter proteins. These pathways mediate GH regulation of gene transcription, the cytoskeleton, and other cellular responses.

on carbohydrate metabolism include both an enhancement of insulin release and an insulin-antagonistic effect, mediated in part by the hormone's marked lipolytic activity. The insulin resistance is responsible for the diabetogenic effects of the hormone. GH enhances amino acid uptake and protein synthesis in GH-responsive tissues such as muscle, liver, and kidney and is important in tissue hypertrophy. GH effects on mineral metabolism include enhancement of both bone turnover and bone mineral deposition and are important in bone growth and maintenance of normal bone integrity.

GH Effects in the Central Nervous System

Small amounts of GH are produced in several different brain regions, and there appear to be mechanisms for GH transport across the capillary bed-blood–brain barrier. GH exerts trophic effects within the brain in both embryonic and postnatal development and may also have some neuroprotective effects. However, many, if not all, of the effects of GH may be mediated by IGF-1 that is produced locally.

Disorders of GH Secretion and Therapeutic Uses of GH

Short stature resulting from GH deficiency occurs with a frequency ranging from 1 in 4000 to 1 in 10 000 births. Some cases are associated with midline developmental defects, and up to 30% may have a genetic basis, though the cause remains unknown in the majority of cases. The familial isolated GH deficiencies (IGHDs) include at least four distinct disorders. IGHD-1A is the most severe and is associated with deletions or inactivating mutations of the GH gene. In IGHD-IB, GH levels are low but detectable. Some cases appear to involve more-subtle mutations at the GH1 locus, but many cases are likely to involve mutations in other genes, such as the GHRH receptor gene. Both IGHD-IA and -IB exhibit autosomal recessive inheritance. IGHD-II patients have clinical characteristics similar to those with IGHD-IB but exhibit an autosomal dominant mode of inheritance. IGHD-II is most commonly caused by mutations in the third intron of the GH gene, leading to a splicing defect and loss of exon 3, though other missense mutations have also been observed. IGHD-III is an X-linked recessive disease that is clinically diverse and may represent mutations at multiple loci. Animal models of GH deficiency include the Snell and Jackson dwarf mice, which result from mutations in the transcription factor Pit-1 and represent a loss of the thyrotroph, somatotroph, and lactotroph lineages; the phenotypically similar Ames dwarf mouse, which is caused by a mutation in the Prop1 transcription factor gene; the Little mouse, which is a mutation in the pituitary receptor for GHRH and a model for IGHD-IB; the spontaneous dwarf rat, which results from abnormal splicing of the GH mRNA; and the Lewis dwarf rat, which most likely represents a defect in the GHRH signal transduction pathway.

Hypersecretion of GH results in gigantism when it occurs prior to closure of the long bone epiphysial growth plates, or acromegaly when it occurs afterward, and is most commonly associated with a GH-secreting pituitary tumor. Strong evidence exists for clonality of these somatotroph tumors. As many as 40% of such tumors are associated with activating mutations in the stimulatory G-protein alpha-subunit in somatotroph cells that result in the constitutive presence of a cAMP signal normally modulated by the actions of GHRH and somatostatin. A small minority of cases of acromegaly result from the hypersecretion of GHRH by a variety of endocrine tumor types and, rarely, by ectopic GH secretion. Animal models for GH hypersecretion include transgenic mice that grow to be twice normal size, resulting from transgenic overexpression of the GH. Transgenic mice that overexpress GHRH serve as a model for tumors with ectopic GHRH secretion.

GH therapy has been extensively used in the treatment of short stature associated with GH deficiency, particularly after the availability of recombinant human GH in 1986. Treatment with recombinant human GH produces few side effects. However, when administered in excess, GH causes fluid retention, swelling of hands and feet, arthralgias, and neural entrapment (carpal tunnel syndrome) similar to the early signs and symptoms of acromegaly. With the increased availability of GH, its use as a therapeutic agent has increased dramatically in the past decade. Recombinant human GH has proven an effective means of stimulating growth in children with primary GH deficiency or growth failure associated with Turner's syndrome, chronic renal failure, Prader-Willi syndrome, or intrauterine growth retardation. More recently, it has been used to stimulate growth in children with idiopathic short stature, unassociated with GH deficiency, who are presumed to have varying degrees of GH insensitivity.

In addition to its uses in the clinical management of growth deficiencies in children, GH is used for treatment of GH-deficient adults and has been evaluated in postsurgical and burn patients and in patients with AIDS, among others. The use of GH therapy in GH-deficient adults is controversial. In most studies, treatment has been reported to result in increases in lean body mass and bone density, decreases in body fat and serum cholesterol, and in some, an increased

quality of life. However, the increases in lean body mass do not appear to lead to increased muscle function. Some of these effects of GH therapy have also been reported in normal aging adults, where a progressive reduction in endogenous GH secretion occurs. However, a relatively high incidence of adverse treatment effects has limited overall enthusiasm in this population, and at present, the use of GH in aging must still be considered as investigational. Evidence that GH therapy restores the reduced life expectancy of hypopituitary patients to normal is lacking, and observations of mice with genetic models of GH deficiency (described earlier) as well as humans with genetic disorders of GH deficiency have found no shortening of life expectancy or premature atherosclerosis.

Hair Cell Differentiation

C Puligilla and M W Kelley, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

The primary transducers for the sensations of hearing, balance, and acceleration are mechanosensory hair cells located within the auditory and vestibular regions of the inner ear. The auditory region comprises the spiral-shaped cochlea, which contains the organ of Corti, an elongated sensory epithelium with approximately 20 000 mechanosensory hair cells arranged into four or five distinct rows (Figure 1(a)). The vestibular system comprises three semicircular canals, each with associated ampullae and two saclike structures, the utricle and the saccule. The ampullae of each semicircular canal contain a sensory crista that detects angular acceleration, and the utricle and saccule each contain a macula for the detection of linear acceleration (Figure 1(b)). Regardless of location within the ear, all sensory epithelia are composed of two basic cell types, mechanosensory hair cells and nonsensory supporting cells, arranged in a pseudostratified configuration with hair cells located adjacent to the lumenal surface and single or multiple layers of supporting cells located between the hair cell layer and the basement membrane (Figure 1(c)). Because the epithelium is pseudostratified, all supporting cells extend processes that terminate at the lumenal surface. Mechanosensory hair cells derive their name from a group of modified group of microvilli, referred to as stereocilia, that extend from the lumenal surface of each cell. The group of stereocilia appears similar to a tuft of hair. Deflection of the stereociliary bundle in response to fluid movement in the lumenal space results in a depolarization of the resting potential and changes in the rate of neurotransmitter release.

Prosensory Specification

All hair cells are derived from one or two specialized regions, referred to as prosensory patches, which arise in the ventromedial wall of the bilateral otocysts, placodally derived structures that originate adjacent to the hindbrain. With continued development, the otocysts undergo a number of morphogenetic changes to give rise to all of the auditory and vestibular structures of the inner ear. At the same time, cells from these prosensory patches become distributed throughout the ear to form the various sensory epithelia just described. The factors that specify the prosensory patches have not been conclusively identified, but several genes that are known to regulate cellular identity in other systems are expressed at early times in prosensory patch development. These include *Jagged1, Sox2, Lunatic fringe (Lfng), Pax2, Bmp4,* and *FGF10* (Figure 2). Functional data concerning the roles of some of these factors are discussed next.

Role of Notch Signaling in Prosensory Specification

The Notch signaling pathway has been highly conserved throughout evolution and has been shown to regulate multiple events in embryonic development. In mammals, four Notch genes code for membrane-bound receptors that are activated on binding with any one of a family of membrane ligands that includes Jagged1, Jagged2, Delta1, and Delta3. Ligand binding results in the cleavage of the Notch protein to yield an intracellular component (Notch-ICD) that is then translocated to the nucleus. Notch1 is expressed throughout the developing inner ear, beginning at the early otic placode stage and persisting throughout development. Jagged1 expression begins about the time of placodal invagination and, although initially diffuse in expression, rapidly resolves to the developing prosensory patches. Historically, the primary role of Notch signaling has been considered to be to mediate lateral inhibitory interactions between cells. However, more recent data suggest that Notch signaling can have a positive, inductive effect on cell fate. The early expression of Notch1 and one of its ligands within developing prosensory patches is consistent with a role in the specification of these patches. And, as would be predicted, the deletion of *Jagged1* within the otocyst leads to a nearly complete loss of hair cells. However, an equivalent deletion of *Notch1* does not result in a similar phenotype. In fact, the loss of *Notch1* results, instead, in an overproduction of hair cells. The bases for these differences are only partially understood, but they strongly suggest that Jagged1 acts through the activation of another Notch gene. The potential role of Notch signaling in the specification of prosensory patches was recently supported by the demonstration that the transient overexpression of a constitutively active Notch1-ICD construct in chick otocysts results in the induction of ectopic sensory patches. Furthermore, the expression of serrate (the chick Jagged1 homolog) was upregulated within ectopic sensory patches, suggesting the existence of a positive feedback loop mediated through Jagged1/Notch activity leading to a lateral induction process.

Figure 1 Diagrammatic cross-sections through the sensory organs of the mammalian inner ear: (a) the organ of Corti, the sensory epithelium of the mammalian cochlea; (b) a crista ampullaris, the sensory epithelium within a semicircular canal; (c) a vestibular sensory epithelium such as the sacculus or utriculus. In (a), the sensory epithelium of the organ of Corti is composed of two basic cell types, hair cells (green nuclei) and supporting cells (red nuclei) that lie on a basement membrane referred to as the basal lamina. Beneath the basal lamina is a layer of mesenchymal cells (blue nuclei). Hair cells have a specialized stereociliary bundle (black) on their apical surface that comes in contact with an overlying extracellular matrix called the tectorial membrane (gray). The displacement of this extracellular matrix relative to the hair cells provides the primary stimulus for mechanotransduction through deflection of the stereociliary bundle. In (b), as in the cochlea, the crista ampullaris is composed of hair cells and supporting cells. The hair cell stereocilia come in contact with an overlying extracellular matrix that is similar in composition to the tectorial membrane; it is referred to as a cupula. In (c), hair cells, supporting cells, and mesenchymal cells are present in a pattern similar to that in other hair cell sensory epithelia. Stereocilia project into an overlying extracellular matrix, the otoconial membrane, which also contains individual calcium carbonate-based otoconia (black hexagons).

Figure 2 Summary of signaling molecules that are known to mediate hair cell commitment and differentiation. In the first step in hair cell formation, cells within the otocyst become specified to develop as prosensory cells. Although the factors that mediate this transition are not fully understood, a number of genes, including *Jagged1, Notch, Bmp4, Lnfg, Sox2, Pax2,* and *Fgf10,* are expressed in patterns that are consistent with a role in prosensory specification. Next, prosensory cells become committed to develop as hair cells through the expression of *Atoh1*. However, subsequent cell–cell interactions divert some prosensory cells from the hair cell fate through Notch-mediated lateral inhibitory interactions. During the first step of hair cell differentiation, committed hair cells begin to express Pou4f3 and Gfi1. In addition, early hair cell differentiation requires the activation of retinoic acid receptors (RAR and RXR). Finally, later differentiation requires signaling through thyroid hormone receptors (TR).

SOX2

The SRY-related transcription factor SOX2 is also expressed from the early otocyst stage, and its pattern of expression overlaps with Jagged1. However, expression of Sox2 is downregulated in *Jagged1* null mutants, suggesting that it is downstream of Notch signaling. Deletion of *Sox2* specifically within the developing inner ear results in a complete loss of hair cells and hair cell precursors, demonstrating the importance of this gene in hair cell development. A hypomorphic *Sox2* mutant with limited expression within the inner ear shows a partial loss of the prosensory patches, indicating a gene dosage effect.

BMP4

The secreted morphogen BMP4 is considered to be the earliest and most definitive marker for prosensory patches, even though it is expressed in all developing prosensory patches in birds but excluded from the saccular, utricular, and cochlear sensory patches in mammals. Consistent with a role in specification of the prosensory patch, treatment with BMP4 protein *in vitro* results in increased hair cell formation in both chicken otocyst cultures and mammalian cochlear cultures, whereas inhibition of BMP4 signaling using Noggin results in a decrease in the number of hair cells. However, it is important to consider that an additional study actually obtained contradictory results for the role of BMP4 and Noggin in chick otocysts, suggesting that the role of BMP4 may not be straightforward.

Pax2, *Gata-3*, and *Lfng*

As noted, several other molecules with known developmental roles, such as *Pax2*, *Gata3*, and *Lfng* are also expressed in patterns that are consistent with a role in prosensory specification. However, prosensory

patches and hair cells still form in mice with specific deletions in each of these genes, strongly suggesting either that these factors are dispensable for hair cell formation or that compensatory mechanisms exist either normally or in response to loss of gene function.

Exit from the Cell Cycle

Following specification of prosensory patches, individual progenitor cells must become specified to develop as either hair cells or supporting cells. The results of a number of studies have demonstrated a strong link between cell cycle exit and the onset of cellular commitment and differentiation. Within the inner ears of mammals, cell cycle exit occurs in precise patterns that are specific for each sensory epithelium. In the mouse cochlea, cell cycle exit occurs in a gradient that begins in the apex around E12.5 and proceeds toward the base over the next 72 h. In the vestibular epithelia, cell cycle exit typically occurs in a central to peripheral gradient in which cells in the center of the patch are the first to become postmitotic. Cell cycle exit in the inner ear is controlled through the cyclin-dependent kinase (Cdk) inhibitors $p27^{kip1}$ and $p19^{ink4dA}$ and the retinoblastoma tumor suppressor gene pRb, all of which act as negative regulators of proliferation. pRb appears to act as a primary regulator of cell cycle based on a pattern of expression that accurately precedes the pattern of terminal mitosis (except in the cochlea) and the fact that deletion throughout the otocyst results in ongoing proliferation of sensory progenitor cells and an overproduction of hair cells and supporting cells. In the cochlea, the pattern of expression of pRb does not match either the spatial or temporal gradient of terminal mitoses. Instead, cell cycle exit is preceded by expression of $p27^{kip1}$. Moreover, in *p27kip1* null mice, cell cycle exit is delayed, allowing one or two additional rounds of mitosis, and the pattern of terminal mitosis is altered to follow the pattern of expression of pRb. Finally, deletion of *p19Ink4d*, which is also expressed in hair cells, results in postnatal hair cells reentering the cell cycle, suggesting that hair cells rely on $p19^{Ink4d}$ to maintain a postmitotic state.

Commitment of Hair Cells

As discussed, cellular commitment typically follows closely behind terminal mitosis. Therefore, once cells within the prosensory patches exit the cell cycle, individual progenitor cells must be specified to develop as either hair cells or supporting cells. Based on morphological characteristics and expression of cell-specific markers, hair cells become specified first. The earliest indication of hair cell commitment is the expression of the basic helix–loop–helix transcription factor Atoh1 (formerly, Math1) (Figure 3). Atoh1 is initially expressed in a group of cells that appears to include progenitors that ultimately develop as both hair cells and supporting cells. However, as development continues, the expression of Atoh1 becomes restricted to cells that will develop as hair cells. The role of Atoh1 in hair cell development has been examined in a number of different studies. First, targeted deletion of *Atoh1* in a mouse model leads to a complete lack of hair cells in the both the auditory and vestibular sensory epithelia. In addition, the forced expression of Atoh1 in the developing cochlear sensory epithelium is sufficient to induce hair cell formation. And, surprisingly, forced expression of Atoh1 outside of the prosensory patches also leads to hair cell formation. The ability of Atoh1 to induce hair cell formation appears to persist even into the adult because the introduction of an *Atoh1*-expressing adenovirus into the ears of adult guinea pigs results in the formation of ectopic hair cells.

Figure 3 Regulation of hair cell fate through the Notch pathway. Prior to hair cell commitment, cells express Atoh1 along with members of the Id family. In response to downregulation of Ids, some cells are able to increase the expression of Atoh1, leading to the activation of Notch ligands, Jag2 and Dll1. Activated Jag2 and Dll1 bind to Notch1 receptors, leading to the generation of an intracellular fragment of Notch1, referred to as Notch-ICD (N-ICD). N-ICD is translocated to the nucleus, where it activates the expression of the inhibitory bHLH genes, *HES1* and *HES5*. HES1 and HES5 combine with Ids to downregulate the expression of Atoh1, leading to the inhibition of the hair cell fate.

As discussed, Atoh1 is apparently initially expressed in a larger number of cells than ultimately develop as hair cells. This observation suggests that some of the cells that initially become committed to a hair cell fate are subsequently diverted from that fate through cell–cell signaling. In all inner ear sensory epithelia, hair cells and supporting cells are arranged in a mosaic such that hair cells are completely surrounded by supporting cells. However, laser ablation of developing hair cells in either the embryonic mammalian cochlea or in mature amphibian lateral-line

neuromasts results in a change in the fate of neighboring cells, leading to a regenerative response. Based on the mosaic pattern and the observed effects of the removal of existing hair cells, a lateral-inhibitory mechanism was initially proposed to regulate the generation of the cellular mosaic. As previously discussed, the Notch signaling pathway was characterized based on its ability to mediate lateral inhibitory interactions. Therefore, a second role for Notch signaling during inner ear development seemed likely. Consistent with this hypothesis, developing hair cells in different species express one or more Notch ligands, including *Jagged2* and *Delta1*, whereas surrounding supporting cells express *Notch1*. In addition, supporting cells also express the Notch target genes *HES1* and *HES5* Therefore, the patterns of expression for all these genes are consistent with an inhibitory interaction in which developing hair cells use Jagged2 and Delta1 to activate Notch1, and subsequently HES1 and/or HES5, in neighboring cells with the effect of that activation being to inhibit those cells from developing as hair cells. As would be expected based on this hypothesis, the deletion of any of the genes in this pathway leads to an overproduction of hair cells. Similarly, the disruption of the Notch signaling pathway in zebra fish as a result of mutations in the *deltaa* gene or in *mindbomb*, a gene that encodes an E3 ubiquitin ligase that is responsible for targeting Notch for degradation, also leads to an increase in the number of hair cells with a concomitant decrease in the number of supporting cells. In addition, recent work has demonstrated that Atoh1 is a target of Notch1 in the ear and that overexpression of HES1 is sufficient to inhibit the ability of Atoh1 to induce hair cell formation. These results strongly suggest that developing hair cells directly inhibit their neighbors from developing as hair cells through a Notch-mediated inhibition of Atoh1.

One intriguing aspect of the role of Notch signaling in hair cell development is the observation that Jagged2 and Delta1 are not expressed in all Atoh1-positive cells. In many systems in which Notch signaling is used to sort cells into multiple fates, Notch and one or more Notch ligands are initially expressed throughout the population of progenitor cells with subsequent cell–cell interactions leading to some cells increasing the expression of Notch while other cells increase the expression of the Notch ligand. However, in the ear, only developing hair cells appear to express Notch ligands, suggesting that these cells may be biased toward the hair cell fate. Recently, a group of molecules referred to as inhibitors of differentiation (Ids) has been shown to play a role in this bias. Ids are helix–loop–helix molecules that are similar to bHLH molecules, except that they lack the basic domain that is required for DNA binding. As a result, Ids act as negative regulators of bHLH molecules, such as *Atoh1*, through competition for a common dimerization partner. The Id genes, *Id1*, *Id2*, and *Id3*, are expressed in the developing cochlea, but become specifically downregulated in developing hair cells. Moreover, prolonged expression of Id3 in individual cells within the ear leads to the inhibition of hair cell formation. Based on these results, it seems likely that downregulation of Id expression plays key step in the determination of which, and how many, cells within the ear develop as hair cells.

It is also important to consider that, with the exclusion of mammals, all vertebrates classes are able to generate new hair cells throughout the life of the organism, either as a result of normal turnover or as part of a regenerative response. In either case, the generation of new cells requires the specification of progenitors as hair cells. In most cases, the specification of new hair cells in adult animals involves existing cells within the epithelium, presumably supporting cells, reentering the cell cycle to divide and give rise to progenitor cells that then become specified as hair cells or supporting cells through a recapitulation of the developmental processes already described. However, there is also evidence indicating that under some circumstances supporting cells can develop as hair cells through a direct transformation referred to as transdifferentiation. During transdifferentation, supporting cells are presumed to downregulate supporting cell-specific genes and then to upregulate hair cell-specific factors, starting with cAtoh1 (the chick Atoh1 homolog). The subsequent events that lead to the development of these cells as hair cells have not been determined. Moreover, it is not clear how much of the subsequent signaling events described are recapitulated in transdifferentiating cells. For instance, would transdifferentiating hair cells need to activate the Notch signaling pathway to inhibit neighboring cells from developing as hair cells because these cells are already supporting cells? Clearly the answers to these questions, as well as, a more complete understanding of the differences between hair cell development and hair cell regeneration should have significant implications for the development of regenerative strategies.

Differentiation and Survival of Hair Cells

Following the commitment to a hair cell fate, the earliest molecule that is known to be expressed exclusively in differentiating hair cells is the unconventional myosin, myosin-VI. In the developing mammalian cochlea, myosin-VI can be detected in developing hair cells at almost the same time as

Atoh1. However, despite its early onset of expression, myosin-VI does not appear to play a role in hair cell differentiation because mutations in myosin-VI do not result in defects in hair cell development. The same is true for another unconventional myosin, myosin-VIIa, which is expressed soon after myosin-VI but is also not required for hair cell formation. At this point, the early functions, if any, of myosin-VI and myosin-VIIa remain unclear. Both molecules are required for the normal development and maintenance of the stereociliary bundle, but because the bundle does not develop until several days after initial commitment and differentiation, it is assumed that both myosins must play additional roles in early hair cell formation.

POU4f3, Gfi1, and Barhl1

Soon after the onset of expression of myosin-VI and myosin-VIIa, developing hair cells begin to express a group of transcription factors that are required for hair cell survival and possibly differentiation. The first of these factors is the class IV Pou-domain transcription factor, Pou4f3 (also known as Brn-3c or Brn-3.1). Expression of Pou4f3 is first detected approximately 24–48 h after the onset of expression of Atoh1. In cochleae from *Pou4f3*$^{-/-}$ animals, the initial development of hair cells appears normal, as determined by expression of myosin-VI and myosin-VIIa; however, there is a rapid degeneration leading to hair cell death and auditory and vestibular deficits, indicating that Pou4f3 is required for hair cell maintenance. Moreover, late-onset progressive hearing loss occurs in an Israeli Jewish family with an 8 bp deletion in the homeodomain of *POU4F3,* further demonstrating the importance of this gene in hair cell maintenance.

Following the onset of expression of Pou4f3, developing hair cells upregulate Gfi1, a zinc finger transcription factor that has been implicated in development of the hematopoietic system. As is the case for *Pou4f3*, the deletion of *Gfi1* leads to early degeneration of hair cells; however, the expression of Atoh1, myosin-VI, myosin-VIIa, and Pou4f3 is not disrupted, indicating that Gfi1 acts downstream of Pou4f3.

Beginning about the same time as Pou4f3, hair cells also express Barhl1, a member of the Bar family of homeobox genes. In Drosophila, barh1 and barh2 are required for the development of sensory organs. However, the development of hair cells in mice with a targeted deletion of *Barhl1* appears normal, with a full complement of hair cells formed at postnatal day (P)0. Although hair cells develop normally, signs of hair cell degeneration are present beginning at P6 and all hair cells ultimately die, but not until P300. Based on these results, it seems likely that *Barhl1* acts as a hair cell survival gene, whereas *Pou4f3* and *Gfi1* may act as both survival and differentiation genes. Because the hair cells die during the differentiation process in both *Pou4f3* and *Gfi1* mutants, it is not possible to determine whether survival, differentiation, or both are disrupted.

Role of Retinoic Acid Signaling in Hair Cell Differentiation

Another group of transcription factors that are expressed in developing hair cells soon after the onset of cellular differentiation is the nuclear receptors for retinoic acid (RA) and thyroid hormone (TH). Receptors for RA and TH belong to the steroid/thyroid receptor superfamily containing a zinc finger DNA binding domain and a ligand dimerization domain. RA signaling is mediated by two different forms of receptors, RARs (α, β, and γ) and RXRs (α, β, and γ), both of which are expressed in inner ear-sensory epithelia. The treatment of cochlear explant cultures with RA results in supernumerary hair cells and supporting cells, and it similarly induces hair cell differentiation in chicken otocyst cultures. The inhibition of RA synthesis or antagonism of RARα results in a decrease in the number of cells that develop as hair cells. However, Brn3.1 and myosin-VI are still expressed in hair cells, even in the presence of RA inhibitors, suggesting that initial differentiation of hair cells does not require RA. Based on these results, it was suggested that RA signaling through RARα plays a direct role in hair cell differentiation during early stages in development. However, a small number of hair cells are present in RARα/RARγ double-mutant mice (RARα mutant mice are phenotypically normal), suggesting that hair cell differentiation is not completely dependent on RA. However, considering that there are three *RAR* genes and three *RXR* genes, and that functional redundancy of RA receptors has been demonstrated in other systems, it would be informative to inactivate all three RAR genes or all six RA receptor genes within the inner ear.

Role of TH Signaling in Hair Cell Differentiation

Hypothyroidism or iodine deficiencies in pregnant women are known to cause hearing deficits in children, and induced hypothyroidism in animal models results in severe morphological abnormalities in the organ of Corti that appear consistent with a delay in cellular differentiation. Thyroid hormone signaling is mediated through three functional receptors, Trα1, Trβ1, and Trβ2, and a nonligand binding, Trα2.

All of these receptors are expressed within the developing inner ear; however, the expression of *Trβ1* and *Trβ2* is confined to the developing cochlear epithelium. Elimination of TRβ1 and TRβ2 through deletion of the *Trβ* gene results in animals that are deaf as a result of a defect in the maturation of a hair cell ionic conductance that is required for cellular function. However, the overall structure of the organ of Corti is not comparable with hypothryroid animals and, in fact, appears normal, suggesting a possible functional redundancy. Consistent with this hypothesis, the deletion of both *Trα* and *Trβ* results in a more profound hearing loss than in animals lacking just *Trβ*, and the morphology of the organ of Corti in these mice is consistent with the hypothyroid phenotype.

In both hypothyroid animals and *Trα/Trβ* double mutants, the phenotype of the organ of Corti is consistent with a delay or arrest in cellular differentiation. To determine whether this is in fact the case, the expression of a molecule that is turned on fairly late in the development of a subset of hair cells, Prestin, was examined in hypothyroid animals. As expected, Prestin expression is delayed in hypothyroid hair cells. Moreover, an analysis of the promoter region for the *Prestin* gene identified two specific TR binding elements, strongly suggesting that ongoing differentiation of hair cells is dependent on thyroid hormone signaling.

Summary

The specification of hair cells within the inner ear is dependent on the activation of a number of molecular signaling pathways that progressively direct the development of prosensory patches and subsequently direct individual cells within those patches to develop as hair cells. Although the factors that direct the specification of prosensory patches are not fully understood, the Notch signaling pathway and the transcription factor Sox2 clearly play important roles. Within each prosensory patch, the bHLH transcription factor Atoh1 is necessary and sufficient to induce progenitors to develop as hair cells, whereas subsequent Notch-mediated inhibitory interactions actually determine how many cells will develop as mature hair cells. Once committed, developing hair cells activate a number of genes, including *Pou4f3* and *Gfi1,* that are required for their survival and, probably, for differentiation. In addition, developing hair cells become dependent on external signaling factors, such as RA and TH, to stimulate further steps in their differentiation toward functioning hair cells.

Millions of lives are affected by hearing and balance deficits that arise when sensory hair cells in the inner ear are killed by loud sounds, head trauma, infections, autoimmune disorders, and certain drugs. Those deficits permanently affect humans and other mammals, but nonmammalian vertebrates can regenerate lost hair cells and recover their hearing and balance within a matter of weeks. Here we review the biology of hair cell regeneration and the prospects for stimulating the replacement of lost hair cells in humans and other mammals.

Hair Cell Structures and Functions

Sensory hair cells are named for a microscopic, directionally polarized hair bundle composed of 30–300 actin-filled modified microvilli, called stereocilia, and a single eccentrically positioned true cilium, the kinocilium. The hair bundle extends from the cell's apical surface into the fluid in the inner ear or the lumen of one of the lateral line organs on the head or body of a fish or aquatic amphibian (Figure 1). Hair cells detect sounds, accelerations of the head, and water motion around the body when small, stimulus-driven forces deflect their hair bundles. Deflections open and close mechanosensitive transduction channels, which leads to changes in transmembrane potential, Ca^{2+} entry, and the release of neurotransmitter.

Humans normally begin life with each ear's snail-shaped cochlea containing ~16 000 sound-sensitive hair cells precisely arranged in four rows in the organ of Corti sensory epithelium, which runs ~30 mm along the basilar membrane (Figure 1(b)). Those hair cells detect sound waves transmitted to the inner ear by the middle ear bones and provide the accurate frequency discrimination we rely on for communication by speech. Each ear also contains ~19 000 and ~33 000 hair cells in the gravity-sensitive saccule and utricle, respectively. Angular accelerations of the head are detected by the three semicircular canals, which contain ~7600 hair cells apiece (Figure 1(b)). The saccule, utricle, and semicircular canals constitute the vestibular division of the inner ear. The occurrence of age-related hearing impairments and the deterioration of visual stability reflexes and balance correlate with progressive age-related declines in the number of hair cells present in the human cochlea and vestibular epithelia.

The Developmental Production of Hair Cells

Mammals produce nearly all of their hair cells during embryonic development, but hair cell production can continue well beyond birth in other vertebrate classes. Like mammalian ears, the ears and lateral line organs of fish, amphibians, and reptiles develop reasonably large complements of hair cells during embryogenesis. However, the sensory epithelia in those animals continue to give rise to substantial numbers of new hair cells throughout life. For example, counts from scanning electron microscopy have shown that sharks add hundreds of thousands of hair cells in the inner ear as juveniles grow to adulthood. Sensory cell production continues even in the oldest animals within natural populations of fish and amphibians.

In the postembryonic sensory epithelia of those animals, proliferation and interstitial addition of hair cells occur at a low frequency throughout their maculae, but proliferating cells and newly produced hair cells are more frequently found near the peripheral edges of the sensory maculae. The occurrence of growth zones at the outer margins of these diverse types of hair cell epithelia suggests the possible existence of latent or slowly replicating progenitor cells that may be maintained near the progressively moving zone of transition between the expanding sensory epithelium and surrounding nonsensory epithelium. If such stem cells exist in growing hair cell epithelia, they are as yet unidentified, but there is the possibility that combinations of signals and cellular environment may support a stem cell niche at the edges of these sensory epithelia, similar to the reserve stem cell pools that persist at the outer edges of the retina in fish, amphibians, and birds.

Vestibular organs in mammals and both auditory and vestibular epithelia in chickens develop via a pattern of radial or appositional growth, similar to postembryonic growth in fish and amphibians. The first cells to withdraw from cycling are located near the center of each sensory epithelium in a zone of nonproliferation that expands radially outward until all the cells in the epithelium have been produced. Late in embryogenesis or soon after birth, cell production is believed to effectively cease in the

Figure 1 Schematic diagrams of the human inner ear: (a) approximate size and location of the sensory organs of the inner ear; (b) drawing of the auditory and vestibular labyrinth (the sensory patches within each organ are indicated by the dark coloration); (c) representation of a section of the sensory epithelium from a vestibular organ to demonstrate the general structure and organization of the sensory epithelium.

mammalian vestibular epithelia and the avian cochlea. During embryogenesis of those organs, however, mechanisms operate to sustain a yet-to-be-identified class of proliferative cells at the outer margins of growing hair cell epithelia, which may be widely conserved across all vertebrates and may persist throughout life in fish and amphibians.

The Regenerative Replacement of Hair Cells

Identification of the cells that give rise to replacement hair cells is critical to an accurate understanding of the events that lead to regenerative recovery of hearing, balance, and lateral line functions. Sensory

epithelia in the inner ear contain at least two distinct resident cell types – sensory hair cells and supporting cells (Figure 1(c)) – and lateral line epithelia contain hair cells and both internal supporting cells and mantle-type supporting cells.

Supporting cells occupy the spaces between neighboring hair cells, extending from the apical to the basal surfaces of the epithelium and ensheathing the sides and bases of the hair cells and nerve terminals. When hair cells are lost, surviving supporting cells divide and give rise to progeny that can continue to divide or can differentiate as replacement hair cells and supporting cells (Figure 2). Regeneration also can occur after the loss of entire lateral line neuromasts as well as in cases in which only hair cells have been lost from the neuromast.

In fish and aquatic-stage amphibians, entire groups of lateral line neuromasts regenerate after tail amputation. All the cells that make up those neuromasts arise from a cell lineage produced when mantle-type supporting cells located near the outer edge of the last remaining neuromast on the stump of the tail begin to divide. The epithelial progenitor cells produced from those cell divisions migrate out of the neuromast, divide further, and give rise to migratory cells that form a regenerative placode that extends posteriorly beneath the epidermis of the regenerating tail. As tail regeneration progresses, small groups of cells break away from the trailing anterior edge of the posteriorly moving regenerative placode. Those loose collections of progenitor cells progress through aggregation, self-organization into rosettes that will become replacement neuromasts, and the subsequent production of the first replacement hair cells, which arise in the very center of each radially symmetrical rosette.

In birds, the sensory epithelium of the cochlea forms in the embryo, and tracer experiments have shown that, under normal conditions, there is no replication of nuclear DNA in hair cells or supporting cells after hatching. When the sensory epithelium has been injured, however, many of the previously quiescent supporting cells that are in or near the lesion reenter the cell cycle, divide, and generate new cells that can quickly differentiate into replacement hair cells and supporting cells. Six days after the end of a 48 h exposure to a loud tone that kills hair cells, small hair bundles become visible within the confines of the former lesion. Those bundles grow rapidly and

Figure 2 Hair cell regeneration in the chicken basilar papilla: (a) Following 48 h of acoustic overstimulation at 1.5 kHz, hair cells within the region of the cochlea tuned to 1.5 kHz are lost and can be seen extruding from the epithelium; (b) after being allowed 10 days to recover following acoustic overstimulation, the epithelium has been repaired and hair cells can be seen throughout the formerly damaged regions; (c) diagram of regenerative proliferation by supporting cells. In (c), in response to the loss of a hair cell (1), the supporting cell nucleus migrates toward the epithelial surface (2–3), where it undergoes mitosis (4). The progeny of that division then go on to form replacement hair cells or supporting cells (5–6). (a, b) Corwin and Cotanche (1998).

appear nearly mature by 10 days after the end of the sound exposure (**Figures 2(a) and 2(b)**).

Bundle form differs progressively along a gradient extending between the ends of the avian cochlea. The hair bundles at the high-frequency-sensitive proximal end of the chicken's cochlea contain over 200 short stereocilia, whereas the bundles at the low-frequency-sensitive distal end have less than 50 long stereocilia. Remarkably, the replacement hair cells develop hair bundles appropriate for the position the regenerated cells occupy, indicating that positional identity cues are maintained. How this occurs remains to be determined.

New cells that arise from the divisions of supporting cells appear to differentiate as hair cells by default when they develop in a region that does not already contain hair cells. Lateral inhibition by hair cells suppresses hair cell fate in immediate neighbors, setting up a mosaic pattern in which each hair cell is surrounded by supporting cells. Notch signaling may underlie the fate choices, as in the *mindbomb* mutant zebra fish line with disrupted Notch signaling, all of the progeny differentiate into hair cells and no supporting cells are produced.

The Innervation of Regenerated Hair Cells

In the weeks after regeneration of hair cells in birds, the replacement cells become innervated as synapses progress through stages of maturation similar to those that occur in embryos. In the cochlea, afferent terminals synapse on all the hair cells early in the regeneration process, but afferents subsequently withdraw from the short hair cells. After vestibular hair cell regeneration in birds, bouton, dimorphic, and calyceal afferent terminals grow slowly and progressively for up to 1 year, by which point the regeneration of those afferents has largely recapitulated the developmental stages that normally lead to their topographic organization.

Functional Recovery Follows Hair Cell Regeneration

After antibiotic-induced hair cell loss, thresholds for auditory-evoked potentials in the cochlear nuclei of chickens shift by 40–50 dB. By 16–20 weeks, they recover significantly in all but the high-frequency regions. Behavioral sound discrimination and precise vocal production in birds also recover after hair cell regeneration.

After streptomycin treatment, pigeons exhibit severe head and postural instability, with tremors, head shakes, staggering, and circling. These vestibular dysfunctions last for weeks, but gradual recovery that corresponds with the time for hair cell regeneration restores the capacity for spatial orientation and path navigation.

The Potential for Regeneration of Mammalian Hair Cells

There is little if any credible evidence for innate regenerative capacity in the mature mammalian organ of Corti. It appears likely that limits to regeneration relate to developmental controls inherent in the formation of the highly ordered arrangement of inner and outer hair cells and the specialization of the distinct types of supporting cells in the mammalian organ of Corti (Deiter's cells, Hensen's cells, Pillar cells, and phalangeal cells), which are unmatched in the ears of nonmammals. There are, however, limited regenerative responses in mammalian vestibular epithelia, which share structural similarities to their counterparts in the ears of fish, amphibians, and birds (**Figure 3**). When juvenile guinea pigs have been treated with aminoglycoside antibiotics, hair bundles are lost from certain regions of the utricle, but when other guinea pigs have been allowed to recover for 4 weeks after such treatments, their utricles contain many small hair bundles, reminiscent of bundles on regenerating hair cells in the avian ear. Small hair bundles are also present in very small but consistent numbers throughout the utricles of adult guinea pigs. Aminoglycoside antibiotics have been used in culture to kill the majority of the hair cells in utricles from adult guinea pigs and adult humans. The loss is followed by the proliferation of up to 100 or more supporting cells. However, the modest proliferative responses of mature mammalian vestibular epithelia are considerably below those observed in nonmammals.

Proliferation Controls in Hair Cell Epithelia

Treatments with transforming growth factor (TGF-)α, epidermal growth factor (EGF), insulin-like growth factor (IGF-1), insulin, glial growth factor (GGF2), and heregulin can increase mammalian supporting cell proliferation to varying degrees. The cells from the ears of young mammals are most responsive, and there is a significant decline in the number of supporting cells that respond to mitogenic growth factors as neonatal rodents mature during the first weeks after birth. Supporting cells continue to express growth factor receptors and small numbers of those cells can be induced to divide, but more research is needed to discover what limits the production of cells in mature mammalian hair cell epithelia.

Figure 3 Diagrams showing the general structural organization of sensory epithelia: (a) organization of otolith macular organs in all vertebrates; (b) organization of the semicircular canal cristae; (c) organization of the mammalian cochlea; (d) the lateral line neuromasts found along the body of fish and amphibians; (e) the basilar papilla of birds. In (a), the sensory patch, indicated by the dark color in the inset, comprises hair cells and supporting cells in a mosaic pattern. The hair cells insert their hair bundles into a gelatinous matrix covered by otoconial crystals that provide inertial weight to acceleration of the head (arrow). The sensory epithelium is surrounded by a nonsensory epithelium, made up of supporting-like cells. In (b), the barbell-shaped sensory patch is organized very similarly to that of the otolith macular organs. The hair bundles, however, are inserted into a large cupula, which transduces rotational movement of fluid through the canal to the hair bundles (arrow). In (c), in contrast to the generally uniform population of supporting cells in vestibular organs, the cochlear supporting cells show discrete morphological specializations to form the unique structure of the organ of Corti. In (d), the lateral line neuromasts in fish and amphibians are organized in a way similar to vestibular organs, although there are many fewer hair cells per organ. In (e), the basilar papilla of birds shows some similarity to the vertebrate cochlea, although the supporting cells do not form morphologically discrete subtypes or show high levels of specialization.

The contributions of mitogen-activated protein kinase (MAPK), phosphatidyl inositol 3′ kinase (PI-3K), target of rapamycin (TOR), and protein kinase C (PKC) to the proliferative response appear similar in young birds and neonatal rodents, but they may differ as mammals mature. Tumor suppressors have important roles in the embryonic development of the ear, but it is unclear whether they are the limiting factors that restrict the regenerative replacement of hair cells in postnatal mammals. The cyclin-dependent kinase inhibitors (CDIs), such as $p27^{Kip1}$ and $p19^{Ink4}$, both appear to inhibit cell cycle progression in developing the mammalian ear. $p27^{Kip1}$ is selectively expressed in supporting cells, and the disruption of the gene allows cell proliferation to continue in postnatal mouse organ of Corti beyond the time when mitosis normally has ceased. It has not been determined whether differences in CDI regulation or expression exist between mammalian and nonmammalian ears. Additional research is needed to identify the upstream controls that restrict proliferation and to discover treatments that may overcome that restriction and promote effective regeneration in mammals.

Hair Cell Death and Regeneration

Hair cell death can occur through necrosis or apoptosis, but there are reasons to believe that clinically relevant forms of hair cell loss occur primarily through apoptosis. Unlike the populations of hair cells in the mammalian ear and those in the avian cochlea, the hair cell populations in the vestibular organs of birds turn over throughout life, with the hair cells typically living for only a few months. Experimental decreases in apoptotic hair cell death have been achieved using caspase inhibitors, and that results in reduced rates of ongoing proliferation. Thus, the rate of hair cell death regulates the rate of proliferation, but the specific factors that limit the life span of avian vestibular hair cells remain to be discovered. Identification of those factors could contribute to understanding the causes of age-related hair cell loss and other conditions that reduce the life span of human hair cells, whose longevity is believed to extend to a century or longer under normal conditions.

Potential Triggers for Regeneration

Although the loss of hair cells and the initiation of proliferation appear closely tied, the specific signals that trigger the regeneration responses remain to be identified. Loss of contacts between hair cells and supporting cells may result in signals transmitted from cell to cell through the subapical epithelial junctions or via gap junctions or Notch–Delta signaling. Laser microbeam ablations of hair cells in the avian cochlea have shown that the initial proliferative responses occur in supporting cells that lie up to ~200 μm beyond those cells that had direct contact with the lost hair cells. This suggests that the signals that trigger regenerative proliferation go beyond simple loss of cell–cell contact but are unlikely to be widely diffusing signals.

The onset of proliferation in the mantle-type supporting cells that contribute to the regeneration of hair cells in neuromasts in salamanders correlates with the recruitment of macrophages to the vicinity of the wound after tail amputation. TGFα and tumor necrosis factor (TNF-)α are cytokines secreted by macrophages and can promote the proliferation of avian and mammalian supporting cells. The inhibition of cytokine production reduces the proliferation of avian supporting cells *in vitro*, but the specific role that the immune response has in triggering hair cell regeneration *in vivo* remains to be determined.

Reserve Stem Cells versus Dedifferentiation

Persistent but unresolved questions revolve around the potential existence of a discrete subpopulation of reserve stem cells that might retain the capacity to produce new hair cells. The alternative question is whether all or nearly all supporting cells may be capable of dedifferentiating and contributing to regeneration. Currently, both possibilities derive support from indirect evidence. Neither has been ruled out, but the case for the importance of reserve stem cells is not as strong as that for dedifferentiation of supporting cells. Progenitor cells that have replicated DNA in preparation for cell division have thus far remained morphologically indistinguishable from other supporting cells in the ears of fish, amphibians, and birds. When treatment with a mitotoxin was used to eliminate initially dividing cells in experimentally damaged ears of fish, this did not prevent regeneration subsequent to a second round of damage. In chicken ears, the majority of supporting cells in regions of damage downregulate expression of G_0 markers, begin expressing markers for passage to the late G_1 phase, and begin to replicate their DNA. These data and the absence of immunocytochemical evidence for distinct supporting-cell subtypes are consistent with the possibility that the majority of supporting cells have the capacity to reenter the cell cycle and divide. Other evidence indicates that hair cell production in lateral line organs occurs via symmetrical division of a single progenitor to produce two hair cells during development and regeneration,

but still other evidence indicates that asymmetric divisions of supporting cells can produce both replacement hair cells and supporting cells.

Other experiments have suggested that a small number of cells from the adult mouse utricle may act as colony-forming stem cells whose progeny can differentiate into hair cells, neurons, muscle cells, kidney cells, liver cells, and skin cells. The suggestion that a handful of stem cells may exist within mature mammalian vestibular epithelia is enticing for its apparent consistency with observations that have shown only a limited number of dividing cells in cultures of mammalian vestibular epithelia, but such attractive interpretations should be taken cautiously until replicated by others.

Although most (if not all) supporting cells in nonmammalian vertebrates appear to be capable of returning to the cell cycle and dividing, it remains to be determined exactly what controls and limits the proliferation of supporting cells in the ears of mature mammals. As already noted, *in vitro* investigations have shown that treatments with appropriate growth factors and pharmacological agents can stimulate proliferation in the majority of supporting cells in epithelia cultured from the utricles of neonatal rodents. Thus, the observed proliferative capacity of supporting cells in the perinatal utricular epithelium appears to be more consistent with the hypothesis that nearly all supporting cells may be capable of proliferating as opposed to the hypothesis that proliferation depends on relatively rare reserve stem cells. Experiments that found age-related decreases in the response of mammalian supporting cells to growth factor stimulation suggest that maturing mammalian supporting cells may change in ways that restrict their capacity to act as progenitors. Whether the proposed stem cells in the mature mammalian inner ear are simply retained as less-differentiated supporting cells, whether there may be multiple subclasses of supporting cells that have different capacities for proliferation, or whether all mammalian supporting cells can be induced to return to the cell cycle remains to be determined.

Although evidence indicates that supporting cells can act as multipotential progenitors to produce new hair cells and new supporting cells, the supporting cells in many types of otic epithelia spend the majority of their life as mitotically quiescent, differentiated cells. For differentiated cells to reenter the cell cycle, they must first dedifferentiate. Some of the best-studied cases of dedifferentiation occur as urodele amphibians regenerate lost limbs or tails, in which cells from the neural tube, muscle, connective tissue, and Schwann cells have all been observed to dedifferentiate and contribute to the mass of proliferating multipotent cells that form the regeneration blastema. As regeneration progresses, the progeny from those cells differentiate into each of the cell types needed to replace all of the structures in the missing parts of the limb or tail. In a situation that appears somewhat similar to that in the inner ear, after damage amphibian myotubes readily dedifferentiate and contribute to the regeneration of lost structures, but mammalian myotubes remain differentiated and mitotically quiescent. Identification of the factors that restrict or control differentiation in the ear may provide fruitful targets for manipulation to promote the regeneration of hair cells.

Nonproliferative Recovery after Hair Cell Damage

Although proliferation of supporting cells and differentiation of the progeny into replacement hair cells and supporting cells seem to be the primary mechanisms for regeneration following injury, there is evidence that nonproliferative mechanisms may also contribute to recovery. In the mature mammalian vestibular system, there is evidence for significant recovery of new hair bundles but of only very limited proliferation of supporting cells. Two hypotheses have been put forth to account for this quantitative mismatch: repair of damaged hair cells and direct phenotypic conversion of supporting cells into hair cells without intervening mitosis (**Figure 4**).

In response to sublethal doses of aminoglycoside antibiotics, hair cells are able to survive the insult, with some losing their hair bundle and descending below the epithelial surface. Loss of a hair bundle does not always lead to hair cell death, which calls into question the conclusions of many studies that have relied on counts of hair bundles as the sole metric for hair cell loss and replacement.

Evidence for the nonproliferative conversion of supporting cells into hair cells is often less direct. During murine cochlear organogenesis, newly produced supporting cells convert directly into hair cells if the preexisting hair cells are lesioned through laser microbeam ablations, but this appears to occur only during the first 48 h after the production of the original hair cells. It has been proposed that supporting cells in other vertebrate sensory epithelia may be capable of phenotypic change, sometimes inappropriately termed transdifferentiation, long after organogenesis. When tracers for newly replicated DNA are administered after aminoglycoside-induced injury in birds and amphibians, the first hair cells that appear in the regions of damage have not incorporated the mitotic tracers, although in birds the later-produced hair cells do incorporate the mitotic tracers. Also, cells with some morphological characteristics intermediate between hair cells and supporting cells have been found in damaged sensory

Figure 4 Diagrams of two proposed mechanisms of nonproliferative regeneration: (a) repair of damaged hair cells; (b) direct conversion of a supporting cell into a hair cell without an intervening mitosis. As shown in (a), in response to damage, the hair cell loses its hair bundle and apical cytoplasm, but over time is able to regenerate a new bundle that matures into a normal hair bundle. As shown in (b), when a hair cell is lost (1–2), one of the neighboring hair cells, no longer suppressed by an adjacent hair cell (3), is able to redifferentiate into a hair cell and develop a morphologically mature hair bundle (4–5).

epithelia. Finally, there can be recovery of hair bundles in damaged organs cultured in a mitotic inhibitor that prevent proliferation. However, it can be difficult to determine what contribution to recovery of hair bundles is due to intracellular repair and what is attributable to phenotypic conversion.

Significantly, the clinical correspondence between hair cell loss and the onset of permanent auditory and vestibular deficits in mammals suggests that any such nonproliferative mechanisms do not lead to the same level of functional recovery observed in nonmammalian vertebrates, in which robust regenerative proliferation occurs. The restriction in supporting cell proliferation, therefore, appears to be the primary factor that leaves mammals uniquely vulnerable to permanent hearing and vestibular deficits due to loss of hair cells.

Gene Therapy to Stimulate Conversion of Supporting Cells into Hair Cells

The hypothesis that supporting cells may have an endogenous capacity for direct phenotypic conversion into hair cells has received support from *in vitro* experiments that have established that supporting cells and other cells that reside just outside the sensory epithelia can be converted into hair cells through transfection and overexpression of the basic helix–loop–helix (HLH) transcription factor *Atoh1* (the mammalian homolog of *atonal*). Those cells take on the morphological characteristics of hair cells, express hair-cell-specific proteins, and develop hair bundles, suggesting that forced conversion could be used to promote hair cell recovery *in vivo*. In fact, it has been reported that, after aminoglycoside poisoning, viral delivery of the *Atoh1* gene *in vivo* leads to remarkably complete structural recovery of the four rows of hair cells in the rodent cochlea and recovery of hearing sensitivity, but replication and further investigation of these intriguing possibilities are necessary to understand the exact contribution that genetically converted hair cells make to the reported recovery.

Conclusion

Hair cell losses can produce severe hearing and balance deficits in mammals and nonmammals alike, but nonmammals recover within weeks because epithelial supporting cells divide and give rise to replacement hair cells. In mammalian ears, the capacity for cell production decreases soon after birth, but processes that do not depend on cell proliferation continue and may contribute to structural recovery after damage. However, such nonproliferative forms of repair may not normally bring about complete restoration of function, because hair cell losses in humans and other mammals typically result in permanent sensory deficits.

Balance epithelia cultured from the ears of rodents and adult humans respond to hair cell loss with low levels of supporting cell proliferation, and small hair bundles have been found throughout the vestibular epithelia of adult rodents, suggesting that the cellular machinery necessary for regeneration is present but held to a low level in the ears of mature mammals. Investigations are continuing to explore the mechanisms that underlie the robust hair cell regeneration that occurs in nonmammalian vertebrates, the mechanisms

that limit proliferation and regeneration in the mammalian ear, and experimental strategies that eventually may have the potential to stimulate effective regenerative responses and functional recovery in mammals.

Hair Cells: Sensory Transduction

Structure of Sensory Epithelia

In each of the organs of the vertebrate inner ear, hair cells occur in specialized patches or strips of sensory epithelium, which generally contain just hair cells and supporting cells. Because the organs are formed during development by the infolding of an otic cyst, derived from surface ectoderm, the apical surfaces of hair cells face a closed compartment. Specialized epithelial cells supply this chamber with a unique fluid, termed 'endolymph,' which has a high potassium concentration and low sodium and calcium concentrations. Tight junctions ringing the apical surfaces of hair cells and supporting cells separate the endolymph from perilymph, a fluid similar to normal saline that bathes the basolateral surfaces of hair cells. In the mammalian cochlea, proton pumps in epithelial cells of the stria vascularis raise the potential of endolymph to about + 80 mV; elsewhere, however, the endolymph potential is within a few millivolts of zero.

Structure of the Hair Bundle

The mechanosensitive hair bundle comprises a few tens to a few hundreds of modified microvilli, termed 'stereocilia,' arranged in multiple rows of increasing height (Figures 1(a) and 1(b)). Adjacent stereocilia adhere to each other by means of interciliary links (Figures 1(c)–1(e)), so that when the bundles are deflected the stereocilia do not separate, but instead slide past one another: ankle links connect the stereocilia bases and lateral links couple the shafts of the stereocilia (Figure 1(c)), and tip links extend from the apical tip of a stereocilium to the side of its tallest neighbor (Figures 1(d) and 1(e)). The stereocilia have an internal structure similar to microvilli: they are bundles of several hundred actin filaments, tightly cross-linked by actin-bundling proteins espin and fimbrin. While ranging in length from about 1 μm (in mammalian cochlea) to over 60 μm (in semicircular canals), stereocilia have such stiff actin cores that they do not normally bend. The cores taper at their bases to a few actin filaments, which anchor the stereocilia into a cuticular plate just beneath the apical surface (Figure 1(f)). Since stereocilia have rigid cores and taper at their bases, they do not bend but instead pivot around their insertion point. Many hair bundles also contain a single, eccentrically placed true cilium, the kinocilium, which, in mature cells, has the 9 + 2 arrangement of microtubules characteristic of motile cilia (Figure 1(g)). The kinocilium may serve to organize the bundle during development (it is lost in mature hair bundles of the mammalian cochlea), and it couples the stereocilia to accessory structures in most other organs.

Axis of Polarity

The staircaselike variation in heights of stereocilia (Figures 1(a) and 1(b)) and the eccentric placement of the kinocilium at one edge of the bundle (Figure 1(g)) confer a morphological axis of polarity to the bundle. The positive direction is defined as toward the kinocilium or the tallest stereocilia (Figure 2(a)); negative is toward the shortest stereocilia. This also describes the physiological axis of the bundle: a positive deflection of the stereocilia evokes an excitatory response. It increases the membrane conductance by triggering the opening of nonselective cation channels (transduction channels), allowing positively charged ions to flow into the cell and thereby depolarize the cell. At the bundle's resting position, ~10% of the transduction conductance is active (Figure 2(b)). Thus, a negative deflection decreases the membrane conductance (closes channels open at rest) and hyperpolarizes the cell. This feature allows hair bundles to signal stimuli of either polarity.

The sensitivity of the hair bundle to mechanical stimuli is remarkable: a deflection of a few tenths of a micrometer in the positive direction is sufficient to activate the conductance completely, and deflections at the auditory threshold are estimated to be a few tenths of a nanometer. Side-to-side deflections of the bundle, even several micrometers, cause no conductance change, so that the cell has a vector sensitivity and only senses the component of the stimulus along the bundle's axis of polarity.

The Mechanism of Transduction

The past quarter century has provided a good understanding of the mechanoelectrical transduction process, whereby deflections of the stereocilia cause the opening of transduction channels. The process is extremely fast: at mammalian temperatures, channels begin to open within about 10 μs after deflection of the bundle. This can explain a sensitivity for frequencies as high as 100 kHz in some animals, but the speed also rules out transduction mechanisms involving an

Figure 1 The structure of the vertebrate hair bundle. (a) Scanning electron micrograph of a hair bundle protruding from the apical surface of a mouse utricle hair cell. Utricular hair bundles are composed of ~65 stereocilia of graded heights and a single taller kinocilium. (b) Scanning electron micrograph of a guinea pig cochlea hair bundle. While a kinocilium is present in immature cochlear hair cells, it is lost after ~postnatal day 3. (c) Transmission electron micrograph of a chick utricle hair bundle. Just above the cuticular plate, the stereocilia are interconnected by ankle links (large arrowheads). Shaft connectors (small arrowheads) link the lateral aspects of the stereocilia. (d) At the tip of each stereocilium are tip links (long arrows) and horizontal top connectors (short arrows). (e) High-resolution freeze-etch image of a tip link from a guinea pig cochlea hair bundle. (f) Transmission electron micrograph of a longitudinal section of the apex of a hair cell from the saccule of a goldfish. The stereocilia taper at their bases and contain a large number of tightly packed actin filaments that converge into a dense bundle where they insert into the cuticular plate. (g) Thin cross-section of a hair bundle from the bullfrog saccule, which reveals the hexagonal arrangement of stereocilia with cores of actin and the single, microtubule-based kinocilium at the right. Scale bar = 5 μm (a), 1 μm (b), 200 nm (c, d, f), 100 nm (e), 500 nm (g). (a) Reproduced from Holt JR, Gillespie SKH, Provance DW, et al. enzyme cascade or second messenger molecules. It was proposed, instead, that deflections exert a force directly on transduction channels to open them, much as transmembrane voltage exerts a force directly on charged domains of voltage-gated channels. Several experiments have succeeded in measuring small movements of hair bundles that occur with channel opening. These experiments provide strong support for the idea of directly gated channels, as well as estimates of some of the mechanical properties of the transduction apparatus. The mechanical force required to open a single transduction channel is estimated to be about 2 pN and upon opening, the channel protein undergoes a conformational change of ~2 nm. Mechanosensitive transduction channels represent a third class of ion channel, in addition to those gated by voltage and ligand binding. A variety of mechanically gated channels have been identified in other systems. Properties of the hair cell transduction channel resemble those of ion channels of the transient receptor potential (TRP) family, inparticular TRPN1 (also known as NOMPC, absent from the mammalian genome) present in the *Drosophila* bristle. Recently, TRPA1 was presented as a candidate for the mechanosensitive channel of vertebrate hair cells, but lack of an auditory or vestibular deficit in TRPA1 knockout mice has called that suggestion into question. Thus, conclusive evidence of the identity of the hair cell transduction channel awaits.

Figure 2 Models for hair cell transduction and adaptation. (a) Deflection of the hair bundle toward the tallest stereocilia opens mechanosensitive transduction channels. (b) A 0.5 μm step deflection rapidly opens channels. Over the subsequent 100 ms the open probability declines or adapts to a new steady-state level. The stimulus response relationship (right) shifts in the direction of the applied stimulus. In the example of a positive stimulus the curve shifts to the right (dashed line). The relationship is best described by a second-order Boltzmann function. (c) The prevailing model for adaptation posits that following an excitatory stimulus calcium enters open transduction channels and promotes a decline in open probability on two timescales. Fast adaptation occurs within the first few milliseconds and may result in change in the relationship between tension and open probability such that the channels are forced closed (reclosure model). This force is predicted to generate a negative movement in bundle position. Alternatively, fast adaptation may result from a release of tension within the transduction complex, which allows channels to close and the bundle to move farther in the positive direction (release model). Slow adaptation (not shown) follows fast adaptation and results from slipping of the adaptation motor down the side of the taller stereocilium, which also decreases tension and allows the channels to close. (b) Adapted from Pickles JO and Corey DP (1992) Mechanoelectrical transduction by hair cells. *Trends in Neuroscience* 15: 254–259.

Hair cell transduction channels are not particularly selective, passing all of the alkali cations, many divalent cations (including calcium), and small organic cations up to about 0.7 nm in diameter. Thus, the reversal potential is close to 0 mV. Taken together with a single-channel conductance of 90–100 pS and estimates of up to 200 channels per cell (1 or 5 per stereocilium), deflections of the hair bundle can evoke transduction currents of up to ~1 nA. Several independent experiments, including measurement of extracellular current and focal application of channel blockers, have localized transduction channels to the tips of stereocilia. This was confirmed by imaging calcium that flows into the cell through the transduction channels. Intracellular calcium was seen to rise first at the tips of the stereocilia and then more slowly

along their lengths. Furthermore, these experiments concluded that the channels could be found at either end and probably at both ends of tip links.

Hair cell transduction channels are opened by force applied to elastic elements, termed 'gating-springs,' that are stretched by positive deflections (toward the tallest stereocilia) of the hair bundles. Tip links seem ideally positioned to be gating-springs because they run parallel to the staircase arrangement of the hair bundle and join the top of one stereocilium to the side of its adjacent taller neighbor along the axis of polarity. The discovery that breaking tip links, by treatment with low concentrations of extracellular calcium, abolishes transduction provides compelling evidence that tip links are an essential element. However, the concept that tip links act as the gating-springs has recently been challenged. High-resolution images have revealed that tip links are rigid extracellular filaments, ~10 nm in diameter and 150–200 nm long (Figure 1(e)). They appear to consist of two to three coiled fibers with a helical period of ~25 nm and multiple globular domains ~4 nm in diameter. These measurements are consistent with the molecular dimensions of cadherin 23 (CDH23), which has 27 cadherin domains. CDH23 has been immunolocalized to the hair bundle and mutations in the gene that encodes CDH23 cause deafness and balance disorders in mice and humans. However, the notion that CDH23 is a component of the tip link remains controversial because hair bundle immunolocalization is lost in adult mice despite the persistence of tip links, which suggests that CDH23 may play a role in hair bundle development instead. Nonetheless, the rigid structure of the tip link suggests that the search for the molecular identity of biophysically defined gating-spring should be shifted to other elements, mechanically in series with the transduction channel.

The Process of Adaptation

Steady deflection of the bundle in the excitatory direction causes an initial activation of transduction channels, followed by a decline in the response toward the resting level as transduction channels close (Figure 2(b)). The instantaneous activation curve measured after 100 ms or so is shifted to the right, relative to its position at rest (Figure 2(b)). Tension on transduction channels relaxes during the deflection so that additional deflection can reactivate the channels. Similarly, a negative deflection that closes channels is followed by adaptation that increases the tension and shifts the activation curve to the left. This process, commonly referred to as adaptation, allows hair cells to retain high sensitivity over a broad operating range and filters out slower stimuli in favor of rapid stimuli. The current decline to constant stimuli typically exhibits a bimodal decay, which reveals two rates of adaptation: fast adaptation occurs within a few milliseconds or less while slow adaptation is about 10 times slower. The two forms of adaptation, although both dependent on calcium, reflect distinct mechanisms.

Circumstantial evidence has suggested that slow adaptation requires myosin molecules, perhaps in a cluster of a few dozen molecules. Members of the myosin family are the only molecules known to move on actin, and actin in the cores of stereocilia is polarized so that myosin would climb up to reset tension. The rate at which the climbing phase of adaptation (for negative stimuli) occurs and the rate at which muscle myosin-coated beads climb up the actin core are 1–2 $\mu m\, s^{-1}$, similar to the rate of myosin in other systems. Compounds that block myosin–actin interaction abolish adaptation.

Like myosin–actin interactions in other systems, the hair cell adaptation mechanism is regulated by calcium and the calcium-binding protein, calmodulin. The increase in intracellular calcium concentration that results from open transduction channels increases the rate of adaptation. When calcium levels rise, the myosin motors dissociate from actin and slip down the side of the stereocilium, which in turn relieves tip-link tension and allows the channels to close.

Out of ~40 members of the myosin superfamily, immunolocalization data focused the search for the adaptation motor on myosin 1c (formerly known as myosin 1-beta). A role for myosin 1c in adaptation was confirmed physiologically, using a mouse model in which myosin 1c was mutated, sensitizing it to a chemical inhibitor. When the inhibitor was added, both slow and fast adaptations were abolished in mutant but not wild-type vestibular hair cells.

Several other members of the myosin superfamily, including myosin 7a and myosin 15, appear to be critical for normal hair bundle development and function. Naturally occurring mutations in myosin 7a cause altered hair bundle morphology and, as a result, auditory and vestibular deficits in mice and humans. Taken together with localization data, this suggests that myosin 7a may be involved in holding the stereocilia together and maintaining the hair bundle within the properly erect mechanosensitive range.

It should be noted that slow (>10 ms) myosin-based adaptation has been most fully characterized in vestibular hair cells of bullfrogs and mice. Fast adaptation has been well characterized in hair cells of the turtle auditory organ and recently in the rat cochlea. In these cells, fast adaptation is also calcium dependent and causes a similar shift of the activation curve. It has been suggested that calcium entering through an open transduction channel can bind to

and force reclosure of the channel (reclosure model: Figure 2(c)). A second model for fast adaptation has been proposed that suggests that entering calcium triggers the release of a mechanical element in series with the transduction channel (release model: Figure 2(c)). The release reduces tension to the gating-spring and allows the transduction channels to close. Although both models explain the rapid decay in transduction current, they make opposite predictions on the movement of the hair bundle that occurs during fast adaptation. The reclosure model predicts that channel reclosure will increase tension in the gating-spring, which will pull the bundle in the negative direction (to the left in Figure 2(c)). The release model predicts that there will be a reduction in gating-spring tension which will allow the bundle to move further in response to a constant force (to the right in Figure 2(c)). Recent data from mice and rats are consistent with the release model, whereas data from turtle and some from frog hair cells support the reclosure model. The models are not mutually exclusive and both mechanisms may coexist in the same cell or to varying degrees in hair cells of different organs and species.

Cochlear Amplification

Mechanical amplification of sound stimuli in mammals requires the activity of outer hair cells which reside in three rows along the entire length of the mammalian cochlea. The process is known as cochlear amplification and functions to enhance sensitivity to faint sounds, and to tune or sharpen fine pitch perception. Two mechanisms have been proposed to underlie cochlear amplification: somatic motility, driven by the hair cell receptor potential, and active movements of the hair bundle, associated with fast adaptation.

Somatic motility requires the voltage-sensitive membrane protein, prestin, which is abundant in the lateral membranes of mammalian outer hair cells but absent in hair cells of lower vertebrates. The somatic motility theory for cochlear amplification posits that sound stimuli generate receptor potentials that evoke voltage-dependent conformational changes in prestin such that the protein contracts with depolarization and expands with hyperpolarization. Because the collective motion of the densely packed molecules occurs parallel to the lateral membranes, outer hair cells shorten and elongate in time with changes in membrane potential. The force produced by somatic motility in isolated outer hair cells is about 100 pN mV^{-1}. Forces of this amplitude are predicted to generate synchronous motion of outer hair cells; this, in turn, amplifies the overall motion of the basilar membrane in phase with the sound stimulus. However, because somatic motility depends on the hair cell receptor potential, the membrane time constant will likely limit force production at the high stimulus frequencies to which auditory organs are known to be sensitive. In addition, because cochlear amplification also occurs in lower vertebrates that lack outer hair cells and prestin, a second mechanism has been invoked.

The other model suggests that the forces generated by the hair bundle during adaptation are sufficient to drive amplification of sound stimuli in the auditory organs of many different species. Although the mechanism of fast adaptation is controversial, there is agreement that fast adaptation can drive active hair bundle movements. The active bundle movements are on the order of tens of nanometers. If the hair bundle movements are in phase with the sound stimulus, their collective motion is also predicted to drive amplification of basilar membrane oscillations. To tease apart the relative contributions of somatic motility and hair bundle motility will require their selective inactivation in live animals.

The Receptor Potential

Mature hair cells lack voltage-gated sodium channels, therefore they do not generate action potentials. Rather, changes in transduction channel activity evoke graded receptor potentials of up to 40 mV. The receptor potential is modified by the activity of voltage- and ion-sensitive conductances in the basolateral membrane. In some hair cells depolarizing receptor potentials elicit oscillations of the membrane potential that may serve to tune the cell to a particular stimulus frequency. These oscillations result from an interplay between activation of α-1D calcium channels and BK calcium-dependent potassium channels. Variation in the kinetics of BK channels results from both alternative splicing and co-assembly with β subunits and gives rise to membrane potential oscillations that vary in frequency among hair cells of the same organ.

The ability of hair cells to signal stimuli of either polarity is preserved at the afferent synapse. At the cell's resting potential (−50 to −70 mV), voltage-sensitive calcium channels are tonically active. This results in a steady release of neurotransmitter, which in turn results in a steady background firing in the fibers of the eighth nerve. Thus, receptor potentials of either polarity modulate calcium channel activity and hence transmitter release. A presynaptic electron-dense body (~0.5 μm in diameter) at each release site, around which vesicles cluster, is reminiscent of the synaptic ribbon in photoreceptors and may serve a

similar role in mediating continuous release. Neurotransmitter release is modulated with submillisecond precision to encode the frequency and intensity of sound and head movements. The excitatory amino acid glutamate has been shown to be released by hair cells, but it is not clear whether it is the primary transmitter or whether other transmitters are co-released.

The efferent synapse, carrying feedback control from the central nervous system (CNS) via the olivocochlear fibers, uses acetylcholine as the transmitter. The synapse may be excitatory in some hair cells, but in most organs efferent stimulation causes a slow inhibitory hyperpolarization. The inhibition is caused by activation of calcium-dependent potassium channels (SK). SK channels are voltage insensitive and can be activated by micromolar concentrations of calcium. The $\alpha 9$ and $\alpha 10$ nicotinic cholinergic subunits have been shown to form the receptor that mediates synaptic transmission between the efferent fiber and hair cells. The high degree of calcium permeability of this receptor may permit sufficient calcium entry to activate SK calcium-dependent potassium channels, and this, in turn, inhibits the cell.

Headache

D G Jamieson, Weill Medical College of Cornell University, New York, NY, USA

Introduction

Headaches are a universal human experience; almost everyone has had a headache at some time. Chronic headaches are one of the most common patient complaints in a general medical, and certainly in a neurological, practice. Although most headaches cause only self-limited head, neck, or face pain, some headaches may be a symptom of a life-threatening vascular, anatomic, or infectious disorder. In 2004 the International Headache Society (IHS) published definitions of headache types in an effort to standardize headache diagnosis and to improve recognition and treatment. The second edition of the International Classification of Headache Disorders (ICHD-II) divided headaches into primary and secondary types, with multiple subcategories within each type.

Primary Headaches

Primary headaches, the most common headache type, are not caused by anatomic, inflammatory, infectious, or physiological abnormalities. Approximately 98% of patients who present for medical evaluation will have a type of primary headache. The three major primary headache categories are migraine headache (with or without aura), tension-type headache (TTH), and cluster headache or other trigeminal autonomic cephalalgias, as described in Table 1. Other more unusual types of primary headaches occur less frequently, but are especially common in individuals who are prone to migraine headaches. The recognition of the primary headache type is useful for identifying the cause of the headache and directing appropriate treatment. However, the headache-prone patient may suffer from multiple primary headache types, which often respond to the same acute and preventative medications. Also, as useful as this categorization is in diagnosing headaches, patients' descriptions of their pain and associated symptoms may overlap the different categories.

Migraine

Most patients who seek medical attention for chronic headaches have migraine headaches. Almost 28 million Americans (21 million women and 7 million men) have frequent or severe migraines. Half of these individuals have functional disability as a result of these headaches. The American Migraine Prevalence and Prevention (AMPP) study estimated a 1-year period prevalence of 11.7% (5.6% for men and 17.1% for women) for migraine according to the strict migraine diagnostic criteria of ICHD-II. Headaches span the human life cycle, with young children and centenarians suffering from migraine headaches; however, the peak age for migraines is 25–55 years. According to the AMPP study, approximately a quarter (24.4%) of all women aged 30–39 years suffer from migraine headaches. The study found that migraine was more prevalent in women, in Caucasians more often than in African-Americans, and in those of lower, as compared to higher, incomes.

Migraine is a disabling, neurobiological disorder caused by complex and incompletely understood pathophysiological mechanisms. The majority of patients with migraine have a family history of headaches, inherited in an autosomal dominant pattern with unclear genetic linkage. A rare subtype of migraine with aura, familial hemiplegic migraine, has been mapped to specific genes, including a mutation of a P/Q voltage-gated Ca^{2+} channel gene (*CACNA1A*) on chromosome 19p13. A channel disturbance may be linked to the migraine aura, which is triggered by a reduced threshold for cortical spreading depression, the neuronal depolarization that may explain the evolution of the aura over time and space. The cranial vessels and their innervation through the trigeminal vascular system mediate migraine pain, which is characteristically throbbing and often unilateral. Stimulation of the dorsal horn neurons of the upper cervical ganglia, as well as of the trigeminal nucleus caudalis, explains the posterior head and neck pain frequently noted by migraine sufferers. The dura is innervated by the nerves of the ophthalmic (V-1) division of the trigeminal nerve, with trigeminal ganglion stimulation resulting in release of inflammatory neuropeptides and dilation of meningeal vessels. Interest in blocking the action of these neuropeptides has been disappointing for substance P antagonists, but calcitonin gene-related peptide antagonists show promising initial results in treating acute migraine. During a migraine attack, patients have a lower threshold for cortical activation (explaining migraine aura) and sensory stimuli (explaining sensitivity to light, sound, and smell). Patients also report that ordinarily innocuous stimuli can be perceived as painful, the definition of allodynia. Activation of first-order trigeminal sensory neurons (peripheral sensitization of dural nociceptors) causes the throbbing pain and exacerbation of head pain with movement. Cutaneous

Table 1 ICHD-II criteria for primary headaches

Migraine without aura
A. At least five attacks fulfilling B–D
B. Attacks lasting 4–72 h
C. At least two of the following four characteristics:
  1. Unilateral location
  2. Pulsating quality
  3. Moderate or severe intensity
  4. Aggravation by physical activity
D. Accompanied by at least one of the following signs:
  1. Nausea or vomiting, or both
  2. Photophobia and phonophobia

Episodic tension-type headache
A. At least ten episodes occurring on <1 day per month on average (<12 days per year) and fulfilling criteria B–D
B. Headache lasting from 30 min to 7 days
C. Headache has at least two of the following characteristics:
  1. Bilateral location
  2. Pressing/tightening (nonpulsating) quality
  3. Mild or moderate intensity
  4. Not aggravated by routine physical activity such as walking or climbing stairs
D. Both of the following:
  1. No nausea or vomiting
  2. No more than one of photophobia or phonophobia
E. Not attributed to another disorder

Cluster headache
A. At least five attacks fulfilling criteria B–D
B. Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15–180 min if untreated
C. Headache is accompanied by at least one of the following:
  1. Ipsilateral conjunctival injection and/or lacrimation
  2. Ipsilateral nasal congestion and/or rhinorrhoea
  3. Ipsilateral eyelid edema
  4. Ipsilateral forehead and facial sweating
  5. Ipsilateral forehead miosis and/or ptosis
  6. A sense of restlessness or agitation
D. Attacks have a frequency from one every other day to eight per day
E. Not attributed to another disorder

From Headache Classification Committee of the International Headache Society (IHS) (2004) International Classification of Headache Disorders II. *Cephalalgia* 24(supplement 1): 9–160.

allodynia, present to some degree in up to 80% of patients with migraine, involves central sensitization of second-order neurons of the trigeminal nucleus caudalis and potentially the third-order neurons in the thalamus. Central modulation of migraine pain has been shown in positron emission tomography studies to occur in the dorsal midbrain, including the periaqueductal gray, and in the dorsal pons near the locus coeruleus. Stimulation of these and other pontine and midbrain regions may mediate cerebral blood flow, facilitating trigeminovascular pain processing. Pain relay networks connect the brain stem nuclei and the upper cervical ganglia to thalamic nuclei, particularly in the ventroposteromedial thalamus.

Migraine headaches may be triggered in susceptible individuals by environmental stimuli that are innocuous to nonmigraine sufferers. The most common migraine triggers include change in sleep habits (too much or too little sleep), stress or relief from stress, alcohol, change in weather, and hunger and/or dehydration. Some foods may trigger some headaches in some people at some time, but in general strict food avoidance has little effect on migraine attacks. The most common food triggers include processed or cured meats, moldy cheese, artificial sweeteners, and monosodium glutamate. In many women, their menstrual period is a very strong trigger for their most severe migraine headaches.

Women are particularly prone to migraine headaches, with different susceptibilities to headaches throughout their life influenced by hormonal (estrogen) changes. Migraines may start during puberty, at onset of menses. About 70% of women with migraine will have an exacerbation of their headaches associated with their menstrual cycle, with most of these menstrual migraines occurring in the 2–3 days of decreasing estrogen levels prior to menstrual flow. Migraines may occur in the first or second trimesters of pregnancy, but they improve as pregnancy progresses parallel with increasing estrogen levels. The general improvement in migraines in pregnancy, especially in the later months, is fortuitous, as absolutely risk-free options for treatment with acute and preventative medications during pregnancy are limited. About 40% of women will report their first migraine during pregnancy or shortly after delivery. Migraines may worsen after delivery as estrogen levels drop along with sleep deprivation and stress. Many women report an increase in frequency and severity of their headaches at the onset of perimenopause, but headaches generally lessen significantly after menopause and migraines are rare in elderly women and men.

The linkage between migraine and vascular disease is complex, as about one in three adults has some form of cardiovascular or cerebrovascular disease, and migraine afflicts a large number of adults who may also be at vascular risk. The relationship is more than a coincidental overlap, as migraine represents a vascular risk for both ischemic stroke and myocardial infarction. The Women's Health Study found that women who had migraine with aura had an increased risk of vascular events, including ischemic stroke, myocardial infarction, angina, and vascular death. This increased risk was not found in women who had migraine without aura. The highest association between migraine with aura and ischemic stroke was in younger women. This study confirmed that women with migraine with aura have a greater risk of cardiovascular, as well as cerebrovascular, disease; however the precise mechanisms to explain this association are

currently unknown. Since migraine without aura is far more common than migraine with aura, a majority of migraine patients are not at increased vascular risk. This mildly increased vascular risk should be considered when counseling and treating patients with migraine with aura.

Patients with chronic headaches often describe that they have sinus headaches; however, chronic headaches due to recurrent cranial sinus infections are rare, and nasal polyps and deviated septa do not cause chronic headaches. Headaches due to acute bacterial infections of the ethmoid or maxillary sinuses cause perinasal, periocular, or frontal facial pain with purulent nasal discharge. Sinus headaches occur with fever and evidence of significant sinus disease on imaging of the cranial sinuses. The great majority of patients with recurrent, intractable 'sinus headaches' have migraine or other primary headaches. Nasal congestion, rhinorrhea, and facial pain are common associated symptoms of migraine headaches. Change in weather and environmental allergies, often misperceived to be associated with chronic sinus infections, are common migraine triggers.

Migraine with aura Most migraines are not accompanied by any focal neurological symptoms; however, about 30% of migraine sufferers have some headaches that are presaged by a neurological aura which is most commonly visual. Focal neurological symptoms (visual disturbances, numbness, unilateral weakness, speech difficulty) occur prior to or during the head pain of migraine with aura. The visual aura generally lasts less than 60 min, with positive (photopsias, wavy, or zigzag lines) or negative (scotomata, tunnel vision) visual phenomena often described as lasting 15–30 min. The most commonly described visual aura is binocular alteration in vision with a scintillating scotoma in the peripheral vision that increases in size over time, and then disappears. There may be a symptom-free period of up to 60 min before the contralateral headache pain begins.

Probable migraine Most migraine suffers have some migraine-like headaches that do not conform to the strict IHS criteria for migraine, with or without aura. These probable migraine headaches respond to migraine treatment, both acute and preventative. The pain of a migraine headache may be sharp or pressure-like, rather than throbbing, or it may be bilateral, rather than unilateral. Nausea and vomiting, as well as sensitivity to light, sound, and movement, may not be present with every migraine headache in every migraine sufferer. The AMPP study found that probable migraine, defined as migraine fulfilling all but one criterion for migraine with or without aura, was a frequent, undertreated, and sometimes disabling condition, found more often in older men and women, ages 30–59 years. In contrast to migraine, probable migraine was more prevalent in African-Americans than in Caucasians in the AMPP study.

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headaches occur much more frequently in middle-aged men than in women, and may be associated with chronic smoking and excess alcohol use. Cluster headaches characteristically occur in the early morning hours, awakening the man from sleep with excruciating pain and autonomic symptoms. As compared to migraine suffers, who seek quiet and isolation during a migraine attack, men with cluster tend to be agitated or even violent. The attacks tend to occur daily, once to multiple times a day, for a period of weeks to months, and then they may remit for months to years. The attacks of cluster pain are relatively short in duration, but the pain is very intense, and the attacks are best treated with preventative medication, such as verapamil, steroids, or topiramate. Acute attacks may be treated with nasal oxygen, subcutaneous sumatriptan, and nasal triptans.

Other headache types present as attacks with pain and associated symptoms similar to those of cluster headaches, but are shorter lasting and more frequent. They occur more commonly in females than in males, and may respond to indomethacin. These headaches include episodic and chronic benign paroxysmal hemicrania. The multiple daily attacks of paroxysmal hemicrania are severe, unilateral, orbital, supraorbital, or temporal pain lasting 2–30 min. They are generally accompanied by conjunctival injection, nasal congestion, lid swelling or ptosis, or facial swelling. Paroxysmal hemicrania characteristically responds to daily indomethacin prophylaxis.

A syndrome with short-lasting attacks of unilateral pain lasting for 5–240 s, occurring from 3 to 200 times per day, is called SUNCT (short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing). The pain is stabbing or pulsating in an orbital, supraorbital, or temporal location and may be refractory to acute and preventative treatment.

Tension-Type Headache

The TTH is the most common type of primary headache, with the lifetime prevalence in the general population of 30–78%. Most patients treat their TTH with over-the-counter medications and do not seek medical attention, but the disability from these headaches can be severe. There may be a neurobiological basis

for the more severe subtypes of TTH, but the exact pathophysiological mechanism of these headaches is not known. TTHs may be episodic or chronic. Diagnoses of chronic TTH and episodic TTH are based on the same criteria, except that the chronic TTH occurs ≥15 days per month on average for >3 months (≥180 days per year). Chronic tension-type headaches may evolve over time from episodic TTHs, especially with the overuse of acute pain medications.

Chronic Daily Headaches

Chronic daily headaches diminish the quality of life for patients and their families and pose a therapeutic challenge to physicians. A chronic daily headache is a headache of any type, either primary or secondary, that occurs for at least 15 days per month for longer than a month. Primary chronic daily headaches, which afflict up to about 5% of the population, are divided into short-duration (<4 h) and long-duration types. The most common long-duration types are chronic TTH, chronic migraine, and transformed migraine. The IHS classification emphasizes the increasing frequency of these headaches, which segue from episodic to chronic. Headache attributed to medication overuse, an important cause of primary chronic daily headache, can occur with excess and prolonged use of acute pain medication. The ICHD-II definition of this chronic headache type, which may show dramatic improvement with discontinuation of acute pain medications, is shown in Table 2. The use of a daily preventative medication, with judicious use of acute pain medication, can decrease primary chronic daily headaches, which may then evolve back to episodic headaches. The treatment of secondary chronic daily headaches depends on the underlying cause of the headaches.

Table 2 Headache attributed to medication overuse

A. Headache present on >15 days, fulfilling criteria C and D
- Characteristics of headache depend on drug

B. Regular overuse of a medication for >3 months
- Amount of overuse depends on drug
- Ergotamine, triptans, opioids, and combination analgesics, ≥10 days per month
- Over-the-counter analgesics, >15 days per month

C. Headache has developed or markedly worsened during medication overuse

D. Headache resolves or reverts to its previous pattern within 2 months after discontinuation of overused medication

E. Over the counter

From Headache Classification Committee of the International Headache Society (IHS) (2004) International Classification of Headache Disorders II. *Cephalalgia* 24(supplement 1): 9–160.

Other Primary Headache Types

Other primary headache types include heterogeneous, poorly understood, headaches. When the pain is identified as due to one of these relatively rare primary headaches, the sufferer can be reassured and appropriately evaluated and treated. Primary stabbing headaches consist of multiple episodes of transient stabbing pain, lasting seconds, in the distribution of the ophthalmic division (V–1) of the trigeminal nerve. Short-lasting stabbing pains are commonly described by patients with migraine. Exertion, such as exercise, cough, Valsalva, or orgasm, can precipitate a headache in patients who may or may not have a prior headache history. These headaches may be responsive to indomethacin or they remit on their own. Hemicrania continua, a unilateral continuous headache, with ipsilateral conjunctival injection, nasal congestion, or ptosis, is characteristically responsive to indomethacin. A new daily-persistent headache produces bilateral, mild/moderate pain which is daily and unremitting for greater than 3 months after its onset.

Secondary Headaches

Most secondary headaches are due to distinct and known anatomic, physiological, or infectious causes. While they are much less common than primary headaches, secondary headaches should be considered in patients who present for evaluation of either acute or chronic headaches. Patients who have a primary headache disorder may also develop unrelated secondary headaches, so primary headache patients should be questioned about a marked change in headache character or frequency that could indicate a new superimposed headache type. There are many types of secondary headaches, only some of which are mentioned here. Some of the major secondary headaches types according to the ICHD-II criteria are listed in Table 3.

Cerebrovascular disease is a major cause of secondary headaches, as outlined in Table 4. In a patient with ischemic stroke the complaint of headache is usually less prominent than the focal neurological symptoms. However, in a patient with a cerebellar infarct, a headache with nausea and vomiting may be a prominent symptom at presentation or it may be noted with the development of cerebellar edema and hydrocephalus. Although the headache due to a subarachnoid hemorrhage is most often described as being excruciatingly severe, a headache due to aneurysmal rupture is most remarkable for being maximally severe at onset, as opposed to the more gradual onset of pain with most other headache types.

Table 3 Secondary headaches

- Head and neck trauma (posttraumatic, intracranial hematoma, postcraniotomy)
- Vascular disorder (ischemic stroke, intracranial hemorrhage, vascular malformation, dissection, arteritis, venous thrombosis)
- Nonvascular intracranial disorders (increased or decreased cerebrospinal fluid pressure, inflammatory disease, neoplasm)
- Substance use or withdrawal (medications, illicit drugs, alcohol, toxins)
- Infection (intracranial infection, systemic infection, HIV/AIDS)
- Disorders of homeostasis (hypoxia, hypercarbia, dialysis, hypertension, hypothyroidism)
- Headaches and facial pain due to facial structures (cranial bones, neck, eyes, ears, temporomandibular joint, sinuses)
- Psychiatric disease (somatization disorder, psychotic disorder)
- Cranial neuralgias (trigeminal and other neuralgias, cranial nerve compression, central causes of facial pain)

From Headache Classification Committee of the International Headache Society (IHS) (2004) International Classification of Headache Disorders II. *Cephalalgia* 24(supplement 1): 9–160.

Table 4 Secondary headaches due to cerebrovascular disease

Subarachnoid hemorrhage (SAH)
Risk: women > men; cigarette smoking, OCP, head trauma, anticoagulation
Pathophysiology: ruptured cerebral aneurysm, trauma, venous hemorrhage
Symptoms: sudden onset of moderate/severe headache; maximal pain at onset, syncope, seizures, coma
Diagnosis: CT scan (<10% negative for blood), LP, MRI/MRA, CTA, angiogram
Treatment (very high morbidity/mortality): nimodipine, clip/coil aneurysm, ↑ BP, ↑ fluids
Warning: have a low threshold to investigate a sudden, severe headache to rule out SAH

Cerebral venous thrombosis (CVT) (sagittal sinus thrombosis)
Risk: women > men, head trauma, dehydration, infection, thrombophilias, pregnancy, OCP, HIV
Pathophysiology: clotting of cerebral venous sinuses (sagittal sinus)
Symptoms: moderate/severe headaches, sudden-onset headaches/seizures, coma
Diagnosis: enhanced CT scan (empty delta sign); MRI/MRV, cerebral angiogram
Treatment: heparin, ↑ fluids, antibiotics, intrasinus thrombolysis
Warning: intracerebral hemorrhage is not a contraindication to anticoagulation with CVT

Intracerebral hemorrhage (ICH)
Risk: HTN, head trauma, anticoagulation, vascular malformations (AVM, cavernous malformation), amyloid angiopathy, ↑ bleeding due to medications/conditions
Pathophysiology: rupture of normal or abnormal blood vessels with hemorrhage in characteristic locations for HTN (basal ganglia, thalamus, cerebellum, pons) and cerebral amyloid angiopathy (lobar)
Symptoms: sudden-onset moderate/severe headache; neurological deficits, seizures, coma
Diagnosis: hyperdensity on unenhanced CT scan; MRI/MRA, cerebral angiogram
Treatment: supportive care, BP stabilization, surgical evacuation
Warning: presentation of an ICH can be identical to that of an ischemic stroke

Subdural hematoma (SDH)
Risk: head trauma, dural metastases, medications/conditions that ↑ bleeding, intracranial hypotension
Pathophysiology: rupture of dural bridging veins with hemorrhage into dural space
Symptoms: new-onset mild/moderate/severe headache; neurological deficits, seizures, coma
Diagnosis: concave hyperdensity on unenhanced CT scan; MRI/MRA
Treatment: surgical evacuation, supportive care (small)
Warning: bilateral isodense SDHs with symmetric mass effect can be occult on CT scan

Epidural hematoma (EDH)
Risk: head trauma, skull fracture
Pathophysiology: rupture of menigeal arteries with rapid hemorrhage above the dura space
Symptoms: new-onset moderate/severe headache; syncope, neurological deficits, seizures, coma
Diagnosis: convex (lens) hyperdensity on unenhanced CT scan; MRI/MRA
Treatment: immediate surgical evacuation
Warning: transient period of consciousness followed by loss of consciousness

AVM, arteriovenous malformation; BP, blood pressure; CTA, computed tomography angiogram; HTN, hypertension; LP, lumbar puncture; MRI, magnetic resonance imaging; MRA, magnetic resonance angiography; MRV, magnetic resonance venography; OCP, oral contraceptive pill.

The most important cause of a 'thunderclap headache' is aneurysmal subarachnoid hemorrhage, since timely aneurysmal obliteration can decrease the significant mortality due to aneurysmal rebleeding. Other causes of the sudden onset of severe headache without gradual buildup of pain include cerebral venous thrombosis, pituitary apoplexy, and intracerebral hemorrhage. Despite these dire causes of

Table 5 Headaches due to disorders of cerebrospinal fluid dynamics

Increased cerebrospinal fluid pressure headache (pseudotumor cerebri; idiopathic intracranial hypertension)
Risk: obesity (in women), steroids, cerebral venous thrombosis (CVT)
Symptoms: holocephalgic pain, pulsatile tinnitus, VI palsy, transient visual obscurations
Diagnosis: ↑ opening pressure on LP; papilledema; normal or 'slit-like ventricles' on CT
Treatment: acetazolamide, topiramate, ↓ weight; optic nerve decompression, serial LPs
Warning: untreated, can result in visual loss from optic nerve compression
Decreased cerebrospinal fluid pressure headache (spontaneous intracranial hypotension)
Risk: lumbar puncture, trauma, spontaneous
Pathophysiology: leakage of cerebrospinal fluid through dural tear
Symptoms: holocephalgia pain worse upright, improved recumbent
Diagnosis: enhancement of leptomeninges on magnetic resonance imaging, bilateral subdurals
Treatment: lumbar blood patch, time, hydration, caffeine
Warning: may take weeks to months to resolve; may be associated SDHs

LP, lumber puncture; SDH, subdural hematoma.

thunderclap headache, crash migraine is the most common cause of the sudden onset of a severe headache. Migraine variants such as primary cough headache, exertion-related headache, and sex-related headache can also present with the sudden onset of severe head pain.

The etiology of a secondary headache may be deduced based on the patient's history and physical examination. Body habitus may point toward a headache cause; idiopathic intracranial hypertension and obstructive sleep apnea may result in headaches associated with obesity. Disorders of cerebral spinal fluid (CSF) dynamics may cause characteristic headaches (Table 5). The distinctive feature of a headache due to intracranial hypotension is the prominent increase of pain while upright, with marked improvement in pain while recumbent. This headache, due to dural leakage of CSF, can occur spontaneously or after a lumbar puncture and may be associated with subdural hematomas. Brain tumors are generally heralded by focal neurological signs and symptoms. Central nervous system infections, including meningitis, encephalitis, and brain abscess, may present with isolated headache, but are most often accompanied by fever, an alteration in consciousness, and focal neurological signs and symptoms. When there is a suspicion of a secondary headache, neuroimaging with a magnetic resonance imaging (MRI) scan (or computed tomography scan if MRI is contraindicated) may indicate the diagnosis.

Facial Pain Syndromes

Some primary headaches present with pain confined to the face and periorbital area. Other types of facial pain are considered secondary headaches. While most facial pain is not caused by an underlying anatomic lesion, new-onset facial pain that does not fit into an idiopathic pain syndrome should be investigated for a benign or metastatic neoplasm, especially if there is a focal neurological deficit.

Trigeminal neuralgia (TN) causes abrupt, paroxysmal pain that occurs in the unilateral distribution of one of the three branches of the trigeminal nerve. Patients characteristically discover trigger areas on the face or activities such as eating or brushing teeth that precipitate flashes of sharp stabbing electrical like pain. The lacinating pain of TN occurs frequently for days to months and then it may remit spontaneously, only to return years later. Medication and rarely surgery can offer significant relief, although some patients may be particularly difficult to treat. Postherpetic neuralgia is another cause of facial pain in older individuals. The pain after a herpes zoster infection is generally constant, not episodic like TN, and occurs at the location of the preceding cutaneous lesion.

Temporomandibular disorders cause facial pain and may trigger or perpetuate headaches. Inflammation of the temporomandibular joint (TMJ), as well as displacement of the articular surface of the joint, may lead to local or referred facial pain. Indications of TMJ disease include facial pain precipitated by joint movement, TMJ pain on joint palpation, joint noise, and limited range of motion. Treatment may include use of a splint therapy, anti-inflammatory medications, relaxation therapy, and rarely surgery. The contribution of temporomandibular and dental disorders to chromic primary headaches is incompletely understood.

Headaches at Different Ages

Children

Primary headaches are generally an adult affliction, but children also suffer from chronic headaches. Children may have migraines, tension-type headaches, idiopathic stabbing headaches, or non-classifiable headaches. Boys are more likely than girls to have preschool onset of primary headaches including migraine, but they have a higher remission rate as they get older. Children with a preschool age onset of headache generally have a relatively benign prognosis for remission or improvement, with the type of primary headache predicting outcome. A child with tension-type or idiopathic stabbing headaches is more

likely to have remission with age than is a child with migraine. Children with migraine without vomiting are more likely to have fewer headaches as they grow up than will children who have vomiting with migraines. Family history of headache is common in children, with early-onset headaches in a child correlating with a history of an early onset of headaches in the child's parents.

Between 4% and 11% of children ages 5–15 years have migraines. From 1% to 3% of even younger children, ages 3–7 years, have migraines, with a slight male predominance. The distinctive migraine symptoms and syndromes in children do not fit easily into the criteria for diagnosis of migraine in adults. Younger children may have difficulty describing the quality and localization of the pain. The accompanying nonpain migraine symptoms, such as photophobia and phonophobia, may have to be inferred from the child's behavior. Preschool children have shorter duration migraine and the child's accompanying gastrointestinal symptoms, including nausea, intractable vomiting, and abdominal pain, may be more prominent than is the head pain. Head pain, generally unilateral in adults, is commonly bilateral in young children. Localization of the migraine head pain, which is relatively variable in adults, is usually frontotemporal in children. Pediatric migrainous disorders include cyclic vomiting syndrome, abdominal migraine, and benign paroxysmal vertigo, which may overlap with migraine headaches.

The impact of chronic headaches, including migraine, in children is significant, with missed school and social activities compromising quality of life. Pulling children out of school because of frequent absences due to headaches may have irreparable social and academic consequences. The accurate diagnosis of primary headache disorders in children, including preschoolers, can lead to improved treatment and decreased disability for these youngest of headache sufferers.

Older Adults

Although primary headaches tend to remit with age, certain headache types are characteristically seen in individuals in their 50s and older. Hypnic headache, an idiopathic headache disorder with a characteristic nocturnal pattern, is seen in older men and women. The headache occurs multiple times a month, awakening the patient from sleep with moderate to severe dull or throbbing pain. The pain is generally diffuse or frontotemporal and while it may be accompanied by nausea, it usually lacks the other associated features of migraine headaches or trigeminal-autonomic cephalalgias. Because the patient experiences the headache at the same time each night, the hypnic headache may be a rapid eye movement (REM) sleep disorder related to melatonin deficiency. The hypnic headache may be difficult to treat, although some patients experience relief with lithium, which may indirectly increase melatonin levels. Direct treatment with melatonin is of variable benefit.

Giant cell arteritis (GCA) is a cause of headache of variable description in patients older than age 50 years. The headache may be associated with systemic symptoms, including polymyalgia rheumatica, malaise, jaw claudication, and weight loss. Untreated GCA may progress to monocular or binocular visual loss due to involvement of posterior ciliary and central retinal arteries. Ischemic strokes occur rarely, generally in the posterior circulation. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels are generally elevated, but the diagnosis is confirmed by the granulomatous changes with multinucleated giant cells and lymphocytes seen pathologically on temporal artery biopsy. Prednisone to decrease the ESR, CRP, and headache and systemic symptoms may be needed for months to years, as relapses may occur with steroid tapering.

Headache Evaluation

The evaluation of a patient with headache depends on obtaining a detailed history of the headaches and other medical complaints. Table 6 outlines some of the points that may lead to the appropriate evaluation, diagnosis, and treatment of a patient who presents with headache. While most patients will have a benign cause of headaches, the clinician evaluating the patient should be aware of symptoms or signs that are suspicious for headaches that deserve a more detailed investigation and specific treatment. In general a focused neurological examination, concentrating on the mental status (ascertained during the history taking), cranial nerve evaluation including visualization of the optic nerve, strength and coordination testing, and muscle stretch reflexes will suffice to rule out an abnormal neurological examination due to a headache-related lesion. The majority of the time evaluating the patient should be spent obtaining a history, realizing that the neurologist will have more time to talk with the patient than will the primary care practitioner or emergency medicine physician.

Most patients who present with chronic primary headaches do not need to have a neuroimaging procedure. If the history and physical examination are consistent with migraine or tension-type headaches, without concerning aspects to the evaluation, then brain imaging is not needed. Table 7 lists some aspects of the evaluation that may indicate a secondary cause of headaches for which brain imaging should be

Table 6 Headache history

History	*Details/comments*
Age at onset	Childhood and teens (TTH, migraines); young adulthood (TTH, migraines); elderly (GCA, hypnic headache)
Duration of headache history	The longer the duration the less the likelihood of secondary cause
Family history	Up to 80% of migraine patients have some family history of headaches
Migraine history accompaniments	Motion/car sickness; brain freeze; episodic vertigo/dizziness
Medical history	Depression/anxiety; irritable bowel; insomnia
Onset of pain	Sudden onset with SAH; gradual onset with migraine or tension-type headaches
Location of pain	Unilateral with some migraines; bitemporal with TTH (not specific); focal pain in specific neuralgias
Quality of pain	Throbbing with migraine; pressure with TTH (not specific)
Severity of pain	Milder with tension type, more severe with migraine (use 1–10/10 pain scale)
Pain-associated symptoms	Nausea; vomiting; sensitivity to light/sound/smell; migraine aura
Duration of pain	Minutes with some primary headaches, hours to days with migraine, hours to years with tension-type headache
Relief of pain (meds)	Over-the-counter medications for TTH; triptans for migraine
Relief of pain (non-meds)	Rest/quiet/dark/temporal pressure/ice/sleep with migraines
Frequency of medication use	Pills per headache, pills per week/month (get very specific answers)
Frequency of pain	Headache days per week/month
Disability of pain	Missed work/social activities; job or family concerns; anticipation of disability

TTH, tension-type headache; GCA, giant cell arteritis; SAH, subarachnoid hemorrhage.

Table 7 'Red flags' in the headache history

- Unusually severe headache of sudden, rather than gradual, onset
- Unexplained marked worsening or change in character of previously existing headaches
- Headache awakening the patient at night (as opposed to waking up with a migraine headache)
- Headache that worsens when recumbent, coughing, sneezing (may also be noted in migraine)
- New-onset headaches at an older age (>50 years) without prior or family history of headaches
- Headaches in patients with cancer known to metastasize to brain or skull
- Headaches in patients with HIV or other systemic infections
- Headache associated with unexplained systemic illness (e.g., fever, chills, rash, stiff neck)
- Abnormal neurological examination in a headache patient, including presence of papilledema
- Focal neurological signs that persist at the conclusion of headache pain
- Chronic headaches, transient visual abnormalities, pulsatile tinnitus in an obese young woman

arranged. If the patient does not respond as expected to the appropriate migraine or TTH headache treatment, then imaging, generally an MRI scan of the brain without contrast, may be obtained. The MRI of the brain in a patient with migraine may show changes that are remarkable but not clinically significant, leading to unnecessary anxiety and physician consultation. Findings noted on the brain MRIs of patients with migraines include atrophy greater than expected for age and white-matter lesions. Deep white-matter lesions have been shown to be increased in women with migraines, with or without aura, and are associated with increased migraine frequency. Cerebellar lesions consistent with infarcts have been noted associated with migraine with aura occurring more than once a month. The correlation of these MRI lesions with pathological damage is not clear, but their presence may indicate those patients who should be treated to decrease the frequency of their migraines with aura.

Headache Treatment

Acute Treatment of Primary Headaches

General principles of primary headache treatment include establishing an accurate diagnosis and educating patients about their condition, including its natural history and specific treatment. Realistic expectations about treatment of a chronic condition should be encouraged. Patients must be enlisted to participate in the management of their headaches, complying with the evaluation and the lifestyle and medication recommendations. The patient and physician should discuss the patient's treatment and medication preferences in order to encourage cooperation with the recommendations. A headache diary to monitor the frequency and severity of headaches is encouraged to document the disability of the headaches and the patient's response to treatment.

Patients often need multiple nonpharmacological and pharmacological therapies. The first step in headache prevention is regulation of lifestyle to avoid triggers. Unfortunately, many major migraine triggers

are difficult or impossible to avoid (e.g., stress and change in weather) and medication may be indicated to decrease the disability associated with frequent episodic or chronic headaches. Nonpharmacological treatment of primary headaches can include stress reduction, regular pleasurable exercise, biofeedback, relaxation techniques, and counseling. Multiple medication types – including acute treatment to treat the pain when it occurs, preventative medication to decrease the frequency and severity of the headaches, and rescue medication to treat acute intractable pain-are used to decrease headache disability. Patients may need multiple different strategies in order to choose the best treatment for each particular headache. Treatment often combines medication and withdrawal from stimulation (e.g., sleep or rest in a quiet, dark room for migraine sufferers), with patients discovering over time what works best for different headache types.

Patients with acute headaches generally take over-the-counter (OTC) pain relief medications, including aspirin, acetaminophen, ibuprofen, and naproxen, even before seeking medical consultation. Acute therapy should be appropriate for the degree of pain, with OTC therapy for mild or TTH headaches, and migraine-specific medication (generally triptans) for more severe migraine headaches. The specific 5-hydroxytryptamine (5-$HT_{1B/1D}$; serotonin) receptor agonists (triptans) and the nonspecific 5-HT agonists (ergotamine and dihydroergotamine) are specific for acute migraine pain relief. The multiple triptan medications that are available in the United States to treat acute migraine headaches are listed in Table 8. Barbiturates, opioids, and isometheptene may be combined with anti-inflammatory medications for treatment of pain, although their use should be monitored because of the risk of headache associated with medication overuse (Table 2). When acute medications (OTCs and triptans) are ineffective, rescue with barbiturates and opioids used sparingly may be necessary. A prolonged migraine that is intractable to oral medications can be treated with parenteral drugs, including intravenous valproate or dihydroergotamine, often in combination with intravenous hydration and antiemetic medication.

Table 8 Triptans for treatment of acute migraine[a]

Sumatriptan (Imitrex): oral, 25, 50, 100 mg; nasal, 5, 20 mg; autoinjector, 6 mg, 4 mg
Zolmitriptan (Zomig): oral, 2.5, 5 mg; ODT,[b] 2.5, 5 mg; nasal, 5 mg
Naratritpan (Amerge): oral, 1, 2.5 mg
Rizatriptan (Maxalt): oral, 5, 10 mg; ODT, 5, 10 mg
Almotriptan (Axert): oral, 6.25, 12.5 mg
Frovatriptan (Frova): oral, 2.5 mg
Eletriptan (Relpax): oral, 40 mg

[a]Triptans are serotonin (5-hydroxytryptamine; 5-$HT_{1B/1D}$) receptor agonists.
[b]ODT, orally disintegrating tablet.

Preventative Treatment of Primary Headaches

Migraine sufferers who have frequent disabling headaches may need a daily medication to decrease the frequency and severity of primary headaches and to decrease the use of acute medications. The decision to start a preventative medication is individualized, after discussion between the patient and physician, but there are guidelines to indicate the appropriate treatment of patients with chronic primary headaches. The AMPP study defined three groups of patients, depending on whether prevention should be offered, considered, or not considered. Prevention should be offered to migraine sufferers reporting six or more headache days per month, four or more days per month with at least some impairment, or three or more headache days per month with severe impairment. Prevention should be considered for migraine sufferers reporting either four to five headache days per month with normal functioning, three headache days per month with at least some impairment, or two headache days per month with severe impairment. Patients with less frequent or severe headaches would generally not be appropriate for preventative therapy, realizing that some patients' jobs or lifestyles may dictate prevention for even rare headaches. With most migraineurs having one to four headache attacks per month with severe impairment, the AMPP found that approximately a third of the patients who had never used a preventative medication met the criteria for offering or considering its use. Physicians should try to obtain a history indicating the headache frequency, severity, and level of disability in order to evaluate the appropriateness of preventative treatment.

Table 9 lists some types of medications that have been used to decrease the frequency and severity of headaches. The choice of preventative medication

Table 9 Preventative medications for treatment of chronic headaches

- Beta blockers (propranolol, atenolol, timolol, metoprolol)
- Calcium channel blockers (verapamil)
- Angiotensin receptor blockers/angiotensin-converting enzyme inhibitors (candesartan, olmesartan, lisinopril)
- Tricyclic antidepressants (nortriptyline, amitriptyline)
- Anticonvulsant medications (gabapentin, valproate, topiramate)
- Selective serotonin reuptake inhibitors
- Nonsteroidal antiinflammatory drugs
- Other therapies (riboflavin, Mg, feverfew, vitamin B_2, butterbur, botulinum toxin)

is often dictated by the migraine patient's other medical or psychiatric conditions. Common conditions found in migraine patients that may also respond to treatment with a headache preventative medication include depression, anxiety, obesity, sleep disorders, hypertension, and wrinkles. A tricyclic antidepressant dosed at bedtime may be particularly helpful in a migraine patient with insomnia. A selective serotonin reuptake inhibitor can be used when there is a significant component of depression or anxiety triggering headaches. A medication that also lowers blood pressure is appropriate for the hypertensive migraineur. The potential for weight loss with topiramate is attractive to many migraine patients, as many other migraine prevention medications may cause weight gain. Patients often report improved response to triptan medication when they are also taking a preventative medication. Injection of botulinum toxin into muscles of the face, head, and neck may have a role in headache prevention, with wrinkle prevention benefits as well.

A headache is an annoyance at best; rarely is it an indication of a life-threatening condition. The suffering associated with severe or frequent primary headaches can be extreme. Patients who have lived with headache pain for years often think that having headaches is a 'normal' part of life for which there is no treatment. Historical details, the neurological examination, and, when indicated, brain imaging provide guidance in diagnosing these headache patients. Recognition of the disability of headaches along with a compassionate, consistent approach to the care of headache sufferers can markedly improve the quality of life for headache sufferers, many of whom are undiagnosed and undertreated.

Hearing and Echolocation in Dolphins

S H Ridgway, Space and Naval Warfare Systems Center, San Diego, CA, USA
W W L Au, University of Hawaii, Kailua, Hawaii

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Humans surpass most mammals in such important qualities of hearing as intensity and frequency discrimination and sound localization. During the past 40 years, research has shown that dolphins can localize sound and discriminate frequency and intensity as well as humans; moreover, it is now known that the range of dolphin hearing is about seven or eight times as broad as the range of human hearing which extends only to about 20 kHz. Audiograms have been done on several species of smaller odontocetes by both behavioral and electrophysiological techniques. *Tursiops* (Figure 1) responds to frequencies at least as high as 150 kHz with great sensitivity between about 10 and 120 kHz (Figure 2). Sensitive ears coupled with a massive auditory central nervous system are fundamental to the dolphin's extensive use of sound for communication and echolocation. As dolphins age, hearing sensitivity may degrade somewhat, especially in older males, where loss above 50 or 60 kHz appears to be common. Also, there is some evidence that long-term treatment with aminoglycoside antibiotics may degrade high-frequency hearing.

Open-Water Echolocation Studies with Trained Dolphins

Many echolocation studies have been done in the open waters of Kaneohe Bay, where a calm surface and muddy bottom help provide good acoustic conditions for the tests. In all dolphin echolocation experiments, here and elsewhere, the dolphins have emitted short (40–100 μs) pulses to search for underwater targets. The intense pulses (Figure 3), up to 230 dB re 1 μPa in peak-to-peak amplitude and with peak frequency often greater than 100 kHz, are directed forward in a narrow beam. With peak frequencies well outside the human hearing range, it is difficult for us to appreciate the intensity of dolphin echolocation pulses. An analogous airborne sound might be a pistol shot. At 1 m under water, dolphin pulses can have peak intensities as great or greater than the sounds of shots experienced by humans firing low-caliber rifles.

We still do not understand exactly how a dolphin can produce such loud pulses. The keen ears are located in the dolphin's head only a few centimeters away from pulse production mechanism. Anatomical structure, including sinuses containing highly reflective air, and various physiological mechanisms presumably help the animal avoid damaging its own ears.

Using these intense pulses, their sensitive hearing, and a nervous system specialized for rapid acoustic processing, dolphins can detect echoes from small objects at long ranges. For example, in behavioral studies, dolphins detected a 2.54 cm diameter steel ball 1.2 m under the surface to a range of 73 m and they detected a 7.62 cm water-filled sphere 113 m away. At 16 m range, dolphins distinguished objects of several different metals of identical size and shape. At the same range, dolphins detected a 0.23 mm difference in wall thickness of otherwise identical aluminum cylinders. Our studies have shown that over the range of 1–113 m, echolocating dolphins are superior to any human-made sonar for object detection and discrimination.

Studies of Dolphins in the Wild

It has only in recent times that detailed studies of dolphin echolocation in the wild have been undertaken using a multiple hydrophone array so that the echolocating animal could be localized. One remarkable finding is that the echolocation signals measured with five different species of odontocetes in widely separate locations suggest that these animals use a form of time-varying gain or automatic gain control. Time-varying gain is a technique used in technological sonar by which the gain of the receiver increases with time as a function of 40 log R, where R is the range in meters, to compensate for two-way spherical spreading losses that the signal and echo experience while propagating to the target and back. Dolphins instead vary the peak-to-peak source level (sound pressure level reference to 1 m in front of any projector) so that the further away a target is, the greater the output level of the echolocation signal, or, conversely, the closer the target the lower the output level. Variations in the pulse output level of five species of free swimming dolphins are shown in Figure 4. The solid line is the curve $K + 20 \log R$, that best fit the data with the r^2 value shown for each species. Not only are the data shown in Figure 4 from five different species of odontocetes, but the measurements were made at widely separated locations. The data for *Stenella frontalis* were obtained in the waters of the Bahama Islands, *Lagenorhynchus albirostris* in the waters of Iceland, *Orcinus orca* in the waters of

Figure 1 The bottlenose dolphin *Tursiops truncatus*. Note the absence of any signs of an external ear or pinna.

Vancouver Island, British Columbia, *Lagenorhynchus obscurus* in the waters of Kailoura, New Zealand, and *Neophocaena phocaenoides* in the Yangtze River of China.

The dynamic control of the echolocation source level is probably not the result of a cognitive process, at least not on a pulse-by-pulse basis, but rather a natural consequence of how echolocation clicks are produced. Dolphins typically emit echolocation clicks at a rate that allows the echoes to return to the animal before the next click is emitted. Consequently, the repetition rate increases as an animal closes on a target. The clicks are produced within the nasal system. Dolphins manipulate the air flow through the phonic lips within the nasal or blowhole complex. Dolphins initially pressurize their nasal system and then emit a click train with the individual clicks occurring at relatively low repetition rates. The animal continually adjusts the rate as targets are located. If the dolphin chooses to keep the amount of acoustic energy emitted relatively constant or within certain limits for each pressurization cycle, then the amplitude of the signal can be high when the repetition rate is low but the amplitude must continually decreases as the repetition rate increases. The data are consistent with the notion that there is a dynamic coupling between reception of echoes, repetition rate, and source level of transmitted signals.

Figure 3 An example of a dolphin pulse train with the frequency vs. time plotted on the left and individual pulses presented with their peak frequencies and levels (dB re 1 μPa peak to peak) on the right. From a dolphin in an echolocation task in Kaneohe Bay, Hawaii.

High-Frequency, Narrow-Band Echolocators

Numerous species of bats have developed their own specialized echolocation signals to cope with various different ecological niches. A few small whale species such as porpoises of the family Phocoenidae, the genus *Kogia*, pygmy sperm whales, and dolphins of the genus *Cephalorhynchus* specialize in brief narrow-band, very high frequency, lower-intensity echolocation pulses with energy centered around 130 kHz. We suggest that as in the case of bat echolocators, ecological demands such as feeding advantage or predator avoidance have driven the evolution of specialized echolocation pulses in these small whale species. For example, specialized high-frequency, narrow-band echolocation pulses might not be heard by the killer whale, a potential cetacean predator that does not have significant hearing sensitivity at 130 kHz.

Communication Sounds

Although echolocation pulses may also be used in communication, the lower-frequency sounds such as whistles and bursts of pulses are often considered in the context of emotional or social communication. Whistles are tonal, frequency-modulated signals lasting roughly 0.5–5 s with fundamentals that are rarely outside a frequency range of about 3–30 kHz. Pulsed sounds described by terms such as 'buzzes,' 'squeaks,' 'yelps,' and 'squawks' are rapid trains of broadband pulses, usually 100–2000 s^{-1}. Such pulsed sounds usually contain energy from 1 kHz or less to over 150 kHz. On occasion, a dolphin can modulate the repetition rate of such pulses so that they sound humanoid. Unlike echolocation pulses mentioned above, these bursts of pulses often contain peak intensities below 20 kHz.

The Peripheral Auditory System

In keeping with a swimming-and-diving, entirely aquatic lifestyle, the pinna has disappeared (Figure 1), remaining only as a subcutaneous cartilagenous vestige within the dolphin's streamlined head. From a minute depression a few centimeters posterior to the eye, the vestigial external auditory meatus (EAM)

leads inward along a sinuous path to the tympanic bone, which lies deep in the lateral tissues of the head and is partly ringed by extensions of the exoccipital and basioccipital bones of the skull. Over much of this path the EAM lumen is tiny or even absent. Near the tympanic bone, the tiny meatus expands in a membranous funnel shape – the tympanic conus which attaches to the margins of a kidney-shaped opening in the dorsal surface of the tympanic bone. The same margins support the ligamentous tympanic membrane.

From the internal surface of the tympanic membrane, and from one edge of the bony margins, a thick tympanic ligament arises and runs anteroventrally to insert on the malleus. There appears to be no direct contact of the tympanic membrane with the malleus.

The ossicles are large and heavy. The malleus is rigidly attached to the bulla and to the incus; however, the joint between incus and stapes is movable. Like the ossicles, the temporal bones are unusually dense. Unlike their human homologs, dolphin ear bones do not touch the skull, being suspended by ligaments and tough fibrous tissue. The Eustachian tube feeds from the nasal cavity into the middle ear and auditory sinuses around the ear, creating an air cavity, especially on the medial and posterior sides, around much of the cochlea-containing periotic bone. Recently, computed tomography (CT) scans of living dolphins have been used to show the extent of these air cavities which no doubt play an important role in hearing.

The histological structure of the cochlea's organ of Corti is sturdy with large closely packed supporting cells giving it an appearance of great strength and rigidity. It contains the usual elements such as arch of Corti, Hansen's cells, Deiters' cells, and hair cells,

all overlain by the tectorial membrane, but the usual lymph spaces are much reduced. The basilar membrane of the cochlea shows a systematic variation in width and in the manner and rigidity of suspension. In the basal region, the basilar membrane is suspended by bony laminae on both the outer and inner edges. This suspension becomes progressively less rigid toward the apical end where the membrane is held by connective tissue. The basilar membrane varies in width by 14 times – ranging from 25 μm at the basal end to 350 μm in the upper apical. The human basilar membrane, by comparison, varies in width only 6.25 times and is not nearly so narrow at the basal end (Figure 5). EG Wever and colleagues compared the numbers of hair cells and ganglion cells and their distribution along the cochlea to values from humans. The human had about 3500 inner and 11 500 outer hair cells, whereas the dolphin had roughly 3500 inner and 14 000 outer hair cells. The ratio of ganglion cells to hair cells in the human cochlea is about 2:1, whereas the ratio is more than 5:1 in the dolphin.

Sound Conduction in the Dolphin Ear

McCormick et al. surgically placed an electrode on the round window of the cochlea in anesthetized dolphins and recorded the electrical potential of the cochlea in response to various sound stimuli; then, they observed changes produced in the cochlear potential due to manipulations of auditory structures including damping, immobilization, application of tension, or removal. Because such actions on parts of the outer ear produced no cochlear potential changes, the researchers concluded that the outer ear – EAM, tympanic conus, and tympanic membrane – plays no significant part in sound conduction to the dolphin cochlea in the frequency range of 20 kHz and above where the dolphin is most sensitive. The ossicles are involved, since 30 g of tension on the ossicular chain produced an 18 dB drop in the cochlear potential which was restored by relief of the tension. Severing the malleus produced only a 4 dB drop; therefore, a complete conductive chain is apparently not essential. These results were therefore interpreted to indicate that acoustic vibrations passing through the tissues produce a relative motion between the cochlear capsule and the ossicles – the inertia and stiffness of the ossicular chain result in relative movement by the stapes attached to the oval window – producing motion in the cochlear fluids which freely move because of air over the round window.

Figure 5 A tracing comparing length and width of dolphin (right) and human (left) basilar membrane. From Wever EG, McCormick JG, Palin J, and Ridgway SH (1971) Cochlea of the dolphin, *Tursiops truncatus*: The basilar membrane. *Proceedings of the National Academy of Sciences of the United States of America* 68(11): 2708–2711.

Air is some 700 times less dense than water. The acoustic impedance of the two media differs by a factor of about 3660. Sound is readily transmitted through the dolphin, because body tissues have a similar acoustic impedance to water; however, air adjacent to the ear bones is important for at least two reasons. First, compressible air makes possible movement of the cochlear fluid in response to relative forces between the stapes and cochlear capsule – the round window membrane is free to move in and out. The dolphin round window membrane is multilayered, interlaced with tough fibrous strands and many times thicker than the corresponding human structure. Second, the air–fluid interface is an excellent reflector of sound; therefore, the air around the ear bones may serve to protect the ears from the dolphin's intense pulses and to isolate one ear from the other. This idea is supported by body-mapping studies of sound-sensitive areas which showed a 12 dB difference in contralateral stimulation required to produce an equivalent cochlear potential in the opposite ear. This isolation of the ears aids in localization by directing the pattern of received sound.

Air compression during diving may be of some consequence, since dolphins are capable of diving to more than 300 m. The thorax and lungs are structured for collapse. The nasal system which pressurizes by muscle action during sound production connects directly to the ear cavities by the eustachian tube. At 300 m depth, a bottlenose dolphin's air supply is compressed to about 250 ml in the air cavities of the head. This small volume of air is apparently sufficient for sound production and hearing at depth. Even a 1 mm thickness of air serves as a very efficient reflector of sound and air adjacent to the round window membrane is sufficient for its elasticity. Hearing tests conducted with another member of the superfamily Delphinoidea, the white whale (*Delphinapterus leucas*), showed that hearing was just as acute at a depth of 300 m as near the surface.

The Path of Sound to the Ear

Human divers can hear ultrasonics underwater, but they cannot perceive pitch in the ultrasonic region above ~20 kHz. Even though humans hear ultrasound underwater, sensitivity is much reduced compared with hearing in air; moreover, human ability to localize sound is degraded when we go underwater. The evolution of the dolphin ear has apparently been a process of enhancing those characteristics that allowed for greater high-frequency hearing sensitivity and complex auditory processing in the underwater environment where sound travels about 5 times faster than in air. Early in the Eocene epoch, when the distant land-mammal ancestors of the cetaceans with their aerial ear entered the water, it is almost certain that they could immediately hear ultrasonics conducted through their tissues which are fairly well matched to the water for conducting sound.

Despite the acoustic conductance match between tissue and water, there has been a good deal of controversy about how sound reaches the dolphin ear. Many of the experiments on sound transmission have been done with dead specimens. Since acoustic impedance increases after death, these findings must be interpreted with caution. KS Norris, intrigued by the form and structure of the dolphin's lower jaw and its relation to the ear bones and 'acoustic fat,' has postulated that sounds enter through the thin flared posterior end of the mandible into the mandibular fat body and are transmitted to the middle ear. Experimental results seem to support Norris' theory on the role of the lower jaw in sound reception. Electrophysiological measurements of evoked potentials in the inferior colliculus and cochlear potentials indicated that maximum responses were obtained when a sound source was placed in the vicinity of the lower jaw. With the exception of air cavities, the impedance of dolphin head tissue is similar to that of water; thus, Johnson suggested that the directionality in dolphin sound reception may be caused not so much by discrete directional paths through the jaw as suggested by Norris but more by directional characteristics of the ear and its adjacent air cavities, and, possibly, by processing in the central nervous system.

Beam Patterns and Localization

Whatever the mechanism by which sound reaches the ear, we know that sounds approaching from certain directions are efficiently coupled to the ears, whereas sounds from other directions may be poorly coupled. Au and Moore measured the receiving beam pattern of a bottlenose dolphin in both the vertical and horizontal planes by determining the animal's masked threshold as the position of either the noise or signal sources varied in their angular position about the animal's head (Figure 6). The receiving beams are frequency dependent, narrowing beams in both planes at higher frequencies and broadening at lower frequencies. The horizontal beam points forward and is nearly symmetrical about the longitudinal axis of the dolphin. The vertical beam points upwards by 5–10° with respect to the posterior–anterior axis of the tooth row and is asymmetrical,

Figure 6 Sound reception characteristics of bottlenose dolphins. Receiving (a) vertical beam patterns and (b) horizontal beam patterns for frequencies of 30, 60, and 120 kHz.

decreasing faster as a function of angle above the animal's head than below. Most likely, as the angle of a sound source increases above a dolphin's head, the air spaces of the head shadow the ear and cause the dolphin's hearing sensitivity to decrease rapidly. The animals generally swim in a slightly beak-down attitude; thus the vertical beam points straight ahead of the swimming animal.

The energy from the outgoing echolocation clicks is also directed forward in a narrow pattern. Since dolphins, often constantly calling and clicking, frequently travel in large herds and feed in groups, the directionality of both transmission and reception systems seems to be critical. This directionality determines the amount of ambient and other noises that actually enter the animals' auditory system to mask echoes from its own clicks and other sounds of interest. The receiving beam can also affect a dolphin's ability to localize sound.

The high sound speed in water should make localization difficult because of the much reduced time-of-arrival difference between the two ears. Anatomical structures such as special 'acoustic lipids' that may help to focus sound and air sinuses that help to isolate the ears in some planes and to shadow the ears in other planes no doubt are critical in sound localization. Localization of sounds in the vertical plane is likely dependent on the width and shape of the vertical beam. In the horizontal plane, localization should depend on either time or intensity difference of a sound arriving at the two ears of the dolphin. However, the narrower the beam, the better the signal-to-noise ratio will be, which should lead to keener localization ability. A narrow beam will also reduce any front–back ambiguity in localizing sounds in the horizontal plane. Renaud and Popper measured the minimum-audible angles (MAAs) of a bottlenose dolphin in the horizontal and vertical planes. They measured MAAs between 1° and 3° in both planes for pure-tone signals with frequencies between 20 and 90 kHz. At 6 and 100 kHz, the MAA increased to approximately 4°. Using a simulated echolocation click with a peak frequency of 64 kHz, MAAs of 0.7–0.8° were measured. The underwater pure-tone localization capability of dolphins is about as good as the in-air capabilities of several mammals, including humans. Dolphins localize broadband clicks considerably better than other mammals.

Auditory Performance Characteristics

The dolphin and human audiograms are similar in shape, with the dolphin's shifted by a factor of about 8 to higher frequencies (Figure 2). The absolute sensitivity to sounds is comparable between the dolphin and human. Johnson also determined the hearing threshold of a bottlenose dolphin as the duration of the pure-tone stimulus was varied. The dolphin's threshold decreased as the tone duration increased to approximately 0.3 s, after which the threshold leveled off.

For the brief echolocation pulses, a concept of critical interval or integration time has been developed. Au et al. measured the integration time of the dolphin auditory system when receiving echolocation echoes to be approximately 264 μs. When delays between pulse pairs are reduced below this critical interval, the dolphin no longer perceives them as separate pulses. Comparable values for humans would be 1–5 ms. A delay of 264 μs is equivalent in echo delay from an object only about 20 cm from the pulse source within the dolphin's nasal system. Even though individual echolocation pulses may be much shorter, the integration time for pulses might be necessary to mitigate interference from echoes within the dolphin's own head.

For longer tonal signals, Johnson measured the integration time to be on the order of 100–200 ms. Bottlenose dolphins are sensitive in detecting frequency changes. The dolphin's best frequency discrimination occurred between 2 and 55 kHz, with relative difference limens (DLs) ranging from 0.2% to 0.4%. Relative DLs remained within 1% for all frequencies between 1 and 140 kHz (Figure 7). The frequency discrimination capabilities of dolphins compare well with the in-air capabilities of humans, but shifted toward higher frequencies. Intensity discrimination ability is also very good – on the order of 1 dB (apparently better than that of any other vertebrate studied except humans).

The Auditory Nervous System

In total diameter and in numbers of fibers, the eighth nerve, the largest of the dolphin's sensory cranial nerves, is much larger and contains several times as many fibers as the human auditory nerve. The larger fiber diameter has physiological significance since a doubling in fiber diameter of myelinated axons in laboratory mammals approximately doubles conduction speed. On a comparative basis, central auditory structures are even more enlarged. In the common dolphin, a small animal with a brain just over half as large as a bottlenose dolphin (800 vs. 1500 g), the cochlear nucleus and inferior colliculus are about 12 times as large as those of the human, the trapezoid is twice as large, the medial geniculate about 7 times as large, the superior olive is 150 times as large, and the nucleus of the lateral lemniscus is over 250 times as large as the equivalent structure in humans.

Figure 7 Frequency discrimination capability of bottlenose dolphin and human plotted in terms of the relative difference limen in percent. Thompson RKR and Herman LM (1975) Underwater frequency discrimination in the bottlenosed dolphin (1–140 kHz) and human (1–8 kHz). *Journal of Acoustical Society of America* 57: 943–948.

Physiological study of dolphin hearing and auditory processing has shown that temporal resolution of successive sounds is extremely rapid; the typical midbrain auditory evoked potential (AEP) was specialized for ultrasonic, ultrabrief, fast-rising, closely spaced sounds like the echolocation clicks. Physiological studies have also shown that the dolphin brain might possess two separate auditory systems, one specialized for ultrabrief, fast-rising sounds like echolocation clicks while the other appears to be specialized for longer, slower-rising sounds like dolphin whistles. Studies of the averaged brain stem response (ABR) have shown that clicks evoke a series of seven far-field waves cresting in the first 10 ms; these appear remarkably similar in several species. Dolphin ABRs are larger than those of other mammals previously investigated – about 10 times larger than similar waves recorded from the human scalp. In general, the ABR waves decrease in amplitude and increase in latency as click stimuli are attenuated. Brain stem transmission time (BTT) is considerably faster in the bottlenose dolphin, a species with mean brain weight around 1500 g, than in humans or domestic cats and is similar to that of the rat. Despite a much longer nerve pathway, BTT in the dolphin is equal to or faster than that in much smaller-brained species such as rats and cats.

Another characteristic of the dolphin ABR that differs from that in other mammals studied is the influence of stimulus repetition rate on the response. In adult humans, for example, latency increases by about 0.5 ms for each rate increase of $10\,s^{-1}$. The dolphin ABR latencies increase only slightly as stimulus rate is increased from 0.5 to $200\,s^{-1}$. In the cat, clicks at $80\,s^{-1}$ reduce all components to about 50% of recovered amplitudes, while dolphin ABR wave amplitudes show only little change at rates of $160\,s^{-1}$.

It is apparent that the dolphin brain is specialized for rapid processing of auditory stimuli. If given enough time, the human auditory system seems to perform as well on some echolocation tasks. When pulses similar to dolphin echolocation pulses were projected at targets at short range by instrumented divers and the received echoes stretched 128 times (tantamount to a slowed-down tape recording and therefore reduced equivalently in frequency), human divers performed with as few errors as *Tursiops* in distinguishing between paired metal targets of copper, brass, or aluminum and geometrical aluminum shapes covered with neoprene rubber. Studies with static metal targets may give only limited detail of the dolphin's echolocation processing ability. In addition, the static metal target discrimination may not be a very challenging echolocation task for a dolphin. However, if the findings are a fair comparison of human and dolphin echolocation ability, we must conclude that the major advantage in the sonar

processing component of the dolphin auditory system, in comparison with the human auditory system, is the ability to process high frequencies and to process sound rapidly. The large diameter of auditory nerve fibers, the short latency, and the relatively flat latency–intensity function of the dolphin ABR waves, and the rapid temporal resolution of successive sounds, are ample indication of an auditory system wired for rapid sound analysis. In fact, much of the great hypertrophy of the dolphin auditory system – and perhaps the entire cerebrum – may result from the animal's need for great precision and speed in processing sound.

Heart Rate Variability: A Neurovisceral Integration Model

J F Thayer, The Ohio State University, Columbus, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

> When the heart is affected it reacts on the brain; and the state of the brain again reacts through the pneumo-gastric (vagus) nerve on the heart; so that under any excitement there will be much mutual action and reaction between these, the two most important organs of the body. (Darwin, 1998, pp. 71–72; originally published in 1872)

Like many organs in the body, the heart is dually innervated. Although a wide range of physiologic factors determine cardiac functions such as heart rate (HR), the autonomic nervous system (ANS) is the most prominent. Importantly, when both cardiac vagal (the primary parasympathetic nerve) and sympathetic inputs are blocked pharmacologically (e.g., with atropine plus propranolol, the so-called double blockade), intrinsic HR is higher than the normal resting HR. This fact supports the idea that the heart is under tonic inhibitory control by parasympathetic influences. Thus, resting cardiac autonomic balance favors energy conservation by way of parasympathetic dominance over sympathetic influences. In addition, the HR time series is characterized by beat-to-beat variability over a wide range, which also implicates vagal dominance as the sympathetic influence on the heart is too slow to produce beat-to-beat changes. There is an increasing interest in the study of HR variability among researchers from diverse fields. Low heart rate variability (HRV) is associated with increased risk of all-cause mortality, and low HRV has been proposed as a marker for disease. The following sections discuss the assessment of HRV, the neural control of HRV, and the relationship of HRV to important aspects of self-regulation, including physiological, cognitive, and emotional regulation.

Heart Rate Variability

The basic data for the calculation of all measures of HRV is the sequence of time intervals between heartbeats (Figure 1, top trace). This interbeat interval time series is used to calculate the variability in the timing of the heartbeat. As mentioned previously, the heart is dually innervated by the autonomic nervous system such that relative increases in sympathetic activity are associated with HR increases and relative increases in parasympathetic activity are associated with HR decreases. Thus, relative sympathetic increases cause the time between heartbeats (the interbeat interval) to become shorter and relative parasympathetic increases cause the interbeat interval to become longer. The parasympathetic influences are pervasive over the frequency range of the HR power spectrum, whereas the sympathetic influences 'roll off' at approximately 0.15 Hz (Figure 1, bottom). Therefore, high-frequency HRV represents primarily parasympathetic influences, with lower frequencies (below approximately 0.15 Hz) having a mixture of sympathetic and parasympathetic autonomic influences. The differential effects of the ANS on the sinoatrial node, and thus the timing of the heartbeats, are due to the differential effects of the neurotransmitters for the sympathetic (noradrenaline) and parasympathetic (acetylcholine) nervous systems. The sympathetic effects are slow, on the timescale of seconds, whereas the parasympathetic effects are fast, on the timescale of milliseconds. Therefore, the parasympathetic influences are the only ones capable of producing rapid changes in the beat-to-beat timing of the heart (Figure 1, middle).

Measures of Heart Rate Variability

A variety of measures have been used to operationalize HRV. Long-term measures such as the standard deviation of all interbeat intervals in 24 h, short-term measures such as the standard deviation of 5 min intervals, and beat-to-beat measures such as the root mean square of successive RR differences (RMSSD) have all been used. Respiratory sinus arrhythmia (RSA) is another measure and is defined as the change in heart period corresponding with the inspiratory and expiratory phases of the respiratory cycle. In addition, power spectral analysis of interbeat interval time series is frequently used to quantify HRV. The power spectrum of short-term time series contains two major components – a high-frequency (0.15–0.40 Hz) and a low-frequency (0.01–0.15 Hz) component reflecting cardiac vagal tone and a mixture of vagal and sympathetic influences, respectively. RSA, RMSSD, and the high-frequency component of the power spectrum are closely related, and all reflect vagal cardiac influence. Measures derived from nonlinear dynamics have been used to describe aspects of HRV. One such measure is approximate entropy (ApEn). It quantifies the complexity or irregularity of time series data. This and other 'chaos'-derived parameters have proved valuable in the area of cardiovascular pathology, for example, in discriminating cardiac patient groups with respect to the dynamics of their cardiovascular system. The following sections review some of the many measures available.

Frequency band	*Peak (Hz)*	*Power (ms²)*	*Power (%)*	*Power (n.u)*
VLF (0–0.04 Hz)	0.0391	23	3.5	
LF (0.04–0.15 Hz)	0.0547	321	49.6	51.4
HF (0.15–0.4 Hz)	0.2930	304	46.9	48.6
Total		648		
LF/HF		1.058		

Frequency band	*Peak (Hz)*	*Power (ms²)*	*Power (%)*	*Power (n.u)*
VLF (0–0.04 Hz)	0.0000	318	33.4	
LF (0.04–0.15 Hz)	0.0977	354	37.2	55.8
HF (0.15–0.4 Hz)	0.2930	281	29.4	44.2
Total		953		
LF/HF		1.263		

Figure 1 The top trace shows an IBI time series. The highlighted portion is shown in more detail in the second trace. The figure and values on the left are from an FFT analysis and those on the right are from an autoregressive analysis of the highlighted data. The tables show the frequency band, peak frequency, power, percentage power, and power in normalized units. Although the values from the two methods are similar, they are not identical. Adapted from the output of free software provided by the Department of Applied Physics, University of Kuopio, Finland. (See Niskanen JP, Tarvainen MP, Ranta-aho PO, and Karjalainen PA (2004) Software for advanced HRV analysis. *Computer Methods and Programs in Biomedicine* 76: 73–81).

Time Domain Indices of HRV

Time domain indices may be based on the interbeat intervals directly or on differences between successive interbeat intervals. In addition, there are both short-term and long-term indices. Short-term indices are based on recordings with a duration on the order of minutes. Long-term indices are usually based on 24-h recordings. Measures that are based on the interbeat intervals directly do not distinguish the autonomic sources of the variability. These indices include the standard deviation of all N–N (normal to normal) intervals (SDNN) and the standard deviation of the average of N–N intervals for each 5 min period over 24 h.

The second type of indices are those based on the differences between successive N–N intervals. These indices are based on the comparison of the lengths of adjacent cardiac cycles and include the percentage of adjacent cycles that are >50 ms apart (pNN50) and the root mean square of successive differences in milliseconds (RMSSD). RMSSD is the most commonly used measure derived from interval differences. This index uses what is called first-differencing in the econometrics literature and acts like a high-pass filter, thus removing long-term trends and slower frequency variability from the signal. Due to the frequency characteristics of the autonomic influences on the heart such that vagal influences cover the full

frequency range and sympathetic influences are primarily restricted to the lower frequencies, RMSSD reflects primarily vagal influences.

Frequency Domain Indices of Heart Rate Variability

Frequency domain analysis gives information about the amount of variance or power in the heart rate or heart period time series explained by periodic oscillations at various frequencies. Power spectral analysis of the time series provides basic information on the amount of variance or power as a function of frequency. Typically, four frequency bands can be distinguished from 24 h recordings and two frequency bands can be reliably discerned in short-term recordings. These are high-frequency (HF; 0.15–0.4 Hz), low-frequency (LF; 0.04–0.15 Hz), very low-frequency (VLF; 0.003–0.04 Hz), and ultra-low-frequency (ULF; $\leq$0.003 Hz). The HF and LF bands are prominent in short-term recordings, with a VLF or direct current (DC) component being associated with aperiodic and artifactual variance (Figure 1). Thus, the VLF and ULF bands are not usually interpretable in short-term recordings. It is important to note that the total spectral power is exactly equal to the time domain variance of the HR time series. This useful relationship can be helpful in troubleshooting spectral analysis algorithms. Moreover, this makes clear that spectral analysis is similar to analysis of variance in that both techniques are used to partition variance and attribute it to various sources.

HF power is primarily parasympathetically mediated. The HF band primarily reflects the respiration-mediated HRV at 0.15–0.4 Hz. The defined frequency band for this parameter usually encompasses the frequency range corresponding to the frequency of normal respiration. Thus, the HF power predominantly measures the variability in HR induced by respiration. This index of vagally mediated cardiac control correlates highly with the time-domain-based measure of RMSSD. A detailed accounting of the other frequency bands is given later.

The measurements of frequency power components described previously are usually expressed as absolute values of power (milliseconds squared). The absolute power measurements represent the variance of the measured signal about its mean value. The so-called normalized scores represent the relative value of each power component in proportion to the total power. In addition, the VLF or DC component is often subtracted from the total power in calculating the normalized values. The DC component is defined as the spectral components with a frequency $<$0.03 Hz. The LF-to-HF ratio has been proposed to reflect the sympathovagal balance.

There are numerous algorithms for doing spectral analysis. Historically, the fast Fourier transform (FFT) was used. However, there are several disadvantages to this approach, including the necessity of specifying the boundaries of the frequency bands in advance. This is called 'windowing' and can lead to serious misinterpretations of the data if they fail to capture the frequencies in which one is interested. For example, in doing spectral analysis on infants or other species such as rodents, the ranges of the frequency bands we have described will not apply. The frequency of respiration varies greatly from infancy to adulthood and across species, so to capture respiratory modulated HRV one has to adjust the 'windows' in an FFT. Whereas bioengineers have called the FFT the 'classical' approach to spectral analysis, more modern approaches based on linear prediction analysis have been developed. The major algorithm in this approach is the autoregressive algorithm, which overcomes the windowing problem by using a true components analysis in which the central frequency and width of the bands are determined empirically and on an individualized basis.

Still more recent developments include the use of wavelets and algorithms for time–frequency analysis. These approaches go even further and do not make assumptions concerning stationarity and thus allow for relatively continuous estimates of spectral power. In addition, numerous indices based on nonlinear dynamical systems or chaos theory have proved to be useful in the analysis of HRV. However, detailed discussion of these techniques is beyond the scope of this article. A particularly important resource for the analysis of complex signals including HRV, called PhysioNet, has been funded by the National Institutes of Health and provides numerous software solutions for the interested researcher.

Whereas the best signal source for the assessment of HRV is the ECG signal, sometimes a researcher will have an HR or interbreath interval (IBI) time series derived from a photoplethysmograph or from a pulse wave such as might be derived from a blood pressure recording. Research has shown that these devices can give adequate time series for the calculation of HRV under certain conditions.

One controversial issue in measuring HRV is the need for respiratory control. That is, given the close links between the cardiovascular and respiratory systems, some researchers suggest that measures of HRV need to take account of respiration. However, not all measures of HRV are correlated with respiration. It was shown in a large sample that ApEn was uncorrelated with respiration frequency. Moreover, this need for respiratory control is predicated on the idea that changes in respiration cause changes in HRV and thus might distort their interpretation. However, for

more than 100 years it has been known that HR might influence the initiation of inspiration. Thus, controls for respiration might throw out the baby with the bathwater, so to speak. Nonetheless, it is useful to examine respiration when interpreting the results of HRV analyses. If one does not have an independent measure of respiration, an index of breathing frequency can be derived from the HR or IBI time series. One way is via spectral analysis, where the central frequency of the high-frequency component of the HRV spectrum is highly correlated with strain gauge measures of respiratory frequency.

A brief overview of the various frequency bands associated with HRV is given in the following sections.

Ultra-Low-Frequency Band: ≤0.003 Hz

The ULF band has shown strong relationships with mortality and therefore an understanding of this band is important. Whereas, as noted previously, all frequencies of HRV reflect autonomic, particularly parasympathetic, influences to some degree, the utility of the ULF band to predict morbidity and mortality appears to lie in its relation with the functional capacity of the patient. Roach and colleagues have shown that SDNN and ULF power in 24 h recordings is related to the range of physical activity that patients engage in and not to differences in autonomic control of the heart *per se*. Given that approximately 1 h is needed to observe approximately ten cycles at this frequency, it is clear that this band cannot be resolved in short-term recordings and is thus not a meaningful index in such circumstances.

Very Low-Frequency Band: 0.003–0.04 Hz

The physiological origins of the VLF band have remained elusive. This band has been variously linked to fluctuations in the renin–angiotensin system and to thermoregulation. We undertook a study to investigate the relation between ambient temperature and HRV with an emphasis on the VLF band. In that study, with humidity controlled, we exposed participants in a within-subject design to both cold (55 °F) and hot (95 °F) conditions as well as to a control condition of 72 °F for 30 min each. Compared to the hot and control conditions, the cold condition was associated with significantly greater VLF power. This increase in VLF power was accompanied by an increase in diastolic blood pressure (DBP). Moreover, this pattern of an increase in VLF power and DBP was unique to the cold condition. These results suggested that the VLF band responded, at least in part, to variations in ambient temperature and thus was associated with thermoregulation. Again, because of the low frequency of these oscillations (approximately two per minute), this band is not well resolved in short-term recordings.

Low-Frequency Band: 0.04–0.15 Hz

There has been a great deal of controversy surrounding the meaning of variations in power in the LF band. Oscillations in this frequency band have been identified for more than 100 years and are associated with baroreflex-mediated blood pressure variations. In this context, it is important to appreciate that blood pressure is under complex control by the ANS. Mean arterial pressure is a function of cardiac output (CO) and total peripheral resistance (TPR). Furthermore, CO is a function of HR and stroke volume (SV). The major determinant of long-term BP regulation is fluid volume. However, the major determinant of short-term BP regulation is the ANS via the baroreflex. The most rapidly modulated component of BP is HR due to its primarily vagal control. As such, the most efficient way to modulate short-term BP is via changes in HR and therefore via changes in CO. SV is primarily regulated by changes in β-adrenergic control and in healthy individuals is relatively constant over a wide range of conditions. This leaves HR as the major factor in changes in CO. TPR is largely associated with α-adrenergic activity and thus is a relatively inefficient way to modulate short-term BP. Taken together, these relations suggest that variations in short-term BP that are thought to be associated with LF power will represent a complex mix of ANS influences, and thus earlier ideas that raw LF power represents activity of the sympathetic nervous system were clearly incorrect. However, this analysis does indicate that LF power should largely reflect parasympathetic influences. The empirical data support this analysis because LF power has been shown to correlate very highly with HF power (0.70 or higher) in numerous studies. Therefore, raw LF power most likely reflects significant parasympathetic nervous system activity. Given that approximately 2 min of data are necessary to provide adequate spectral resolution of this frequency (approximately ten oscillations), LF power can be reliably assessed in short-term recordings.

High-Frequency Band: 0.15–0.4 Hz

There is little controversy about the fact that power in the HF band represents respiratory-modulated HR variations. Moreover, given the transfer function characteristics of the ANS influences on the heart, there is little controversy that the HF band largely reflects parasympathetic influences.

Neural Control of Heart Rate Variability

The neurovisceral integration model has identified a flexible neural network associated with self-regulation and adaptability that might provide a unifying framework within which to view the diversity of observed responses across domains. In this model, a set of neural structures that regulates physiological, behavioral, emotional, and cognitive responses can be indexed via peripheral indices such as HRV. This model emphasizes the role of HRV as an index of self-regulation and its ability to reflect neural feedback mechanisms between the central nervous system (CNS) and the ANS.

At the core of this model is the central autonomic network (CAN). Functionally, CAN can be regarded as an integrated component of an internal regulation system, in which the brain controls visceromotor, neuroendocrine, and behavioral responses that are critical for goal-directed behavior, adaptability, and health. Structurally, CAN includes a number of components, such as the anterior cingulate, insular, orbitofrontal, and ventromedial prefrontal cortices; the central nucleus of the amygdala; the paraventricular and related nuclei of the hypothalamus; the periaqueductal gray matter; the parabrachial nucleus; the nucleus of the solitary tract (NTS); the nucleus ambiguus; the ventrolateral medulla; the ventromedial medulla; and the medullary tegmental field. These components are reciprocally interconnected such that information flows both from the bottom up and from the top down. Importantly for the current discussion, the primary output of CAN is mediated through the preganglionic sympathetic and parasympathetic neurons that innervate the heart via the stellate ganglia and the vagus nerve, respectively. The interplay of these inputs to the sinoatrial node of the heart generates the complex variability that characterizes the healthy HR time series. Furthermore, sensory information from the heart and other peripheral systems is fed back to CAN. Thus, HRV can be used to index a set of neural structures associated with self-regulation and health.

CAN is under tonic inhibitory control via the main inhibitory neurotransmitter within the CNS, γ-aminobutyric acid, in interneurons within the NTS. Disruption of this inhibitory pathway can cause, for example, hypertension and sinus tachycardia, which represents a disinhibition of sympathoexcitatory circuits within CAN.

Both animal and human data support this model. Retrograde viral staining studies in both primates and rodents have identified the central sources for the neural control of the heart. For example, Ter Horst and Postema identified frontal, insula, prelimbic, and anterior cortices as the forebrain concomitants of the parasympathetic influences on the heart in rodents. Although the viral labeling was bilateral, it was predominantly right sided. Similarly, Chuang et al. found predominantly right-sided viral labeling of parasympathetic neurons in the nucleus ambiguous in primates. In humans, using pharmacological blockade, it was found that deactivation of the anterior portions of the brain by sodium amobarbital produced HR increases and vagally mediated HRV decreases that were larger on the right side. In addition, numerous human neuroimaging studies have identified several prefrontal regions associated with HRV, including the medial prefrontal and anterior cingulate cortices.

Thayer and Lane suggested that a common reciprocal inhibitory cortico-subcortical neural circuit serves as the structural link between psychological processes, such as emotion and cognition, and health-related physiological processes, and that this circuit can be indexed with HRV. Thus, because of these reciprocally interconnected neural structures that allow prefrontal cortex to exert an inhibitory influence on subcortical structures, the organism is able to respond to demands from the environment and organize their behavior.

Physiological Regulation

The regulation of physiological systems that are important for health and disease has been linked to HRV. Thayer and Sternberg summarized data linking HRV to glucose regulation, hypothalamic–pituitary–adrenal axis function, and inflammation. In addition, Thayer and Lane reviewed the literature on the relationship between vagal function and the risk for cardiovascular disease (CVD) and stroke. The National Heart, Lung, and Blood Institute of the National Institutes of Health lists eight risk factors for heart disease and stroke (http://www.nhlbi.nih.gov). Six of these factors are considered to be modifiable. Three of these modifiable risk factors are associated with what could be called biological factors: high blood pressure (hypertension), diabetes, and abnormal cholesterol. Three others listed as modifiable could be considered lifestyle factors: tobacco use (smoking), physical inactivity (exercise), and overweight (obesity). Two factors are considered as nonmodifiable: age and family history of early heart disease or stroke. It is interesting to note that there are at least some data that suggest that each of these risk factors is associated with decreased vagal function as indexed by HRV. Furthermore, emerging risk factors for CVD and mortality, such as inflammation and psychosocial factors, are also associated with decreased HRV. In addition, several large epidemiological studies have shown that reduced HRV is a risk factor for all-cause mortality and morbidity. Thus, HRV, in part due

to its relation with physical health and physiological regulatory systems, may be of special relevance to researchers in medicine and biology. Another area of importance for neuroscience researchers is emotional regulation.

Emotional Regulation

We and others have reviewed the literature on the relation between HRV and emotional regulation. Emotional regulation is a valuable skill that has clear implications for health. Emotions represent a distillation of an individual's perception of personally relevant environmental interactions, including not only challenges and threats but also the ability to respond to them. Viewed as such, emotions reflect the integrity of one's ongoing adjustment to constantly changing environmental demands. When the affective system works properly, it promotes flexible adaptation to shifting environmental demands. In another sense, an adequate emotional response represents a selection of an optimal response and the inhibition of less functional ones from a broad behavioral repertoire, in such a way that energy use is matched to fit situational requirements. Resting HRV represents a type of resource that can be brought to bear in situations in which emotional regulation is called for. We have shown that individuals with higher levels of resting HRV, compared to those with lower resting levels, produce context-appropriate emotional responses as indexed by emotion-modulated startle responses and phasic heart rate responses in addition to behavioral and self-reported emotional responses. It has also been shown that phasic increases in HRV in response to situations that require emotional regulation facilitate effective emotional regulation. Therefore, the relation between HRV and emotional regulation will have important implications for those who study the link between emotional states and dispositions such as depression, anxiety, anger and hostility, alexithymia, and physical health. Yet another area of interest for neuroscientists involves research on cognitive functioning and HRV.

Cognitive Regulation

We have reviewed our research on the relationship between HRV and cognitive regulation. Attentional regulation and the ability to inhibit prepotent but inappropriate responses are important for health in a complex environment. Many tasks important for survival in today's world involve cognitive functions such as working memory, sustained attention, behavioral inhibition, and general mental flexibility. These tasks are all associated with prefrontal cortical activity. Deficits in these cognitive functions tend to accompany aging and are also present in negative affective states and dispositions such as depression and anxiety. In a series of studies, we showed that compared to individuals with low levels of resting HRV, those with higher resting levels performed better on tasks that required executive function, such as the Stroop task and the n-back task. Furthermore, we showed that when resting HRV levels were decreased by aerobic detraining, performance on executive function tasks suffered. Stress can also impair cognitive function and may contribute to the cognitive deficits observed in various mental disorders. It is also possible that autonomic dysregulation contributes to decline in attention and cognitive performance with aging.

Conclusions

The neurovisceral integration model proposes that the relation between HRV and the important physiological, cognitive, and emotional regulation functions is due to the ability of HRV to index activity in a flexible network of neural structures that is dynamically organized in response to environmental challenges. The neuroanatomical, pharmacological blockade, and neuroimaging studies provide support for the forebrain influences on HRV. It is hoped that this review will help neuroscientists better understand and contribute to this growing literature.

Hebbian Plasticity

T H Brown, Y Zhao, and V Leung, Yale University, New Haven, CT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Hebbian synaptic plasticity is hypothesized to play an important role in storing information in the nervous system and in using pre- and postnatal experience to guide normal development. Named after the Canadian psychologist Donald Hebb, Hebbian plasticity has been securely demonstrated to exist in the hippocampus, neocortex, and amygdala as well as certain invertebrate circuits. Here we review the evolution of the current understanding of Hebbian plasticity – including the fundamental concepts, the neurophysiological evidence and mechanisms, and the resulting neuronal computations.

We start with antecedents to Hebb's conceptualization, showing that the concept of the Hebb synapse has a long evolutionary history. As we shall see, some neuroscientists, such as James Anderson, credit William James with proposing the essential ideas, 60 years before Donald Hebb's monograph. Others, such as Thomas Brown, also emphasize the obvious fact that contemporary quantifications of these earlier ideas are based on neurophysiological and theoretical results that were unavailable to Hebb. We discuss the history of neurophysiological experimentation on Hebbian plasticity within the broader framework of two synaptic phenomena that have been analyzed *in vitro* and *in vivo*: long-term potentiation (LTP), an activity-dependent, persistent, increase in synaptic strength, and long-term depression (LTD), a corresponding decrease in synaptic strength. We note that there are different varieties of LTP and LTD, only some of which are Hebbian.

Historical Antecedents

Contiguity and Associations

The concept of Hebbian plasticity reflects a natural evolution of ideas that have a long history in philosophy and psychology. More than 2000 years ago, Aristotle (*c.* 350 BC) proposed a theory of memory that held spatiotemporal 'contiguity' to be a fundamental principle governing the formation of associations. According to this principle, the closer ideas occur in space and time, the larger the probability of making an association between them. Aristotle's contiguity principle was later revived and extended by British associationists. In the late nineteenth century, contiguity was given a neurophysiological interpretation by the American philosopher and psychologist William James. According to James' 'law of neural habit,' which specifies the neurophysiological conditions that lead to a modification, "When two elementary brain processes have been active together or in immediate succession, one of them on recurring tends to propagate its excitement to the other" (William James, 1890).

Three years later, in 1893, the Italian neuroanatomist Eugenio Tanzi proposed that the functional junction between neurons is the locus of the physical modification responsible for learning. The hypothetical junction was named 4 years later when Charles Sherrington proposed the term 'synapse' (originally 'synapsis'). By the beginning of the twentieth century, the synaptic hypothesis had been embraced by the famous Spanish neuroanatomist Ramón y Cajal and was being presented in introductory psychology texts. At about the same time, Ivan Pavlov was describing the acquisition of conditional responses in theoretical terms that were similar to those of William James. The thoughts of Tanzi, James, Sherrington, Cajal, and Pavlov were combined and underwent further evolution with the publication of *The Organization of Behavior* by DO Hebb in 1949. In this influential monograph, Hebb proposed that the synapse is the locus of the physiological change that represents stored information and that the condition for causing the synaptic modification is the co-occurrence of activity between synaptically connected neurons.

Nothing in Hebb's monograph suggests an influence from what we regard today as his most obvious intellectual predecessors, including William James. At the network level James was thinking of associative learning as being driven by "a conjunctive learning rule that looks very much like the architectures for modern models of cognition," according to James Anderson, whose own work on associative memory structures has helped us better understand "what Hebbian synapses build." Donald Hebb evidently regarded his own ideas about synaptic plasticity to be among his less original contributions. According to Hebb's now-famous postulate:

> When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased. (Hebb, *The Organization of Behavior*, 1949, p. 62)

Although Hebb's postulate was not exceptionally novel, it did furnish a convenient qualitative starting point for others (such as Gunther Stent, John Hopfield, and James Anderson) who were interested in neurobiological or quantitative formulations of this idea. Hebb was necessarily imprecise about what was meant by 'firing' the cell, because his monograph predated any meaningful understanding of cellular neurophysiology. He knew nothing about the statistical and biophysical factors that contribute to the timing and modulation of the initiation, spread, or suppression of Na^+- and Ca^{2+}-dependent spikes along the various parts of a neuron.

Adaptive Computations

Hebb also did not attempt to quantify his postulate into a formal 'learning rule,' or algorithm. That task was left to the next group of theoreticians (such as David Willshaw, Christoph von der Malsburg, Terrence Sejnowski, Teuvo Kohonen, James Anderson, William Levy, and Erkki Oja), who began to appreciate and explore the computational implications of Hebbian plasticity for associative learning and self-organization. The earliest useful thoughts about how single neurons or groups of neurons might compute were advanced by Warren McCulloch and Walter Pitts in 1943 in their influential paper, "A logical calculus of the ideas imminent in nervous activity." A decade later, psychologist Frank Rosenblatt furnished an early demonstration of how circuits composed of adaptive, 'neuronlike' processing elements can exhibit an interesting form of learning.

Much of the subsequent research on adaptive neural computing can be seen as variations or improvements on Rosenblatt's 'perceptron learning.' In 1960, Bernie Widrow and Marcian Hoff developed a learning algorithm and associated mathematical theory that elucidates how activity input vectors can be adaptively mapped onto desired output vectors using the so-called delta rule for changing connection strengths. The delta rule changes connections as a function of an error term that is computed from the difference between the current output and a 'desired output.' This is called 'supervised learning,' because the desired output is furnished by an external 'teacher signal.' The versatile and popular backward-error-propagation algorithm is a mathematical extension of the delta rule.

Psychologists Robert Rescorla and Allan Wagner, in 1972, distilled into a simple 'learning equation' for Pavlovian conditioning a computationally simple version of the delta rule. The Rescorla–Wagner (R–W) learning rule furnished a valuable connection between error-driven learning algorithms and the variables and facts associated with Pavlovian conditioning. The R–W learning rule accounted for a surprisingly large body of experimental research and made novel and testable predictions. In the R–W rule, the unconditional stimulus (US) 'supervises' learning in that it furnishes a global error signal to populations of neurons. A most significant feature of the R–W equation is that this interpretation of the error signal later facilitated understanding how Pavlovian conditioning phenomena can be computed using Hebbian plasticity and conventional neurophysiological principles.

Modern Hebbian learning rules include bidirectional changes in synaptic strength, for theoretical and empirical reasons explained by Thomas Brown and co-workers in 1990. We often think of associative LTP working together with a form of LTD to store or represent some measure of the contiguity, covariation, or contingency between pre- and postsynaptic activity levels. In a sense, Hebb only addressed half of what we usually recognize as a useful learning rule – namely, the conditions that cause an increase in synaptic strength. Hebb's postulate is loosely captured by the mnemonic, 'cells that fire together, wire together.' Starting in the 1970s, theoreticians, such as Terrence Sejnowski, began to address the other half of the learning rule. Rules for decreasing synaptic efficacy are captured by the mnemonic, 'firing out of synch, weakens the synaptic link.'

Contemporary Understanding of Hebbian Plasticity

Neurophysiological studies and formal theoretical analysis combined to bring about further evolution of the idea of Hebbian plasticity. Today, the essence of a Hebbian computation is one that strengthens synaptic connections as a function of the conjunction or positive contingency or covariation between pre- and postsynaptic activities. As already noted, modern algorithms allow for bidirectional control of synaptic strength. The contemporary concept of Hebbian plasticity recognizes three defining features (interactive mechanism, time-dependent mechanism, and local mechanism) summarized in the following sections.

Interactive Mechanism

A Hebbian synaptic modification depends on the interaction between presynaptic and postsynaptic activity. An interactive mechanism means that whether a modification occurs depends on activity on both sides of the synaptic cleft. Changes that depend on either presynaptic or postsynaptic activity alone, or on the linear summation of changes attributable to activity in the presynaptic and postsynaptic sides of the synapses, would be termed 'noninteractive' and are non-Hebbian.

Time-Dependent Mechanism

Hebbian synaptic modifications are driven by a time-dependent mechanism, meaning that the change is produced by the co-occurrence of pre- and postsynaptic activity. Synaptic enhancement depends on the exact time interval between presynaptic and postsynaptic activities. This contrasts with learning algorithms in which modifications are only a function of the output error – not the timing of activity. In theoretical studies, the synaptic learning rule or algorithm is sometimes based on the covariance between presynaptic and postsynaptic activities. The critical 'activities' may be chemical or electrical. The timing of pre- and postsynaptic activity is what drives synaptic modification. The modification, in turn, can be regarded as representing the contiguity, covariation, or contingency – assessed over some time period – between pre- and postsynaptic activity.

Local Mechanism

Hebbian modifications are produced by a local mechanism in the sense that all of the information that is necessary to drive the synaptic change is available to the synapse as a consequence of ordinary synaptic transmission. This is in contrast to strictly supervised learning mechanisms, such as the 'back propagation' algorithm, which use a systems-level, external 'teacher' signal to instruct change on a synapse-by-synapse basis. Such learning schemes are not found in neurobiology. They would incur severe neuroanatomical overhead because they require independent presynaptic teaching signals to target every modifiable synapse. Furthermore, the environment usually does not afford an organism the information required to compute the error terms. On the other hand, there are neurobiological examples of 'diffuse' or 'global' reinforcement signals that control the induction or consolidation of plasticity in selected populations of synapses.

Hebbian Plasticity and Associative LTP

Technology for Finding Hebbian Plasticity

The experimental discovery of Hebbian plasticity was partly a by-product of research on LTP, evidence of which was first reported by Tim Bliss and Terje Lomo in 1973. They observed that repetitive stimulation of an afferent input to the dentate gyrus could cause a persistent increase in the size of the extracellular field potentials recorded in the dentate gyrus and evoked by the same afferent input. One limitation of this approach was that *in vitro* recordings of field potentials usually lack the spatiotemporal resolution necessary to make secure inferences about synaptic modifications.

Figure 1 Associative long-term potentiation in the hippocampal brain slice preparation. Interactions between two excitatory afferent inputs to a CA1 pyramidal neuron were examined. By adjusting the strengths of the stimuli delivered to the two input pathways, one was made to generate a weak synaptic response and the other a strong synaptic response. Simultaneous tetanic stimulation of both input pathways resulted in subsequent long-term enhanced synaptic efficacy in the weak input under conditions in which the same tetanic stimulation of either input alone failed to have this effect. Sch/com, Schaffer collateral/commissural; DG, dentate gyrus. Adapted from Barrionuevo G and Brown TH (1983) Associative long-term potentiation in hippocampal slices. *Proceedings of the National Academy of Sciences of the United States of America* 80: 7347–7351, with permission. Copyright 1983 by National Academy of Sciences, USA.

Numerous *in vitro* studies conducted by Thomas Brown, Daniel Johnston, and co-workers, done in the 1980s, were designed to solve this problem by recording from individual neurons bathed in defined media.

The hippocampal brain slice proved to be particularly useful because much of the intrinsic local circuitry remains intact in a transverse slice. Figure 1 illustrates the classical 'trisynaptic circuit,' which emphasizes three projections: from entorhinal cortex to the dentate gyrus (DG), from DG to hippocampal region CA3, and from region CA3 to region CA1. Within the hippocampus proper, the most commonly studied synapse is the Schaffer collateral/commissural (Sch/com) input to pyramidal neurons of the CA1 region. These afferents arise from ipsilateral CA3 cells and from the ipsilateral and contralateral hippocampus. As discussed next, the Sch/com synapses were the first to reveal an underlying Hebbian mechanism.

Associative Nature of Hebbian LTP

LTP has been studied most extensively in the Sch/com synapses of the hippocampal formation (Figure 1). These synapses exhibit three classical properties (associativity, cooperativity, and input specificity) that

are signatures of Hebbian modifications. Associativity refers to a synaptic modification in one afferent input to a neuron that is conditional upon coactivity in a separate input to the same neuron. Cooperativity refers to the fact that the probability of inducing LTP increases with the number of stimulated fibers. The idea was that multiple axons 'cooperate' in triggering LTP. Input specificity refers to the fact that LTP induction is restricted to just those synapses that receive the necessary or critical activation at the right time. All three of these classical properties are signatures of a Hebbian modification.

The associative nature of LTP was first suggested in studies that William Levy and Oswald Steward performed *in vivo* on the perforant-path-to-granule-cell synapse (see Figure 1). Stimulation electrodes placed bilaterally in the entorhinal cortices elicited extracellular population field potentials in the granule cell layer of the dentate gyrus. Due to differences in the number of ipsilateral and contralateral axonal projections, stimulation of the entorhinal cortex ipsilateral to the recording site produced a large field potential response (strong input), whereas stimulation of the entorhinal cortex contralateral to the recording site produced a small field potential response (weak input). Stimulation of the (weak) contralateral input alone failed to induce LTP in that pathway. However, LTP could be induced in the contralateral input when it was stimulated concurrently with the converging (strong) ipsilateral input. Importantly, activity in the ipsilateral input, by itself, did not induce LTP in the contralateral input (a phenomenon called heterosynaptic LTP; see later, section titled 'Heterosynaptic LTP').

Associative LTP and Hebbian Plasticity

Using the hippocampal brain slice preparation, in 1983, German Barrionuevo and Thomas Brown demonstrated 'associative LTP' intracellularly in the Sch/com synaptic inputs to hippocampal CA1 neurons (see Figure 1). The experiment examined interactions between weak (W; small number of stimulated afferents) and strong (S; large number of stimulated afferents) inputs in a hippocampal brain slice. Tetanic (high-frequency) stimulation of the W input by itself failed to produce LTP in that pathway unless this stimulation was temporally paired with tetanic stimulation of the S input. LTP was induced in the W input only when its activity was associated with activity in the S input. S stimulation never induced LTP in the W input, meaning that heterosynaptic LTP (see later) did not occur in these synapses. The use of brain slices enabled pharmacological manipulations that ruled out the possibility that the overall increase in synaptic efficacy resulted from LTD in inhibitory interneurons.

In 1986, Stephen Kelso and Thomas Brown then examined the spatiotemporal specificity of associative LTP in these synapses, calling attention to the relationships between W and S inputs and Pavlovian conditioned and unconditioned stimuli (CSs and USs), respectively. W–S pairings were ineffective in inducing associative LTP when the periods of W and S stimulations did not overlap temporally, but were separated by a small fraction of a second. By using two W inputs (W1 and W2), these experiments simultaneously demonstrated the spatial specificity of the synaptic changes. Modifications only occurred in the synapses associated with the particular W input (W1 or W2) with an activity that overlapped temporally with that of the S input. More recently, Nelson Spruston and co-workers further refined the precise timing requirements for the induction of associative LTP.

The demonstration of associative LTP did not prove that a Hebbian mechanism was involved, because there was no direct demonstration that postsynaptic activity or depolarization *per se* was critical to the mechanism for LTP induction. A popular alternative possibility was that activity in the S input released a critical amount of an 'LTP factor' that enabled LTP in the coactive W input. Determining whether associative LTP in the Sch/com synapses resulted from a Hebbian mechanism required an experiment designed to force or prevent simultaneous presynaptic and postsynaptic activity. If a critical amount of postsynaptic depolarization or activity could be shown to be a necessary condition for inducing LTP in active synapses, this would be persuasive evidence in favor of a Hebbian mechanism.

There had been two previous failures to discover Hebbian plasticity. In 1982, a year before the experiments of German Barrionuevo and Thomas Brown, Holger Wigstrom and co-workers incorrectly concluded that the postsynaptic membrane potential had no effect on LTP induction. The error resulted from not appreciating the large difference that can exist between the voltage recorded by an intrasomatic microelectrode and the actual voltage across the dendritic membrane that is immediately postsynaptic to the active synapses. Two years later, Thomas Carew and co-workers repeated this same error in studies of synaptic plasticity in a ganglion of *Aplysia*.

In 1986, Thomas Brown and co-workers corrected the error in hippocampus. They furnished definitive experimental evidence for a Hebbian conjunctive mechanism in the Sch/com synapses of hippocampal region CA1 (Figure 1). The rationale for this study was simple. If the synapses were Hebbian, then it should be possible to induce LTP under experimental conditions, in which one substitutes for the usual S input direct depolarization of the postsynaptic

neuron via the recording microelectrode. Results are shown in Figure 2, which plots the mean amplitude of the excitatory postsynaptic potentials (EPSPs) evoked in the CA1 pyramidal neurons as a function of time and the various experimental manipulations.

The EPSPs were tested every 12 s by delivering a single extracellular stimulation to the Sch/com afferent inputs. Once a stable EPSP baseline was established, the postsynaptic neuron was depolarized alone (Figure 2, Depol. Alone) to demonstrate that this manipulation was without effect. Next, a tetanic stimulation (100 Hz) was given to the W input while the postsynaptic soma was maintained at −80 mV under voltage clamp conditions (Figure 2, 100 Hz + voltage clamp). Then the same presynaptic tetanic stimulation was given while the postsynaptic cell was depolarized under current clamp conditions (Figure 2, 100 Hz + depol.).

These studies demonstrated, unequivocally, that Hebbian plasticity does exist in the hippocampus and that this Hebbian mechanism could account for the spatiotemporal specificity of the activity–modification relationship. Using two separate weak inputs (W1 and W2) to the same cell, it was demonstrated that only the W input that was activated during postsynaptic depolarization exhibited LTP. Temporal specificity was evidenced by the fact that, to be effective, postsynaptic depolarization and presynaptic stimulation (at 100 Hz) had to occur nearly simultaneously.

In agreement with these findings, Holger Wigstrom and co-workers also published a brief note in 1986 suggesting that their previous conclusion had been erroneous. Starting in the 1990s, work by David Glanzman and co-workers corrected the earlier error in *Aplysia*. Glanzman's recent work suggests that Pavlovian conditioning in *Aplysia* results from a mechanism that requires postsynaptic Ca^{2+} influx and *N*-methyl-D-aspartate receptors (NMDARs). The mechanism in *Aplysia* appears to be remarkably similar to that responsible for NMDAR-dependent associative LTP in the Sch/com synapses.

Heterosynaptic LTP

Heterosynaptic LTP, in contrast to associative LTP, is not input specific. Heterosynaptic LTP implies that stimulation of one pathway causes synaptic changes in another, unstimulated pathway. For a variety of reasons, heterosynaptic LTP, which has been studied most extensively *in vitro* in *Aplysia*, is not considered to be a viable candidate synaptic substrate for associative learning and memory in mammals. However, David Glanzman and co-workers raise the interesting possibility that heterosynaptic plasticity in *Aplysia* could serve to modulate the induction and/or persistence of Hebbian synaptic modifications.

Anti-Hebbian Plasticity

As summarized, Hebbian plasticity is one that uses an interactive, time-dependent, and highly local mechanism to increase synaptic efficacy as a function of the contiguity, contingency, or association between pre- and postsynaptic activity. Synapses that decrease

Figure 2 Demonstration of Hebbian plasticity in the hippocampus. Illustrated are excitatory postsynaptic potential (EPSP) amplitudes as a function of the time of occurrence (arrows) of three manipulations: the postsynaptic cell is first given an outward current step, resulting in postsynpatic spiking but no potentiation of the EPSP amplitude (depol. alone). Next, the postsynaptic soma is voltage clamped at −80 mV while delivering presynaptic stimulation trains of 100 Hz, resulting in no EPSP potentiation (100 Hz + voltage clamp), or an outward current step is delivered, causing the cell to fire, at the same time that the presynaptic input is stimulated at 100 Hz, resulting in potentiation of the EPSP amplitude (100 Hz + depol.). Each point is the average of five consecutive EPSP amplitudes. Adapted from Kelso SR, Ganong AH, and Brown TH (1986) Hebbian synapses in hippocampus. *Proceedings of the National Academy of Sciences of the United States of America* 83: 5326–5330, with permission. Copyright 1986 by National Academy of Sciences, USA.

efficacy under the same conditions are sometimes termed 'anti-Hebbian.' Anti-Hebbian plasticity has been most commonly studied in certain neurons of the cerebellum that are important in adaptive motor changes. In these neurons, conjunctive presynaptic and postsynaptic activity results in long-term synaptic depression (LTD). The best understood example of associative LTD occurs at the parallel fiber-to-Purkinje cell synapse, where the mechanism is thought to involve an increase in the Ca^{2+} concentration ($[Ca^{2+}]_i$) in parts of the postsynaptic neuron. Anti-Hebbian synapses were anticipated by the theoretical studies of James Albus in 1971. Because the output from the Purkinje cells is inhibitory, associative LTD in the cerebellum results in disinhibition, or a net increase in excitatory drive on the ultimate target cells.

Induction of Associative LTP

Much evidence has accumulated suggesting a role for NMDARs in the induction of associative LTP. Two properties of the NMDAR are pertinent to a role in the induction of associative LTP. First, NMDARs are permeable to Ca^{2+} (in addition to Na^+ and K^+). This is significant because the intracellular Ca^{2+} concentration near the postsynaptic membrane is thought to play a critical role in inducing associative LTP. Second, the channel permeability is a function of both presynaptic and postsynaptic events, thus serving as a 'coincidence detector.'

The NMDAR conductance depends on coactivation of both pre- and postsynaptic neurons. Presynaptic activity is required for release of glutamate, the endogenous neurotransmitter that binds to NMDARs on the postsynaptic membrane. Postsynaptic activity is required to relieve a Mg^{2+} block of the NMDAR. The NMDAR-mediated conductance is therefore both ligand gated and voltage gated, allowing Ca^{2+} entry only when presynaptic release co-occurs with sufficient depolarization of the postsynaptic membrane to relieve the Mg^{2+} block. In some neurons, the elicitation of back-propagating action potentials (BAPs; see later) may also be necessary to achieve sufficient depolarization of the postsynaptic dendritic membrane.

We can now envision how these biophysical events could account for the properties of associativity, cooperativity, and input specificity. Active synapses release glutamate, which can bind to postsynaptic NMDARs, causing Ca^{2+} influx into dendritic spines on the postsynaptic neuron. Ca^{2+} influx into the spine acts on local enzymes that control LTP induction, resulting in input specificity. The Ca^{2+} influx into the spine occurs only when the synaptic input is strong enough to depolarize the postsynaptic membrane sufficiently to relieve the Mg^{2+} block, giving rise to cooperativity. Activity in a W input is not sufficient to depolarize the postsynaptic membrane sufficiently to remove the Mg^{2+} block, unless this activity is properly timed in relationship to activity in an S input to the same cell. If the S input elicits BAPs, this causes additional depolarization that can increase Ca^{2+} influx. Associativity results from the fact that the depolarization of the postsynaptic membrane resulting from combined activity in the W and S inputs is necessary to induce LTP in the W input.

Biophysical Models of Hebbian Plasticity

The laboratories of Thomas Brown and William Levy independently created biophysical models that elucidate the role of NMDARs in Hebbian plasticity. In both computational models, nearly concurrent presynaptic activity (producing glutamate release) and postsynaptic activity (relieving the Mg^{2+} block of the channel) allowed Ca^{2+} influx into the dendritic spine of the postsynaptic neuron. The increased $[Ca^{2+}]_i$ in a critical region of the dendritic spine, close to the NMDAR, activated Ca^{2+}-dependent enzymes, such as Ca^{2+}/calmodulin-dependent kinase II (CaMKII), that are thought to play a key role in LTP induction.

Both models wrestled with the fact that the voltage dependence of the NMDAR was insufficient to account for what is known about associative LTP. Both laboratories attempted to solve this problem by taking into account the additional nonlinearity in the relationship between postsynaptic depolarization and Ca^{2+}-dependent enzyme activation. Brown and co-workers also examined an additional nonlinearity – the effects of BAPs. The main finding was that back-propagating Na^+ spikes were only effective in promoting LTP induction if they in turn elicited dendritic Ca^{2+} spikes.

Dendritic Ca^{2+} spikes were included in the model for several reasons. First, Robert Wong and co-workers, in 1979, had shown that Ca^{2+} spikes can be elicited in the dendrites of hippocampal pyramidal neurons. Second, Stephen Kelso and co-workers, in 1986, noted that, whereas Hebbian LTP can be readily induced in hippocampal neurons under conditions in which Na^+ spiking was blocked, Ca^{2+} spikes continued to be elicited when the cell was sufficiently depolarized to enable LTP induction. Finally, in 1987, Thomas Richardson and associates provided evidence that BAPs can be readily elicited in hippocampal neurons by synaptic inputs. Their inference was based on extracellular recordings combined with current–source–density (CSD) analysis. The CSD data strongly

suggested that synaptic inputs can elicit spikes in the soma that then propagate into the dendrites. The role of BAPs in promoting or enabling Hebbian plasticity was only an interesting theoretical possibility in 1990.

However, further work by Johnston and co-workers provided compelling evidence in support of this possibility. Using patch clamp recordings from the soma and dendrites, combined with direct Ca^{2+} imaging, Johnston and colleagues furnished a detailed understanding of the elicitation and back-propagation of Na^{+} and Ca^{2+} spikes as well as the manner in which dendritic spikes are controlled by K^{+} currents. Even more important, in the present context, is the finding that the elicitation of BAPs appears to be essential for inducing LTP in some synapses. As noted previously, BAPs furnish an additional nonlinearity that can be computationally desirable. BAPs also introduce useful dynamics into synaptic activity–modification relationships in terms of the critical temporal relationship among W activity, S activity, and dendritic spiking.

Distribution and Varieties of LTP

Not all forms of LTP are Hebbian, nor do they all involve the NMDAR. In the peripheral nervous system, the rat superior cervical sympathetic ganglion exhibits a non-Hebbian form of LTP that relies on the nicotinic acetylcholine receptor. Robust and long-lasting LTP is also reported in the crayfish neuromuscular junction, where glutamate is the neurotransmitter. It is uncertain whether postsynaptic depolarization plays a role in this modification. As we have already noted, an NMDAR-dependent form of Hebbian LTP has also been described in *Aplysia* ganglia and fruit flies. Interestingly, the mossy fiber synapses of the hippocampus exhibit a Hebbian form of LTP that does not rely upon NMDARs.

Recent interests in NMDAR-independent forms of Hebbian LTP have focused on the role of Ca^{2+} influx triggered by BAPs. Timothy Teyler and co-workers have raised the interesting possibility that NMDAR-independent LTP is preferentially involved in longer-term information storage in cortex. Joseph LeDoux has made the same suggestion for information storage in the amygdala. Much more research is clearly needed on the critical question of how the various types of LTP are (or are not) related to specific aspects or forms of learning and memory.

Summary

In reviewing the evolution of the current understanding of Hebbian plasticity, including supporting neurophysiological evidence and biophysical mechanisms, it is seen that the suggestion by James and Hebb – that learning and memory emerge from a contiguity-based neuronal modification – dovetails nicely with current research on associative LTP and LTD. Today we are experiencing a grand confluence of ideas from philosophy, psychology, neurophysiology, and computation. Theoretical studies leave little doubt about the impressive learning and self-organizing capabilities of circuits containing Hebbian synapses. Experimental studies have shown that Hebbian plasticity is widespread throughout the nervous system and across phylogeny. A reasonable hypothesis is that Hebbian plasticity plays a fundamental role in some of the adaptive functions of the nervous system. The most pressing need is to elucidate precisely the relationships between various types of LTP (and LTD) and specific aspects or forms of learning and memory – what Daniel Johnston and co-workers have termed 'the missing link.'

Helix–Loop–Helix (bHLH) Proteins: Hes Family

R Kageyama, T Ohtsuka, R Ohsawa, and J Hatakeyama, Kyoto University, Kyoto, Japan

© 2009 Elsevier Ltd. All rights reserved.

Structure and Transcriptional Activity

Hes genes are mammalian homologs of *Drosophila hairy* and *Enhancer of split* [*E*(*spl*)], which are known to inhibit neurogenesis. There are seven members in the Hes family, and each member has a conserved basic helix–loop–helix (bHLH) domain (Figures 1(a) and 1(b)), which is required for dimer formation and DNA binding. Hes1 forms homodimers and binds with high affinity to the DNA motif, the N-box (CACNAG) or the class C site (CACGCG), and with low affinity to the E-box (CANNTG). In contrast, many other bHLH factors, such as the proneural bHLH factors Mash1 and E47, form heterodimers and bind only to the E-box with a higher affinity. In the basic region, all Hes factors have a proline residue (Figures 1(a) and 1(b), asterisk), unlike other bHLH factors, suggesting that this proline residue might be responsible for the Hes-specific DNA binding activity. At the C-terminus, Hes factors have Trp-Arg-Pro-Trp sequence (the WRPW domain), which functions as a repression domain by recruiting the co-repressors TLE/Grg factors, homologs of *Drosophila* Groucho (Figures 1(a) and 2(a)). Thus, Hes factors act as transcriptional repressors, while proneural bHLH factors function as transcriptional activators. One of the targets of Hes1 is the proneural bHLH gene *Mash1*. There are class C sites in *Mash1* promoter, and Hes1 represses *Mash1* expression by directly binding to these class C sites. Hes1 also forms heterodimers with bHLH activators such as Mash1 and E47, but these heterodimers do not bind to the DNA, indicating that Hes1 inhibits the activities of proneural bHLH activators by forming non-DNA-binding heterodimers (Figure 2(b)). Thus, Hes factors repress gene expression by two different mechanisms: by recruiting co-repressors (active repression) and by forming non-DNA-binding heterodimers (passive repression) (Figure 2).

There are several Hes-related factors such as Hey/Hesr/Herp. They have a Hes-related bHLH domain and WRPW-related sequence and form heterodimers with Hes. Interestingly, Hes/Hey heterodimers bind to the class C site with a higher affinity and repress transcription more efficiently than Hes and Hey homodimers.

Between the bHLH and WRPW domains, Hes factors have the Orange domain (Figure 1(a)), which consists of two amphipathic helices. Some bHLH factors preferentially form heterodimers with each other while others do not, and this specificity for bHLH factor interaction is regulated by the Orange domain. This domain is also involved in transcriptional repression, although a co-repressor mediating this repression is not known.

Hes3 has two forms, Hes3a and Hes3b, which are generated by alternative promoters and first exons. Hes3a lacks the amino-terminal half of the basic region and thus cannot bind to the DNA, although it forms a non-DNA-binding heterodimer complex with other bHLH factors. Hes3a is specifically expressed by Purkinje neurons in the cerebellum, but the function of Hes3a in Purkinje neurons remains to be determined. In contrast, Hes3b has a complete basic region and represses transcription by binding to the N-box. Hes3b is expressed by neural progenitors (see following sections), unlike Hes3a. In the rest of this article, Hes3b is designated as Hes3.

Unlike other Hes factors, Hes6 does not bind to the N-box or the E-box, although it has a complete bHLH domain. Furthermore, Hes6 has an opposite activity to Hes1: Hes6 antagonizes Hes1 by physical interaction and supports Mash1 activity, thereby promoting neuronal differentiation. The loop region of Hes6 is shorter than that of the other Hes factors (Figure 1(b)), and it is likely that this short loop region is responsible for such unique activities of Hes6.

Regulation of *Hes* Gene Expression

Hes1 and *Hes5* expression is regulated by Notch signaling in the nervous system (Figure 3). The transmembrane protein Notch is activated by its ligands such as Delta. Upon activation, the intracellular domain of Notch (ICD) is cleaved from the transmembrane region and translocated into the nucleus. In the nucleus, the ICD forms a complex with the DNA-binding protein RBP-J, which binds to the *Hes1* and *Hes5* promoters. Before Notch activation, RBP-J interacts with a histone deacetylase co-repressor complex and functions as a transcriptional repressor, but Notch activation disrupts the repressor complex and leads to the formation of the ICD–RBP-J complex, which functions as a transcriptional activator. Thus, Notch activation induces expression of *Hes1* and *Hes5* genes. However, while *Hes5* expression is lost in the absence of Notch signaling, *Hes1* expression is not in some regions, suggesting that *Hes1* expression is additionally controlled

Figure 1 Features of Hes bHLH factors. (a) The bHLH, Orange, and WRPW domains and their functions. (b) Sequence alignment of the bHLH domain of Hes factors. Proline is conserved in the middle of the basic region (asterisk). The loop region of Hes6 is shorter than that of other Hes factors.

Figure 2 Two different mechanisms of Hes1-mediated transcriptional repression. (a) Active repression. Hes1 homodimer binds to the N-box and the class C site, and the co-repressors Groucho/TLE/Grg interact with the WRPW domain. This complex actively represses transcription by recruiting the histone deacetylase. (b) Passive repression. Hes1 forms a non-DNA-binding heterodimer with bHLH activators such as E47 and thereby represses transcription.

Figure 3 Notch signaling. The transmembrane protein Notch is activated by its ligands such as Delta. Upon activation, the intracellular domain (ICD) of Notch is cleaved and translocated into the nucleus. In the nucleus, the ICD forms a complex with the DNA-binding protein RBP-J, which binds to the *Hes1* and *Hes5* promoters. RBP-J alone is a transcriptional repressor, but the ICD–RBP-J complex is a transcriptional activator. Thus, Notch activation induces *Hes1* and *Hes5* expression.

by other factors. In agreement with this notion, Wnt, Shh, and BMP have been reported to upregulate *Hes1* expression. *Hey* gene expression is also induced by Notch signaling, indicating that Hes and Hey function together in Notch signaling.

Another important feature regulating *Hes* expression is that there are multiple N-box sequences in the *Hes1* promoter where Hes1 can bind and autorepress its own expression. Strikingly, when the promoter is activated, *Hes1* autonomously starts oscillatory expression with the periodicity of about 2 h (Figure 4). This oscillation depends on the negative feedback, as follows. *Hes1* promoter activation leads to accumulation of Hes1 protein, which represses its own transcription. This repression immediately leads to the disappearance of Hes1 mRNA and protein because they have extremely short half-lives (about 20 min). Disappearance of Hes1 protein then relieves the negative feedback, allowing the next round of transcription. In this way, *Hes1* displays oscillatory expression when the promoter is activated. Similarly, Hes7 expression also oscillates with the periodicity of about 2 h in the presomitic mesoderm. This oscillation is thought to be an integral component of the segmental clock that cycles every 2 h in the mouse, thus allowing another bilateral pair of somites to bud off at the anterior end of the presomitic mesoderm. Indeed, in the absence of Hes7, cycling of the clock is disrupted and somites are severely fused. It is likely that *Hes1* also acts as a 2-h-cycle biological clock in many cell types including neural progenitors. Supporting this idea, immunohistochemical analysis shows that Hes1 protein levels are variable in neural progenitors (see the following section), although further studies are required to determine whether or not *Hes1* expression oscillates in these cells *in vivo*.

Hes Expression in the Developing Nervous System

Differentiated neural cell types are generated from the neuroepithelial cells that line the ventricles of the developing brain and spinal cord. When they first appear in development, neuroepithelial cells initially undergo self-renewal by symmetric cell division (Figure 5). As development proceeds in the forebrain and midbrain, the neuroepithelial cells become radial glial cells, with cell bodies located to the ventricular zone and with long processes (radial fibers) reaching the pial surface (Figure 5). Radial glia have long been thought of as specialized glia (this is why they are named as such), but it has now been revealed that they are the second form of embryonic neural progenitors. Radial glial cells undergo asymmetric cell division, by which each radial glial cell produces one radial glial cell and one neuron (or neuronal precursor). Some radial glial cells undergo symmetric cell division, giving rise to two radial glial cells or two neurons. Neurons migrate along the radial fibers of radial glial cells toward the outer layers. Radial glial cells also give rise to ependymal cells, the internal

Figure 4 Oscillatory expression of Hes1. *Hes1* promoter activation leads to accumulation of Hes1 protein, which represses its own transcription. This repression immediately leads to disappearance of Hes1 mRNA and protein because they have extremely short half lives (about 20 min). Disappearance of Hes1 protein then relieves the negative feedback, allowing the next round of transcription. In this way, *Hes1* displays oscillatory expression when the promoter is activated.

Figure 5 Expression patterns of *Hes* genes. In the developing nervous system, neuroepithelial cells are initially formed. Later, they become radial glial cells, which give rise to neurons, ependymal cells, oligodendrocytes, and astrocytes. *Hes1* and *Hes3* are expressed by neuroepithelial cells. *Hes1* is also expressed by radial glial cells while there is a switch from *Hes3* expression to *Hes5* expression during transition from neuroepithelial cells to radial glial cells. Notch signaling is also activated during this transition.

lining of ventricles (Figure 5). After production of neurons, radial glial cells are differentiated into glial cells (oligodendrocytes and astrocytes) (Figure 5). After birth, radial glial cells mostly disappear, but neural progenitors remain in a few neurogenic regions including the subventricular zone of the forebrain and the subgranular zone of the hippocampus. Thus, neural progenitors change their morphology and competence over time.

Initially, *Hes1* and *Hes3* are widely expressed by neuroepithelial cells (Figure 5). This expression occurs before *Notch1* and its ligands *Deltalike* (*Dll*) *1* and *Dll3* are expressed, indicating that *Hes1* and *Hes3* expression is independent of Notch signaling. During the transition from neuroepithelial cells to radial glial cells, *Hes3* expression is gradually downregulated and finally lost while *Hes5* expression starts together with *Notch1* and *Dll1* expression (Figure 5), suggesting that *Hes5* expression is controlled by Notch signaling. In contrast, Hes1 expression is maintained by radial glial cells (Figure 5) but becomes mostly complementary to *Hes5* expression (Figure 6). *Hes1* expression gradually overlaps with *Notch1* and *Dll1* expression, suggesting that *Hes1* expression is also controlled by Notch signaling at later stages. Interestingly, in the absence of *Hes1*,

Figure 6 *Hes1* and *Hes5* expression in the developing brain. *Hes1* and *Hes5* expression are mostly complementary to each other at E9.5 in mouse embryos. *Hes1* is highly expressed in the zona limitans intrathalamica (arrowhead) and the isthmus (arrow) while *Hes5* is not.

Hes5 is expressed in the regions that normally express *Hes1* only, and vice versa, suggesting that *Hes1* and *Hes5* compensate each other. As development proceeds, *Hes1* and *Hes5* expression is downregulated but is retained in both the slowly dividing, niche localized neural stem cells, and the rapidly amplifying progenitors in the subventricular zone of the lateral ventricles, and the subgranular zone of the dentate gyrus. Thus, *Hes* genes are continuously expressed by neural progenitors. *Hes* genes are also expressed by subsets of glial cells such as Müller glia in the retina.

Hes Genes Regulate Maintenance of Neural Stem Cells

Many aspects of Hes function in the developing nervous system are explained by their ability to inhibit neurogenesis, thereby preventing neuronal differentiation of progenitors at earlier stages and promoting gliogenesis at later stages. Interestingly, in the absence of proneural bHLH genes such as *Mash1*, *Neurogenin* (*Ngn*), and *Math3*, progenitor cells that should normally become neurons are inhibited from neuronal differentiation and remain undifferentiated for a while but then adopt the glial fate prematurely. Thus, it is likely that proneural bHLH genes not only promote neuronal fate determination but also inhibit premature gliogenesis. In agreement with this notion, the proneural bHLH factor Ngn1 activates neuronal-specific gene expression and inhibits glial-specific gene expression by sequestering a p300/CBP–Smad complex. The phenotypes of proneural bHLH gene inactivation, inhibition of neurogenesis, and promotion of gliogenesis, are very similar to those of misexpression of *Hes* genes, suggesting that *Hes* genes exert their phenotypes by repressing proneural bHLH genes. Proneural bHLH genes are also required for *Hes* expression and maintenance of neural progenitors. These genes induce Delta expression, thereby activating Notch signaling in neighboring cells. In the absence of proneural bHLH genes, Notch is not activated, and *Hes* expression is downregulated, resulting in loss of neural progenitors. Thus, *Hes* and proneural bHLH genes form a network to regulate maintenance of neural progenitors and the formation of neurons and glial cells.

Hes1, Hes3, and Hes5 likely act to inhibit neurogenesis by repressing proneural gene expression directly. For example, the proneural bHLH gene *Mash1* contains class C binding sites in its promoter, and Hes1 represses *Mash1* expression by directly binding to these sites. In agreement with this result, *Mash1* expression is upregulated in the absence of *Hes1* and is even more severely upregulated in the absence of *Hes1*, *Hes3*, and *Hes5*. Furthermore, other proneural genes such as *Ngn* and *Math1* are also highly upregulated in the absence of these *Hes* genes, suggesting that Hes1, Hes3, and Hes5 negatively regulate proneural bHLH gene expression. Hes proteins might also inhibit neurogenesis through other targets, including the cyclin-dependent kinase (CDK) inhibitors p21 and p27, both of which inhibit cell cycle progression by retarding G1 phase. It is likely that Hes1, Hes3, and Hes5 promote cell cycle progression, and thus the maintenance of neural progenitors, by repressing p21 and p27. However, paradoxically, it has been also shown that persistent and high levels of Hes1 expression inhibit cell proliferation (see following section). Because p21 and p27 are also required for assembly of cyclin D1–CDK4 complex and nuclear import of cyclin D, complete repression of these CDK inhibitors by persistent and high levels of Hes1 may be inhibitory on cell cycle progression.

Based on their expression patterns and mutant phenotypes, the Hes1, Hes3, and Hes5 proteins subserve different although overlapping functions within the developing neuroepithelium. In the absence of *Hes1* and *Hes5*, radial glial cells prematurely differentiate into neurons and are depleted without generating later-born cell types. Premature depletion of radial glial cells leads to intermingling of neurons from the left and right walls of the neural tube and disruption of the neural tube structures (**Figures 7(f)–7(h)**, compare with **Figures 7(c)–(e)**), because radial glial cells have the junctional complex and the basal lamina at the apical and basal side, respectively, both of which serve as barriers to prevent neurons from spilling over. Conversely, transient misexpression of *Hes1* or *Hes5* in mouse brain at embryonic day 13.5 inhibits neuronal differentiation and maintains radial glial cells, leading to the increase of later-born neurons and glial cells. In contrast to the peripheral nervous system, where transient Notch activation instructs a glial fate (Schwann cells), transient Notch activation or transient misexpression of *Hes1* or *Hes5* in the central nervous system (CNS) does not seem to instruct gliogenesis. Instead, Hes1 and Hes5 seem to be required to maintain undifferentiated neural progenitors until later stages, when neurogenesis ceases and gliogenesis begins. Thus, *Hes1* and *Hes5* maintain neural progenitors without affecting their temporally changing competency in the CNS. *Hey1* and *Hey2* also have a similar activity: transient misexpression of *Hey1* or *Hey2* does not instruct gliogenesis but promotes maintenance of neural progenitors.

In the absence of *Hes1*, *Hes3*, and *Hes5*, not only radial glia but also neuroepithelial cells are not properly maintained and prematurely differentiated into neurons. However, even in *Hes1*:*Hes3*:*Hes5*

Figure 7 Structural defects of *Hes1*;*Hes5*-double-null mice. Mouse embryos were analyzed by scanning electron microscopy. (a) The optic vesicle (yellow arrow), the zona limitans intrathalamica (zli) (arrowhead), and the isthmus (white arrow) are formed in the wild type. (b) In the absence of *Hes1* and *Hes5*, the optic vesicle and the zli are not formed. The isthmus is only partially formed (asterisk and arrow). (c–e) Cells are aligned radially in the walls of the neural tube in the wild type. (f–h) Cells from the left and right walls are intermingled with each other at E9.5 in the ventral part of *Hes1*;*Hes5*-double-null embryo (f, g). This defect becomes severer at E10.5 (h). Boxed regions in (c) and (f) are enlarged in (d) and (g), respectively. Scale bar = 100 μm.

triple knockout mice, neuroepithelial cells are initially formed, indicating that *Hes* genes are required for maintenance of, but not formation of, neuroepithelial cells. It remains to be determined which factors are responsible for initial formation of neuroepithelial cells. Based on these phenotypes of *Hes*-mutant mice and expression patterns of *Notch* and *Hes* genes, the neuroepithelium develops stepwise in the following way: (1) an initial *Hes*- and *Notch*-independent phase, (2) a subsequent *Hes*-dependent but *Notch*-independent phase, and (3) a *Hes*- and *Notch*-dependent radial glial phase (Figure 8). During the second phase, the neuroepithelial cells go through a transitory stage, in which they usually do not give rise to any neurons, but without *Hes* genes, prematurely differentiate into neurons.

Based on the expression patterns, it is likely that *Hes1* and *Hes3* are mainly responsible for transitory neuroepithelial cells, while *Hes1* and *Hes5* are required for radial glial cells. *Hes1* and *Hes5* expression in radial glial cells may be controlled by Notch

Figure 8 Temporal changes of neural progenitor characteristics. Embryonic neural progenitors change their characteristics as follows: (a) the initial *Hes*- and *Notch*-independent neuroepithelial cells, (b) the subsequent *Hes*-dependent but *Notch*-independent transitory neuroepithelial cells, and (c) *Hes*- and *Notch*-dependent radial glial cells. *Hes*-dependent but *Notch*-independent transitory neuroepithelial cells prematurely differentiate into neurons in the absence of *Hes* genes.

signaling (Figure 5), but it remains to be determined which factors regulate *Hes1* and *Hes3* expression in transitory neuroepithelial cells. While transitory neuroepithelial cells usually undergo symmetric cell division and do not produce any neurons, radial glial cells give rise to neurons by asymmetric cell division. Interestingly, during the switch from transitory neuroepithelial cells to radial glial cells, expression of both *Notch* and its ligands begins together, suggesting that neural stem cells undergoing asymmetric cell division express Notch signaling molecules whereas those undergoing symmetric cell division do not. Thus, it is likely that expression of Notch signaling molecules is a key feature of the switch from symmetric to asymmetric cell division.

Eye formation also depends on *Hes1* and *Hes5*. In the absence of *Hes1*, neuronal differentiation is accelerated and retinal neural stem cells are prematurely depleted, resulting in disruption of the neural retina structures. Strikingly, in the absence of *Hes1* and *Hes5*, the optic vesicles are not formed (Figure 7(b), compare with Figure 7(a), yellow arrow), although the homeodomain gene *Rax*, which is essential for eye formation, is expressed normally in the prospective eye regions. Normally, no neurogenesis occurs during the optic vesicle formation, but without *Hes1* and *Hes5*, neurogenesis is severely accelerated in the prospective eye regions. Thus, *Hes1* and *Hes5* are required for maintenance of retinal progenitors from the earliest stage of eye development and seem to function together with *Rax*.

Hes Genes Regulate Boundary Formation

The CNS is partitioned into many compartments by boundaries (Figure 9), which are formed by specialized neuroepithelial cells or radial glial cells. Boundaries act as organizing centers which function by producing morphogens, thereby patterning nearby compartments and specifying regional aspects of neural differentiation. For example, the isthmus, a midbrain–hindbrain boundary, expresses Fgf8 and regulates neuronal specification in the midbrain and the hindbrain while the zona limitans intrathalamica (zli), a boundary between the dorsal and ventral thalamus, expresses Shh and regulates specification of dorsal and ventral thalamic neurons. Boundary cells restrict cell migration and do not proliferate as efficiently as neuroepithelial and radial glial cells of compartments. In addition, neurogenesis usually does not occur in boundaries. *Hes1* is expressed at high levels in most boundaries, while *Hes3* is expressed in the isthmus. *Hes5* is not expressed in boundaries, but it is ectopically expressed in some boundaries in the absence of *Hes1*.

Hes genes are not only required in neuropithelial cells within the compartments but also for the formation of neuroepithelial cells that comprise the boundaries. In the absence of *Hes1* and *Hes3*, the isthmus is not maintained and differentiated into neurons. As a result, Fgf8 expression is prematurely lost, resulting in defects of midbrain- and hindbrain-specific neuronal differentiation. Similar defects occur in the

Figure 9 Boundaries in the developing CNS. The developing CNS is partitioned into compartments by boundaries, which function as organizing centers. Hes1 is highly expressed in boundaries and, without *Hes* genes, boundaries are prematurely lost or not formed. zli, zona limitans intrathalamica.

isthmus of *Hes1*;*Hes5*-double-null embryos (Figure 7(b), arrow and asterisk, compare with Figure 7(a), white arrow). In addition, in the absence of *Hes1* and *Hes5*, the zli is not formed (Figure 7(b), compare with Figure 7(a), arrowhead) and Shh expression does not occur. In the absence of *Hes1*, *Hes3*, and *Hes5*, ectopic neurogenesis and loss of the organizer activities occur in all boundaries, resulting in defects of regional-specific neuronal differentiation. *Hes1* is persistently expressed at high levels by many boundary cells (Figures 6(a) and 6(c), arrow and arrowhead). In contrast, *Hes1* expression is variable in compartments: some cells express Hes1 protein at high levels while others express at lower levels or do not express Hes1 protein. When Hes1 expression is reduced, proneural bHLH factor expression is upregulated, displaying an inverse correlation between Hes1 and proneural bHLH factor expression (Figure 10(a), upper panel). As stated above, Hes1 expression could oscillate in compartmental progenitors (Figure 10(a), lower panel). In boundaries, it is likely that persistent and high levels of Hes1 expression constitutively repress proneural bHLH gene expression and thereby block neurogenesis (Figure 10(b)). In agreement with this notion, inactivation of *Hes1*, *Hes3*, and *Hes5* leads to ectopic expression of proneural bHLH genes and premature loss of organizing activities in boundaries. Furthermore, when *Hes1* is misexpressed at persistent and high levels in compartmental neural progenitors, these cells encounter blockade of neurogenesis and reduction of proliferation rates, two important features of boundary cells. Thus, expression mode of Hes1 is different between compartments (variable) and boundaries (persistent) (Figure 10), and it is likely that this different expression mode regulates compartment versus boundary cell characteristics. Interestingly, both Hes1 mRNA and protein are highly expressed in boundaries, suggesting that the negative feedback does not work in

Figure 10 Different Hes1 expression modes in compartments and boundaries. (a) In compartments, Hes1 expression is variable: either gradual downregulation or oscillatory expression. Downregulation of Hes1 expression leads to upregulation of proneural bHLH gene expression. (b) In boundaries, persistent and high levels of Hes1 constitutively repress proneural bHLH gene expression, thereby maintaining neuron-free zones and organizing centers. It is likely that dynamic versus persistent expression of Hes1 regulates compartment versus boundary formation.

boundaries. Further studies are required to demonstrate how this unique expression mode is regulated.

Summary

In sum, *Hes* genes act to inhibit neurogenesis by repressing proneural bHLH genes but do so in different ways along the neuraxes. In the neurogenic compartments, *Hes* gene expression tends to be dynamic, and a loss of *Hes* gene function results in accelerated neuronal differentiation and a premature loss of neural progenitors at the expense of later-born cells. Thus, *Hes* genes are required in neurogenic regions to ensure the generation of differentiated cells in both the correct numbers and full diversity. In regions of the neuroepithelium that form boundaries, *Hes* gene expression persists at high levels and thereby constitutively represses proneural bHLH gene expression. In the absence of *Hes* genes, ectopic neurogenesis occurs in boundaries and their organizing activities are

lost. These different aspects of *Hes* gene function are likely to depend on the different modes by which their expression is regulated (i.e., dynamic versus persistent).

bHLH Transcription Factor Family

The basic helix–loop–helix (bHLH) family of proteins comprises transcriptional regulators of a variety of developmental processes including cellular differentiation and lineage commitment, not only in the nervous system but also in the pancreas, muscle, and heart. Data collected from several model organisms have implicated bHLH transcription factors in the determination of neuronal lineages and the specification of distinct cell fates. *Drosophila* studies have underscored the importance of bHLH factors in the acquisition of neuronal identity in the ectoderm. In this context, bHLH proteins are both necessary and sufficient to confer a neuronal fate to ectodermal cells; consequently, several bHLH factors, including achaete–scute and atonal, have been dubbed 'proneural genes,' while inhibitory bHLH factors such as hairy and enhancer-of-split suppress neurogenesis. Vertebrate homologs of the *Drosophila* proneural genes have been isolated and neural expression and function appears to be conserved.

The bHLH proteins mediate their effects by protein dimerization and DNA recognition. The binding to a core hexa-nucleotide e-box, CANNTG, is mediated by the ~60-amino-acid bHLH motif. The crystal structures of the bHLH proteins E47 (Tcfe2a, MGI) and Myod1 bound to DNA demonstrated that the bHLH region is composed of two α-helices separated by a loop. The basic region contacts DNA in the major groove, while the HLH domain is involved in protein dimerization. The bHLH proteins are classified by three criteria: (1) dimerization capabilities, (2) DNA binding specificities, and (3) tissue distribution. Two broadly defined groups are class A (class I) and class B (classes II–VII). Class A proteins are broadly expressed and are often called E-proteins. These E-proteins, including HEB (Tcf12, MGI), E2-2 (Tcf4, MGI), and the two splice variants of E2a (Tcfe2a, MGI), E12 and E47, in vertebrates, and Daughterless in *Drosophila*, form homodimers, as well as heterodimers with class B proteins. Class B bHLH proteins are further categorized into six subclasses termed classes II–VII based upon protein motifs and activity.

Different members of these subclasses of bHLH factors act to either inhibit or promote transcription of downstream targets. Particularly important for neural differentiation and cell-type specification is the neural expressed subset of class II bHLH factors that include Mash1 (Ascl1, MGI), Math1 (Atoh1, MGI), Math5 (Atoh7, MGI), Ngn1,2,3 (Neurog1,2,3, MGI), and Neurod1. These factors form heterodimers with E-proteins, bind to DNA at e-box elements, and act as positive regulators of neurogenesis and neuronal specification. Table 1 lists some class II bHLH factors chosen for their expression in progenitor zones in the neural tube. In each case, loss-of-function studies have determined their importance in the formation of discrete neural cell types. In addition, class VI factors that include Hes proteins (homologs to *Drosophila* hairy and enhancer-of-split) also play essential functions in these processes but they act to suppress neurogenesis. The class II and class VI bHLH factors are in a regulatory loop that involves cell–cell signaling via the Notch–Delta signaling pathway and serves to limit the number of cells differentiating from the progenitor domain (Figure 1). In one cell, the Class II proneural bHLH increases levels of Notch ligand Delta. Notch signaling is activated in the neighboring cell resulting in an increase in Hes levels. Hes proteins suppress levels of the proneural bHLH factor. The cell with high levels of the proneural bHLH will undergo neuronal differentiation, whereas the cell receiving Notch signaling is more likely to remain as a progenitor, or to later become an astrocyte. This pathway was worked out originally using *Drosophila* genetics, but many components and mechanisms appear to be conserved in vertebrates as well.

Neuronal Differentiation

Several lines of evidence have determined roles for bHLH factors in neural development, particularly those of the achaete–scute and atonal classes. Members of these subclasses of bHLH factors are transiently expressed in restricted progenitor domains throughout the developing nervous system. Loss-of-function studies have demonstrated their absolute requirement for the formation of specific subsets of neurons, while overexpression assays have been particularly important in revealing their function in neural differentiation. In *Drosophila*, the achaete–scute complex genes (AS-C) are required for external sensory organs, and atonal is required for chordotonal organs and photoreceptor cells. In the absence of these bHLH factors, neuroblasts fail to form. Conversely, overexpression of achaete, scute, and atonal led to neuronal hyperplasia.

A role for vertebrate neural bHLH factors in inducing neuronal differentiation has been repeatedly demonstrated in multiple paradigms across a variety of species. Overexpression of Mash1, Ngn1, Neurod1, Neurod2, and Math1 conferred neuronal properties to the mouse embryonal carcinoma cell line, P19, by inducing cell cycle exit and expression of neuronal specific genes. In *Xenopus*, injection of mRNA for XNgnr1, Xneurod, Xath1, and Xash1/3 increased primary neurogenesis to varying extents at the expense of ectodermal cells. Forced expression of Ngn1 in primary rat cortical cultures induced neurogenesis while suppressing gliogenesis. Additionally, forced expression *in ovo* of Mash1, Math1, Ngn1, and Ngn2 in chick neural tube has clearly demonstrated the activity of these factors in driving neuronal differentiation. In these experiments, the proliferating progenitors in the ventricular zone were forced out of the cell cycle, moved laterally out of the ventricular zone into the marginal zone, and began expressing neuronal specific genes. In some cases, the interpretation of loss-of-function mutations

Figure 1 Proneural bHLH transcription factors and the Notch–Delta signaling pathway interact to control neuronal differentiation. In a cell with high levels of a proneural bHLH protein, expression of Delta ligand is enhanced. This in turn signals the neighboring cell, through the Notch receptor, to turn on the Hes bHLH transcription factors that repress the proneural bHLH proteins in that cell. The cell with high levels of Notch signaling and low levels of the proneural bHLH will remain as a progenitor cell or ultimately differentiate to an astrocyte. The cell with low levels of Notch signaling and high levels of the proneural bHLH will undergo neuronal differentiation. The type of neuron that is generated depends on the combination of the proneural subtype plus additional transcription factors.

in mouse are more difficult to interpret in regards to neuronal differentiation, since in the absence of one neural bHLH factor, neighboring or co-expressed bHLH factors can compensate. While compensation is a major issue, there are many examples where loss of one bHLH factor has dramatic consequences for neurons in a specific region (see Table 1).

Neurons versus Glia

The bHLH factors are not only involved in the differentiation of various neuronal lineages but they are also intrinsic mediators of the decision between neuronal and glial cell fates. As mentioned above, in cortical cultures, Ngn1 induces neurogenesis while suppressing astrocyte development. *In vivo*, neuronal and glial cell generation are temporally separated, where neurons are generated first followed by overlapping waves of oligodendrocytes and astrocytes. The loss of neural bHLH factors such as Mash1, Math3 (Neurod4, MGI), and Ngn1/2 results in an increase in astrocytes. This is seen in the cortex in the absence of Mash1 and Ngn2; likewise, loss of Mash1 and Math3 in the midbrain and hindbrain results in an increase in astrocytes. Single mutants do not clearly show the increase in astrocytes, probably due to redundant function of these bHLH factors in neurogenesis. Indeed, in mouse models where Ngn2 replaces Mash1 or vice versa, to a first approximation their neurogenesis activity is interchangeable. Studies in retina have also contributed to establishing a role for several bHLH factors in promoting neuronal fate and inhibiting glial fate. Overexpression of Math3 or Mash1 in retinal explant cultures increased neuron production while inhibiting the generation of Müller glial cells. Consistently, the absence of Mash1 results in an increase in the production of Müller glial cells. Together, these results demonstrate the requirement for class II neural bHLH factors to produce neurons; in their absence, glial cells form. As opposed to the function of the class II, class VI bHLH factors, particularly Hes1 and Hes5, suppress neuronal differentiation. In mutants for this class of bHLH proteins, premature neuronal differentiation is detected.

Oligodendrocytes are another major class of glia cells, and they also require bHLH proteins. Olig1 and Olig2 are required for oligodendrogenesis and maturation in brain and spinal cord. In the developing ventral spinal cord, Olig2 and Ngn2 are involved in the specification of oligodendrocytes and motor neurons. A precursor cell expressing Ngn2 and Olig2 will generate motor neurons. However, when Ngn2 levels are reduced, the Olig2 cells generate oligodendrocytes. Motor neurons and oligodendrocytes are not generated from a common Olig1/2-expressing progenitor; instead, these divergent cell types appear to be generated sequentially from neuroepithelial stem cells.

As stated previously, multiple lines of evidence place Mash1 as a neuronal differentiation factor.

However, there are increasing reports that Mash1 functions in oligodendrocyte formation as well. Mash1 is present in progenitors to neurons early and then oligodendrocytes later in the spinal cord. Mash1 is also present in the subventricular zone (SVZ) and rostral migratory stream (RMS) in the telencephalon in progenitors to neurons and oligodendrocytes. When cells from this region were cultured from Mash1 mutants, there was a loss of neurons and oligodendrocytes but not astrocytes relative to that seen with wild-type cultures. Together, these studies demonstrate the importance of some bHLH factors for generation of neurons, such as Ngn1 and Ngn2, and also reveal the importance of bHLH factors in oligodendrocyte development, such as Olig1, Olig2, and Mash1. In the absence of these bHLH factors, excess astrocytes are formed. This balance between neurons and oligodendrocytes on the one hand, and astrocytes on the other, involves the activation of Notch signaling (described above), a pathway known to be activated by the proneural bHLH factors (Figure 1). Through Notch signaling, the Hes bHLH factors are induced, which in turn suppress the proneural bHLH factors, and, thus, suppress neurogenesis.

Figure 2 Class II bHLH factors are present in distinct populations of neuronal progenitor cells that are required for neuronal differentiation and cell-type specification. The pattern of expression of a subset of bHLH factors is shown in the ventricular zone of the spinal neural tube. Some progenitor cells express multiple bHLH factors. The dorsal interneurons (dI1–dI6), ventral interneurons (V0–V3), and the motor neurons (MN) require a distinct combination of bHLH factors to develop. RP, roof plate; FP, floor plate.

Neuronal Subtype Specification

Once a cell has committed to the neuronal lineage, it is specified to a certain neuronal cell type. Neural bHLH proteins in some regions of the nervous system have been shown to play roles in this aspect of nervous system development as well (see Table 1). In many regions of the developing embryo, the expression domains of the bHLH factors and the neuronal populations they specify are tightly linked. Expression of Mash1, Math1, and Ngn1 throughout the neural tube is nonoverlapping. Loss-of-function mutations in each of these bHLH factors have established their requirement for formation of specific neuronal populations. For example, in the dorsal spinal cord where interneuron populations are defined by the combination of homeodomain transcription factors they express, Math1 is required for dI1 neurons, Ngn1 is required for dI2 neurons, Mash1 is required for dI3 and dI5 neurons, and Ptf1a is required for dI4 neurons (Figure 2). Furthermore, ectopic expression of Math1, Ngn1, and Mash1 in ventricular zone cells in the chick neural tube results in an increase of a specific neuronal subtype at the expense of the others. This neuronal specification function of the bHLH factors is thought to work in combination with other factors. For example, when Math1 is ectopically expressed in the dorsal neural tube, it appears to convert dI2 and dI3 neurons to dI1, but when it is expressed ventrally it does not induce dI1 neurons, suggesting that a factor present dorsally but not ventrally is required for dI1 cell specification in combination with Math1. In addition, ectopic expression of Mash1 with another bHLH Olig3 increases dI3 neurons while Mash1 plus the homeodomain factor Lbx1 increases dI5. Thus, the generation of each interneuron population in the dorsal neural tube requires a distinct neural bHLH factor, but to specify the specific neuronal cell type, additional factors are required.

Neurotransmitter phenotype is a major facet of neuronal subtype that has also been shown to be specified, at least in part, by bHLH factors. GABAergic neurons in the dorsal horn of the spinal cord and in the cerebellum have an absolute requirement for the bHLH factor Ptf1a. However, the relationship between the requirement for a specific neural bHLH factor and a specific neurotransmitter phenotype is usually not this clear. For example, Mash1 is required for adrenergic neurons in the sympathetic nervous system and in the hindbrain, serotonergic neurons in the enteric nervous system and hindbrain, and GABAergic neurons in the cortex. Similarly, Ngn1

and Ngn2 are required for glutamatergic neurons in the cortex, sensory ganglia, and cholinergic neurons in the ventral spinal cord. Although the bHLH subtype does not appear linked to the neurotransmitter subtype when assessed in this global manner, regionally, neurons of specific neurotransmitter subtype require distinct bHLH factors. In the cortex, the GABAergic neurons migrate from ventral regions and are Mash1 derived, while glutamatergic neurons are generated dorsally and are Ngn1 and Ngn2 derived.

The requirement for factors in addition to the bHLH proteins for neuronal subtype specification, particularly the homeodomain class of transcription factors, is best illustrated from studies of retina development. In the retina, as in the brain and spinal cord, both gain- and loss-of-function studies have demonstrated the importance of the bHLH factors in both neuronal differentiation and in subtype specification. And although specific retinal cell types are lost or reduced when neural bHLH factors are absent, ectopic expression of these factors is not sufficient to specify the correct cell type. In addition, even with loss of function, often more than one bHLH must be mutated to lose a cell type. Retinal ganglia cells require Math5, amacrine cells require both NeuroD and Math3, and bipolar cells require Mash1 and Math3. The requirement for the concerted activity of bHLH and homeodomain factors for specification of these cell types was shown in overexpression assays. For example, to obtain bipolar cells in retinal explants requires the activity of the homeodomain containing factor Chx10 together with Math3 or Mash1. A similar situation arises in the specification of amacrine cells where the homeodomain factors Pax6 or Six3 are required with Math3 or Neurod1 to get specification to this cell type. Thus, although bHLH factors are important components of the code that determine the neuronal subtype, they appear to work in combination with homeodomain factors. The mechanism by which these two classes of transcription factors interact is largely unknown. Synergistic interaction between LIM homeodomain proteins and two bHLH factors, Ngn2 or NeuroM, that activate transcription of the Hb9 enhancer may play a role in motor neuron specification.

Control of bHLH Protein Expression

Controlling expression of the bHLH factors is critical for normal nervous system formation. The different neural bHLH factors can be classified into those expressed in mitotically active cells of the ventricular zone, to those expressed in newly postmitotic cells, to those that are maintained in mature neural cells in the adult. This article highlights the factors expressed and functioning at the early stages of neural differentiation (Table 1). In some cases, the later-expressed bHLH factors are downstream targets of the early factors, as is seen in Ngn1 and Ngn2 regulation of the postmitotic bHLH factor NeuroD. There are many additional mechanisms controlling bHLH expression including autoregulation, repression by Notch signaling (Figure 1), response to signaling pathways, and cross-repression between different bHLH factors. Autoregulation includes positive autoregulation seen with Math1 and Math5, and negative autoregulation seen with Mash1. The latter likely involves a regulatory loop with Notch/Delta signaling where Mash1 induces Delta, which in turn activates Notch signaling in the neighboring cell, resulting in Hes repression of Mash1 (see Figure 1). As discussed earlier, this may control the timing of expression of a bHLH factor that drives neuronal differentiation. Patterning signals influence the spatial expression pattern of a bHLH factor. For example, bone morphogenetic protein (BMP) signaling is required for expression of Math1 and Ngn1 in the dorsal neural tube, and Math1 in the cerebellum. And finally, cross-repression of expression was demonstrated in the dorsal neural tube where Math1 and Ngn1 suppressed expression of neighboring bHLH factors. This mechanism ensures strict boundaries of expression that may be important in generating the correct composition of neurons.

Concluding Remarks

Overwhelming evidence implicates bHLH transcription factors in the neuronal differentiation and cell-type specification in multiple regions of the developing nervous system. The bHLH family of transcription factors includes factors that are positive regulators of neurogenesis, negative regulators of neurogenesis, and positive regulators of oligodendrogenesis. Even with these different subclasses of bHLH factors, there are complexities that arise from formation of homodimers and heterodimers across these distinct subclasses of bHLH proteins. These complexes may bind DNA and activate or repress transcription, they may form inactive complexes that bind DNA but have no transcription activity, or they may not bind DNA at all. Other intricacies that modulate the function of the neural class II factors include the formation of higher-order complexes. For instance, the bHLH factor Ptf1a that is required for GABAergic neurons in the dorsal horn and cerebellum, is known to form a trimer complex in pancreas with an

E-protein (HEB, E12, or E2-2) and Rbpsuh, an effector of Notch signaling. Another example is the putative complex formed between bHLH heterodimers, and tetrameric or hexameric complexes containing Lim homeodomain factors. Interactions between these classes of transcription factors are suggested by their synergistic activity in the ventral spinal cord in generating motor neurons and ventral interneurons. Together, there is extensive evidence supporting essential roles for neural bHLH transcription factors in the timing and process of neuronal differentiation, and in the specification of neuronal subtype. However, the mechanistic complexities involved in these functions remain a fertile area for future studies.

Migraine: General Principles

Migraine is a common primary headache disorder, typically characterized by disabling attacks of severe throbbing unilateral headache, accompanied by nausea and sensitivity to sound and light and head movement, lasting approximately 1 day. In one-third of patients there is a preceding aura that typically lasts 20–60 min. It usually consists of homonymous visual symptoms, such as flashing zigzag lights and visual loss, which begin paracentrally and slowly expand over minutes as a hemifield defect. Migraine aura may also include other transient focal neurological symptoms. Table 1 summarizes the diagnostic criteria for migraine according to the International Headache Society. The disease is broadly classified into (1) migraine with aura, in which at least some of the attacks are temporally associated with distinct transient focal neurological aura symptoms; and (2) migraine without aura, in which there are no associated neurological symptoms of a focal nature. Many patients believe that their attacks are precipitated by specific trigger factors, as listed in Table 1. A small group of patients have limb weakness with their attacks, which is termed hemiplegic aura.

Hemiplegic Migraine

Patients may present isolated (sporadic) or with a family history of similar attacks (familial) of an aura that involves weakness in the limbs, termed hemiplegic migraine (Table 2). Although most patients have weakness (hemiparesis) as opposed to paralysis (hemiplegic), the term hemiplegic is used to indicate either clinical manifestation. These patients have substantially similar headache phases, the pathophysiology of which is discussed elsewhere in this encyclopedia. Here, we discuss

- clinical features of familial hemiplegic migraine (FHM),
- the genetics of hemiplegic migraine,
- functional consequences of FHM mutations,
- the pathophysiology of aura – animal and human studies, and
- clinical features of FHM.

FHM is a rare, severe, monogenic subtype of migraine with aura characterized by at least some degree of hemiparesis during the aura. The hemiparesis may last from minutes to several hours or even days. Patients are frequently initially misdiagnosed with epilepsy. Apart from the hemiparesis, the other headache and aura features of the FHM attack are identical to those of attacks of the common types of migraine. Perhaps a major difference between the aura symptoms and the attack proper is that the attack itself is effectively treated with relatively specific antimigraine treatments, the serotonin 5-$HT_{1B/1D}$ receptor agonists (the triptans), whereas there is no established treatment that can abort the aura phase. Moreover, since hemiplegic migraine was systematically excluded from clinical trial programs with triptans, they are explicitly contraindicated in hemiplegic migraine. The most rational reason to continue this prohibition derives from a placebo-controlled trial that demonstrated that acute triptan administration during aura was ineffective for both aura and consequent headache. It is widely considered that the prohibition should be based on safety, but since triptans do not measurably alter brain blood flow, this is a theoretical issue. In addition to attacks with hemiparesis, the majority of FHM patients also experience attacks of 'normal' migraine with or without aura. As in the common forms of migraine, attacks of FHM may be triggered by mild head trauma. Thus, from a clinical standpoint, FHM seems a valid model for the common forms of migraine. Major clinical differences, apart from the hemiparesis, include that FHM in 20% of cases may also be associated with cerebellar ataxia and other neurological symptoms, such as epilepsy, mental retardation, brain edema, and (fatal) coma. To date, three genes for FHM have been published, but based on unpublished linkage results in several families, there are more.

Genetics of FHM

The FHM1 *CACNA1A* Gene

The first gene identified for FHM was the *CACNA1A* gene on chromosome 19p13. It is responsible for approximately 50% of all known families with FHM (Figure 1). The FHM1 gene encodes the ion-conducting, pore-forming α_{1A} subunit of $Ca_v2.1$ (P/Q-type), voltage-gated, neuronal calcium channels. The main function of neuronal P/Q-type calcium channels is to modulate release of neurotransmitters, both at peripheral neuromuscular junctions and at central synapses, mainly within the cerebellum, brain stem, and cerebral cortex. More than 50

Table 1 International Headache Society features of migraine and triggers believed to precipitate migraine attacks

Features of migraine	
Repeated episodic headache (4–72 h) with the following features:	
Any two of	Any one of
Unilateral	Nausea/vomiting
Throbbing	Photophobia and phonophobia
Worsened by movement	
Moderate or severe	
Triggers believed to precipitate migraine attacks	
Altered sleep patterns: becoming tired or oversleep	
Skipping meals	
Overexertion	
Weather change	
Stress or relaxation from stress	
Hormonal change, such as menstrual periods	
Excess afferent stimulation: bright lights, strong smells	
Chemicals: alcohol or nitrates	

Table 2 Familial hemiplegic migraine and sporadic hemiplegic migraine

Familial hemiplegic migraine

Description: Migraine with aura including motor weakness and where at least one first- or second-degree relative has migraine aura including motor weakness.

Diagnostic criteria

A. At least two attacks fulfilling B–E.
B. Fully reversible motor weakness and at least one of the following other aura symptoms: visual, sensory, or speech disturbance.
C. At least two of the following:
   1. At least one aura symptom develops gradually over $\geq$5 min and/or different symptoms occur in succession.
   2. Each aura symptom lasts less than 24 h.
   3. Headache that meets criteria B–D for migraine without aura (1.1) begins during the aura or follows aura within 60 min.
D. At least one first- or second-degree relative has migraine attacks with aura including motor weakness.
E. Not attributed to another disorder.

Sporadic hemiplegic migraine

Description: Migraine with aura including motor weakness but no first- or second-degree relative has aura including motor weakness.

Diagnostic criteria

A. At least two attacks fulfilling B–D.
B. Fully reversible motor weakness and at least one of the following other aura symptoms: visual, sensory, or speech disturbance.
C. At least two of the following:
   1. At least one aura symptom develops gradually over $\geq$5 min and/or different symptoms occur in succession.
   2. Each aura symptom lasts less than 24 h.
   3. Headache that meets criteria B–D for migraine without aura (1.1) begins during the aura or follows aura within 60 min.
D. No first- or second-degree relative has migraine attacks with aura including motor weakness.
E. Not attributed to another disorder.

CACNA1A mutations have been associated with a wide range of clinical phenotypes (Figure 1). These include pure forms of FHM, combinations of FHM with various degrees of cerebellar ataxia or fatal coma due to excessive cerebral edema, and disorders not associated with FHM such as episodic ataxia type 2, progressive ataxia, spinocerebellar ataxia type 6, and absence and generalized epilepsy. Interestingly, in several FHM families, FHM1 *CACNA1A* mutations were also found in family members who only had 'normal' nonparetic migraine aura. This suggests that gene mutations for FHM may also be responsible for the common forms of migraine, probably due to different genetic and nongenetic modulating factors.

The FHM2 *ATP1A2* Gene

The *ATP1A2* FHM2 gene on chromosome 1q23 encodes the α_2 subunit of a Na^+, K^+ pump ATPase. This catalytic subunit binds Na^+, K^+, and ATP, and it utilizes ATP hydrolysis to exchange Na^+ ions out of the cell for K^+ ions into the cell. Na^+ pumping provides the steep Na^+ gradient essential for the transport of glutamate and Ca^{2+}. The gene is predominantly expressed in neurons in neonates and in glial cells in adults. In adults, an important function of this specific ATPase is to modulate the reuptake of potassium and glutamate from the synaptic cleft into the glial cell. Mutations in the *ATP1A2* gene are responsible for at least 20% of FHM cases (Figure 2) and have been associated with pure FHM and FHM in combinations with cerebellar ataxia, alternating hemiplegia of childhood, benign focal infantile convulsions, and other forms of epilepsy. In an Italian family, a variant in the *ATP1A2* gene segregated with basilar-type migraine, a subtype of migraine with aura characterized by aura symptoms attributable to the brain stem and both occipital lobes. In two non-FHM migraine families, *ATP1A2* variants were identified, suggesting that this gene may be involved in the susceptibility to common forms of migraine.

The FHM3 *SCNA1* Gene

The *SCNA1* gene on chromosome 2q24 encodes the α subunit of a neuronal voltage-gated sodium ($Na_v1.1$) channel. The $Na_v1.1$ channel is mainly responsible for the generation and propagation of neuronal action potentials. Different mutations in this gene are known to be associated with epilepsy and febrile seizures. A novel Q1489K mutation has been identified in three German FHM families of common ancestry. Another new *SCNA1* mutation was found in a North American FHM family, confirming the relationship between *SCNA1* and FHM3 (Figure 3).

Figure 1 The *CACNA1A* gene with mutations. The $Ca_v2.1$ pore-forming subunit of P/Q-type voltage-gated calcium channels is located in the neuron membrane and contains four repeated domains each encompassing six transmembrane segments. Positions of mutations and associated clinical phenotypes are depicted in the schematic representation of the protein. *CACNA1A* ref. seq.: GenBank Ac. nr. X99897.

Sporadic Hemiplegic Migraine

Hemiplegic migraine patients are not always clustered in families. Sporadic patients, without affected family members, are often seen and may sometimes represent the first 'FHM patient' (*de novo* mutation) in a family. Apart from sharing the clinical phenotype with the common forms of migraine, similar to FHM, sporadic hemiplegic migraine (SHM) and normal migraine also show a remarkable genetic epidemiological relationship. SHM patients have an highly increased risk of also suffering from typical migraine with aura, and their first-degree relatives have a highly increased risk of both migraine with aura and migraine without aura. Although in an initial study *CACNA1A* mutations were found in only 2 of 27 SHM patients, a much larger study did find mutations in the FHM genes in a higher proportion of SHM patients, confirming a genetic relationship between FHM and SHM.

Functional Consequences of FHM Gene Mutations

Understanding the functional consequences of gene mutations is crucial to the understanding of the disease pathways.

Functional Studies in Cellular Models for FHM1 *CACNA1A* Mutations

Several FHM and episodic ataxia type 2 mutations have been analyzed with electrophysiological techniques in neuronal and nonneuronal cell models. Whereas episodic ataxia type 2 *CACNA1A* mutations all show a dramatic decrease or even complete loss of current density, FHM1 mutations cause different effects on channel conductance, kinetics, and/or expression in transfected cells. The most consistent change found with FHM1 mutations, when tested in a single channel configuration, was a hyperpolarizing

Figure 2 The *ATP1A2* gene with mutations. The α_2 subunit of sodium potassium pumps is located in the plasma membrane and contains 10 transmembrane segments. Positions of mutations and associated clinical phenotypes are indicated in the schematic drawing of the protein. *ATP1A2* ref. seq.: GenBank Ac.nr. NM_000702.

shift of approximately 10 mV of the activation voltage. The change in calcium influx could, however, alter during high neuronal activity. Mutant T666M and V714A channels have a low conductance mode that may sometimes switch to the wild-type state. For other FHM mutations, such as R583Q and D715E, accumulation of inactivated channels was observed during repetitive stimulation. Such phenomena could contribute to the paroxysmal presentation of symptoms.

The gain-of-function effects found in single channel test models in theory will lead to an easier opening of channels in neurons. The overall change in calcium influx, however, is difficult to predict and seems to depend, at least in part, on the model that is being used. For instance, evidence for reduced calcium influx at the whole cell level in transfections of cultured mouse hippocampal neurons has been reported. What will happen in the mutant brain will be determined by the delicate interplay between the functional effects of a particular mutation, the different channel properties and density, the different channel subunits, and the direct and indirect cellular environment. The observation that different auxiliary β subunits of calcium channels can modulate the consequence of FHM mutations adds to the complexity of predicting calcium channel functioning. Therefore, it seems more appropriate to study the functional consequences of gene mutations in knockin mouse models carrying human pathogenic mutations.

Functional Studies in Naturally Occurring *Cacna1a* Mouse Mutants

Naturally occurring mouse mutants with *Cacna1a* missense mutations (Tottering, Rocker, and Rolling Nagoya) or *Cacna1a* truncation mutations (Leaner) display different combinations and severities of various types of epilepsy and ataxia. A reduction in calcium current density appears to be the main effect of these mutated P/Q-type channels, with a change in channel kinetics for the Leaner and Rolling Nagoya mutants. Two *Cacna1a*-null (knockout) mouse models were generated showing ataxia, dystonia, and lethality at a young age. The total Ca^{2+} influx in cerebellar cells and neurotransmission at the neuromuscular junction was reduced in these mice. Loss of P/Q-type channels could be (partly) compensated for by N-, R-, and-L-type channels. Moreover, Leaner mice showed an increased threshold for cortical spreading depression and a reduced release of cortical glutamate.

Figure 3 The *SCN1A* gene with mutations. The pore-forming subunit of $Na_v1.1$ sodium channels is located in the neuron membrane and contains four repeated domains each encompassing six transmembrane segments. More than 150 mutations have been identified for severe myoclonic epilepsy in infancy (SMEI) or generalized epilepsy with febrile seizures plus (GEFS+). For clarity, only SMEI and GEFS+ mutations are shown that reside in two functional domains (e.g., inactivation gate and D4/S4 voltage sensor) where familial hemiplegic migraine mutations were identified. Positions of mutations and associated clinical phenotypes are depicted in the schematic representation of the protein. *SCN1A* ref. seq.: GenBank Ac.nr. NM_006920.

Functional Studies in FHM1 *Cacna1a* Knockin Mouse Mutants

A knockin mouse model was generated carrying the human FHM1 R192Q mutation. Unlike the natural *Cacna1a* mutant mouse models, transgenic R192Q mice exhibit no overt clinical phenotype or structural abnormalities. This is very similar to the human situation: the R192Q mutation causes only mild FHM attacks, very similar to the common forms of migraine, albeit with hemiparesis, without other neurological symptoms. Extensive functional analysis revealed multiple gain-of-function effects. These include increased Ca^{2+} influx in cerebellar neurons; increased release of neurotransmitters at the neuromuscular junction, both spontaneous and upon stimulation at low Ca^{2+}; and, in the intact animal, a reduced trigger threshold for cortical spreading depression that propagates with increased velocity. It seems that whole-animal studies may be better suited to dissect the effects of mutations and to understand the integrated physiology of the disease. Other studies aiming at functional changes within the brain stem are under way and will shed more light on the important question of whether migraine-related mechanisms within the trigeminocervical complex are also affected.

Functional Studies in Cellular Models for FHM2 *ATP1A2* Mutations

Functional analysis of mutated proteins revealed inhibition of pump activity, decreased affinity for K^+, and decreased catalytic turnover resulting in reduced reuptake of K^+ and glutamate into glial cells.

Functional Studies in *Atp1a2* Knockout Mouse Models

Two groups have generated α_2 subunit-deficient (*Atp1a2*-null) mice. These mice died immediately after birth because of severe motor deficits and absent respiration. *Atp1a2*-null fetuses of 18.5 days revealed selective neuronal apoptosis in the amygdala and piriform cortex in response to neural hyperactivity. *Atp1a2*-null mice on 129sv genetic background

displayed frequent generalized seizures and died within 24 h after birth. Epilepsy is also a feature of the clinical phenotype in humans with *ATP1A2* mutations. Heterozygous *Atp1a2*+/_ mice are viable. Their heart shows a hypercontractile state with positive inotropic response and resembles what is typically seen after the administration of cardiac glycosides. In addition, they revealed enhanced fear and anxiety behaviors after conditioned fear stimuli; this is probably due to neuronal hyperactivity in the amygdala and piriform cortex. No *Atp1a2* knockin models are available.

Functional Studies in Cellular Models for the FHM3 Mutation

Functional consequences of the Q1489K *SCN1A* mutation have been analyzed in the highly homologous SCN5A protein. This missense mutation is located within a domain critical for fast inactivation of the sodium channel. It causes a two- to fourfold increased acceleration of recovery from fast inactivation. This would predict enhanced neuronal excitation and release of neurotransmitter. No knockout or knockin mouse mutants are available for this gene.

Pathophysiology of Aura

Cortical Spreading Depression in Experimental Animals

It is now well accepted that the migraine aura is not due to reactive vasoconstriction, as was previously believed for several decades, but rather is neurally driven and most likely caused by the human equivalent of the cortical spreading depression (CSD) of Leao. In experimental animals, CSD is a short-lasting (<1 min) intense and steady depolarization of neuronal and glial cell membranes that spreads into contiguous areas of brain cortex at a rate of 2–5 mm min^{-1}, regardless of functional cortical divisions or arterial territories. It is accompanied by a transient total loss of neuroglial membrane integrity, a massive influx of Ca^{2+} and Na^{+}, and a massive efflux of K^{+} causing highly elevated extracellular K^{+} levels. This results in a spreading wave of brief excitation followed by a longer lasting inhibition of spontaneous and evoked neuronal activity that traverses the cortex at a rate of approximately 3–5 mm min^{-1}. In experimental animals, the electrophysiological changes are associated with characteristic triphasic cerebral blood flow (CBF) changes. Initially, there is a small and very brief reduction in CBF. This is followed by a profound increase in CBF for several minutes. The third phase consists of a reduction of CBF that may last for up to 1 h and is accompanied by a loss of the cerebrovascular response to hypercapnia. CSD appears to be a self-defense mechanism of the brain to strong stimuli and can be triggered by electrical stimulation of brain tissue, cortical trauma, cerebral ischemia, or cortical application of high concentrations of K^{+} or neuroexcitatory amino acids such as glutamate.

CSD and the Migraine Aura

There is a considerable body of clinical evidence that CSD is the likely basis of migraine aura. Visual aura symptoms typically spread or march from the center of the visual field to the periphery at a speed of approximately 3 mm min^{-1} when translated to the visual cortex. This is very similar to the propagation rate of CSD in experimental animals. The positive (e.g., scintillations and paraesthesias) and negative (e.g., scotomata and paresis) phenomena of the migraine aura could be well explained by the initial transient hyperexcitation front of CSD followed by neuronal depression. Most important, however, functional neuroimaging studies in humans have convincingly demonstrated that the CBF changes that occur during migraine aura are very similar to those observed in experimental animals during CSD. Using functional MRI, a focal increase in BOLD signal was identified spreading into the occipital cortex at a rate of 3.5 mm min^{-1}. The cortical direction and speed of the spread were congruent with the visual experiences of the patient. The increased BOLD signal was followed by a decrease. This pattern suggests an initial brief rise of CBF followed by a longer-lasting oligemia as is seen in experimental CSD.

Although the evidence that CSD causes the migraine aura is mounting, there is much debate as to whether CSD may trigger the rest of the migraine attack as well through activation of the trigeminovascular system.

Can CSD Trigger the Mechanisms for the Headache Phase?

Whether CSD can initiate the migraine headache cascade is controversial. KCl-induced CSD in the rat parietal cortex activates ipsilateral trigeminal nucleus caudalis neurons and CSD causes a long-lasting blood flow increase in the rat middle meningeal artery and a dural plasma protein leakage that can be inhibited by ipsilateral trigeminal nerve section. Chronic daily, but not acute, administration of migraine prophylactic drugs in rats dose- and duration-dependently suppressed KCl-induced CSD frequency by 40–80% and increased the triggering threshold for inducing CSD, although one study suggested topiramate can acutely inhibit CSD.

However, reviewing a number of mainly clinical arguments casts doubt on whether aura can trigger headache. The fact that migraine aura only occurs in up to one-fourth to one-third of migraine patients makes it difficult to explain how CSD might be involved in the majority of migraineurs in whom attacks are not associated with aura. The only explanation to rescue the 'CSD headache trigger' hypothesis would be that CSD might occur in clinically silent subcortical areas of the brain without propagating through all six cortical laminae within the neocortex. Direct human evidence for such events is difficult to obtain and, apart from possibly one case, is lacking. Other clinical observations that argue against the role of CSD in triggering the headache are that the headache may occur on the same side of the aura instead of the expected opposite side if CSD would have triggered the trigeminovascular system, and that aura may sometimes occur after the headache has started. Furthermore, aura appears to not be confined to migraine; it is reported with attacks of cluster headache, paroxysmal hemicrania, and hemicrania continua. Finally, intranasal ketamine could abort migraine aura without affecting the ensuing headache. From this discussion, it is clear that the exact role of CSD in triggering migraine headache mechanisms in humans remains unclear and needs further investigation.

A Mechanism for Triggering FHM Attacks

Three different genes encoding three very different proteins with apparent different mechanisms have been associated with FHM. How can we fit these apparently very diverting mechanisms into one (final) common pathway? Mutations in the FHM1 calcium gene cause increased neuronal release of neurotransmitters and, in the cortex, specifically the neuroexcitatory amino acid glutamate that can induce, maintain, and propagate CSD. Mutations in the FHM2 sodium/potassium pump gene cause reduced reuptake of K^+ and glutamate from the synaptic cleft into the glia cell. Mutations in the FHM3 sodium channel gene result in hyperexcitability and most likely increased release of neurotransmitters in the synaptic cleft. The overall result is increased levels of glutamate and K^+ in the synaptic cleft, resulting in an increased propensity for CSD. This would easily explain the aura of FHM attacks.

A most important question that remains to be answered is whether the same mechanisms are also involved in the common forms of migraine with and without aura. Interestingly, although drugs with migraine prophylactic activity belong to a wide range of pharmacological classes, such as antiepiletics and blockers of calcium channels and serotinergic, β-adrenergic, and histamine receptors, they all seem to share anti-CSD activity. CSD inhibition may thus be a promising model system to contribute to the development of preventive medicines. An interesting compound in this respect is Tonabersat, which has entered clinical trials in migraine. Tonabersat (SB-220453) inhibits CSD, CSD-induced nitric oxide (NO) release, and cerebral vasodilation. It does not constrict isolated human blood vessels, but it does inhibit trigeminally induced craniovascular effects. Tonabersat is inactive in the human NO model of migraine, as is propranolol, although valproate showed some activity in that model. If proven effective, it would be the first migraine prophylactic agent developed on the basis of the CSD hypothesis.

Hemispheric Specialization and Cognition

Hemispheric Differences in Cognition

Discovery of Hemispheric Differences in Cognition

Paul Broca, a French neurologist and anthropologist, is generally considered the first person to have clearly illustrated hemispheric differences in cognitive function. As such, he is often said to have discovered the phenomenon. His critical insight derived from his visit with a patient who demonstrated an interesting dissociation in language abilities. Although able to understand what was said to him, the man had an inability to produce speech, being able only to utter the syllable 'tan.' Broca's postmortem analysis of his brain showed that damage was localized to the third convolution of the inferior frontal gyrus in the left hemisphere. Broca then went on to examine other patients who exhibited a similar cognitive profile – an inability to produce speech in the face of a retained ability to comprehend speech. In all cases, the damage was localized to the same region but, most important, always in the left hemisphere – a region now known as Broca's area. As a result of these findings, Broca proposed in 1863 that the left hemisphere is specialized, or dominant, for speech output. Thus, Broca's paper was the first systematic and compelling demonstration of hemispheric specialization of function. In fact, unlike most other aspects of hemispheric specialization, this one is absolute: the right hemisphere has no ability to control speech output in practically all right-handed individuals.

Evidence from Patients with Unilateral Brain Damage

As a result of Broca's discovery, the idea of cerebral dominance was overgeneralized. Probably because language was considered synonymous with thought, his work was interpreted to mean that the left hemisphere was dominant for all aspects of cognitive function. This idea only began to erode gradually over the next century as studies of patients with unilateral brain damage demonstrated different consequences depending on which hemisphere was damaged. As apparent to any neurologist or clinical neuropsychologist, left hemisphere damage usually results in deficits in the domains of verbal, sequential, and analytic processing. For example, aphasia is a common consequence of left hemisphere damage. In contrast, right hemisphere damage typically yields deficits in nonverbal, holistic, and Gestalt processing. For example, deficits in visuospatial processing are more often observed after right hemisphere damage.

Evidence from Split-Brain Patients

In the 1960s, research by Nobel laureate Roger Sperry and colleagues with split-brain patients dramatically demonstrated the relative specialization of the cerebral hemispheres. In these split-brain patients, the main nerve fiber tract connecting the cerebral hemispheres, the corpus callosum, is severed for the treatment of intractable epilepsy. As a result, higher order information, such as that about an item's identity (e.g., a car, the letter 'A,' and the face of Bill Clinton), cannot be transferred from one hemisphere to the other. Thus, information directed to a single hemisphere is functionally isolated to that hemisphere. This situation provides a unique opportunity to examine the relative specialization of the cerebral hemispheres because each hemisphere's capabilities can be examined in isolation from those of its partner. As a result, research with split-brain patients has yielded much important information about hemispheric specialization. Absolute differences have been demonstrated only for a couple of functions, namely speech output and phonological processing, which are under sole control of the left hemisphere. Both hemispheres can perform all other tasks, albeit with differing levels of ability and in different manners. Whereas the left hemisphere has a rich ability to perform most all language tasks, the vocabulary of the right hemisphere is much more limited, as is its ability to process complicated grammatical functions. On the other hand, the right hemisphere is superior at processing most types of spatial relationships, especially those involving three-dimensional relations or complicated geometries.

Perceptual Asymmetries in Neurologically Intact Individuals

The relative specializations of the cerebral hemispheres can also be demonstrated in neurologically intact individuals through the use of methods that essentially pit the hemispheres against one another. These methods, which include tachitoscopic presentation, dichotic listening, and dichaptic presentation, all take advantage of the neuroanatomical wiring of the human brain that transfers information from sensory receptors to the contralateral sensory cortex. In these methods, information is presented laterally so it is received either solely or predominantly by one hemisphere. Then behavioral performance, with

regard to either reaction time or accuracy, can be examined depending on which hemisphere initially received the sensory information. These behavioral measures are often referred to as perceptual asymmetries because they reflect the asymmetry in the perception of information depending on the hemisphere to which information was initially directed. Even though the corpus callosum in neurologically intact individuals contains more than 250 million fibers by which the hemispheres can communicate, differences in performance are nonetheless observed. Typically, these effects are in the range of a 10% difference in accuracy in performance or a 20–50 ms difference in reaction time. These studies provide converging evidence with data obtained from patients with unilateral brain damage and from split-brain patients. Myriads of studies have confirmed a left hemisphere superiority for processing verbal information and a right hemisphere superiority for processing nonverbal material, regardless of sensory modality – visual, auditory, or tactile.

Neuroimaging Studies of Hemispheric Specialization

The surge in neuroimaging during the past decade has also served to emphasize that the specializations of the hemispheres are more relative than absolute. These studies have shown that for most all tasks, activation is bilateral, although not necessarily of equal extent nor intensity. Even classic language tasks, such as verbal word reading, activate both hemispheres, although the activation is more left-sided than right-sided. In addition, the complimentarity of the hemispheres is revealed by these studies. For example, single-word processing leads to greater left than right hemisphere activation, but understanding the nonliteral meaning of language, such as analogy or the moral of a story, leads to greater right than left hemisphere activation.

Asymmetries Related to Emotion and Emotional Processing

Hemispheric specialization is not limited to cognitive function; it is found for emotional processes as well. The majority of evidence suggests that the right hemisphere is specialized for the interpretation of emotional information, including information contained in tone of voice and facial expression. Moreover, it is also specialized for the production of emotional cues that serve a communicative function (e.g., a smile that sends a communicative signal to someone else letting him or her know you are happy or pleased).

In contrast, lateralization of mood – that is, the subjective experience of one's internal emotional state – appears to rely on a pattern of brain activation across prefrontal and parietal regions. A large body of research has indicated that asymmetry of activation of frontal regions of the brain is linked to mood states. Greater activation of left than right frontal regions is associated with positive mood and approach behaviors. In contrast, greater activation of the right than left frontal regions is associated with negative mood and avoidance behavior. Moreover, individual differences in these asymmetries have been linked to differences in temperament in infants and to susceptibility to depression in later life. Overlaid on these effects of valence (positive and negative) are differences in activation of right parietal regions, which are linked to arousal. Depressed mood is associated with decreased activity of right parietal regions, whereas the panic associated with heightened anxiety is associated with increased activity of right parietal regions.

Models of Hemispheric Specialization

The broad body of work – from patients with unilateral brain damage, split-brain patients, and studies of perceptual asymmetries with neurologically intact individuals – was originally framed with regard to differences in the type of material that each hemisphere is specialized to process. Initially, the left hemisphere was considered specialized for processing verbal materials, whereas the right hemisphere was considered specialized for processing nonverbal materials. However, in a series of studies in the late 1960s and early 1970s, studies with split-brain patients clearly demonstrated that in many cases both hemispheres were capable of processing a given type of material. What differed, however, was the manner in which they processed that material. This led to a new rubric for understanding hemispheric specialization. The left hemisphere was conceptualized to analyze information in an analytic, piecemeal, and local manner, whereas the right hemisphere was conceptualized to analyze information in a holistic and Gestalt manner. For example, although the right hemisphere of a split-brain patient is superior to the left at identifying a previously viewed face, both can do so. The right hemisphere appears to analyze the overall configuration of the face, such as whether the face is long and narrow or wide and round, and whether the eyes are wide set compared to the width of the face. In contrast, the left hemisphere processes the features or local details, such as the shape of the chin or the eyes. This shift in conceptualizing hemispheric specialization was important because it explained a potential advantage of a specialized brain, namely the ability of simultaneous dual processing. Practically all information can be processed

independently and in a distinct manner by each hemisphere at the same time, providing two distinct ways of simultaneously understanding and interpreting the world.

With this conceptual shift, researchers began to explore hemispheric differences from a computational perspective, with the goal of determining the fundamental differences in computations performed by each hemisphere. One early theory suggested that the hemispheres differed in their ability to process low-level sensory information. In particular, the right hemisphere was conceived as being specialized for processing information of low visual spatial frequency – that is, information that does not shift from dark to light within a small degree of visual space. This information generally provides the general contours and outline of visual forms but not the details. In contrast, the left hemisphere was conceived as being specialized for processing information of high spatial frequency – that is, information that shifts quickly, within a given amount of visual space, from dark to light. Such information provides the detail in visual forms. Moreover, asymmetries in higher order cognitive function were posited to emerge from these sensory asymmetries. For example, the overall configuration of a face would be provided by visual information of low spatial frequency, whereas the detailed information would be provided by visual information of high spatial frequency.

This theory was highly influential and has been subsequently modified. Further research demonstrated that the hemispheres appear to be specialized not for the absolute frequency of sensory information but, rather, for the relative frequency, an effect that holds across different sensory modalities. For example, when individuals are presented with information of high auditory frequency, the left hemisphere exhibits a performance advantage for processing the higher half of those high auditory frequencies and the right hemisphere for processing the lower half of those high auditory frequencies. Findings such as these have been expanded to be accounted for by the double-filtering hypothesis, which argues that hemispheric differences arise from an attentional bias in the information that each processes. It is argued that the right hemisphere employs a low pass filter on incoming information, whereas the left hemisphere employs a high pass filter.

Other researchers have focused on why there might be a need to have distinct ways of processing information in each of the cerebral hemispheres. These theories have focused on how the hemispheres might insulate conflicting or independent processes from one another. For example, in the spatial domain it has been argued that the right hemisphere is specialized to coordinate spatial relationships, considered those that provide information about the distance between objects. In contrast, the left hemisphere is specialized for categorical spatial relations that describe the relationship between items (e.g., above, below, to the right of, and to the left of). These two ways of describing information are considered orthogonal to each other because knowing the coordinate information, such as that one item is 3 ft from another, provides no information about categorical information, such as if one item is behind the other. Computational models suggest that these two types of spatial processing are best supported by independent insulated processing systems because the representations required are mutually incompatible and/or create interference. Performance on spatial tasks is superior in a split rather than unitary computational model, suggesting that the hemispheres are specialized to allow for noninterference of processing.

Similar arguments have been made with regard to language processing. Even though the left hemisphere alone has control over speech output and phonological processing, its specialization for language is also relative. Whereas the left hemisphere has been found to be superior to the right hemisphere in aspects of grammar and syntax, the right hemisphere is superior at processing the nonliteral aspects of language, such as discourse, metaphor, and analogy. These differences may arise from incompatible means of semantic access and/or organization. The left hemisphere appears to access words in a very specific, precise, and local manner, whereas the right hemisphere accesses words in a more diffuse manner that allows activation for more far-flung associates. For example, if a paragraph was about gardening, the left hemisphere would quickly hone in on the particular meaning of 'bug' related to insects, whereas the right hemisphere would hold onto a more diffuse set of meanings, including not only the meaning related to insects but also that related to spying devices. As such, the right hemisphere would be better equipped to make connections across sentences and phrases that would allow for discourse and for nonliteral aspects of language comprehension.

Origins of Hemispheric Asymmetry

Although there was once speculation that cerebral asymmetry is a unique feature of the human brain, hemispheric asymmetry is observed in other species, including not only mammals but also fishes, reptiles, and amphibians. The asymmetries observed in behaviors range from those involved in courtship and copulation to escape behavior and limb use (i.e., 'handedness'). These asymmetries are found not only

for an individual organism (i.e., a right-sided limb preference in a given animal) but also at the population level. For example, apes tend to use the left hand for stabilizing objects and the right hand for fine motor manipulation. Likewise, 59% of certain species of toad prefer to use their right paw to remove an object affixed to their head.

Because hemispheric asymmetries are observed in many other species, much theorizing has focused on how language processing becomes lateralized. Some theories posit that the association of fine motor coordination of the right hand associated with tool use served as the platform for the fine motor control that is associated with the vocalizations that underlie human language. Other theories posit that a lateralized gestural system, when linked to vocalizations, led to language lateralization. Cross-species support for such an idea is provided by research showing that cells in area F5 of the macaque monkey brain, a region homologous to Broca's area in humans, fire when a monkey sees someone else perform a grasping action similar to one which it has just performed. It has been argued that these 'mirror' neurons underlie the ability to form, through gesture, a common communicative system between individuals. Such a common communicative system would then have evolved to include vocalization. Supporting this idea, gestures linked to speech are produced with much more frequency by the right hand in humans and chimpanzees, whereas gestures that do not have a communicative value (e.g., straightening one's clothes) are not produced asymmetrically.

Developmental Issues and Hemispheric Specialization

Given the evidence for an evolutionary history of lateralization of functioning, it is not surprising that hemispheric asymmetries exist at birth. That is not to say, however, that this pattern cannot be modified by environmental factors. Evidence for an inborn pattern of asymmetry comes from numerous sources. First, gyral and sulcul patterns, which differ between right- and left-handers (who, as discussed later, differ in behavioral asymmetry) are present before birth and not modified thereafter. Second, the effects of hemispherectomy at birth differ depending on whether the left or right hemisphere is removed. Although individuals with only one hemisphere acquire both verbal and nonverbal skills, the degree to which these skills are acquired varies by the hemisphere removed. Individuals with only a right hemisphere perform, on average, better on spatial tasks than those with only a left hemisphere, whereas individuals with only a left hemisphere perform better on verbal tasks than those with only a right hemisphere. Third, asymmetries can be observed in the newborn. These include motoric asymmetries, behavioral asymmetries, and asymmetries in brain responses. For example, a larger evoked response is recorded over the left hemisphere to verbal materials and over the right hemisphere to nonverbal materials.

Thus, it appears that the basic blueprint of hemispheric specialization exists at birth. However, the nature of that blueprint can be altered by environmental factors. For example, it has been well documented that after damage to the left hemisphere during approximately the first 2 years of life, the right hemisphere can acquire the ability to control speech. Somewhat more ambiguous are findings that experience can influence the degree of perceptual asymmetry that is observed. For example, a greater left visual field advantage is observed for holistic processing of faces from a racial group with which one is familiar than for faces of a group with which one is not familiar. Whether this result indicates that the nature of hemispheric specialization is changed by experience, or whether more experience tends to engage more specialized processors in the brain, remains unclear.

The Effect of Handedness

One individual difference, that of handedness, has been clearly linked to patterns of hemispheric specialization for cognitive and emotional function. The relative specializations of the cerebral hemispheres described previously appear to hold only for individuals who are right-handed. In contrast, left-handed individuals, who comprise approximately 10% of individuals worldwide, can have a diverse pattern of lateral organization. This difference is well-known by neurologists and neuropsychologists who have long observed that handedness is an important factor in predicting the types of deficits and the amount of recovery that is likely to be observed after unilateral brain damage. However, there is much variability among left-handers regarding the type of lateralized brain organization they display. In some cases, it is similar to that of right-handers, with the left hemisphere specialized for verbal functions and the right for nonverbal functions. In other cases, it is the opposite, with the right hemisphere specialized for verbal function and the left for nonverbal function. It is estimated that such a brain organization is found in only 1% or 2% of right-handers. Finally, other left-handers exhibit a pattern in which both hemispheres appear to be able to process both verbal and nonverbal information, including speech output. Although much research has attempted to isolate a

factor that can predict the type of brain organization a given left-hander will exhibit, for the most part, these efforts have failed. Currently, the leading model of the genetic basis of handedness and its relationship to lateralized brain organization suggests that handedness (and hence brain organization) is randomly distributed, unless one inherits a right-shift allele, which shifts handedness to the right hand and language to the left hemisphere. Such a model assumes that it was evolutionarily advantageous to have motor control of the right hand and control of language co-lateralized to the same hemisphere.

Interhemispheric Integration

After the explosion of research examining hemispheric specialization in the 1970s and 1980s, recent work has examined how the processing of the hemispheres is coordinated and the effects of integration of information between the cerebral hemispheres.

Interhemispheric integration occurs mainly via the massive bundle of nerve fibers connecting the cerebral hemispheres, the corpus callosum. Because information from the peripheral nerves is directed contralaterally, at least for vision, motor, and somatosensory information, integration of information across the hemispheres allows information from each sensory half-field to be bound together. For example, in the visual domain, information is represented contralaterally in V1, V2, and V3a/VP. In fact, there are few, if any callosal connections in BA 17. Representation of information from the ipsilateral visual field first appears at the level of V3a and V4v, which are brain regions whose cells have receptive fields that span the midline. This critical role of the callosum in fusing the sensory worlds is made apparent by split-brain patients who cannot bind information from different sensory fields. For example, if fixated on a central point and shown two items, one on each side visual midline so that they are projected to opposite hemispheres, a split-brain patient cannot determine if they are the same or different.

Although the callosum acts as a mechanism to transfer information between the hemispheres, this transfer involves time costs as well as degradation of information. Transfer of information via the corpus callosum takes approximately 5 ms via the large myelinated fibers that connect sensory and motor areas and 20–50 ms for small unmylineated fibers. The fidelity costs are apparent in old/new memory paradigms. If an item is presented in one visual field, correctly recognizing of that item as previously viewed is poorer if presented to the hemisphere that did not initially view the item as compared to the hemisphere. Such findings are consistent with theorizing that the representations supported by each of the hemispheres are different and are not completely interchangeable.

Integration of information across the cerebral hemispheres plays an additional role above and beyond that of binding together the visual world – that of attentional control. Evidence suggests that the cerebral hemispheres dynamically couple and decouple to meet task demands. When tasks involve relatively low attentional demands, performance is better when all the critical information needed for a decision (e.g., are these two items physically identical?) is directed to a single hemisphere compared to divided between them. It has been proposed that under such conditions, the processing capacity of a single hemisphere is adequate to meet the demands and the cost of interhemispheric communication takes a toll on performance. In contrast, when attentional demands are high, dividing processing between the hemispheres enables more resources to be brought to bear and the advantage provided by these additional resources more than outweighs the cost of callosal transfer. Such an outcome can occur because, as described previously, the specialization of the hemispheres is not absolute but relative, allowing both hemispheres to process almost all types of information. Thus, the additional resources provided by the partner hemisphere, even if not specialized for the task, can nonetheless have a major impact on performance. These findings are consonant with data from individuals in whom the corpus callosum is severed or damaged, such as occurs in multiple sclerosis. A common consequence of callosal damage or insufficiency is problems in attentional control. Although the neural mechanisms that allow the callosum to play such a role remain somewhat obscure, connectionist modeling suggests that the advantage afforded by dividing processing between the hemispheres is an emergent phenomenon of having two somewhat insulated and distinct processors.

Summary

Each of the human cerebral hemispheres has a distinct manner of processing information, with the left hemisphere more adept at attending to and processing more fine-grained information and the right hemisphere more adept at attending to and processing more coarse-grained information. This distinction holds for all types of information, whether verbal or spatial. The complimentarity of these modes of processing means that the human brain contains two processors, each of which provides a unique manner of understanding and interpreting the world.

Moreover, this dichotomy and isolation of processing also provides for a system that can dynamically reconfigure to act in isolation or in tandem depending on attentional demands.

Description

Hepatic encephalopathy (HE) is a complex neuropsychiatric syndrome characterized by the global depression of central nervous system (CNS) activity, with a gradual deterioration of higher mental and motor functions (Table 1). The syndrome is associated either with acute liver failure, commonly precipitated by drug overdose or viral hepatitis, or with chronic liver failure, frequently caused by alcoholic cirrhosis. Liver disease is the fourth largest cause of death in Americans between 45 and 54 years of age, and HE (including minimal HE) is associated with 50–70% of all patients with cirrhosis. Moreover, HE is more prevalent in nations with higher rates of liver disease than occur in the United States.

Although HE has been recognized since the beginning of recorded medical history, the precise pathogenic mechanisms responsible for the syndrome remain complex and poorly defined. Thus, the modalities for treating HE are still evolving. A profusion of metabolic abnormalities and gut-derived toxins result from hepatic failure, resulting in significant alterations in neurotransmission and CNS energy metabolism, superimposed upon a characteristic astrocyte pathology (Alzheimer type II degeneration). Thus, it is difficult to ascribe the neurological and psychiatric manifestations of HE to the presence of a single agent or to changes in a particular metabolic pathway. However, since HE is a metabolic encephalopathy, with few neuroanatomical abnormalities observed in patients who die of either acute or chronic liver failure, it has the potential to be completely reversible.

The neurological manifestations of HE (Table 1) are determined by two principal components of the underlying liver disease: hepatocellular failure and systemic shunting of portal venous contents (Figure 1). Normally, potentially neurotoxic substances are absorbed from the gut and detoxified by the liver. However, in hepatocellular failure these agents may avoid catabolism by passing through the diseased liver unmetabolized and into the systemic circulation (portal–systemic shunting). Alternatively, these toxins may bypass the liver altogether and enter the systemic circulation through portal-venous shunts that are either surgically constructed, or formed spontaneously as a result of portal hypertension associated with cirrhosis. Once these gut-derived substances reach the brain, they modify CNS function either by altering metabolic processes such as oxidative metabolism or neurotransmitter synthesis, or by interacting directly with neurotransmitter receptors.

Hyperammonemia and HE

Ammonia is produced systemically by deamination of amino acids, in the gut wall by the action of glutaminase, and by degradation of amines, amino acids, and urea by gut bacteria. Ammonia diffuses into the portal circulation, where it would normally be converted to glutamine and urea via the Krebs–Henseleit cycle. However, this process is impaired in liver failure, resulting in elevated concentrations of ammonia in the blood. Ammonia in the blood readily diffuses across the blood–brain barrier in its uncharged form. Levels of ammonia in the cerebrospinal fluid (CSF) of patients and animals with clinically significant manifestations of encephalopathy secondary to liver failure range from 70 to 850 μM, compared to concentrations <50 μM in normal humans. Brain ammonia concentrations may reach as high as 1–5 mM in animal models of acute liver failure. While total ammonia levels in the blood are not well correlated with the severity of HE, brain ammonia uptake, as indicated by glutamine levels in CSF and by ^{1}H magnetic resonance spectroscopy, is well correlated with the severity of HE associated with cirrhosis.

Acute exposure to elevated levels of ammonia causes a number of biochemical and electrophysiological derangements in the CNS, including suppression of oxidative metabolism, inhibition of Na^{+}/K^{+}-ATPase activity, inactivation of Cl^{-} extrusion pumps, and decreases in the equilibrium potential of the neuronal inhibitory postsynaptic potential (IPSP). More recent investigations indicate a significant impact of ammonia on astrocytic function. In the presence of ammonia, astrocytes swell (Figure 2), contributing to cerebral edema in acute hepatic failure, while persistent elevations of brain ammonia levels, as observed in chronic hepatic failure, are associated with the development of Alzheimer type II astrocytosis. In the absence of a functional hepatic mechanism for converting ammonia to urea, astrocytes remove ammonia by converting it to glutamine. Exposing astrocytes *in vitro* to elevated concentrations of either ammonia or glutamine results in increased free radical production, possibly by activation of the mitochondrial permeability transition.

Table 1 Clinical stages of HE

Stage	*Mental state*	*Neuromuscular state*
I	Mild confusion, euphoria, depression, decreased attention, slowed analytical ability, irritability, sleep inversion	Mild incoordination, impaired handwriting
II	Drowsiness, lethargy, gross deficits in analytical ability, obvious personality changes, inappropriate behavior, intermittent disorientation; electroencephalogram abnormalities (high-amplitude, low-frequency waves with nonfocal changes)	Asterixis, ataxia, dysarthria, paratonia, apraxia
III	Somnolent but rousable, unable to perform analytical tasks, disorientation with respect to time and/or place, amnesia, rage, slurred speech	Hyperreflexia, muscle spasticity, Babinski's sign present, seizures (rare)
IV_A	Coma	Thalamic–subcortical spasticity of entire body; no response to painful stimuli
IV_B	Deep coma	Death imminent

Figure 1 The concept of portal–systemic shunting as it contributes to the development of HE. Nitrogenous substances arising from the gastrointestinal (GI) system normally are absorbed into the portal venous system and delivered to the liver, where they are extracted and metabolized. However, in liver disease these substances may pass directly into the systemic circulation or bypass the liver completely via portal–venous shunts. Once these compounds enter the systemic circulation, they may gain entry to the central nervous system (CNS) by a variety of mechanisms, including high-capacity active transport or facilitated diffusion, resulting in abnormal brain function. Reprinted from Basile AS, Jones EA, Skolnick P, et al. (1991) The pathogenesis and treatment of hepatic encephalopathy: Evidence for the involvement of benzodiazepine receptor ligands. *Pharmacological Reviews* 43: 27–71, with permission of the American Society for Pharmacology and Experimental Therapeutics.

Figure 2 Alterations in astrocytic function induced by hyperammonemia. Alzheimer type II astrocytosis and cerebral edema are often observed in acute liver failure and contribute to the end stages of hepatic encephalopthy. Exposing astrocytes in culture to elevated concentrations (5 mM) of ammonia (NH_3) for 1–3 days causes them to swell. Astrocytes will try to reduce ammonia levels by fixing ammonia to glutamate (Glu) using glutamine synthase (GS), yielding glutamine (Gln). However, ammonia may be released from glutamine by mitochondrial phosphate-activated glutaminase (PAG), causing the production of reactive oxygen species (ROS) by the mitochondria and induction of the mitochondrial permeability transition (MPT). Elevated ROS levels increase the phosphorylation of a number of mitogen-activated protein kinases (MAPK), such as ERK-1/2, $p39^{MAPK}$, and JNK-1/2/3. Treating astrocytes with appropriate MAPK inhibitors or antioxidants will prevent the astrocytic swelling, glutamate uptake inhibition, and decline in glutamate–aspartate transporter (GLAST) mRNA and protein expression. Suppression of GABA transport (GABA-X), which is reported in experimental hyperammonemic conditions, may also be influenced by these processes and contribute to some of the manifestations of hepatic encephalopathy.

The resulting increase in oxidative stress causes phosphorylation of extracellular signal-regulated kinase-1/2 (ERK-1/2), p38 mitogen-activated protein kinase ($p38^{MAPK}$), and c-Jun N-terminal kinase-1/2/3 (JNK-1/2/3). Ammonia-induced astrocytic swelling, which can be blocked *in vitro* by antioxidants and MAPK inhibitors, may have a number of secondary effects on neuronal function and neurotransmitter levels, as detailed in following sections.

Other Neurotoxins

Hyperammonemia plays a significant role in the pathogenesis of HE, but other conditions/agents are present in hepatic failure/portal–systemic shunting that can alter CNS function. Early work attempting to identify and characterize the potential neurotoxins involved in HE focused on the following classes of agents: mercaptans, fatty acids, imbalances in the ratio of branched-chain to aromatic amino acids, and catecholamines/false neurotransmitters. The relevance of these agents to the pathogenesis of HE is now mostly historical. Mercaptans, phenol, and medium-chain-length fatty acids are present in elevated concentrations in patients with liver disease. However, the neurotoxic concentrations of these substances are 8–15 times higher than the levels commonly observed in patients with HE. While it has been proposed that the toxicity of these agents is enhanced in the presence of ammonia, the concept of 'synergistic neurotoxicity' clearly applies to the effects of all of the metabolic abnormalities and toxic compounds that arise in liver failure, and is not unique to these agents.

CNS levels of aromatic amino acids (e.g., tryptophan, phenylalanine, and tyrosine) are increased between 70% and 300% in patients with cirrhosis. These amino acids are precursors to several monoaminergic neurotransmitters, including serotonin (Table 2). The rate of serotonin turnover in discrete brain regions

Table 2 CNS levels of selected neurotransmitters in HE[a]

Neurotransmitter	*Control*	*Liver failure*	*Liver failure with HE*
Dopamine[b]	2698 ng g^{-1} caudate	2852	4774
Noradrenaline[b]	92 ng g^{-1} caudate	94	154
Serotonin[c]	0.281 ng mg^{-1} protein		1.397
Glutamate[d]	9.54 μmol g^{-1} brain		7.59**
γ-Aminobutyric acid	1.46 μmol g^{-1} brain[d]		1.21
	0.38 μmol l^{-1} plasma[e]		3.37**
Benzodiazepine receptor ligands[f]	78 ng DZ equiv g^{-1} brain		405*

[a]Values represent mean concentrations per unit of brain obtained during autopsy, or plasma from patients with acute or chronic liver failure, with or without HE, or from patients with diseases other than liver failure (controls). DZ equiv., diazepam equivalents. *, **, $P < 0.05$, 0.01 vs. control, respectively.
[b]Levels measured in samples of frontal cortex (Cuilleret et al., 1980).
[c]Levels measured in samples of caudate nucleus (Bergeron et al., 1989).
[d]Levels measured in samples of prefrontal cortex (Lavoie et al., 1987).
[e]Median values of GABA levels measured in plasma samples from controls and patients with acute liver failure, stage IV HE (Levy and Losowsky, 1989).
[f]Levels measured in samples of frontal cortex from patients with acute liver failure (Basile et al., 1991).

increases in liver failure, possibly as a result of increased concentrations of tryptophan associated with liver failure. However, serotonin may play only a minor role in the development of HE (possibly in the development of sleep inversion), since there is no correlation between the severity of HE and the concentration of serotonin or its metabolites. Alternatively, it has been proposed that the elevations in CNS tyrosine and phenylalanine concentrations could enhance the synthesis of 'false' neurotransmitters, such as octopamine or tyramine, which may serve to deplete catecholamine neurotransmitters. However, the levels of the false neurotransmitter octopamine decrease in the brains of patients with HE, while noradrenaline and dopamine levels are generally unchanged or increased (Table 2).

Magnetic resonance imaging (MRI) of some cirrhotic patients reveals hyperintense T_1 signals in the globus pallidus, suggestive of manganese accumulation. Subsequent analysis of necropsy samples from cirrhotics indicated a 128% increase in manganese levels. Manganese is neurotoxic and causes Alzheimer type II astrocytic changes. However, the degree of pallidal hyperintensity resulting from liver failure does not, in itself, appear to be associated with the severity of HE.

Enhancement of GABAergic Neurotransmission and HE

γ-Aminobutyric acid (GABA) is the primary inhibitory neurotransmitter in the CNS, and overactivation of this pathway results in behavioral changes consistent with the primary manifestations of HE, specifically motor dysfunction, cognitive deficits, and altered consciousness. No consistent changes in the $GABA_A$ receptor complex are observed in animal models of HE or in humans with liver failure. While plasma GABA levels are reportedly increased in liver failure (Table 2), they may not impact basal levels of free GABA in the CNS. Nonetheless, there is evidence that synaptic concentrations of GABA may be increased, possibly as a result of ammonia-induced decreases in glial reuptake (Figures 2 and 3) or alterations in release parameters.

GABAergic neurotransmission may also be enhanced by the presence of endogenous, positive modulators of the $GABA_A$ receptor, including agonists of the benzodiazepine-binding site on the $GABA_A$ receptor complex and neurosteroids. Benzodiazepine binding site agonists are increased in several animal models of the syndrome and in humans suffering from HE due to either acute or chronic liver failure (Table 2, Figure 3). Tissues and body fluids from humans and animals with HE, who were otherwise never exposed to 1,4-substituted benzodiazepines, contain numerous benzodiazepine binding site ligands, as determined by radiometric techniques. Only two of these were chemically and immunochemically identified as 1,4-benzodiazepines. However, these compounds comprised less than 20% of the total concentration of benzodiazepine binding site ligands present in HE in both animal models and humans (Table 2, Figure 3). The identification and source of the remaining benzodiazepine binding-site ligands is unclear, but metabolites of hemoglobin, including hemin and protoporphyrin IX, are possible candidates.

Alterations in astrocytic function induced by ammonia may increase the production of neurosteroids such as allopregnanolone, a potent inhibitor of neuronal activity acting through the $GABA_A$ receptor.

Figure 3 GABAergic neurotransmission is enhanced in hepatic failure through a variety of mechanisms. γ-Aminobutyric acid (GABA), benzodiazepine receptor (BZR) agonists, and particularly ammonia, originating from outside of the brain (top tier), make their way into the central nervous system (CNS) either through diffusion or via a permeabilized blood–brain barrier (BBB). Elevations in CNS ammonia levels alter astrocytic function, which may lead to swelling and permeabilization of the BBB and fulminant hepatic failure (FHF), often observed in acute liver failure. Astrocytes in a hyperammonemic state also show a reduction in GABA uptake. The increased access of plasma GABA to the CNS, combined with decreased GABA uptake by astrocytes and evidence of enhanced GABA release, increases the availability of GABA at the synapse. In addition, the presence of positive modulators of the GABA$_A$ receptor, such as neurosteroid and benzodiazepine receptor agonists, as well as ammonia itself, yields a net increase in GABAergic neurotransmission. These changes, in combination with the suppression of oxidative metabolism of neurons by elevated ammonia levels, cause neuronal depression, which is expressed as the core manifestation of HE (see **Table 1**).

The peripheral-type benzodiazepine receptor (PBR), located on glial mitochondria, plays a role in neurosteroid synthesis. The density of PBRs is increased in animal models of HE, and in postmortem samples from humans with hepatic failure, but interestingly is not observed using positron emission tomography (PET) imaging in patients with HE. Nonetheless, allopregnanolone has been measured in postmortem samples of brain from patients with HE in concentrations sufficient to enhance GABA-gated chloride currents, which may serve to depress neuronal activity.

Evidence also indicates that ammonia can enhance GABAergic neurotransmission through direct actions at the GABA$_A$ receptor. An electrophysiological study using isolated cortical neurons indicated that the maximal level of GABA-activated current is enhanced by pathophysiologically relevant concentrations of ammonia, as is the potency of GABA. Subsequent investigations of the effects of ammonia on radioligand binding to sites on the GABA$_A$ receptor confirmed and extended these observations. Pathophysiologically relevant concentrations of ammonia selectively increased the density of agonist (flunitrazepam) ligand binding to the GABA-binding site of the GABA$_A$ receptor complex, with no effect on antagonist (flumazenil) ligand binding. Further, ammonia increased the affinity of agonist binding to the benzodiazepine-binding site on the GABA$_A$ receptor complex, without altering antagonist binding. The latter effect was further enhanced (threefold) in the presence of GABA. It appears that the ability of ammonia to modulate ligand binding to the GABA$_A$ receptors (a heterooligomeric complex composed of members from five families of subunits) depends on the presence of the β subunit, as ammonia can enhance [^{3}H]flunitrazepam binding to recombinant GABA$_A$ receptors composed of $\alpha_1\beta_2\gamma_2$ subunits (the pharmacology of which most resembles that of the native GABA$_A$ receptor) but has no effect on binding

to $\alpha_1\gamma_2$ constructs. Taken together, the numerous neurochemical changes present in hepatic failure may enhance GABAergic neurotransmission, leading to the motoric and behavioral changes characteristic of HE.

Suppression of Glutamatergic Neurotransmission and HE

Contrasting with GABA, glutamate is the primary excitatory neurotransmitter. Accumulating evidence suggests that there are alterations in glutamatergic neurotransmission in acute liver failure. Total brain glutamate levels are decreased under hyperammonemic conditions, including liver failure, consistent with the conversion of glutamate to glutamine by astrocytes in order to reduce ammonia levels. Basal extracellular glutamate levels increase in models of acute hepatic failure, but not in the portal–systemic shunted rat model of chronic hepatic failure. In the latter model, stimulated release of glutamate is variably increased. Glial glutamate transporter (GLT-1 and/or GLAST) expression is transiently decreased in portal–systemic shunted rats and is more consistently decreased in rats with acute liver failure. Glutamate uptake by astrocytes *in vitro* is also reduced in the presence of ammonia. Thus, there is evidence for increased extracellular glutamate levels in acute liver failure, resulting from either increased release or decreased reuptake. There is no consistent evidence of a change in *N*-methyl-D-aspartate (NMDA) receptor density in animal models of acute liver failure.

The specific contribution(s) of the alterations in glutamatergic neurotransmission to the manifestations of HE is unclear. It has been proposed that increased glutamate levels may contribute to glial swelling and cerebral edema, but there is no correlation between the onset of glutamate elevations and increased intracranial pressure. Similarly, changes in glutamate levels may contribute to the sleep-inversion, extrapyramidal disorders and to the cognitive deficits observed in HE, particularly when associated with chronic liver failure. However, the evidence for alterations in extracellular glutamate levels in animal models of chronic liver failure is variable, and the role of glutamatergic neurotransmission in the aforementioned behavioral changes is weak. Nonetheless, the significance of glutamatergic neurotransmission to CNS function is so great as to warrant continued investigation of its role in HE.

Therapy

Therapeutic strategies for allaying the manifestations of HE may focus on the target organ, the CNS, and the gut. Current, standard therapeutic regimens are directed at reducing ammonia production and absorption from the gut. Restricting oral protein consumption in order to reduce a source of ammonia was a primary treatment for decades, but is now discouraged because it aggravates lean body wasting in cirrhosis. Another approach to reducing gut ammonia production from dietary sources is to prescribe less encephalopathogenic, vegetable-based protein diets. Nonabsorbable antibiotics and cathartics (lactulose and lactitol) have also been used to reduce ammonia production and absorption. In addition to its antibiotic actions, neomycin may reduce ammonia production by inhibiting intestinal glutaminase. Bacterial overgrowth in the small intestine and other disturbances of the microecology of indigenous gut flora are common in cirrhosis, and may impact toxin/ammonia production. The ammonia-lowering actions of lactulose/lactitol may be due in part to their effects on gut flora. However, despite their widespread use, controlled trials have indicated that lactulose/lactitol and neomycin therapies are not superior to placebo in the treatment of HE. The utility of these agents in the treatment of HE is currently being reassessed using randomized, placebo-controlled trials. Similarly, the efficacy of modulating intestinal flora, such as through the administration of *Enterobacter faecium SF 68*, in treating HE is receiving renewed interest.

Another mode of therapy is to enhance the excretion of waste nitrogen from the body in patients with liver failure. Sodium benzoate, phenylacetate, and L-ornithine-L-aspartate (LOLA) promote this process through a variety of mechanisms. LOLA may improve HE by lowering ammonia levels and suppressing ammonia-induced neurotoxicity by stimulating urea cycle function. Moreover, LOLA is more effective than placebo in clinical trials.

Other therapies for HE shown to be effective in placebo-controlled trials include acarbose and the centrally acting benzodiazepine receptor antagonist, flumazenil. There are a number of anecdotal reports of the efficacy of flumazenil in treating patients suffering from HE. It has been claimed that the reversal of coma by flumazenil in these reports reflects the abuse of benzodiazepines by patients with liver disease. However, these claims do not take into account that endogenous benzodiazepine receptor ligands have been found in multiple animal models of HE. Moreover, a number of placebo-controlled trials of the efficacy of flumazenil in controlled patient populations have been conducted. Typically, low doses (1–5 mg) of flumazenil reverse HE in 30% of patients within 0.5–5 min of administration. In a meta-analysis of 12 randomized trials, eight with cross-over design, flumazenil was associated with a significant improvement of HE (30%) compared to placebo (7%), particularly in a subpopulation of patients

with low-grade encephalopathy. While no follow-up therapy was employed in these studies, long-term suppression of HE has been reported with chronic oral administration of flumazenil (25 mg). Development of a long-acting, orally available form of a benzodiazepine antagonist should enhance the use of this therapy for HE.

Finally, can the evidence implicating ammonia in the enhancement of GABAergic neurotransmission be used to develop therapeutic modalities for treating HE? An agent that can reverse ammonia's enhancement of GABA and benzodiazepine receptor function with minimal convulsant activity would be desirable. Such an agent may be an antagonist of the neurosteroid-binding site on the $GABA_A$ receptor complex, such as pregnenolone. As previously noted, ammonia enhances the binding of [^{3}H]flunitrazepam. Performing these assays in the presence of pregnenolone sulfate completely abolished the ability of ammonia to enhance the binding of [^{3}H]flunitrazepam. Similar effects were seen on ligand binding to the GABA site on the $GABA_A$ receptor complex. These preliminary observations suggest a potential use for neurosteroid antagonists in reversing some of the psychomotor symptoms of HE. Interestingly, present therapeutic protocols aimed at reducing ammonia levels by restricting dietary intake and modifying colonies of enteric bacteria may also reduce the synthesis or uptake of benzodiazepine receptor ligands or their precursors.

Conclusion

In summary, multiple factors contribute to the pathogenesis of HE, including agents that impair oxidative metabolism or neurotransmitter synthesis in the CNS, or which interact directly with neurotransmitter receptors. The principal effect of this is to suppress neuronal activity, in part by enhancing GABAergic neurotransmission. The renewed emphasis on the role of abnormal CNS function in the manifestations of HE suggests that future therapeutic modalities for this disorder will focus upon the brain as well as the gut.

Introduction

This article profiles ten examples of chemicals derived from herbal preparations that influence ionotropic receptors for the brain's major inhibitory neurotransmitter γ-aminobutyric acid (GABA). Many herbal medicines are used to influence brain function in order to treat anxiety, cognitive disorders, and insomnia. Such disorders are considered likely to involve GABA receptors, particularly ionotropic receptors that are responsible for fast synaptic transmission via ion channels. The evidence of efficacy, or otherwise, in the use of herbal medicines to treat central nervous system (CNS) disorders remains to be established unequivocally in many cases. There is no doubt, however, that these products contain chemicals that in their pure form can be shown to influence brain function in specific ways. The structural diversity of these chemicals provides valuable leads for the development of new therapeutic agents and tools with which to investigate nervous system function.

Herbal medicines are usually complex mixtures of chemicals. The combined actions of these chemicals may contribute to the overall effects of the medicines. Thus, it is important to study interactions among the individual chemicals. With respect to ionotropic GABA receptors, there are examples of synergistic interactions between two chemicals and examples of what has been termed second-order modulation, in which a second modulator enhances the action of a first-order modulator. This may represent a new form of drug action and lead to the identification of new drug targets. Investigating the complex ways in which these chemicals interact could lead to a better understanding of the function of ionotropic GABA receptors.

GABA itself is an important plant constituent, and thus it should not be surprising that plants contain a range of other chemicals that can influence GABA function. In addition, there are examples of plant-derived GABA mediating some form of communication among animals, bacteria, fungi, and plants. Thus, GABA may represent a conserved and ubiquitous biological signaling molecule.

Quality control of herbal medicines is a significant problem. Identification of key active ingredients in herbal medicines and the interactions among them may provide the means to better quality control using functional assays in addition to the currently used chemical assays. Many of the advances in studies of herbal products and GABA receptors have come from ligand binding studies, for example, from the binding of benzodiazepines to brain membranes and, more recently, from functional studies in which GABA receptors of known subunit composition are expressed in cells that do not usually express such receptors (e.g., frog oocytes).

Ionotropic GABA Receptors

The discovery that the plant alkaloid bicuculline could antagonize certain inhibitory actions of GABA in the CNS provided a vital pharmacological agent with which to probe GABA-mediated inhibition. This observation was a key component of the pharmacological basis for the original classification of GABA receptors into $GABA_A$ and $GABA_B$, with $GABA_A$ receptors being sensitive to bicuculline antagonism and insensitive to the $GABA_B$ agonist baclofen and $GABA_B$ receptors being insensitive to bicuculline and sensitive to baclofen. Subsequently, a third class of GABA receptors was described, $GABA_C$ receptors, that were insensitive to both bicuculline and baclofen. $GABA_A$ and $GABA_C$ receptors are ionotropic receptors, being ligand-gated ion channels, whereas $GABA_B$ receptors are metabotropic G-protein-coupled receptors.

Ionotropic receptors for the inhibitory neurotransmitter GABA are found on most, if not all, neurons in the CNS. They mediate fast neurotransmission via a central ion pore constituted by five surrounding protein subunits that, on activation by GABA, are permeant to chloride ions. They belong to the nicotinicoid superfamily of ligand-gated ion channels (also called cys-loop receptors) that includes nicotinic acetylcholine, strychnine-sensitive glycine, and serotonin 5-HT_3 receptors. The family of ionotropic GABA receptors may be divided into two subfamilies, $GABA_A$ and $GABA_C$ receptors, on the basis of their ability to form endogenous functional heteromeric and homomeric receptors, respectively, and of significant differences in their physiological and pharmacological properties.

The heteromeric $GABA_A$ receptors are made up of different protein subunits (e.g., a common makeup involves two $\alpha1$, two $\beta2$, and one $\gamma2$ subunits). There are 16 different subunits making up the $GABA_A$ receptor family in human brain: $\alpha1$–6, $\beta1$–3, $\gamma1$–3, δ, ε, π, and θ. In addition, there are splice variants of many of these subunits. Although the potential combinatorial diversity of $GABA_A$ receptors is huge,

studies of native $GABA_A$ receptors suggest that there may be fewer than 20 widely occurring $GABA_A$ receptor subtype combinations. There is less diversity in the homomeric $GABA_C$ receptors in that they are made up exclusively of either $\rho1$, $\rho2$, or $\rho3$ subunits, although pseudoheteromeric $GABA_C$ receptors have been described *in vitro*.

Enhancing the action of GABA on $GABA_A$ receptors is a key property of several classes of important therapeutic agents, including the benzodiazepines, barbiturates, and many general anesthetics. With advances in our understanding of the molecular diversity of $GABA_A$ receptors, there is an urgent need for the development of agents acting selectively on subtypes of these receptors.

Agents that enhance the action of GABA on $GABA_A$ receptors are known as positive modulators and are generally considered to involve action at allosteric sites on $GABA_A$ receptors remote from the GABA recognition sites (orthosteric sites). Such allosteric sites are highly valued as targets for the development of subtype-specific drugs because there is generally greater diversity between receptor subtypes in amino acid sequence at allosteric sites than at orthosteric sites. Agents that reduce the action of GABA on $GABA_A$ receptors are known as negative allosteric modulators (once known as inverse agonists because they have the opposite actions to those of the classical benzodiazepines). Agents that block the actions of both positive and negative modulators are known as neutralizing allosteric modulators (e.g., the classical benzodiazepine antagonist flumazenil).

$GABA_C$ receptors are much less widely distributed than $GABA_A$ receptors. There is evidence for functional $GABA_C$ receptors in the retina, spinal cord, superior colliculus, pituitary, and gastrointestinal tract. Given the lower abundance and less widespread distribution of $GABA_C$ receptors compared to $GABA_A$ receptors, $GABA_C$ receptors may be a more selective drug target than $GABA_A$ receptors. The major indications for drugs acting on $GABA_C$ receptors are in the treatment of visual, sleep, and cognitive disorders. Agents acting on $GABA_C$ receptors may be useful for the treatment of myopia. A recent study has linked $GABA_C$ receptors to the possible treatment of Alzheimer's disease by providing evidence that the stimulation of $GABA_C$ receptors has a neuroprotective action against β-amyloid protein.

GABA Receptor Antagonists/Negative Modulators

Many of the chemicals currently used to study ionotropic GABA receptors, including the antagonists bicuculline and picrotoxin, are of plant origin. Bicuculline is used extensively to characterize $GABA_A$ receptor function, but has no known therapeutic use. Picrotoxin was used as an analeptic to treat barbiturate overdose and may have therapeutic use in the treatment of vertigo. Other plant-derived antagonists include bilobalide and the ginkgolides from *Ginkgo biloba*, extracts of which are used to treat mild cognitive impairment, and α-thujone, one of the active constituents of the psychotropic beverage absinthe prepared from *Artemisia absinthium*.

Bicuculline

Bicuculline (**Figure 1(a)**) is a phthalide isoquinoline alkaloid first isolated from the plant *Dicentra cucullaria* and subsequently from a variety of *Corydalis*, *Dicentra*, and *Adlumia* species. The discovery of the GABA antagonist action of bicuculline came from a systematic study of convulsant alkaloids following the discovery of the glycine antagonist action of strychnine. Extensive studies of convulsant alkaloids showed that, whereas many isoquinoline alkaloids are convulsants, most are glycine antagonists, with GABA antagonism being restricted to the phthalide isoquinoline alkaloids that have the 1S,9R configuration (i.e., bicuculline, corlumine and (+)-hydrastine).

Bicuculline is a competitive antagonist of $GABA_A$ receptor activation. There is substantial evidence that bicuculline interacts with the same binding sites as agonists. Point mutations of $\alpha1$ subunits of $GABA_A$ receptors alter both agonist and competitive antagonist properties, suggesting a close structural association of $\alpha1$ Phe64 with agonist/antagonist binding sites.

Figure 1 Plant-derived agonists and antagonists of ionotropic GABA receptors: (a) bicuculline; (b) picrotoxinin; (c) bilobalide; (d) ginkgolide B; (e) muscimol.

Substitution of this Phe by Leu results in a large decrease in the apparent affinity for both GABA and bicuculline.

Quaternary salts of bicuculline, such as bicuculline methochloride and bicuculline methiodide, are easier to use than the ternary salts such as the hydrochloride in that they are more water soluble and more stable; however, the lactone ring can still open in these derivatives, rendering them inactive as GABA antagonists. Unlike bicuculline, the quaternary salts do not pass the blood–brain barrier on systemic administration. The quaternary salts are more potent inhibitors of acetylcholinesterase than the hydrochlorides. Other actions of bicuculline and its derivatives include effects on 5-HT_3, nicotinic, and *N*-methyl-D-aspartate (NMDA) receptors, as well as voltage-activated potassium channels.

Picrotoxin

Picrotoxin is an equimolar mixture of picrotoxinin and picrotin isolated from *Anamirta cocculus* and related poisonous plants of the moonseed family. Picrotoxinin (**Figure 1(b)**) is a relatively potent convulsant and a noncompetitive $GABA_A$ receptor antagonist, whereas picrotin is some 50 times less active than picrotoxinin. Picrotoxinin is one of a number of structurally related convulsants of plant origin, including coriamyrtin and tutin, that act as $GABA_A$ receptor antagonists. Most of the development of picrotoxinin-related compounds has been directed toward the discovery of new insecticides, exploiting differences between insect and mammalian ionotropic GABA receptors.

Picrotoxinin is relatively nonspecific in that it is a potent antagonist at $GABA_A$ and $GABA_C$, moderate at glycine, and weak at $5HT_3$ receptors. Interestingly, picrotin is equipotent with picrotoxinin as an antagonist of glycine receptors, indicating substantial differences in the picrotoxinin binding sites of ionotropic GABA and glycine receptors.

Unlike bicuculline, picrotoxinin can act as a GABA antagonist when administered intracellularly, probably by entering open chloride channels. It is clear that bicuculline and picrotoxinin act at different sites to antagonize GABA. The actual mechanisms by which picrotoxinin blocks ionotropic GABA receptors are complex. Site directed mutagenesis studies show that picrotoxinin acts at sites within the chloride channels of $GABA_A$, $GABA_C$, and glycine receptors.

Because the antagonist action of picrotoxinin is directed toward the GABA-activated chloride channels rather than the GABA recognition sites on ionotropic GABA receptors, picrotoxinin should perhaps be classified more correctly as a negative allosteric modulator, even though it is traditionally described as an antagonist.

Bilobalide and Ginkgolides

Bilobalide (**Figure 1(c)**), a sesquiterpenoid lactone from *Ginkgo biloba* that bears some structural similarities to picrotoxinin, including a lipophilic side chain and a hydrophilic cage, acts as an antagonist at $GABA_A$ and $GABA_C$ receptors. Like picrotoxinin, bilobalide appears to act at sites in the chloride channels of ionotropic GABA receptors and is thus more appropriately considered as a negative allosteric modulator.

There is, however, a major difference between the effects of bilobalide and picrotoxinin *in vivo*. Whereas picrotoxinin is a convulsant, bilobalide is an anticonvulsant. The lack of convulsant action in an agent that reduces GABA action may be important for the enhancement of cognition. The lack of convulsant action of bilobalide may result from inhibition of glutamate release, thus reducing synaptic excitation and outweighing reductions in synaptic inhibition. Bilobalide has a neuroprotective action in a variety of animal models.

The structurally related ginkgolides, especially ginkgolide B (**Figure 1(d)**), also act as negative modulators at $GABA_A$ receptors. They also inhibit strychnine-sensitive glycine receptors and platelet-activating factor. Bilobalide and the ginkgolides reduce barbiturate-induced sleeping time in mice, an effect perhaps relevant to the clinically observed vigilance-enhancing and antidepressant-like actions of *Ginkgo* extracts.

There are extensive, well-controlled clinical trials on *Ginkgo* extracts, particularly the standardized leaf extract code named EGb761, for the treatment of cognitive and vascular disorders. This extract contains 24% flavonoids and 6% terpenoids (including bilobalide and ginkgolides). It exerts multiple effects including reducing apoptosis, lipid peroxidation, inflammation, and β-amyloid aggregation, in addition to effects on GABA receptors and glutamate release. The cognition-enhancing effects of *Ginkgo* extracts may be partly mediated by bilobalide acting to enhance hippocampal pyridamidal neuronal excitability.

GABA Receptor Agonists

Two well-known agonists at ionotropic GABA receptors are found in plants and fungi: GABA itself, which occurs in all plants, and muscimol, a psychoactive agent from the mushroom *Amanita muscaria*.

GABA

As an important plant constituent, GABA is part of our regular diet. In recent years, chocolate, tea, wine, and yoghurt rich in GABA have been developed and promoted as being beneficial to health. Such products are reported to reduce blood pressure and increase mental alertness. Pure GABA is promoted for body building, acting via human growth hormone to increase muscle and reduce fat.

Because GABA is not considered to pass the blood–brain barrier on systemic administration, dietary GABA may be acting on GABA systems in the periphery. $GABA_A$ and $GABA_B$ receptors have been described on peripheral smooth muscle, cerebral blood vessels, and the sinus node of the heart. Alternate transcripts of the ε subunit of $GABA_A$ receptors have been found in human and rat heart; the effects of GABA and related compounds on blood pressure may be mediated in part through $GABA_A$ receptors in the heart containing ε subunits that have not been studied extensively to date. Bicuculline methiodide, a quaternary salt of bicuculline that does not cross the blood–brain barrier, increases mean arterial pressure and heart rate in rats on intravenous administration, thus providing functional evidence for bicuculline-sensitive GABA receptors outside the CNS that influence blood pressure.

Plant-derived GABA is a confounding factor in the bioactivity-guided fractionation of extracts of herbal preparations using ligand binding or functional assays of GABA receptors.

Muscimol

Muscimol (**Figure 1(e)**) is one of the most widely used agonists in the investigation of ionotropic GABA receptors. It is a more potent agonist at $GABA_C$ receptors than at $GABA_A$ receptors. The agonist action of muscimol at $GABA_C$ receptors is not blocked by bicuculline but is sensitive to picrotoxinin.

Muscimol is a conformationally restricted analog of GABA in which a hydroxyisoxazole moiety replaces the carboxyl group of GABA. The 3-hydroxyisoxazole is recognized as a carboxyl group equivalent by $GABA_A$ and $GABA_C$ receptors but not by $GABA_B$ receptors. The neuronal GABA uptake system recognizes the 3-hydroxyisoxazole moiety, in that muscimol is a weak inhibitor of GABA uptake but is neither an inhibitor of nor a substrate for GABA aminotransferase, indicating that this enzyme does not interact with the 3-hydroxyisoxazole moiety.

Muscimol became a prototype substance for the design and development of a range of isoxazoles with varying activities on GABA systems. THIP (Gaboxadol) is a conformationally restricted analog of muscimol with analgesic and sleep-promoting properties. It was investigated for the treatment of insomnia, but was recently withdrawn from phase III clinical trials due to efficacy and side-effect problems. THIP shows selectivity for $GABA_A$ receptors that contain a δ subunit, at which it is a more efficacious agonist than GABA. At similar concentrations, THIP is a $GABA_C$ receptor antagonist.

GABA Receptor Modulators

Flavonoids are responsible for many of the brilliant colors of fruits and vegetables and are important constituents of red wine, green tea, and many herbal preparations. More than 5000 different flavonoids have been identified. It has been estimated that the average daily intake of flavonoids is 1–2 g. Their antioxidant properties are regarded as important in our diet. They have a wide variety of biological activities and are being studied intensively as anticancer agents and for their effects on the vascular system.

Flavonoids have a range of activities on $GABA_A$ receptors and have been described as a new family of benzodiazepine receptor ligands. They were first linked to $GABA_A$ receptors when three isoflavans isolated from bovine urine were shown to inhibit diazepam binding to brain membranes. These isoflavans were most probably derived from plant sources in the bovine diet. Subsequently, many flavonoids directly isolated from plants were shown to influence benzodiazepine binding. A low-affinity benzodiazepine site has emerged as a possible target for the modulatory action of some flavonoids. This site is insensitive to the classical benzodiazepine antagonist flumazenil and has been described on a wide range of $GABA_A$ receptors, including those made up of only $\alpha1\beta2$ subunits. Flumazenil-insensitive effects of flavonoids on $GABA_A$ receptors have been extensively described.

Terpenoids are widespread in plants, especially in what are known as essential oils that can be extracted from plants. They have a wide range of uses from perfume constituents to paint thinners. Terpenoids are oxygenated products formally derived from C5 units and are classified by the number of C5 units in their structure. The sesquiterpenoid lactone picrotoxinin is the most widely used terpenoid in studies on ionotropic GABA receptors. However, a number of other terpenoids are of interest for their actions as positive modulators of $GABA_A$ receptors.

Another important class of herbal products that act as positive modulators of $GABA_A$ receptor function are α-pyrones, especially the kava lactones found in kava-kava (*Piper methysticum*). There are many random controlled trials of extracts of kava-kava that show a reduction in anxiety relative to placebo.

Apigenin

Apigenin (Figure 2(a)) is a common flavonoid found in a range of plants, including chamomile (*Matricaria recutita*). The traditional use of chamomile tea as a treatment for insomnia and anxiety led to investigations of its active constituents, including apigenin. Apigenin was found to have anxiolytic properties, and it competitively inhibited the binding of flunitrazepam to brain membranes without influencing the binding of muscimol to $GABA_A$ receptors.

Recent studies on human recombinant receptors in oocytes have shown that apigenin inhibited the activation of $GABA_A$ receptors in a flumazenil-insensitive manner and had a similar effect on $GABA_C$ receptors. Other studies on recombinant $GABA_A$ receptors also found an inhibitory effect of apigenin on GABA responses and, in addition, an enhancement of the diazepam-induced positive allosteric modulation of GABA responses by lower concentrations of apigenin (1 μM), described as a second-order modulation by apigenin of the first-order modulation by diazepam.

The flumazenil-sensitive anxiolytic effects of apigenin may be the result of apigenin enhancing a subthreshold effect of an endogenous benzodiazepine system. Evidence for physiologically relevant endozepines has come from the discovery of a mutant $GABA_A$ receptor in childhood absence epilepsy and febrile seizures that has diminished sensitivity to benzodiazepines with no other apparent alteration in function.

Figure 2 Plant-derived positive modulators of the activation of $GABA_A$ receptors by GABA: (a) apigenin; (b) epigallocatechin gallate; (c) hispidulin; (d) (+)-borneol; (e) kawain.

Overall, it seems that the effects of apigenin on $GABA_A$ receptors are complex and involve both flumazenil-sensitive and flumazenil-insensitive components, and that other receptors could be involved in the behavioral effects of apigenin. Like most flavonoids, apigenin is known to have a wide variety of biological actions, including effects on adenosine receptors and progestational activity. Of particular interest are the findings that apigenin, at concentrations that inhibit $GABA_A$ and $GABA_C$ receptors, also inhibits NMDA receptors. Such an action could contribute to the flumazenil-insensitive sedative actions of apigenin.

Epigallocatechin Gallate

Green tea polyphenols are being considered as therapeutic agents in well-controlled epidemiological studies aimed to alter brain-aging processes and to serve as possible neuroprotective agents in progressive neurodegenerative disorders such as Parkinson's and Alzheimer's diseases.

Epigallocatechin gallate (Figure 2(b)) (EGCG) is the major polyphenol in green tea (*Camellia sinensis*). Studies on $\alpha1\beta2\gamma2L$ $GABA_A$ receptors showed that EGCG at low concentrations (0.1 μM) has a potent second-order modulatory action on the first-order modulation by diazepam but inhibits the action of GABA at higher concentrations (>1 μM). EGCG was an order of magnitude more potent than apigenin in acting as a second-order modulator. In addition, it has been found that EGCG, at concentrations that have no influence on the activation of $GABA_A$ receptors by GABA, was able to reverse the negative modulation of such receptors by methyl β-carboline. This indicates that EGCG may act as a second-order modulator with respect to the first-order modulation by both positive and negative modulators that act on benzodiazepines sites on $GABA_A$ receptors.

The novel second-order modulation by EGCG and apigenin of the maximum first-order modulatory action of diazepam of the activation by GABA of $GABA_A$ receptors observed in these studies may result from altering the coupling of the benzodiazepine allosteric sites with the orthosteric GABA sites on $GABA_A$ receptors. There is evidence from binding studies that the nexus between the benzodiazepine and GABA sites on $GABA_A$ receptors is complex and involves other factors such as phospholipids. EGCG and apigenin may serve as lead compounds for the development of more selective agents for the second-order modulation of benzodiazepine enhancement of the action of GABA on $GABA_A$ receptors.

There is much interest in the anticancer and antitumor properties of EGCG associated with the consumption of green tea. EGCG has anticancer effects on ovarian carcinoma cell lines, is a selective inhibitor of COX-2 expression, and induces apoptosis in monocytes. Little is known about the CNS actions of this flavan. However, it is found in the brain after gastric administration to mice and is neuroprotective in rats on intraperitoneal (IP) injection after focal ischemia and in a mouse model of Parkinson's disease. This neuroprotective action may be associated with its antioxidant properties, but enhancement of $GABA_A$-mediated synaptic inhibition could also contribute. In addition, EGCG is known to reduce glutamate-induced cytotoxicity via intracellular Ca^{2+} ion modulation, suggesting that other neurotransmitter systems may be involved.

Hispidulin and Related Flavonoids

Hispidulin (Figure 2(c)) (the 6-methoxy derivative of apigenin) was isolated together with apigenin from *Salvia officinalis* (sage) recently using a benzodiazepine binding assay-guided fractionation. Hispidulin was some 30 times more potent than apigenin in displacing flumazenil binding. Preparations of sage have been used in herbal medicine to assist memory, and an extract of *Salvia lavandulaefolia* (Spanish sage) has been shown to enhance memory in healthy young volunteers. Unlike apigenin, hispidulin has been shown to act as a positive allosteric modulator of $GABA_A$ receptors. The positive modulatory action of 10 μM hispidulin at $\alpha1\beta2\gamma2S$ receptors was reduced from 47% to 17% by flumazenil, indicating that sites other than classical flumazenil-sensitive benzodiazepine sites were involved in the action of hispidulin. Because hispidulin did not influence the action of GABA on $\alpha1\beta2$ $GABA_A$ receptors, this indicates that it did not interact with low-affinity flumazenil-insensitive benzodiazepine sites. Hispidulin was shown to have an anticonvulsant action in seizure-prone Mongolian gerbils and to pass the blood–brain barrier.

Flavonoids structurally related to hispidulin that influence benzodiazepine binding have been isolated from *Scutellaria baicalensis*, an important herb in traditional Chinese medicine. Oroxylin A (5,7-dihydroxy-6-methoxyflavone, i.e., hispidulin lacking the 4′-hydroxy group) inhibits flunitrazepam binding at 1 μM, and on oral administration acts as a neutralizing modulator blocking the anxiolytic, myorelaxant, and motor incoordination effects but not the sedative and anticonvulsant effects elicited by diazepam. 6-Methylapigenin isolated from *Valeriana wallichii,* a known sedative herb, influences benzodiazepine binding at 0.5 μM in manner suggesting it may be a positive modulator of $GABA_A$ receptors. 6-Methylapigenin has anxiolytic properties, and it can act synergistically to potentiate the sleep-enhancing properties of hespiridin, a flavanone glycoside from *Valeriana*.

Thus, flavones substituted in the 6 position with a methoxy or methyl substituent have interesting effects on $GABA_A$ receptor function and may contribute to the properties of some herbal preparations. Several flavonoid glycosides, including goodyerin, linarin, and hesperidin, are also being studied as sedative and anticonvulsant agents likely to interact with $GABA_A$ receptors.

(+)-Borneol

(+)-Borneol (Figure 2(d)) is a bicyclic monoterpenoid found in high concentrations in extracts of *Valeriana officinalis* that are widely used to reduce the latency of sleep onset and to increase the depth of sleep and the perception of well-being. Extracts of *Valeriana* are known to contain a large number of constituents, including flavonoids and terpenoids, many of which are considered to be active at $GABA_A$ receptors.

(+)-Borneol was shown to be a flumazenil-insensitive positive allosteric modulator of human recombinant $\alpha1\beta2\gamma2L$ $GABA_A$ receptors of low potency (median effective concentration (EC_{50}) 250 μM) but very high efficacy, producing a ten-fold enhancement of the action of 10 μM GABA at a concentration of 450 μM. (−)-Borneol showed similar positive modulatory properties to (+)-borneol, whereas isoborneol, (−)-bornyl acetate, and camphor (a known convulsant) were much less active. The relatively rigid cage structure of these bicyclic monoterpenes and their high efficacy may aid in a greater understanding of the molecular aspects of positive modulation.

Kava Lactones

Kava lactones (α-pyrones) have been recognized as the active constituents responsible for the reported anxiolytic and sedative effects of kava-kava. The six major kava lactones are kawain (Figure 2(e)), dihydrokawain, methysticin, dihydromethysticin, yangonin, and demethoxyyangonin, and they occur in varying proportions in different cultivars.

There is evidence to indicate that kava lactones may mediate their anxiolytic and sedative effects via positive modulation of $GABA_A$ receptor function acting at sites different from the classical benzodiazepine binding sites. Individual kava lactones have been shown to enhance the binding of bicuculline methochloride and muscimol to brain membranes without

influencing the binding of diazepam or flunitrazepam, indicating that they interact with the agonist/competitive antagonist binding sites on $GABA_A$ receptors. The enhancement of muscimol binding showed regional selectivity to be highest in the hippocampus, amygdala, and medulla, with minimal effect on the cerebellum and frontal cortex, suggesting that the kava lactones may show subtype specificity for particular $GABA_A$ receptors. Functional studies of recombinant $\alpha1\beta2\gamma2L$ $GABA_A$ receptors have shown that kava lactones do act as positive modulators, but such studies need to be extended to investigate different subunit combinations.

Hereditary Spastic Paraplegia

J K Fink, University of Otago, Christchurch, New Zealand

© 2009 Published by Elsevier Ltd.

Following normal prenatal and early childhood development, subjects with uncomplicated hereditary spastic paraglegia (HSP) develop leg stiffness and gait disturbance (stumbling and tripping) due to difficulty dorsiflexing the foot and weakness of hip flexion. Although the majority of patients experience symptom onset in the second through fourth decades, symptom onset from infancy through age 85 has been observed. Gait disturbance progresses insidiously without exacerbations, remissions, or saltatory worsening. Subjects may experience paresthesiae below the kness. Urinary urgency progressing to urinary incontinence is a frequent, although variable, late manifestation. It should be noted that some autosomal dominant, uncomplicated HSP kindreds exhibit onset of progressive spastic paraplegia in childhood (before age 6 years) and relatively little progression of symptoms beyond adolescence. These patients often do not experience urinary bladder disturbance and generally remain ambulatory with assistance. Age of symptom onset, rate of progression, and extent of disability may be variable both within and between families.

Neurologic abnormalities in uncomplicated HSP are limited to the lower extremities which demonstrate increased muscle tone and weakness that is particularly noted at iliopsoas, tibialis anterior, and, to a lesser extent, hamstring muscles. Distal muscle wasting has been reported in uncomplicated HSP although is usually mild and limited to atrophy of the shins in wheelchair-dependent elderly patients. Mildly diminished vibratory sense in distal lower extremities is often noted. Although the combination of mildly impaired vibratory sense and lower extremity spasticity is helpful in recognizing HSP, vibration perception may be normal in mildly affected subjects. Slight terminal dysmetria is observed occasionally on finger-to-nose testing in older affected subjects. Deep tendon reflexes are pathologically increased in the lower extremities. Crossed adductor reflexes, ankle clonus, and extensor plantar responses are present. Gait is abnormal with circumduction owing to hip flexor and ankle dorsiflexion weakness. Pes cavus is generally present in older affected subjects.

Currently, there is no specific treatment to prevent, retard, or reverse HSP's progressive disability. Symptomatic reduction in spasticity often occurs with oral and intrathecal lioresal and oral dantrolene. Bladder spasticity has been improved with oxybutynin.

Nerve conduction studies in uncomplicated HSP are generally normal although subclinical sensory impairment has been reported. Lower extremity somatosensory evoked potentials show conduction delay in dorsal column fibers. Cortical evoked potentials, used to measure neurotransmission in corticospinal tracts, show reduced corticospinal tract conduction velocity and amplitude of evoked potential in muscles innervated by lumbar spinal segments but normal or only mildly reduced conduction velocity in muscles innervated by cervical segments. These findings indicate that there are fewer corticospinal tract axons reaching the lumbar spinal cord and that conduction velocity is reduced in those that remain.

Neuropathology

Autosomal dominant, uncomplicated HSP is characterized by axonal degeneration that is maximal in the terminal portions of the longest descending and ascending tracts (crossed and uncrossed corticospinal tracts to the legs, fasciculus gracilis fibers, and to a lesser extent, spinocerebellar fibers). Neuronal cell bodies of degenerating fibers are preserved. Some cases of HSP exhibit mild loss of anterior horn cells. Dorsal root ganglia, posterior roots, and peripheral nerves are normal. There is no evidence of primary demyelination.

Differential Diagnosis

Diagnosing HSP is straightforward when the family history indicates autosomal dominant inheritance of progressive spasticity as an isolated symptom. Documenting associated deficits (such as ataxia, retinitis pigmentosa and periphereal neuropathy and extrapyramidal signs) is important to classify HSP patients and to distinguish them from other spinocerebellar syndromes including Machado–Joseph disease. Other diagnostic considerations are most relevant when examining patients with apparently sporadic disorders. The primary differential diagnosis of insidiously progressive, spastic para- or tetraparesis in children and young adults includes structural spinal cord disturbance from tethered cord syndrome, Arnold-Chiari malformations, spondylosis, neoplasm, multiple sclerosis, and arteriovenous malformations of the spinal cord. Myelopathies associated with vitamin B12 deficiency, vitamin E deficiency, and abetalipoproteinemia (Bassen–Kornzweing disease) are typically accompanied by peripheral neuropathy. It is important to consider progressive dystonia with diurnal variation in all individuals with progressive

gait disturbance, as this disorder is completely treatable with low-dose levodopa-carbidopa. Although corticospinal tract signs occasionally precede weakness and wasting in amyotrophic lateral sclerosis (ALS), electromyography readily distinguishes ALS from HSP. Rare, adult variants of adrenomyeloneuropathy (ALD/AMN), globoid cell (Krabbe) leukodystrophy, and metachromatic leukodystrophy (MLD) can be evaluated with serum long-chain fatty acid, leukocyte galactocerebrosidase, and arylsulfatase A assays (respectively). Tropical spastic paraparesis due to HTLV I infection and acquired immunodeficiency syndrome (AIDS) related myelopathy may be evaluated by appropriate antibody titres, although each typically has a subacute course. Similarly, myelopathy as a paraneoplastic syndrome usually has a subacute presentations in contrast to HSP's insidious progression.

Genetic Analysis

Uncomplicated autosomal dominant, autosomal recessive, and X-linked HSP are genetically heterogeneous: different genes cause clinically indistinguishable disorders. A locus for autosomal recessive HSP is on chromosome 8q. Loci for autosomal dominant HSP have been identified on chromosomes 2p, 14q, and 15q. Currently, linkage to chromosome 2p is the most frequent among autosomal dominant HSP families linked to any chromosomal locus. For many HSP families, however, the disorder is excluded from known HSP loci. This indicates that the disease is linked to additional, as yet unidentified loci in approximately 45% of autosomal dominant HSP kindreds.

X-linked uncomplicated HSP is rare and mapped to a locus on Xq22 in two families. A missense mutation in the proteolipoprotein (PLP) gene coding sequence was found in affected males of one of these families. This indicates that *uncomplicated* X-linked HSP in this family is allelic to a form of *complicated* X-linked HSP and Pelizaeus–Merzbacher disease, as they all result from PLP gene mutations.

Genetic Counseling

With few exceptions, uncomplicated HSP exhibits nearly complete, age-dependent genetic penetrance. This is an important consideration when counseling subjects from autosomal dominant HSP kindreds, since first-degree relatives of affected subjects will have approximately 50% lifetime risk of developing the disorder. Genetic counseling must consider that although HSP generally exhibits complete genetic penetrance, age of symptom onset, rate of symptom progression, extent of urinary bladder involvement, and functional disability may vary significantly both within and between families. One cannot predict with certainty that a wheel chair will be required or that urinary incontinence will inevitably occur. A cautious wait and see approach is advised. Genetic counselors and physicians must note that the disorder in some HSP kindreds begins in childhood and is relatively nonprogressive after approximately age 10 years. Patients in these kindreds often remain ambulatory.

While the availability of genetic markers tightly linked with HSP loci greatly improves genetic counseling, their use is limited to counseling informative subjects from kindreds linked to these loci who are at risk of transmitting or inheriting this disorder. Although limited to informative members of kindreds linked to known HSP loci, tightly linked markers can be used prenatally to assess the chance that the fetus has inherited HSP. Inheritance of tightly linked markers alone should not be used for early diagnosis of HSP, however. It is important that each patient suspected of having HSP undergo thorough neurologic examination and often neuroimaging to exclude other neurologic disorders. Extreme caution must be used in counseling unaffected parents of a child with suspected HSP about the risk of HSP in other progeny. The disorder in this case could be sporadic (low recurrence risk), due to nonpaternity (uncertain recurrence risk), or autosomal recessive (25% recurrence risk). Furthermore, given the variation in age of symptom onset, observations of genetic anticipation in autosomal dominant HSP, and rare occurrences of incomplete penetrance, it is possible that the disorder is autosomal dominant, inherited from a presymptomatic parent, and that the risk of recurrence in other progeny approaches 50%.

Conclusion

Very strong clinical and pathologic similarity between HSP kindreds linked to different genetic loci suggests that the abnormal gene products from these HSP loci interact in a common biochemical cascade. Disturbance of this pathway results in a degeneration of the distal portions of the longest CNS axons. Identifying the precise gene defects responsible for HSP will advance our knowledge of HSP's pathophysiology and will facilitate rational design of treatments to prevent, retard, or reverse this disorder.

Heritable Microgyrias

B S Chang and C A Walsh, Harvard Medical School, Boston, MA, USA

Introduction

Among the syndromes of human brain malformation that result from disruptions in cerebral cortical development, those conditions involving microgyria, or polymicrogyria (PMG), are among the most clinically common. PMG, generally defined as the presence of an excessive number ('poly') of small ('micro') gyri, and usually associated with an abnormal pattern of cortical lamination, can be focal or generalized, unilateral or bilateral. It can be present in isolated form or can be associated with other brain malformations. Its neurological manifestations can include developmental delay in both the cognitive and motor spheres, focal deficits such as weakness on one side of the body, and epilepsy of varying types and severities. PMG can be associated with known environmental insults during embryonic and fetal development, such as intrauterine cytomegalovirus (CMV) infection or loss of oxygenated blood flow to the developing brain, or it can be part of an inherited syndrome with a germline genetic basis. In this article, we focus on the major heritable microgyria syndromes and review their clinical characteristics, radiological appearance, and genetic basis, when known.

Bilateral Frontoparietal Polymicrogyria

Bilateral frontoparietal polymicrogyria (BFPP) is the only known isolated PMG syndrome whose causative gene has been identified. The study of BFPP serves as an instructive example of the region-specific nature of many inherited PMG syndromes, the importance of brain development genes in not only the patterning of the cortex but also the proper development of subcortical and hindbrain structures, and the utility of detailed genotype-phenotype analyses to the practicing neurological clinician.

Clinical Characteristics

BFPP is usually characterized clinically by moderate to severe delay in both the cognitive and motor spheres, resulting in mental retardation and the spastic form of cerebral palsy. Refractory epilepsy, with focal and generalized seizures, is usually present in these children. Most children die before adulthood either from infections or from complications of seizures, although some patients with BFPP have survived into their 20s. Two distinctive clinical features help to differentiate this condition from similar bilateral PMG syndromes. First, a majority of patients have dysconjugate gaze (usually esotropia, or crossed eyes); many have had corrective surgery for strabismus in early childhood. Second, uncoordinated limb movements (cerebellar ataxia) are often present, although this finding may be hard to detect in the presence of severe spasticity.

Radiological Appearance

The 'classic' BFPP syndrome has a very stereotypical radiological appearance (Figure 1). PMG is present in a widespread distribution on both sides of the brain, but with a prominent anterior–posterior gradient such that the frontal and parietal lobes are most severely affected, while the occipital lobes are least affected or can on occasion even appear completely spared. The PMG is typically diagnosed based on an apparent increase in the thickness of the cerebral cortex (representing 'heaped-up' microgyri superimposed on one another without distinguishable intervening sulci), and an irregular, scalloped junction between gray matter and white matter. In addition to the frontoparietal PMG, however, the classic BFPP syndrome is also characterized by patchy areas of signal change in the white matter on T2-weighted magnetic resonance imaging (MRI), suggestive of abnormal myelination or maldevelopment of the white matter. There is also usually underdevelopment of the brain stem (resulting in a flattened-appearing pons) and cerebellum (affecting both the vermis and hemispheres).

Genetic Etiology

BFPP, originally described in multiple consanguineous pedigrees of Middle Eastern and South Asian origin, is inherited in an autosomal recessive manner. It is now known to be associated with mutations in *GPR56*, a gene that encodes an orphan G-protein-coupled receptor whose exact role in brain development is still unknown. The GPR56 protein is expressed in the ventricular zones of the developing brain, suggesting that the molecular mechanisms underlying PMG may be ones affecting cell fate at an early stage of cortical development, rather than merely late stages of post-migrational cortical organization.

Genotype–Phenotype Analysis and Related Syndromes

The description and genetic characterization of *GPR56*-associated BFPP led to the identification of

Figure 1 BFPP. T1-weighted sagittal (left), T1-weighted coronal (middle), and T2-weighted axial (right) brain MRI of a 1-year-old child with *GPR56*-associated BFPP. White arrowheads indicate the anatomical distribution of the PMG, which is widespread but has a decreasing anterior–posterior gradient of severity and relatively spares the occipital lobes. Black arrowheads indicate patches of T2-weighted signal change within the white matter, a characteristic radiological sign of this disorder.

multiple families with a very similar clinical and radiological condition now referred to as BFPP2, or BFPP-like syndrome. In this disorder, which also appears to be inherited in an autosomal recessive manner, the appearance of the cerebral cortex is essentially identical to that in *GPR56*-associated BFPP, but there are typically no underlying white matter signal changes and no abnormalities of the brain stem or cerebellum, unlike in BFPP. None of the individuals affected by BFPP2 have been found to harbor *GPR56* mutations to date, strongly suggesting that the role of *GPR56* in human brain development may extend beyond cortical patterning to also involve white matter and hindbrain development.

Bilateral Perisylvian Polymicrogyria

Bilateral perisylvian polymicrogyria (BPP) is the most commonly recognized inherited form of PMG. Historically, disorders with overlapping clinical features have been variously described as 'congenital bilateral perisylvian syndrome' and 'Worster-Drought syndrome,' but these and other terms are likely to be references to the same pathologic entity, since many cases have been characterized histologically by PMG lining the Sylvian fissures of the brain bilaterally. BPP is one of the rare cortical malformations for which the clinical features are so distinctive that experienced neurologists may suspect this specific malformation on clinical grounds alone.

Clinical Characteristics

The most distinctive clinical feature of BPP is a difficulty with coordinated oral movements that is commonly referred to as oromotor dyspraxia, or pseudobulbar paresis. This can range in severity from a mild speech impediment that is only evident in later childhood to a severe inability to feed, suck, or swallow in infancy, requiring tube feeding in some cases. In even mild cases, the tongue may have a noticeable limitation of coordinated movement, and children or adults who can speak often do so with significant slurring, or dysarthria. Cognitive disabilities and cerebral palsy are common as well, although the rate of frank mental retardation appears to be relatively low. A seizure disorder is present in most patients but can vary significantly in severity, ranging from the occasional partial seizure to medically refractory epilepsy.

Radiological Appearance

One of the more obvious radiological signs of BPP is an elongation and gross malorientation of the Sylvian fissure (Figure 2). On sagittal MRI images, the fissure often appears abnormally 'open,' without proper apposition of the two sides. The fissure may extend posteriorly and superiorly in an elongated fashion, reaching the vertex, rather than ending below the inferior parietal lobule as usual. On close inspection, the gyri in the perisylvian region, both superiorly and inferiorly, demonstrate PMG with increased apparent cortical thickness and an irregular gray–white junction. In some instances, the PMG can be more widespread, extending into dorsolateral parts of the frontal lobes or posterior parietal regions, but the predominance of the PMG in the perisylvian area, the contiguity of the malformed regions of cortex, and the abnormally oriented Sylvian fissure, if present, usually help to identify these cases as variants of the fundamental BPP syndrome.

Figure 2 BPP. T1-weighted sagittal (left), T2-weighted axial (middle), and T2-weighted coronal (right) brain MRI of a 3-month-old child with BPP. White arrowheads demarcate the two ends of the abnormally open and maloriented Sylvian fissure (left), as well as the presence of PMG along the Sylvian fissures bilaterally, particularly inferiorly (middle and right).

Genetic Etiology

BPP appears to be genetically heterogeneous. One study mapped several families with an inherited form of BPP to a locus at chromosome Xq28, but no causative gene has yet been identified. Other reports describe BPP families whose pedigrees appear consistent with autosomal recessive or dominant inheritance.

Susceptibility of Perisylvian Region

Large series of PMG cases demonstrate that the perisylvian region is the area of cortex most commonly affected by this malformation, either alone or in combination with other areas. Why the perisylvian cortex should be more susceptible to PMG is unclear, but potential factors include region-specific differences in gene expression, differential timing of gyral development, and the particularities of its arterial supply. The abnormally open and maloriented appearance of the Sylvian fissure in many cases of BPP does suggest that the malformation has its basis in an earlier stage of cortical development than simply postmigrational organization.

Bilateral Generalized Polymicrogyria

Bilateral generalized polymicrogyria (BGP) is a unique syndrome of widespread PMG that appears to be inherited in an autosomal recessive manner.

Clinical Characteristics

BGP patients have cognitive delay of variable severity, with about half exhibiting severe delay. Problems with motor development are also nearly universal, and were reported to be severe in just fewer than half of the originally described cases. Seizures are present in the majority of cases, and are occasionally refractory. No specific oral motor dysfunction is seen, unlike in BPP, and no specific eye movement abnormalities or cerebellar dysfunction are seen, unlike in BFPP. Macrocephaly (large head size), rarely seen in other PMG syndromes, was reported in a quarter of the originally described cases.

Radiological Findings

In BGP, the PMG is seen in a generalized distribution in all cases, but about two-thirds of the time there is a perisylvian predominance (Figure 3). Some investigators classify cases such as these as a subtype of BPP that includes extension of the PMG all the way to the frontal and occipital poles, but a distinct BGP syndrome that includes enlarged ventricles, reduced white matter volume, and macrocephaly in some cases, appears to exist. In addition, the Sylvian fissure does not usually extend abnormally to the vertex in BGP, as it does in most cases of BPP. Some BGP patients do have signal change in the white matter on T2-weighted MRI images.

Genetic Etiology

The genetic etiology of BGP is not known. Pedigrees of the original seven families suggest that the disorder is inherited in an autosomal recessive manner. Analyzed pedigrees have not shown evidence of linkage to the BFPP locus on chromosome 16q, despite the widespread nature of the PMG in both syndromes, and *GPR56* mutations have not been found in patients with BGP.

Bilateral Frontal Polymicrogyria

Bilateral frontal polymicrogyria (BFP) was first described as a discrete brain malformation in 2000. Its

Figure 3 BGP. T1-weighted axial (left), T1-weighted coronal (middle), and T2-weighted axial (right) brain MRI of a 7-year-old child with BGP. In all three images, the PMG is widely distributed throughout the cortex, without any particular anterior–posterior gradient, but the perisylvian regions are prominently affected (white arrowheads). Ventriculomegaly, as seen in this patient, is commonly observed in BGP.

restriction to the frontal cortex distinguishes it from the other heritable bilateral PMG syndromes discussed here so far.

Clinical Characteristics

All of the originally described patients with isolated BFP had clinical signs of developmental delay and mild spastic weakness of all extremities. Language impairment was nearly universal, although the extent varied, and mental retardation of varying severity was similarly present in most patients. A minority of the patients had seizures, with partial, generalized tonic-clonic, atypical absence, and clonic seizure types all represented. Oral motor problems are not typically seen in BFP, nor have eye movement abnormalities or cerebellar signs been generally reported.

Radiological Findings

BFP is radiologically characterized by irregular cortical infoldings with an increase in apparent cortical thickness, diagnostic of PMG, in the frontal lobes bilaterally (Figure 4). Most commonly, the malformation in BFP extends from the frontal poles posteriorly to the precentral gyrus, and inferiorly to involve the frontal operculum. The infrasylvian cortex is not affected, unlike in BPP. A few of the originally described BFP patients had small foci of frontal white matter signal change and about half had mild enlargement of the ventricles. No brain stem or cerebellar abnormalities were seen.

Genetic Etiology and Related Syndromes

No known causative gene has been identified for BFP. The condition is presumed to be of autosomal recessive inheritance, given the absence of affected parents and the presence of consanguineity in two of the originally described families. BFP, in association with a thin corpus callosum, is also seen as a component of Warburg Micro syndrome, an autosomal recessive disorder associated with mutations in the *RAB3GAP* gene that is characterized by congenital eye anomalies, underdevelopment of the genitals, and microcephaly (small head size).

Familial Unilateral Right Polymicrogyria

Although unilateral PMG is commonly assumed by clinicians to arise from environmental causes, some cases of unilateral PMG have clear genetic etiologies (e.g., those associated with chromosome 22q11 deletions), and more recently, a familial syndrome of unilateral right-sided PMG has been described in four pedigrees, each of which includes two affected members, suggesting a germline genetic etiology for this condition in at least some cases.

Clinical Characteristics

Patients with familial unilateral right-sided PMG generally present with the clinical triad of cognitive difficulties, left-sided weakness, and partial epilepsy with a seizure focus in the right side of the brain. Most patients have low normal intelligence or mild mental retardation, and the left-sided weakness is generally mild to moderate in severity. The seizure disorder is refractory in nature about half of the time.

Radiological Findings

All four families with this syndrome have a very stereotyped appearance to their unilateral right

PMG, which affects the frontal and perisylvian cortex (Figure 5). In all cases, the Sylvian fissure on the right is deeply invaginated at its posterior extent, and PMG extends from the frontal pole posteriorly to the posterior end of the Sylvian fissure. In addition, the right cerebral hemisphere is smaller than the left hemisphere in all cases, although this asymmetry varies in severity among the families.

Genetic Etiology

No genetic etiology has yet been identified for familial unilateral right-sided PMG. The disorder may in fact be genetically heterogeneous, as three of the four reported families include two affected siblings born to healthy unrelated parents (suggestive of autosomal recessive inheritance) while the fourth family includes an affected mother and son (compatible with autosomal dominant or X-linked inheritance). Unilateral right PMG has been seen in the setting of chromosome 22q11 deletions, usually in the context of associated facial and cardiac anomalies, although sometimes in isolation. It has also been observed in association with an unbalanced translocation resulting in partial 1q monosomy and 12p trisomy,

Figure 4 BFP. T1-weighted axial (left), T1-weighted sagittal (middle), and T2-weighted coronal (right) brain MRI of an 18-year-old woman with BFP. White arrowheads demarcate the extent of the PMG, which involves the frontal lobes bilaterally but does not extend posteriorly to the parietal lobes or inferiorly to the temporal lobes. The coronal image through the frontal lobes (right) demonstrates that the PMG affects most of the frontal cortex equally but relatively spares the orbitofrontal regions.

Figure 5 Familial unilateral right-sided PMG. T2-weighted axial (left), T1-weighted sagittal (middle), and T2-weighted coronal (right) brain MRI of a 4-year-old child with familial unilateral right-sided PMG. White arrows indicate the anatomical extent of the malformation, which involves the frontal and perisylvian cortex, extending from the frontal pole to a deep posterior infolding of the Sylvian fissure. The affected right hemisphere is smaller than the left hemisphere in this syndrome, as demonstrated in these images.

although those cases were also characterized by additional congenital abnormalities outside the central nervous system.

Lessons from Heritable Microgyria Syndromes

Among the human brain malformations, PMG has played an important role in our exploration of the genetic and molecular mechanisms of cerebral cortical development. In particular, the recognition that there are multiple region-specific bilateral and unilateral PMG syndromes offers the opportunity to understand better the unique roles of individual genes involved in cortical patterning and development. In addition, the presence of associated subcortical and hindbrain abnormalities keyed to a particular genotype raises questions about the mechanistic relationship, if any, between PMG and other malformations (such as cobblestone lissencephaly syndromes) that also feature abnormalities in these brain structures.

With many PMG genes yet to be identified, multiple potential genotype–phenotype correlations remain possible in this field – a one-to-one correspondence between discrete PMG syndromes and unique causative genes; genetic heterogeneity, with multiple genes linked to a clinically and radiologically uniform syndrome; or phenotypic variability, with one causative gene for multiple distinct but related PMG syndromes.

Besides the instructive nature of its study from a neurobiological viewpoint, PMG also plays a large role in clinical practice, being one of the more common cortical malformations and potentially presenting with a variety of different clinical manifestations depending on its anatomical location and extent. Thus, a detailed understanding of both the genotype–phenotype relationships and the clinico-anatomical correlates underlying various PMG syndromes will be of use to practicing neurologists seeking to diagnose, treat, and counsel patients with these conditions.

Hibernation

T S Kilduff, SRI International, Menlo Park, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, © 2004, Elsevier B.V.

Hibernation in mammals is an adaptation for energy conservation during periods of cold and limited food availability that involves seasonal modulation of behavioral state and physiological control systems. Contrary to popular belief, animals do not remain continuously torpid throughout the hibernation season; rather, they typically cycle between euthermia and deep hibernation attaining body temperatures (T_b) close to freezing many times during the winter. Individual bouts of torpor can last from several hours to several weeks in length and are punctuated by periods of euthermia (the interbout intervals). These recurring patterns of increased and dramatically decreased T_b and accompanying changes in behavior and physiology are referred to as the hibernation cycle. It is thought that these dramatic changes in arousal state evolved from normal euthermic arousal state control mechanisms. Therefore, the molecular, neurobiological, and endocrine mechanisms regulating the events of the hibernation cycle are likely to be of considerable significance in understanding mammalian arousal state transitions in general.

Four major phases of the hibernation cycle can be identified (Figure 1). The 'euthermic phase' during the interbout intervals is characterized by a high proportion of nonrapid eye movement (NREM) sleep and body temperature regulation between 36 and 38 °C. During 'entrance' to hibernation, an active resetting of the hypothalamic 'thermostat' which regulates T_b occurs, resulting in a decrease in metabolism that approaches 1/30 to 1/100 of the euthermic value at the same ambient temperature. This dramatic decline in T_b and metabolism usually occurs over the course of 12–24 h and is characterized by a predominance of NREM sleep, with a suppression of both wakefulness and REM sleep. The 'deep hibernation phase' is characterized by a low T_b that can either be in equilibrium with environmental temperature or be regulated at a level between environmental and euthermic body temperature. T_b can be as low as 1.2 °C in the ground squirrel *Citellus lateralis*, and there is evidence for subfreezing T_b values in Arctic species. Thus, hibernation is not simply passive hypothermia; rather, T_b is determined by an active thermoregulatory system. Dramatic changes occur in other regulated physiological control systems as well: as T_b declines from euthermic values of 37 to 5 °C in ground squirrels, heart rate decreases from 200–300 beats min^{-1} to 7–10 beats min^{-1}, and respiratory rate drops from 100–150 breaths min^{-1} to 1–2 breaths min^{-1} with long periods of apnea. During the 'arousal' from hibernation, animals return to euthermic T_b by a combination of shivering and nonshivering thermogenesis; the mobilization of energy stores in the brown fat is an important contributor to heat production during the arousal. The specific factors which terminate the deep hibernation phase and provoke the arousal to euthermia are unknown, but recent studies summarized below suggest that sleep homeostasis may be important. The neurobiological mechanisms underlying the dynamic phases of the hibernation cycle, the entrance and arousal, are of interest in understanding transitions between arousal states in mammals.

There are considerable changes in arousal state distribution across the hibernation cycle. Hibernation is entered primarily through NREM sleep and is a regulated lowering of T_b. A downward resetting of the hypothalamic T_b regulator is a general feature of NREM sleep in all mammals studied. These observations have led to the suggestion that NREM sleep and hibernation in mammals are homologous adaptations for energy conservation. Thus, mammalian hibernation may have evolved in species which faced limited food availability as selection favored the energy conservation resulting from the downregulation of T_b that accompanies NREM sleep. Decreasing T_b during NREM sleep and prolonging sleep could have enabled certain species to exploit highly seasonal environments.

Behavioral and electrophysiological studies show that hibernation is not a homogeneous behavioral state. Strumwasser noted that, during deep hibernation ($T_b = 6$ °C), *Citellus beecheyi* made two to three postural adjustments per hour. These adjustments consisted of (1) raising the head and forepart of the body, (2) burrowing deeper into the nesting material, and (3) shifting the position of the body in the nest. In addition, *C. beecheyi* was capable of vocalization and orientation to sounds during deep hibernation. Marmots are also capable of complex behaviors during the entrance into hibernation. For example, they perform stereotyped nest-building behaviors, move in circles in the nest, and curl the body and move the head during the entrance into hibernation. Such complex behaviors generally occur in awake euthermic mammals. The presence of complex behaviors during entrance into, as well as deep hibernation, suggests that their occurrence may be coincident with epochs of wakefulness interspersed throughout a period in which a NREM-like state predominates.

Figure 1 Body temperature recorded every 10 min from a ground squirrel during two consecutive hibernation bouts during the hibernation season. The four major phases of the hibernation cycle are labeled.

Electrophysiological observations support the contention that hibernation is not a homogeneous behavioral state. Above a $T_b = 25\,°C$, hibernating mammals cycle through the range of electrographically defined behavioral states exhibited by euthermic mammals, although both total sleep and NREM sleep time increase while REM sleep time greatly diminishes. During the latter stages of entrance and deep hibernation, cortical activity declines so greatly that standard EEG criteria for state scoring cannot be used below a T_b of about 25 °C. Therefore, arousal state has been assessed in deep hibernation by a combination of thalamic single unit activity and alterations in electromyographic (EMG) activity. At T_b values above 25 °C, arousal states can be clearly distinguished by the activity of single units and the EMG. The same patterns of unit activity and EMG can be used to make arousal state distinctions at lower T_b values. Although the overall activity of thalamic neurons progressively declines as animals enter deep hibernation, spontaneous alterations in the activity of thalamic units and the EMG still occur. These observations have led to the conclusion that animals in deep hibernation (below $T_b = 25\,°C$) continue to cycle through electrophysiologically defined states that are believed to be comparable to euthermic NREM sleep and wakefulness, with NREM predominating. Although REM sleep appears to be completely absent during hibernation, REM sleep occurrence has not been directly addressed by unit studies of subcortical regions associated with REM sleep during hibernation. Thus, both behavioral and cellular neurophysiological studies suggest that a bout of hibernation is mostly, but not exclusively, homologous with NREM sleep.

Although the experiments described previously suggest that hibernation and NREM sleep may be controlled by similar neuronal mechanisms, recent experiments have led to the startling conclusion that animals are actually sleep-deprived during hibernation. The delta range of the EEG (approximate frequencies of 0.5–4 Hz) contains the slow wave activity and can be quantified using spectral analysis of the EEG. The spectral power in the delta range (EEG 'delta power') increases as a function of prior wake duration in many species, including humans, and declines monotonically during the sleep period. These observations have led to the idea that EEG delta power reflects the restoration from preceding waking activities which occurs during sleep. Based on the homology between NREM sleep and hibernation, EEG delta power would be expected to (1) be low right after arousal from hibernation and (2) increase during euthermia because of intervening wakefulness. Furthermore, it might be expected that the longer a hibernation bout, the less the need for subsequent recovery sleep.

The results obtained by two laboratories working independently on different hibernating species were contrary to expectations. Not only did NREM sleep predominate during the interbout periods of euthermia, but EEG delta power was maximal after arousal from hibernation. Delta power declined monotonically until the initiation of the next entrance. Moreover, the longer the hibernation bout, the greater the EEG delta power following arousal. Both the time course of EEG delta power and the high amount of NREM sleep during the interbout euthermic period suggest that animals are sleep-deprived during hibernation and that sleep restoration occurs during the interbout euthermic periods. Although NREM sleep and hibernation appear to be homologous in terms of neuronal control, one possible interpretation of these results is that the low temperatures of torpor might inhibit the underlying cellular and biochemical mechanisms of recovery sleep. Thus, one function of the periodic bouts of euthermia during the hibernation season might be to allow sleep restoration at normothermic brain temperatures. Since the neural bases of the sleep recovery mechanism(s) remain to be elucidated, hibernation should be a valuable model system in which to examine the biochemical and molecular bases of these processes.

Given the complex changes in behavior and physiology described previously, it is evident that mammalian hibernation must involve widespread changes in the activity of the nervous system. The neural events underlying the dramatic arousal state changes and physiological processes occurring during various phases of the hibernation cycle are of direct relevance to understanding arousal state control mechanisms. Depth EEG studies have revealed that brain regions become electrically quiescent in a replicable sequence during entrance into hibernation: the cortex becomes electrically quiescent first at a T_b around 20 °C, followed by

the thalamus and then limbic structures such as the hippocampus. Electrical activity is maintained in the hypothalamus throughout hibernation, whereas intermittent activity occurs in the amygdala. Lesion studies have indicated that the hypothalamus is an important brain region in the regulation of hibernation, as well as in euthermic T_b regulation. Thermoregulatory studies have demonstrated that the regulator of T_b located in the preoptic anterior hypothalamic (POAH) area is continuously reset during entrance to hibernation and remains active during deep hibernation. Pharmacological studies have also suggested that the hypothalamus plays an important role in regulating the entrance to, and arousal from, hibernation.

In order to obtain a more comprehensive view of neural activity during various phases of hibernation than is possible using conventional electrophysiological methods, a series of autoradiographic studies of cerebral metabolic activity was conducted using 2-[^{14}C]deoxyglucose (2-DG). In these studies, two brain nuclei underwent particularly remarkable changes in their metabolic activity relative to other brain structures. The paratrigeminal nucleus (PTN), a little-studied medullary region of unknown function, was the only brain region to significantly increase its relative 2-DG uptake in hibernation when compared to euthermia. A more extensive study across the entire hibernation cycle found that the PTN underwent a state-dependent increase in its relative 2-DG uptake as T_b declined during entrance to hibernation. Consequently, the PTN went from the least metabolically active nucleus during euthermia of the 96 brain regions examined to become the most metabolically active region in hibernation. Although the function of the PTN is unclear at this time, it has been proposed to have thermoafferent and/or chemosensory functions.

The suprachiasmatic nucleus (SCN) of the hypothalamus was the other brain region that underwent a remarkable change in its activity across the hibernation cycle. Like the PTN, the SCN also underwent a state-dependent increase in its relative 2-DG uptake and rank among metabolically active brain regions as T_b declined. The SCN are well known to regulate circadian rhythmicity in mammals and their activity during hibernation may represent maintenance of circadian function during this state. Indeed, circadian rhythms of T_b have recently been shown to persist in the ground squirrel and to be responsible for the timing of arousals, even in the apparent absence of action potentials within the SCN.

To obtain a global view of brain metabolic activity across the hibernation cycle, relative 2-DG uptake in 96 brain regions was measured across seven phases of the hibernation cycle. Statistical analyses revealed that the entrance to hibernation is mediated by two processes: an inhibition of activity in cortical regions and a relative activation of hypothalamic structures. These results are consistent with previous descriptions of a progressive decline in electrical activity in the cortex as entrance to hibernation proceeds and sustained electrical activity in the hypothalamus. In contrast, analysis of the 2-DG results revealed that the arousal from hibernation was primarily mediated by hypothalamic nuclei. Curiously, the four hypothalamic nuclei implicated in the arousal from hibernation are the SCN and three nuclei which receive efferent projections from the SCN. In summary, the entrance to hibernation involves both an inhibition of cortical activity and activation of hypothalamic regions whereas the arousal from hibernation is primarily a hypothalamic function. These results are consistent with those from lesion, physiological, and microinjection studies which have implicated the POAH region as being important in regulating hibernation.

In addition to the central nervous system (CNS), the parasympathetic nervous system appears to play an important role in the entrance to hibernation. Asystoles are commonly observed in the electrocardiogram during entrance to hibernation and can be blocked by intravenous administration of atropine. Whereas high doses of atropine can prevent hibernation from occurring, lower doses administered during hibernation produce a higher resting heart rate than in control animals, further suggesting an increased parasympathetic drive during entrance to hibernation. As the deep hibernation phase is reached, asystoles occur even in the atropinized animal, indicating a decrease in sympathetic drive.

Neurochemical studies of catecholamine levels are consistent with the notion of decreased sympathetic drive during hibernation. In five species studied to date, either no change or decreased levels of norepinephrine (NE) and epinephrine have been found in various brain regions during hibernation, although there is one report of increased levels of NE in the pons/medulla of hibernating *C. lateralis*. Plasma levels of catecholamines also decrease in hibernating woodchucks. Turnover studies indicate either a greatly decreased or complete cessation of catecholamine turnover in the hibernating brain. In contrast, catecholamines appear to play an important role in the arousal process. Both whole brain and hypothalamic NE levels increase during this phase of the hibernation cycle. Arterial infusion of L-DOPA results in arousal in the Turkish hamster; the rate of arousal in golden hamsters is retarded by injection of a tyrosine hydroxylase inhibitor. The crucial brain region for the involvement of NE in the arousal process may be the POAH since microinjections of NE into this area

during deep hibernation evoke a full arousal, whereas control injections into the midbrain reticular formation have no effect. Repeated injections of NE into the lateral ventricles facilitate the rate of arousal.

Changes in brain serotonin (5-HT) metabolism occur prior to and during entrance to hibernation. In the golden hamster, the 5-HT turnover rate increases 18 times in winter compared to summertime levels and increases even further in hibernation. Serotonin levels in several brain areas have been reported to increase greatly during entrance to hibernation. On the other hand, 5-HT levels during deep hibernation have variously been reported to increase, decrease, or not change, but the concentration of the 5-HT metabolite, 5-hydroxyindole acetic acid, has uniformly been found to increase, consistent with the notion of increased 5-HT turnover in this state. Depletion of endogenous 5-HT by injections of parachlorophenylalanine temporarily abolishes the ability to hibernate in the ground squirrel and destruction of at least 30% of the median raphe nuclei completely eliminates hibernation. Hamsters fed a tryptophan-rich diet to increase endogenous 5-HT levels spend a greater amount of time in hibernation. In the squirrel, these changes in serotonin metabolism may act directly upon the thermoregulatory system to decrease T_b, since intracerebroventricular (i.c.v.) 5-HT injections during the hibernation season activate heat loss and inhibit heat production mechanisms. Furthermore, repeated i.c.v. injections of 5-HT during arousal from hibernation slow the rate of arousal by increasing heat loss. Thus, 5-HT appears to promote entry to hibernation and interfere with arousal from this state by affecting thermoregulatory responses.

Acetylcholine (ACh) may be involved in the arousal process as microinjections into either the POAH or midbrain reticular formation can result in a full arousal. The hibernating animal shows a 'progressive irritability' to such ACh injections as a hibernation bout proceeds. Early in a bout, a given dose may have no effect, while the same dose administered progressively later in a bout may result in a thermogenic response or a full arousal to euthermia.

The hippocampus of the hibernator is exquisitely sensitive to injections of thyrotropin-releasing hormone (TRH). Doses as low as 0.1 ng result in arousal, whereas doses in the microgram range have no effect at control sites. Since TRH has been shown to inhibit neuronal activity in several systems, it is thought that TRH blocks the inhibition in the hippocampus normally characteristic of hibernation. Interestingly, microinjections of TRH into the hippocampus during the nonhibernating state have opposite effects on T_b and arousal state, depending on whether injections occur during wakefulness or slow wave sleep.

Endogenous opioids have also been implicated in hibernation. Intraperitoneal injections of naloxone and naltrexone shorten the hibernation bout. I.c.v administration of naloxone decreases bout length in a dose-dependent manner. Increased brain concentrations of both Met- and Leu-enkephalin occur in hibernating squirrels. Lastly, animals administered morphine during hibernation fail to develop physical dependence on morphine, suggesting that a higher proportion of opiate receptors are occupied by endogenous opiates during hibernation.

The pineal gland and its hormone melatonin appear to have different roles in permissive and obligate hibernators. Pinealectomy reduces the incidence of torpor in a photoperiodic species, *Peromyscus leucopus*, whereas melatonin administration increases torpor incidence. It has been suggested that these effects may be secondary to gonadal effects, since testosterone implants block hibernation in two other permissive hibernators, the Turkish and golden hamsters. In obligate hibernators such as the Richardson's and 13-lined ground squirrels, neither melatonin nor pinealectomy influence the incidence or duration of hibernation. However, the second hibernation season after pinealectomy is shortened in the pinealectomized golden-mantled ground squirrel; these animals also do not 'progress' into deeper bouts during the hibernation season. Hence, the pineal may be playing a role of phasing circannual rhythms in obligate hibernators. Interestingly, in the three hibernating species examined to date, the circadian rhythm of pineal or plasma-borne melatonin which peaks at night in the euthermic state is completely abolished during hibernation; melatonin levels remain low throughout a hibernation bout. This may be related to the fact that 2-DG uptake is high in the SCN during hibernation, since there is generally an inverse relationship between the rhythm of 2-DG uptake in the SCN and the rhythm of pineal melatonin.

The biochemical and molecular changes in organ systems which enable hibernation are likely to occur with two distinct time courses. Longer-term biochemical and endocrine changes that are preparatory for hibernation occur on a seasonal basis and have been documented in several organ systems; the numerous examples of involution of endocrine organs prior to the hibernation season are undoubtedly accompanied by major changes in gene expression. Once these seasonal changes in organismal physiology have occurred and the animal is fully prepared for hibernation, the occurrence of a bout of hibernation on any given day is likely to be accompanied by shorter-term changes in gene expression. It likely that shorter-term changes in gene transcription in the CNS are of significance in regulating the various phases of the

hibernation cycle. Because of their central role in regulating numerous downstream 'target' genes, initial studies of gene expression in the CNS across the hibernation cycle have focused on expression of immediate early genes (IEGs). The results published to date indicate a phase-dependent change in IEG mRNA expression in the hypothalamus across the hibernation cycle, with the greatest increases observed during the arousal phase. Furthermore, the anatomical resolution provided by *in situ* hybridization studies indicate that, within the hypothalamus, one locus of the increased c-*fos* expression is the SCN, the same region implicated by the 2-DG studies as undergoing a significant change in its metabolism during arousal. Molecular neurobiological studies of hibernation are likely to be fruitful avenues for future research.

The word 'hippocampus' is used in several different ways. One way is to describe portions of the nervous system of vertebrates that meet certain anatomic requirements, including the presence of 'double' pyramidal cells and interconnections with the septal area and the hypothalamus. In mammals, the area of the hippocampus is an anatomically 'primitive' cortical structure lying largely within the lateral ventricles of the brain. This intraventricular anatomic area is called the 'hippocampus proper' or 'Ammon's horn,' a term coming from the appearance of the dissected hippocampal formation in the human in which two large and distinctive areas spread out into the temporal lobes after meeting near the middle of the brain. This structure vaguely resembles the horns of a ram. Probably at some time in the Middle Ages or earlier, the name of the Egyptian god with a ram's head, Ammon, was given to what is now called the hippocampus.

Another way that the word hippocampus is used is as a loose description of a set of anatomic regions closely connected to the hippocampus proper and whose members have functional interactions with each other and with other brain regions. The best descriptive term for this collection of interconnected brain regions is really the 'hippocampal formation.' When the term hippocampus is used in this article, it refers to the hippocampus proper 'and' the dentate gyrus. Combining these closely related regions seems the simplest approach, even though some authors tend to consider the dentate gyrus as separate from the hippocampus.

In the mammalian brain, the hippocampus is prominent as a ridge along the internal edges of the lateral ventricles. These ridges occupy substantial portions of the lateral ventricles. In the human, the hippocampus is prominent from the anterior termination of the lateral ventricles near the most forward part of the temporal lobes to the merger of the lateral ventricles at the intraventricular foramen. Because of its large size and dorsal extension toward the center of the brain, the hippocampus should not be considered to be only a temporal lobe structure. This is significant because even the most extensive temporal lobe resections in the human that are undertaken for the relief of intractable epilepsy involve only the most anterior portions of the hippocampus, although they involve substantial portions of the hippocampal formation. A photograph of the human hippocampus as seen in a section through the temporal lobe is shown in Figure 1. Note the presence of substantial amounts of choroid plexus that exist in the lateral ventricles.

The hippocampus is a layered structure. Usually, it is considered to have between three and five layers of cells and fibers, depending on the criteria used for distinguishing layers. Myelinated axons cover its ventricular surface. As the hippocampus is exposed through the lateral ventricle during surgery, its surface appears shiny white because of the myelin coating of the axons on its outer surface (the alveus). Most of these axons are efferent from the hippocampal formation and combine to form the fimbria-fornix as they leave the surface of the hippocampus. The more compact tract of the fornix arises from the fimbria as the hippocampus diminishes in size near its dorsomedial termination above the thalamus. In this area, neuronal fibers from each side cross to the other in the hippocampal commissures.

In addition to the major portions of the hippocampus found adjacent in the lateral ventricle, in most mammalian brains, there are a few cells with 'hippocampal characteristics' found in the cortex below the genu of the corpus callosum (the anterior hippocampal rudiment) and a few such cells (the indusium griseum) scattered over the dorsal aspects of the corpus callosum. These areas are connected with the main parts of the hippocampal formation by a small group of fibers that are in, or stretch over the top of, the corpus callosum (the dorsal fornix and the stria of Lancisi).

Internal Structure

The most obvious internal features of the hippocampus are rows of densely packed neurons that are readily apparent in histological sections stained with common Nissl dyes or with noble metals. The cells in these rows have a characteristic appearance in many species. In mammals, the compact rows of cells that define the hippocampus proper begin suddenly at the boundary with the allocortex that forms the transition to the neocortex. Indeed, the areas that contain these distinctive rows of densely packed cells define the hippocampus proper. Other well-defined lines of cells are apparent in the granule cell layers of the dentate gyrus.

The prominent bands of closely packed cells that define the hippocampus proper and the dentate gyrus exist in rows or bands and range from three or four to more than ten cells deep. The width of the bands is

Figure 1 A photograph of a section through the side of the human brain at a level that cuts through the midsection of the temporal lobe. The hippocampus as it exists at this level is shown in the lateral ventricle and is marked by the black arrows. Just above the hippocampus a portion of the choroid plexus of the lateral ventricle can be seen. Adapted from an original photograph by Donald Dewsbury, University of Florida.

Figure 2 A drawing of the bushy dendrites processes of a 'double pyramidal' cell found in prominent rows through the CA1, CA2, and CA3 areas of the hippocampus. The cell body lies in the narrow middle of the dendritic arborizations that extend toward the outer surface and toward deeper layers of the hippocampus. Adapted from Freund TF and Buzsaki GY (1996) Interneurons of the hippocampus. *Hippocampus* 6: 347–470.

related both to the location within the hippocampus and to the species being examined. There is some evidence that there are 'gap junctions' (physical channels) connecting the internal contents of at least some adjacent cells. In the hippocampus, the large, principal cells found in distinctive bands are called pyramidal cells. Many of them differ from pyramidal cells found in the neocortex or other areas in that many of them have bushy dendritic arborizations extending from both the top and the bottom of the cell. These dendritic processes extend toward the surface and depths of the structure at right angles to the direction of the cell layer; they are called 'double pyramidal cells' (Figure 2).

The so-called granule cells of the dentate gyrus, the principal cells of that area, do not resemble the single or double pyramidal cells of the hippocampus. They are smaller, tightly packed cells arranged in a layered formation. These cells have dendritic 'bushes' that extend in only one direction: toward the outer, molecular layer of the gyrus. An illustration of a dentate granule cell is shown in Figure 3. Recently, multipotential cells, possibly stem cells, have been reported localized beneath the granule cells of the hippocampus. There is strong evidence that some of these cells have the ability to divide and differentiate in new neurons throughout life. They appear to differ from granule cells formed at the normal developmental period after birth in that have a rather limited life span. Their functional significance can not be determined at this time.

In mammals, the granule cells of the dentate appear as a U formation at the end of the band of hippocampal pyramidal cells called 'the hilar region.' The hippocampal pyramidal cells and interneurons become diffusely distributed in the middle part of the dentate gyrus.

Figure 3 A schematic drawing of a granule cell of the dentate gyrus drawn to emphasize the large number of synaptic contacts made on the dendritic arborizations that extends toward the molecular layer. As can be seen, the dendritic tree extends only in one direction. The areas reached by afferents from associational areas, including from related areas on the opposite side of the brain, and cells from the entorhinal indicate areas are indicated by arrows on the right side of the figure. The two broken horizontal lines near the bottom of the figure represent the approximate area of the granule cell layer. Adapted from Freund TF and Buzsaki GY (1996) Interneurons of the hippocampus. *Hippocampus* 6: 347–470.

The Labeling of Cytoarchitectural Areas in the Hippocampus

There have been many attempts to provide a useful nomenclature for the areas of the hippocampus and the dentate gyrus. Perhaps the simplest subdivision of the hippocampus is a division into a superior and an inferior region. The superior region begins with a compact band of cells that originates in the boundary area between the subiculum and the hippocampus. Progressing away from the transitional cortex, the band of pyramidal cells becomes somewhat broader and the cells a bit larger and more scattered. This marks the beginning of the inferior region, which continues until the band of cells breaks up into a diffuse group of cells in the middle of the dentate gyrus.

The anatomist Lorente de Nó divided the hippocampal pyramidal cell systems into four subfields. He gave each the prefix CA to indicate they were part of Ammon's horn (*cornu ammonis* in Latin): CA1, CA2, CA3, and CA4. In his system, the superior region is designated CA1, the inferior region CA3. Between CA1 and CA3 is a small region designated CA2. Region CA4 is the area of more diffused patterned large cells found in the open U of the dentate gyrus after the strict laminar pattern of pyramidal cells in CA3 has disappeared. This area is also known as the hilus (or hilar) region of the dentate gyrus.

There has been some question as to whether a CA2 region should be considered as distinct from the adjacent CA1 or CA3 areas. In stained sections of the adult rodent brain, it is difficult to detect a CA2 segment. However, ontogenetically, the CA2 region develops 2 to 3 days earlier than CA1 and CA3. It also shows a higher resistance to destruction by the administration of certain toxins than the adjacent CA areas. This implies that the CA2 area has some special qualitative or quantitative neurochemical differences from its neighbors.

Alternative descriptions of hippocampal areas have been offered from time to time, some of which are still used. One of these is that of the anatomist, M Rose, who in the late 1920s described the hippocampus in terms of 'h' areas. In his terminology, h1 is equivalent to CA1 and to a small portion of the transitional cortex leading into CA1, h2 is equivalent to CA2 and some adjacent regions of CA3, h3 and h4 to remaining regions of CA3, and hs to CA4. The h system is sometimes used by neuropathologists who use it to define the regions affected by damage due to epilepsy or ischemia. This usually involves the CA1 area and some nearby transitional cortex. This damage-susceptible region is sometimes called Sommer's sector. This term refers to the h1 area that includes CA1 and, in addition, some parts of the presubiculum and subicular regions. Some of these designations are illustrated in Figure 4.

The two limbs of the U of the dentate gyrus have been given separate names. Usually, that part of the U closest to the hippocampal fissure is called the 'suprapyramidal limb,' and the other limb, the 'infrapyramidal.' The hippocampal formation folds back on itself so that the outer (molecular) layer of the structure is continuous with the outer, molecular layer of the neocortex. This can be seen by following the outer, molecular layer (layer 1) in Figure 4 into the hippocampus. Note that at the hippocampal fissure, it merges with the molecular layer (stratum moleculare lacunosum) of the hippocampus. This is really the 'outer layer' of the hippocampus. Correspondingly, the stratum oriens is the deepest layer.

Regardless of the designations used, physiological differences are also found in regions of the hippocampus. Cells in the several CA areas and in the the two blades of dentate gyrus differ in their sensitivity to ischemia and certain neurotoxins, nature of membrane ion channels, responsivity to steroid hormones, and content of several types of neuron-related growth factors. Biochemical differences between areas also exist. As one example, immunocytochemical and *in situ* hybridization techniques indicate protein kinase Cα is more heavily concentrated in the pyramidal neurons of CA2 and CA3 than in CA1 pyramids, whereas the opposite profile exists for protein kinase Cβ. Many other genomic and biochemical differences have been noted between various hippocampal areas.

Distinctions within the Transitional Cortical Areas

The subiculum and the presubiculum are adjacent to the CA1 field of the hippocampus. These areas have a simple anatomic structure that becomes increasingly more complex at greater distances from CA1. Although some anatomists have made further subdivisions among subicular regions, the significance of these differences is doubtful. Farther away from CA1 and the subiculum, the cortex becomes increasingly laminated. This marks the beginning of the presubiculum. The presubiculum merges with the retrosplenial cortex (behind the caudal termination of the corpus callosum, the 'splenium') that is found between the presubiculum and the parasubiculum. The latter merges with the entorhinal area. As this transition occurs, the layers of the neocortical tissue become much more distinct. This region also contains a very dense fiber plexus in layers II and III.

Species Variations in Hippocampal Components

The cells in the various subfields of Ammon's horn and transitional cortical areas vary in amount and

Figure 4 A schematic diagram of a horizontal cross-section of a rat brain showing details of the hippocampal formation. Areas CA1, CA2, CA3, and CA4 refer to the designations of Lorente de Nó. The numbers in parenthesis with a preceding 'h' refer to subareas of the hippocampus used by M Rose. The 'S' and 'I' in the dentate gyrus refer to the superior and inferior blades of the granule cell rows. Str. l-m, stratum lacunosum-molecular; Str. rad, stratum radiatum; Str. or, stratum oriens; Str. pyram, pyramidal cell layer in the hippocampus; Parasub, parasubiculum; Presub, presubiculum; Prosub, prosubiculum; Sub, subiculum; Fiss. hippoc, hippocampal fissure. Alvear and perforant pathways are also shown. Adapted from figure 10-4 in Brodal A (1969) *Neurological Anatomy,* 2nd edn. Oxford: Oxford University Press.

shape at different places along the extent of the hippocampus. These changes in character and distinctness are altered over the course of development. There is also considerable variation in appearance and size of the cells among animal species. For example, the CA1 region in the human makes up about 50% of the volume of the hippocampus, whereas it makes up only about 25% of hippocampal volume in the rat. Because the number of synapses made in a cortical area is closely tied to the volume of that area, this suggests that the CA1 may be of greater functional significance in the human than in the rat. In primates, the main source of neuronal input to CA1 arises from neocortex, especially from areas closely related to the processing of sensory information. Despite quantitative differences, the primate CA1 retains essentially the same types of afferents from subcortical regions as are found in the rat. Cortical input to the rat CA1 is restricted to afferents from entorhinal and perirhinal transitional cortical areas. The suggestion is that input to the rodent CA1 is weighted toward information from subcortical systems. The relative expansion of the primate CA1 may reflect in increase in the amount of information coming from the 'higher centers' of the brain, that is, the neocortex.

The projections from the CA1 area are quite diverse. They include axons that reach the subiculum, the entorhinal area, the lateral septal area, portions of nucleus accumbens, the olfactory bulb, and several limbic areas of the forebrain.

Interneurons

Neurons that cannot be classified as pyramidal cells in the hippocampus or as granule cells in the dentate gyrus generally are grouped together as interneuron's. Almost all of these cells synthesize γ-aminobutyric acid (GABA) and use it as their primary transmitter substance. Their terminals generally end on GABA receptors that have inhibitory actions on the recipient cells. This has led the to the use of an alternate descriptive term for interneurons: 'GABAergic nonprincipal cells.' Within the past few years, it has become apparent that these cells play crucially important roles in all hippocampal activities and in activities in many other brain areas as well. The wide rage of interneuron cell types and their many extensive and diverse patterns of dendritic and axonal projections require a re-evaluation of hippocampal functions. Examples of the diversity of such projections are shown in Figure 5.

In the rat, and likely in other species as well, about 10% of the neurons in the hippocampus are interneurons. These cells exert inhibitory influences on the pyramidal cells in the structure of both nearby cells and othrers at a considerable distance. It seems likely that a significant number of axons from the interneurons extend beyond the hippocampus proper into areas of the hippocampal formation and beyond. Interneurons can be found throughout the hippocampus. Although many are diffusely scattered throughout the hippocampus, they also can be found mixed in with principal cells in all the CA and dentate granule cell regions. Although interneurons make up only 10% of the neurons in the hippocampus, the physical extent of the distributions of their neural processes and the number of synaptic contacts made by each cells makes their influence of staggering importance. For example, some axons of interneurons of the CA3 area have axons that extend to more than 50% of the hippocampus and make contact with between 20 000 and 60 000 other cells.

Some of the interneuron axons make contact with the initial segments of axons arising from principal cells in the hippocampus. These are called 'chandelier cells.' Their axons form synaptic contacts with the axons of principle cells after running parallel to these axons for some distance. These cells help regulate the axons of the principal cells and by so doing influence their output. Another major group of interneurons are basket cells. The processes of these cells surround the soma and basal dendrites of other cells, both principal cells and other interneurons. Axons of types of interneurons also access the cell bodies and portions of dendrites of other interneurons.

Interneurons are remarkable in their biologic makeup as well. Although virtually all synthesize and utilize

Figure 5 A drawing of the hippocampus and 15 interneurons of different types. It shows the extensive distributions of axonal and dendritic arborizations of these cells and their extensiveness through many different areas of the structure. The lines representing dendrites are thicker than lines representing axons. a, alveus; s.o., s.p., s.r., s.l-m, strata oriens, pyramidale, radiatum, and lacunosum-moleculare of the hippocampus; s.g, s.m, h, strata granulosum, moleculare, and hilus of dentate gyrus. The CA subfields are as described in the caption for Figure 4. From Freund TF and Buzsaki GY (1996) Interneurons of the hippocampus. *Hippocampus* 6: 347–470. figure 18, p. 382.

GABA for transmission purposes, many other proteins and peptides are colocalized with them. These include several types of calcium binding proteins, neurotrophic factors, neuronal nitric oxide synthase, and many of the peptides known to have importance synergistic activity with neuronal transmitters throughout the brain (e.g., cholecystokinin, substance P, and the enkephalins, somatotropin, vasoinhibitory peptide, and neuropeptide Y). Interneurons have receptors for many different transmitters, including muscarinic and nicotinic receptors for acetylcholine.

One mystery that remains unresolved is how can small groups of neurons in the brain have such profound and wide effects throughout the structure. For example, the cells of origin of all of the biogenic amines are relatively few and are generally localized to relatively small areas. Despite this, they influence activities throughout the brain. It is possible that they do so because their primary targets in the brain are interneurons, including those of the hippocampus, whose neural processes extend so widely. Although the importance of inhibitory neurons in the brain has been discussed for many years, it is only recently that the actual anatomy and physiology of the systems has been elaborated.

A systems Analysis

The Temporoammonic System

The entorhinal cortex is an important source of neocortical input to the hippocampus and provides most of the neocortical input to the hippocampus in rodents. Neuronal pathways originate from cells in all major sensory regions of the neocortex and converge in the entorhinal region, albeit by indirect routes. The entorhinal cortex may be thought of as modulating hippocampal activity on the basis of neocortical activities. Efferents from the lateral entorhinal areas reach the outer portions of the dendrites in the molecular layer of the dentate gyrus. Efferents from the medial portions of the entorhinal cortex reach the middle zones of the dentate. These entorhinal-dentate gyrus connections are called the 'perforant paths.' The axons in the perforant paths are generally glutaminergic and excitatory in function. Axons from the granule cells, in turn, give rise to the 'mossy fiber' system, which is made up of thin axons arising from the granule cells of the dentate gyrus that terminate on the proximal dendrites of neurons in the CA3 region. Axons from cells in the CA3 area leave the hippocampus via the fimbria and fornix, largely terminating in the lateral septal area. However, branches of these efferent axons form the Schaffer collateral system that project to dendrites of the CA1 neurons. Neural outputs from the CA1 cells then exit into the alveus and join the fornix, projecting on the one hand to the septal area and, on the other, to the subicular region. The major output of the hippocampal formation over the fornix system to the forebrain areas arises from subicular areas. Efferent fibers in the fornix distribute to many locations including the nucleus accumbens, the anterior and lateral nuclei of the thalamus, the lateral and preoptic hypothalamic areas, the mammillary bodies, the arcuate and ventromedial hypothalamic nuclei, and the bed nucleus of stria terminalis.

This description of the passage of activity from the entorhinal area through to the subiculum is much oversimplified. For example, some axon collaterals from the granule cells of the dentate and from principal cells in CA3 and CA4 actually turn back to reach dendrites in the outer portions of the molecular layer of the dentate gyrus. There is much yet to be learned about the finer connections among the principal cells.

The principal cells in the CA4 region of the hippocampus, the hilar area, are scattered throughout the area within the U formed by the blades of the dentate gyrus. Many of the larger cells play an important role in modulating activity in the dentate gyrus and in the CA3 region. They are thought to be 'misplaced' pyramidal cells. They are glutaminergic and produce excitatory effects on neurons with which they are connected.

Activity arising from neurons in the entorhinal cortex may or may not progress in a linear fashion through these hippocampal circuits. Whether information reaching the dentate gyrus gets forwarded to the next stations, such as CA3 and CA1, depends on the activity occurring in the hippocampus when the afferent signals arrive. Transmission through this multisynaptic circuit seems least impeded during slow-wave sleep but is restricted at particular points along the pathway during waking states and rapid eye movement sleep. Transmission through the hippocampal formation depends in great part on how each 'station' along the way is being modulated by the diverse influences acting on them.

The Hippocampus as a Chemical Sensor

It is likely that the hippocampus evolved from the same primary sensory epithelium as did the olfactory system, although in living mammals, it is physically remote from the primary odor recptors. Some investigators have suggested that the hippocampus may have turned from the detection of air-borne chemicals to those carried by the certain fluids of the body, including the blood and the cerebrospinal fluid. It is a structure that is well suited for the detection of

changes in the makeup of cerebrospinal fluid because it lies within the lateral ventricle and close to the choroid plexus. It is possible that the hippocampus can detect such chemical changes and can initiate events that are likely to restore an optimal composition by influencing biologic and behavioral actions. Supporting this hypothesis is the fact that receptors for more than 60 hormones, peptides, metabolites, and other chemical ligands of importance have been found in the hippocampus. It has more of these sorts of receptors than any other brain area.

Modulation of Hippocampal Activities

Modulation of activities in the hippocampus and in the 'neural chain' that begins at the entorhinal cortex and runs through the CA areas to the subiculum may occur through influences mediated by the diffusely projecting biogenic amine systems, afferent cholinergic influences, and both localized and systemic neuropeptide and hormonal systems. There are vast numbers of potential modifying influences. Norepinephrine, serotonin, histamine, VIP, cholecystokinin, substance P, somatostatin, the enkephalins, and the hypocretins influence neuronal activity in the hippocampus. In addition, a significant dopaminergic input arising primarily from the ventral tegmental area reaches the hippocampus and the entorhinal cortex.

The substantial norepinephrine projections received by the hippocampus come from cells in the anterior part of the locus coeruleus. These cells are the sole source of the noradrenergic input to the hippocampus, but collaterals of these locus coeruleus cells reach other areas, including the neocortex, thalamus, and spinal cord. Some cells in this nucleus project bilaterally to the hippocampus. The serotonergic fibers that reach the hippocampus arise in large part from the median raphe cell group of the brain stem. Some fibers also reach the hippocampus from the dorsal raphe. These fibers terminate in the dentate gyrus and reach the molecular layers of the CA1 and CA3 to a greater extent than do noradrenergic fibers.

Septohippocampal Interactions

The hippocampal formation and the septal area are reciprocally connected. Principal neurons of the medial septal area and the diagonal band of Broca project to the hippocampus, and neurons of the hippocampus project to the lateral septal area. The projections from the septal region and the diagonal band to the hippocampus are predominately cholinergic and GABAergic. Both are frequently co-localized with various peptides and calcium binding proteins. Based on choline acetyltransferase histochemistry, the cells containing acetylcholine that project to the hippocampus are located in the medial septal area and both the vertical and the horizontal limbs of the diagonal band of Broca. There is a topographic pattern to this projection such that axons originating from the medial septal nucleus and the ventromedial diagonal band enter the fornix and the fimbria, whereas axons originating in the dorsolateral diagonal band reach the hippocampus via the supracallosal stria. The former axons terminate in the anterior three quarters of the hippocampus, and the latter axons terminate in the temporal regions of the hippocampus. Additionally, it is likely that some axons from both pathways terminate in the subiculum and the entorhinal cortex. Although differences in projection patterns exist between individuals and among species, the cholinergic cells of the basal forebrain should probably be regarded as part of a single system, the medial septal area and the diagonal band being continuous with the cholinergic cells of the ventral pallidum and the lateral hypothalamus. To a limited extent, these regions also contribute to the cholinergic innervation of the hippocampus. It is generally agreed no neurons in the hippocampus synthesize acetylcholine. Both the cholinergic and the GABAergic projections to the hippocampus significantly influence the electrical rhythms generated in the hippocampal formation and the overall excitability of the neurons in the structure.

One of the most intensively studied biologic characteristics of the hippocampus, and one that likely exerts a strong modulatory influence on its functions, is the binding of corticosteroids to membrane, cytoplasmic, and nuclear sites of its cells. Both mineralocorticoid and glucocorticoid receptors are found in large numbers in cells in the hippocampus. The net effect of the adrenal steroids on hippocampal function likely depends on the relative occupancy rates of the two receptor types. Adrenalectomy results in impaired performance in behavioral tests, some of which are similar to impairments found after hippocampal damage. However, adrenalectomy produces a highly unusual condition in which both glucocorticoids and mineralocorticoids are largely or entirely absent. Behavioral and functional anomalies are found with both abnormally high and abnormally low adrenal corticoid hormone levels.

Electrical Rhythms of the Hippocampus

In rodents and certain other species, a number of different types of electrical activities can be recorded

from the hippocampus. Probably the most intensively studied hippocampal electrical rhythms are those of steady oscillations that are very regular and of high amplitude. Rhythmic slow activity (RSA) in the rat that varies from 5 to 10 Hz is known as the theta rhythm. This frequency RSA is not in the frequency range of the theta rhythm described in the human. In people, theta rhythms are considered to be oscillations in the 4–7 Hz range. In the rat, theta rhythms, as well as the faster beta (15–50 Hz) and gamma rhythms (40–100 Hz), are observed during directed movements and during rapid eye movement sleep. During periods of immobility, consummatory behaviors and slow-wave sleep, bursts of very rapid neuronal discharges occur that can be called 'sharp-waves' and abbreviated as 'SPW.' Recently, ultrafast rhythms (>60 Hz) in dense dentritic areas of the hippocampus have been subjects of investigation. The oscillations of electrical rhythms in the hippocampal neurons are controlled by the activity of networks of inhibitory interneurons. In addition, ultra-slow oscillations in the excitability of hippocampal neurons have been reported in the rat, and similar changes have been noted in some human patients with epilepsy. Peak-to-peak periods of 40–50 s have been observed. Evidence from animal studies indicates these slow changes originate in neocortical areas and are projected to the hippocampus by relays in the entorhinal cortex.

A significant pacemaker for RSAs of the theta frequency in rats comes from the medial-basal forebrain cholinergic systems. However, although medial septal lesions abolish RSAs, not all RSAs in the freely moving animal depend on cholinergic activities. Atropine, for example, abolishes RSAs only under certain circumstances. A separate, noncholinergic source of RSAs probably comes from the entorhinal cortex. It is possible that some RSAs are produced by cholinergic fibers that are directly exciting inhibitory interneurons, whereas entorhinal input directly excites interneurons of the hippocampus to produce RSAs.

At one time, it was thought that certain frequencies of rhythmic activities were closely tied to certain behaviors being exhibited by the animals. However, it now seems that the rhythmic activity of different forms can occur during various behaviors and probably are a method of coordinating activity among the principal neurons of the hippocampus and among various neuronal nets of the interneurons. However, any universal association between electrical activities and behavior is questionable because many species differences exist in the occurrence of RSAs. They are seldom observed in humans or nonhuman primates but are quite variable among members of some species.

Functional Considerations

Based on observations of patients with temporal lobe epilepsy and especially since the late 1950s, it has been popular to associate damage to the hippocampus with some forms of memory disturbances. This is due in large part to the remarkable recent memory deficiencies found in a patient of Dr. William Scoville, case H.M. While in his 20s, this patient underwent bilateral temporal lobe extirpations for the relief of intractable temporal lobe epilepsy. Ever since, he has demonstrated an extreme form of recent memory loss, a loss far more extreme than that found in any other patient who has undergone temporal lobe surgery for the relief of this disorder. Recent memory loss and some forms of amnesia after temporal lobe damage is most likely to be the consequence of damage to temporal lobe tissue medial and ventral to the hippocampus. Damage to the hippocampus, itself, may not be the critical insult. The actual lesion to the hippocampus in case H.M. was far less than originally reported, and equivalent damage in at least one other patient did not produce a similar memory impairment. Studies with nonhuman primates also indicate that destruction of the hippocampus and/or the amygdala also fails to produce memory anomalies, whereas damage to parahippocampal regions does.

Despite current beliefs associating the hippocampus with memory, either in information storage or in retrieval, a necessary association between the hippocampus and memory is not likely in people or in experimental animals. In rats, the idea that the integrity of the hippocampus is essential for the effective use of spatial information in certain kinds of test situations has been popular for many years. Nevertheless, after complete destruction of the hippocampus in rats, the animals are able to use many kinds of spatial and contextual information for the attainment of desired goals. Still, it is certain that there will be a continuing discussion of the role of the hippocampus in the use of acquired information for many years to come. What is certain is that no single theory has been found to adequately explain all of the available experimental and clinical results.

At the present time, the functional contributions of the hippocampus to mental and behavioral phenomena remain obscure. As we learn more about the functional contributions of the neocortex, basal ganglia, and other neural structures, the contributions of the hippocampus may become clearer.

Hippocampus and Neural Representations

Discovery of Place Cells

Hippocampal representations have been associated with bodily spatial location almost since the first single cells were recorded from this brain area. In 1971, O'Keefe and Dostrovsky reported that a major proportion of complex-spiking neurons in the rat hippocampus had spatial receptive fields. These 'place cells' fire when the rat is in a particular place in its environment (the 'place field' of the cell), but are virtually silent when the rat is in other positions (Figure 1). Firing rates in the place field are often 10–100 times higher than the background rate. Place fields reflect the animal's location as such and not the behaviors emitted at these locations. Different cells have place fields at different places and collectively they cover the entire test environment. Unlike neurons in the sensory cortices, place cells in the hippocampus have nontopographic firing correlates: place fields of neighboring cells are apparently not closer than those of distant cells, and all places seem to be represented within local place cell ensembles in any part of the hippocampus. The size of the place fields appears to increase, however, as recording positions shift from the septal to the temporal pole of the structure.

The discovery of place cells led O'Keefe and Nadel to suggest that place cells form a distributed maplike representation of the spatial environment and that the animal can use this 'map' for navigation. Spatial firing in the hippocampus was thought to reflect the integration of inputs from a general metric navigational system, possibly outside the hippocampus, with stimuli that were specific to the environment. The metric system might maintain a dynamic representation of the animal's position by constantly integrating the distance and direction of its own movement, a process now referred to as path integration. A number of studies from McNaughton and others have supported a role for path integration in the control of firing location in hippocampal place cells. They showed that place fields were, under some conditions, determined primarily by the animal's movement. When a rat was released from a movable start box at an unpredictable location on a linear rail with a fixed goal at the end, place cells fired in relation to the distance from the start box for the first few seconds, before the external visually dominated reference frame took over. These studies imply that output from a path-integration mechanism is sufficient to drive place-selective firing in the hippocampus, although the place-field map is normally calibrated against the external landmarks of the environment. The locations and mechanisms of these proposed computations were not known at the time when O'Keefe and Nadel proposed their 'cognitive map' theory for the hippocampus. An important step toward the identification of the underlying computations was taken in 1984, when Jim Ranck reported the discovery of another component of the brain's navigational system, the head-direction cell, in the dorsal presubiculum. Its extrahippocampal location suggested that spatial representation and navigation might depend on a widespread brain circuit.

Place Cells – More Than Place

During the decades that passed after the discovery of place cells, it became apparent that hippocampal neurons respond to a number of influences, some of which are not associated with particular locations in the environment. Eichenbaum and colleagues showed that hippocampal neurons may fire in response to specific odors, regardless of the location where the odors were encountered, and Deadwyler and colleagues found hippocampal neurons that fired only during specific phases of an operant delayed-nonmatching task, even when the rat was more or less in a constant place. Many of these neurons may have exhibited place-specific firing in addition, but the studies clearly suggested that nonspatial information was represented as well. These findings implied that the hippocampus must represent experience more broadly, with spatial location being only one dimension of the memory stored in the hippocampal network.

Place cells do not merely mirror the spatial and nonspatial sensory input that the animal receives. At least three types of observations point to a role for intrinsic dynamics in the control of hippocampal firing patterns. First, place fields develop slowly. When a rat enters a new environment, place fields stabilize only after some minutes, at a much slower rate than the rate at which sensory information about the specific features of the environment is passed to the hippocampus. Second, changes in place fields cannot be predicted from the amount of change in the physical properties of the environment. Place fields are often maintained after significant landmarks are removed

Figure 1 Place cells in the hippocampus. The firing fields of three place cells are shown, either as maps of the recording enclosure with spike locations (red) superimposed on the animal's trajectory (black) (left), or as color-coded rate maps in the same enclosure (right). The color scale is from blue (silent) to red (peak rate). Peak rates are 10–20 Hz.

from the environment, and if an animal is first trained in two different environments, and one of them is then smoothly transformed into the other, animals quite often keep the representation from the first environment throughout the test sequence, suggesting that firing is determined more by the history of testing than by the actual sensory stimuli impinging on the animal. Third, different locations in the environment are represented by different numbers of active cells; some places are associated with more neuronal firing than are others. In enclosed chambers, place fields appear to be somewhat more common near edges and walls than in the center, and in environments with distinct reward locations, a larger number of cells may have activity fields at the goal location than at other locations. Taken together, these observations suggest that hippocampal neurons do not only map the physical structure of the environment, but also express information about stimuli and events that the animal experiences or has experienced there.

Recent studies have raised the possibility that hippocampal cell assemblies, especially in the CA3 subfield, have different coding schemes for locations and stimuli or events associated with the locations. Global remapping, expressed as a complete redistribution of firing locations and firing rates among simultaneously recorded place cells, is nearly always induced when an animal is moved between two distinct locations. Under some circumstances, global remapping may be induced also at a single location, presumably when the defining features of the local environment change rather extensively. Rate remapping, in contrast, is expressed as a redistribution of the firing rates without an accompanying change in the preferred firing locations of the hippocampal neurons. This form of remapping is often induced after replacement of a salient cue in an otherwise constant environment. The presence of such apparently independent coding schemes suggests that spatial and nonspatial information may be expressed by the same neuronal populations. Changes in spatial location are represented as changes in firing fields, whereas changes in cues within an environment are represented by changes in firing rate. The combination and integration of spatial and nonspatial information in the output from the hippocampus may form the neural basis for the role of the this brain region in episodic memory.

Attractor Dynamics in the Hippocampus

One of the greatest challenges of the brain's episodic memory system is to recognize and encode a novel input without causing interference with other items that are already stored in memory. Each day we meet friends and colleagues in a variety of contexts, but we generally recognize them as the same individuals even when we do not see details because of poor illumination or when their identity is masked by sunglasses, a hat, or new clothes (Figure 2). With such an extraordinary ability to generalize, how can the brain at the same time identify an unfamiliar person as distinct from the wide variation around templates already stored in memory? Theoretical models have suggested that the right balance between fault tolerance and prevention of interference can be reached in a dynamic attractor-based type of neural network.

An attractor network has one or several preferred positions or volumes in state space, such that when the system is started from any outside location, it will evolve until it reaches one of the attractor basins. It will then stay there until the system receives new input. In a neural network with such properties, stored memories (the preferred positions of the

Figure 2 Schematic illustration of attractor dynamics. During retrieval, inputs to the hippocampus converge to one of several preestablished patterns, yielding a similar output for a range of input values (pattern completion). At the same time, they diverge away from other interfering patterns (pattern separation). The nonlinear nature of this process can be illustrated by the fact that multiple images of the same face are recognized as variants of the same person (one of the authors) but as different from images of another person (the other author), even when a number of cues are shared. The nonlinearity of the process (the absence of an intermediate representation) is consistent with the idea that the two faces are represented by discrete attractor states. A similar nonlinearity is thought to be reflected in the firing of hippocampal place cells, as illustrated by the sharp transition between ensemble representations under some test conditions. (Top and bottom rows) Reproduced from Leutgeb JK, Leutgeb S, Treves A, et al. (2005) Progressive tranformation of hippocampal neuronal representations in 'morphed' environments. *Neuron* 48: 345–358, with permission from Elsevier.

system) may be recalled from degraded versions of the original input. This is referred to as pattern completion. At the same time, the retrieved pattern is not mixed up with other memories (other preferred positions) in the same network. This reflects a process referred to as pattern separation. There is considerable evidence for both pattern completion and pattern separation in the hippocampus. Pattern completion is expressed in place cells as persistent firing in the cell's place field after removal of a significant subset of the landmarks that originally defined the environment. Taking away a cue card or turning off the room lights, for example, rarely causes much change in the firing locations of hippocampal place cells. Pattern separation is expressed in place cells as the tendency to undergo 'remapping' after only minor changes in the sensory input, such as a change in the color or the shape of the recording enclosure. Remapping is a property of the cell population; when remapping occurs, it is generally expressed in all place cells.

In agreement with attractor network models of the hippocampus, place cells show abrupt shifts between representations under conditions where inputs change to the point where a different representation provides a better match to the inputs experienced by the animal. O'Keefe and colleagues trained rats in a square and a circular version of a morph box with flexible walls, until place cell representations in the two environments were very different. The rats were then exposed to several intermediate shapes. A sharp transition from squarelike representations to circlelike representations was observed near the middle between the familiar shapes, as predicted if the place cell network had discrete attractor states corresponding to these

shapes. Discrete attractors may not be ideal for storing sequential information, however. If hippocampal networks consisted exclusively of discrete attractors, the ensembles would probably fail to encode the continuous stream of information that is characteristic of experience; the network might not be able to maintain a unified representation of the flow of experience if it fluctuated between preformed states whenever the input was intermediate to any set of previously stored conditions. Recent observations suggest that under conditions where the spatial reference frame is constant, place cells assimilate gradual or moderate deviations in the input into preexisting representations. Stable states can be attained along the entire continuum between two preestablished representations in a single context. This ability to represent continua may allow hippocampal networks to encode and retrieve consecutive inputs as uninterrupted, distinguishable episodes.

Anatomical Location of Attractor Networks

While hippocampal cell ensembles have been known for a while to exhibit some of the key features of an attractor network, the anatomical location of the attractors is just beginning to be unfolded. Attractor dynamics may originate in one of the densely interconnected networks of the hippocampal formation, or these properties may be imposed on hippocampal neurons by other brain areas. Somewhat paradoxically, until a few years ago, nearly all knowledge about hippocampal ensemble dynamics came from population recordings in the CA1 subfield, probably because of the relative ease with which this area could be accessed. Theoretical models of hippocampal function, however, were generally based on the neural architectures of the dentate gyrus and CA3, their dense and modifiable recurrent circuitry, their specific interconnections, and the sparse firing of principal neurons in these networks. Recordings in CA1 might pick up the results of neural computations in these subfields, but because place-selective firing in CA1 is also controlled by direct input from the entorhinal cortex, the use of CA1 as a window to the attractor dynamics of the hippocampus is somewhat questionable.

In the hippocampal formation, the most extensively interconnected associative network is found in CA3. Widespread collaterals interconnect pyramidal cells along nearly the entire length of the subfield. On average, each pyramidal neuron makes synapses with as many as 4% of the pyramidal cells in the ipsilateral CA3, and more than three quarters of the excitatory synapses on a CA3 pyramidal cell are from other CA3 pyramidal neurons. These recurrent synapses show long-term plasticity, allowing the formation of an extensive number of possible cell assemblies in the network. The possibility that attractor dynamics originates in CA3 is supported by a growing body of experimental evidence. The CA3 matrix performs both pattern completion and pattern separation. Pattern completion is apparent in CA3 pyramidal neurons as a remarkably persistent and coherent firing map after removal of significant parts of the original sensory input. *N*-Methyl-D-aspartate (NMDA)-receptor-dependent plasticity in CA3 is necessary for the ability to retrieve spatial memories from small subsets of the cues that originally defined a target location. Pattern separation is apparent in the same network as a nearly complete replacement of the active cell population when animals move between enclosures with common features. Representations in CA3 may undergo complete orthogonalization under conditions where place cells in CA1 retain considerable similarity.

Although the CA3 is by far the most densely interconnected structure of the hippocampal formation, recurrent connections exist also in other subfields. Granule cells in the dentate gyrus, for example, form synapses on the proximal dendrites of the hilar mossy cells, which in turn have excitatory synapses on the dendrites of the granule cells in the molecular layer. Pyramidal cells in the subiculum have extensive axon collaterals that terminate on other pyramidal cells across a substantial part of the subiculum. The degree of interconnectivity in these subfields, as estimated by the number of locally distributed axon collaterals and the density of varicosities on them, is lower than in CA3, however, and it is conceivable that CA3 is responsible for much of the attractor dynamics thought to underlie hippocampal memory.

The Origin of Pattern Separation

A critical step in the encoding of a new episodic memory is the minimization of similarities between the new representation and representations that already exist in the network. When this decorrelation, or pattern-separation, process fails, and the same retrieval cues get associated with multiple episodic memories, retrieval breaks down. Rats with lesions in the hippocampal formation specifically fail to discriminate between contexts or locations with different reinforcement histories when the test stimuli are highly similar. This suggests that a neuronal pattern-separation mechanism may be located in this brain region, but the origin within the hippocampal circuitry has not been determined.

The strong orthogonalization of place-field representations in area CA3 suggests that a major function

of the early stages of the hippocampal formation may be to enhance small differences in information coming into the hippocampus, such that memories can subsequently be stored with minimal overlap. However, although pattern separation is expressed in CA3, theoretical models have for a long time pointed to the dentate gyrus, one synapse upstream, as a more likely origin of pattern separation in the hippocampal formation. These models were, to a large extent, based on analogies between the granule cell layers of the hippocampal formation and the cerebellum. The circuit architecture of the cerebellum provided the first clues about how the brain might decorrelate or orthogonalize inputs. As proposed by David Marr almost 40 years ago, in the cerebellum, incoming sensory information is projected onto an expanded intermediate layer of granule cells before the information reaches the associative synapses of the Purkinje cells. The number of cerebellar granule neurons by far exceeds the number of the input neurons in the brain stem. This allows different incoming signals to be dispersed onto largely nonoverlapping cell populations, such that each granule cell carries only a small and distinct fraction of the total information passed into the network over a period of time. Combined with the sparse firing of the granule cells, the divergence is thought to enable efficient decorrelation of overlapping input patterns. A similar recoding mechanism was later proposed to exist for the hippocampus. Like in the cerebellum, input is spread out on an expanded intermediate layer of granule cells. The number of granule cells of the dentate gyrus is about 5 times larger than the number of afferent projection neurons in layer II of the entorhinal cortex (approximately 1000×10^3 vs. 200×10^3, respectively, in the rat). In addition, the firing of the granule cells is sparse and each granule cell makes synapses with only a limited number of CA3 pyramidal cells, suggesting that a combination of mechanisms might potentially contribute to decorrelation of cortical information in the dentate gyrus. Whether these hypothetical mechanisms represent the origin of pattern separation in the hippocampus remains to be determined.

Off-Line Activity in Place Cells

After the initial encoding of new information, memories are thought to undergo further consolidation off-line when the subject is engaged in other activities. Although much of this activity appears to take place during slow-wave sleep, the specific cascade of events that leads to consolidation of hippocampal memory is not well understood; little is known about whether consolidation has distinct stages, and, if is has, which brain areas and which neuronal computations are involved in each stage. Ensemble recordings from the hippocampus in sleeping rats provide some clues. Cells that are coactivated in the hippocampus during awake behavior exhibit correlated firing during sleep episodes subsequent to the behavioral session. The order of firing is similar but the sequence is replayed at a faster rate. This form of reactivation is temporally specific. It is strongest shortly after behavioral experience and decays during subsequent hours. Reactivation is associated with sharp waves, which are bursts of synchronous activity in hippocampal pyramidal cells during slow-wave sleep and awake rest. These bursts have the capacity to induce plasticity in downstream areas and may therefore potentially be involved in the consolidation of long-term memory within the hippocampus or in the neocortex.

Although reactivation during sleep may provide a mechanism for consolidation of recent memories, the delay between behavior and sleep is often too long to account for the fact that memories are maintained for hours or more independently of whether subjects get an opportunity to take a nap. Recent studies have indicated that replay may also take place during 'interleaved' sharp waves in the waking states, when the animal is resting, eating, drinking, or just stopping briefly as it is exploring the environment. During such 'interleaved' sharp waves, spikes are replayed in reverse order. When a rat is running on a linear track, for example, place cells fire in a certain order as the animal runs across the track. As it reaches the end of the track, where food is available and the rat stops to eat, sharp waves appear and the cells that were active on the track begin firing. The order of firing is backward with respect to the order of firing on the track. Reverse replay may facilitate the storage of behavioral sequences that lead to rewards, and this may take place only seconds after the experience is first imprinted as a pattern of activity in the hippocampal network.

Sequence Coding and Temporal Organization in Hippocampal Representations

The Hebbian postulate for how associations occur in the cortex, through correlated presynaptic and postsynaptic activity, confers a temporal constraint on how neuronal activities can mediate memory encoding. If Hebb's theory is right, areas involved in these processes must be in temporal synchrony during encoding. Hippocampal networks display characteristic oscillatory activity during spatial learning, but the exact significance of temporal firing and coherence patterns is not yet understood. One of the most intriguing observations is the compression of spike sequences into individual theta cycles during phase

precession in hippocampal place cells. Phase precession refers to the fact that as an animal moves through the place field of a cell, the cell fires at a progressively earlier phase of the theta cycle. Because of this precession, the sequence of firing in a set of place cells is reflected at a compressed timescale within each individual theta cycle. This mechanism orders the spiking of sequentially active neurons within the time range of spike-dependent plasticity, and so may result in associative storage of sequences that are longer than a single cycle of the theta oscillation.

Place Cells – Where Do They All Come From?

Place cells exist in all subfields of the hippocampus and in the dentate gyrus, the subiculum, and the entorhinal cortex. The most specific and confined firing fields are observed in the hippocampus proper. The first single-unit recording studies in the subiculum and the entorhinal cortex in the early 1990s reported quite dispersed firing fields, although only limited parts of these regions were sampled. Based on the striking contrast between the weak spatial modulation of entorhinal input neurons to the hippocampal formation and the high spatial information content of principal neurons in the hippocampus, investigators thought that place-specific firing originated from computations within the hippocampal network, presumably in the dentate gyrus and the CA3. This view was challenged, by the observation that CA1 neurons exhibit place-specific firing even after relatively selective lesions of the dentate gyrus or the CA3. These lesions interrupted the trisynaptic circuit, such that all remaining excitatory input to CA1 must have been mediated by the direct perforant-path input. Place fields in CA1 of animals with CA3 lesions were slightly broader than in untreated animals, but the firing was still confined to quite small regions of the area that the animal explored, suggesting that the spatial information might not originate within the hippocampus itself. These studies were followed by work showing that neurons have strong spatial correlates also upstream of the hippocampus, in the medial entorhinal cortex, the major interface between the hippocampus and the neocortex. Many principal neurons in this brain area were shown to have multiple sharply tuned firing fields that collectively signaled the rat's constantly changing position with the same precision as place cells in the hippocampus. The sharpest firing fields were observed in the dorsocaudal part of the entorhinal cortex, which contains the bulk of the entorhinal neurons projecting to the well-characterized place cells of the dorsal hippocampus. As the electrodes were moved toward more ventromedial parts of the entorhinal cortex, the firing fields became wider and more dispersed; in the intermediate-to-ventromedial bands, where most of the earlier recordings were made, neurons fired almost in the entire recording box, with no detectable spatial correlates at the most ventral locations. Spatially modulated neurons were only observed in the medial subdivision of the entorhinal cortex. The localized firing of the entorhinal cells was maintained without an intact hippocampus, suggesting that the map of the rat's current position is established before any signals are passed through this brain region. These data point to a new function for the entorhinal cortex (spatial computation) and suggest that metric spatial signals in the hippocampus are derived mostly from afferent areas rather than being computed in the hippocampus itself. This discovery 'releases' the hippocampus from an exclusive spatial domain and suggests that its primary role is the encoding and storage of associative memory, including both spatial and nonspatial elements.

The principal element of the entorhinal neural map is the 'grid cell' (Figure 3). The multiple firing locations of this cell type, which may comprise the

Figure 3 Periodic firing fields of a grid cell in the medial entorhinal cortex. The firing fields form a periodic triangular matrix tiling the entire environment covered by the animal. Left: Trajectory of the rat, with spike locations superimposed. Middle: Color-coded rate map, showing distribution of firing rate in the same cell (blue, silent; red, peak rate). Right: Autocorrelation matrix for the rate distribution in the two other diagrams (blue, −1; green, 0; red, +1). Place cells in the hippocampus are thought to reflect the integration of output from multiple grid cells with different spacing. Adapted from Hafting T, Fyhn M, Molden S, et al. (2005) Microstructure of a spatial map in the entorhinal cortex. *Nature* 436: 801–806, with permission from Nature.

majority of the neurons in layer II of the medial entorhinal cortex, form a remarkably regular and repetitive pattern. For each cell, the set of active locations defines a regular array that tiles the entire environment of the rat, like the cross-points of graphic paper rolled out over the test arena. However, unlike the rectangular lattices emerging from a Cartesian coordinate system, the entorhinal grid is triangular, with a pair of oppositely oriented equilateral triangles as the repeating unit. Grids of different cells are offset relative to each other such that each position in the environment can be identified, within a certain radius, from the activity of a fairly limited number of adjacent cells. These observations point to ensembles of entorhinal grid cells as elements of a possible neuronal coordinate system used by mammals for metric spatial navigation.

Several observations suggest that the entorhinal spatial map is the path-integration-based metric navigation system proposed as one of the key inputs to the hippocampal cognitive map of O'Keefe and Nadel. The entorhinal map is universal, operating at all times in all kinds of environments. Unlike place cells in the hippocampus, ensembles of grid cells are activated in a stereotypic manner, regardless of the unique landmarks of the environment. Information about position is apparently computed from the animal's own movement, using distance and direction of movement as the primary inputs. Because of its grid-like nature, the map can potentially represent places not visited just as well as places that have been visited. The grid map may thus be infinite, allowing the inclusion of all places and potential places. The existence of a single map that can be applied anywhere is economical and avoids the enormous capacity problems that might arise if the brain were to store rules about spatial interrelations for every single spatial context that the subject experienced.

Grids of neighboring cells have a common spacing and a common orientation. The spacing of the grid increases progressively as one gets deeper into the brain. By integrating inputs from grids at different scales, neurons in the hippocampus or other target areas may provide an unambiguous high-resolution representation of the spatial environment. If all grid cells had a single, common scale, the population code would repeat itself at intervals corresponding to a single period of the grid of individual cells. If activity were integrated across grids with different spacing and orientation, however, the cycle for repetition would get very large, enabling each position within this radius to be expressed by a unique pattern of collective activity in the grid network. The gradual increase in the scale of the firing fields and the distributed nature of the phase of the grid (the apparently random displacement of grid vertices among neighboring cells) are both mirrored downstream in the hippocampus.

Conclusion

Neural representations in the hippocampus carry strong spatial signals. These are expressed reliably throughout the hippocampal neuronal population, and they are likely to originate by integration of outputs from path-integration-based dynamic representations of the animal's location in the medial entorhinal cortex. On top of the spatial signal, hippocampal neurons carry information about other features of the environment, allowing neuronal ensembles in the hippocampus to store a number of discrete or continuous representations for each place or context experienced by the animal. With new powerful techniques that allow neuronal computation to be studied at the ensemble level, the study of place cells has become one of our most important tools to for understanding of how memory and cognition are implemented in the brain.

Introduction

The hippocampus appears to be involved crucially in the acquisition and intermediate term maintenance of novel episodic event memories. For example, in the famous case of patient H.M. the anterior hippocampus and adjacent structures were bilaterally removed surgically. H.M. was consequently unable to form new event memories, but event memories prior to the surgery were preserved. H.M. also retained the ability to converse and perform computations when uninterrupted. In order to understand the functions of the hippocampus and the specific properties of memory acquired and maintained there, it is necessary to understand intrinsic properties of neurons and the complex interactions in networks of neurons. The search for such understanding is greatly aided by computational modeling, due to the ability to make explicit and precise observations in each component of a simulation and the ability to exert similarly precise and explicit control over model structure and parameters.

The following article reviews neural models of hippocampal memory function. (1) We present an anatomical summary of the neural circuitry that is involved. (2) We compare attractor network models of memory retrieval with computational models that achieve memory retrieval in terms of sequences of activity patterns. (3) We discuss recent models of spatial navigation. (4) We highlight the significance of the 'theta' brain rhythm in recent models of hippocampal function, especially during the sequential readout of memory. This includes a recent model mechanism that achieves rapid switching between memory encoding and memory retrieval, thereby enabling specific hippocampus-dependent memory tasks. (5) This leads to the discussion of a model that proposes a mechanism for temporal context-dependent retrieval of episodic memory. (6) We present advances in computational models of proposed short-term buffering in parahippocampal regions, which provide the buffer requirements for associative synaptic storage in the hippocampus. (7) We explicitly state the importance of context for recognition versus recall in memory tasks. (8) We conclude by reviewing models that address the transfer and consolidation of memories stored in the hippocampus into long-term memory and semantic memory.

The Standard Model Based on Anatomical Structure

Recent models have directly addressed data from human cognitive memory tasks using representations based on extensive physiological and anatomical data concerning the hippocampal formation. These hippocampal models utilize many features discussed in priormodels of the hippocampus. Individual stored items such as words are represented as patterns of active and inactive neurons in the entorhinal cortex, which provides input to the hippocampus and which in turn receives converging input from a broad range of neocortical structures. Activity spreads from this input layer into subregions of the hippocampus, including a structure with extensive excitatory recurrent connections – region CA3. Strengthening of the recurrent synapses connecting active neurons within region CA3 provides a mechanism for associating different components of each stored pattern. The experimental phenomenon of long-term potentiation provides support for this mechanism of synaptic modification. Associative storage in region CA3 has been utilized in most models of episodic memory function, which differ primarily in details of the model dynamics. These models allow behavioral features of memory to be related to specific neural substrates.

The dentate gyrus (DG) receives input from entorhinal cortex (EC) and sends output to CA3. Connections diverge from a small number of EC neurons to a large number of DG neurons, resulting in a sparser pattern of activity in DG and CA3 which allows more effective associative storage. In addition, mossy cell and granule cell layers of the dentate gyrus together form a second recurrent network in the hippocampus, which may allow associative encoding in DG. Encoding of novel information may be facilitated by extensive neurogenesis observed in the human adult DG.

Region CA1 of the hippocampus receives input from layer III of entorhinal cortex (ECIII) at distal dendrites via the perforant path synapses and receives input from region CA3 at proximal dendrites through the Schaffer collaterals. Input from ECIII cannot elicit activity in CA1 independently, depending on depolarization by input from CA3. ECIII provides an active context to pyramidal neurons in CA1. By contrast, input via the Schaffer collaterals from CA3 can in some cases cause spiking in CA3 without excitatory input from ECIII. Activity in CA1 forms the output of hippocampal processing, projecting out of the hippocampus via the subiculum. In spatial tasks involving rodents, CA1 pyramidal neuron spiking has been

found to be place specific (place cells), and subiculum activity is direction specific. During theta rhythm in linear track experiments, place cell firing exhibits phase precession.

Models Based on Attractor Network Dynamics

Many early models of the hippocampus represent memories with a single spatial pattern distributed across a population of neurons. During retrieval, activity induced by a memory cue causes activity to evolve toward one of these single spatial patterns – an 'attractor' state. This final attractor state persists indefinitely. Because of this single stable final state, these networks are referred to as fixed-point attractor systems.

Fixed-point attractors can be obtained in networks with extensive excitatory feedback connections and could therefore occur in region CA3 of the hippocampus, or in neocortical structures. One danger of such strong excitatory feedback connections is the possibility that activity can increase exponentially within the network. In early models, units were prevented from firing at rates higher than a particular maximum value, and memory states commonly involved firing at these high rates. More realistic networks obtained attractor dynamics with lower rates of firing by balancing feedback excitation with different types of inhibition, including shunting inhibition, subtractive inhibition, or normalization of total activity. Though fixed-point attractors in models can persist indefinitely, it is likely that neural circuits come under the influence of individual attractors for only brief periods. In very detailed biological models with spiking neurons, attractors require larger numbers of units to be stable, but can be obtained by using very specific point-to-point inhibitory connectivity or saturating synapses.

Sequence Models

Memories can also be represented as sequences of activity patterns within a network. In this framework, each pattern of activity on a population of neurons such as region CA3 is associated with a different subsequent pattern during encoding. During retrieval, presentation of an early pattern then elicits a chain of different subsequent patterns in the network which could potentially be repeated in a limit cycle. Sequences provide a simple means of representing interitem associations in memory tasks, as well as pathways through the environment. Recently, models of sequence storage in region CA3 of the hippocampus have been used to address behavioral tasks, including the transitivity task studied by Bunsey and Eichenbaum and spatial navigation tasks.

An important focus of recent models concerns the phenomenon of theta-phase precession. This experimental evidence suggests sequence storage within the hippocampus. As a rat runs along a continuous track, individual neurons (place cells) in its hippocampus will fire as the rat traverses a location specific to that cell (the place field). The firing of these cells has been measured relating to the phase of a high-amplitude oscillation in the hippocampal electroencephalogram (EEG) called the theta rhythm. As the rat enters the place field associated with a particular place cell, the firing of that cell will occur late in the theta cycle. As the rat crosses and leaves the place field, the firing of the place cell will occur earlier and earlier, suggesting that the cell was initially the end of a sequence being read out in the hippocampus, and as the rat crosses the field the cell becomes an earlier component of the sequence.

Several models of theta phase precession have been published. These models all involve a readout of sequences across time, but two of them involve slow readout of sequences across the full cycle of the theta rhythm (which has a period of about 200 ms). In a model by Tsodyks, Skaggs, McNaughton, and Sejnowksi, this slow readout is obtained with very weak excitatory connections. In a model by Jensen and Lisman, this slow readout is obtained with the slow dynamics of the *N*-methyl-D-aspartate (NMDA) receptor. Recently, Lisman modified this approach by stipulating sequence readout in which the retrieval of successive items is delayed by the time taken to correct an item representation through auto-associative pattern completion. Retrieval is further delayed by feeding back the resulting activity as a cue for the subsequent readout of the next item, using the reciprocal fiber loop that is formed by the pathway from hippocampal region CA3, via the mossy cells to the dentate gyrus, and the mossy fiber pathway from dentate gyrus to hippocampal region CA3. This change in the model was motivated by data showing that NMDA antagonists did not eliminate the phase precession phenomenon.

In contrast, more rapid readout with α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor kinetics is used in a separate model. In this model by Hasselmo, the theta phase precession is obtained by readout of sequences to different lengths during different phases of the theta cycle, due to phasic changes in depolarization or presynaptic regulation of synaptic strength. This phenomenon could allow selective context-dependent retrieval of sequences. Finally,

still other models have proposed that the theta phase precession does not result from sequence readout, but from a precession due to theta oscillations running at different frequencies in the soma versus the dendrites of pyramidal cells. Several of these hypotheses can be tested with pharmacological investigation of the phenomenon of theta phase precession.

Models of Spatial Navigation

The hypothesis that pathways through the environment are stored as sequences of place cell activity gives rise to another prediction, that as a pathway becomes familiar, place fields should expand and move backward along the path. This prediction has recently been confirmed in experimental measurements. Recent models by Burgess, Sharp, Hasselmo, Koene, and Gorchctchnikov have proposed that representations of neural space involve learning of multiple different pathways within that space, which can then be effectively integrated in a flexible relational structure. Many models start with an array of simulated place cells which encode the environment, and then modify the connections between these cells to learn gradients toward specific goals. This can be viewed as instantiating the assumption that space is the dominant parameter for neuronal response, although it is possible that place cells arise from a generic sparse conjunctive coding scheme. One recent model by Samsonovich and McNaughton assumes that generic two-dimensional maps of space are precoded in region CA3, and learning of a new environment involves modification of excitatory input to individual maps, rather than modification of recurrent connections within a map. In contrast, models which start with individual sequences can draw on a range of features in each sequence, building a response to task elements beyond just the spatial layout. Most models use a particular goal to influence the activity of other neurons in order to direct network activity toward a particular location. This remains an important issue, as experiments have not demonstrated 'goal cells' in any particular structure. Functional models of navigation provide an important means of interpreting available physiological evidence from this important experimental paradigm.

The Significance of Hippocampal Theta Rhythm

Recent computational models address the role of the hippocampal theta rhythm. During the peaks and troughs of the theta rhythm, differential modulation of membrane potential and synaptic transmission results in phasic changes in the magnitude of synaptic currents induced in region CA1 by input from EC and CA3 during different phases of theta rhythm. Empirical data show that the phase of theta rhythm in hippocampal regions also affects the strength of synaptic modification by long-term plasticity (LTP). The strongest LTP is elicited by stimulation at the peak of theta rhythm, as recorded in the hippocampal fissure. Combined, these modulatory effects led to the presupposition that opposing phases of theta rhythm may impose rapidly alternating modes that differentially favor encoding (strong input from EC, strong LTP) and retrieval (strong internal spread arising from CA3, weak LTP) in subregions of the hippocampus.

Computational models that propose a mechanism of ongoing alternating encoding and retrieval during task performance allow encoding of new information, interleaved with retrieval of prior knowledge to perform the task. Recent simulations of spatial navigation behavior used a mechanism of alternating encoding and retrieval within each theta cycle. These simulations were based on the hypothesis that information needed to perform the task is retrieved during each theta cycle in hippocampal region CA1. It was proposed that retrieval activity in CA1 is elicited by a convergence of excitatory input from pyramidal neurons in entorhinal cortex layer III through the perforant path and of excitatory input from pyramidal neurons in hippocampal region CA3 via Schaffer collaterals. The models suggested three important uses of theta rhythm. (1) Theta modulation enables rapidly alternating encoding and retrieval modes. (2) Offset phases of theta modulation in the connected networks of the entorhinal cortex and hippocampus enable synchronous operations. For example, the readout of buffered activity in the entorhinal cortex can occur reliably for presentation as input during the encoding phase of activity at the recurrent fiber synapses of hippocampal region CA3. (3) The modulation of membrane potential at theta rhythm in layer II of the entorhinal cortex may be an essential component of a nonsynaptic buffer that can maintain short sequences of spiking activity.

Recent computational modeling proposes explicit mechanisms for the retrieval of episodic memory in a specific temporal context. This effectively models data from Wood and Eichenbaum showing that units fire in a selective context-dependent manner in region CA1 of the hippocampus. Inputs representing forward retrieval could be gated by inputs representing temporal context via convergence in region CA1. Simulations demonstrated performance in a delayed spatial alternation task in which temporal context-specific retrieval is necessary for successful performance of the task.

Short-Term Buffers

Experimental observations and computer modeling by Alonso and Fransen demonstrated that certain pyramidal neurons in the entorhinal cortex exhibit afterdepolarization and the ability to maintain a stable pattern of intrinsic spiking even after input has terminated. In layer II of the entorhinal cortex (ECII), the intrinsic spiking frequency is similar to the frequency of the theta brain rhythm. The persistent firing behavior of those neurons led to proposals for short-term buffers of spike sequences, which can allow the acquisition and encoding of novel input in the parahippocampal and hippocampal regions. The buffer of spike sequences could allow (1) time compression between patterns of spikes to enable spike timing-dependent potentiation, (2) multiple cycles of spike pattern reactivation to repeatedly strengthen active synapses, and (3) maintenance of sequence order for the encoding of episodic memory. Another important element of these models is network-wide competitive inhibition, which serves to suppress activity following a pattern of spikes and thereby guarantee the separation of successive buffered spike patterns. This competitive inhibition and the detection of spiking at a phase of the theta rhythm that indicates a full short-term buffer are the proposed components of a mechanism that enables first-in–first-out replacement of buffered spike patterns with novel spiking input patterns. In addition to its role during sequence encoding, a short-term buffer for short sequences of representative spike patterns may gather and time compress a short sequence of spikes elicited by input that provides a temporal context cue for episodic retrieval in the hippocampus.

Recognition versus Recall

Most humans are familiar with the difference in effort required for recognizing a name versus recalling a name. Recall is more sensitive than recognition to injections of the acetylcholine receptor blocker scopolamine before encoding, and the cellular basis of this sensitivity has been analyzed in a model. In this model, neurons in entorhinal cortex represent the subject's memory for experimental context – that is, the testing room and apparatus – while separate neuronal populations in this area represent individual items – that is, words on a list. During encoding, activity spreads through the dentate gyrus into region CA3, where connections are strengthened among the neurons representing context, among the neurons representing individual words, and between the context and word neurons. The experimentally demonstrated effects of scopolamine were represented by reducing the rate of synaptic modification, reducing the depolarization of neurons, and increasing feedback excitation.

Simulation of scopolamine effects impaired subsequent recall but not recognition. During free recall, a subject is asked, "What words were on the list?" In the model, this is simulated with activation of entorhinal context units, which activate the context representation in region CA3. This context representation then sequentially activates the representations of individual words via strengthened connections (competition between words prevents simultaneous recall). During recognition, subjects are presented with individual words. In the model, neurons representing individual words are activated. If spread of activity across strengthened connections is sufficient to evoke activity in the context neurons, then the item is counted as correctly recognized. Because the context is present more frequently than the words during encoding, it has stronger excitatory feedback and is easier to activate, allowing recognition to persist even when slower synaptic modification during encoding prevents effective recall. This model suggests specific parameters of memory function which should be affected by specific drugs. Drug effects on conditioning phenomena in rats have also been modeled, but space does not allow review of neural models of conditioning.

The model of recognition described previously used one representation of recognition processes – but humans may use two different processes in recognition: (1) a process of rich recollection, in which the details of the specific item are recalled in a specific context and (2) a general sense of familiarity based on component features of an item. The rich recollection process may depend on the hippocampus, whereas the familiarity sense may depend on other cortical structures, including parahippocampal structures. Experimental data on these differences have been addressed in a recent paper which models the dynamics of recollection in a simulation of the hippocampal formation. The activation of representations in region CA3 of this model depends upon a conjunction of cues in the entorhinal cortex. This requirement of a specific conjunction of features prevents recollection from being induced by items containing only a portion of the features of a particular memory. For example, the model was trained on patterns representing word pairs such as 'window-reason' and 'car-oyster' and then tested on repaired lures such as 'window-oyster.' The model was able to recollect studied word pairs and reject many re-paired lures by retrieving the correct pair. The simulation also demonstrated the experimentally observed property that recollection-based recognition decreases with number of words on a list, whereas there is an increase in false alarms

due to the more vague familiarity-based recognition. This familiarity-based recognition may take place outside the hippocampus and contribute to many aspects of memory function. Lesions of the hippocampus alone cause significant impairments in episodic memory tasks including recognition memory, but research indicates that lesions including structures adjacent to the hippocampus cause stronger overall memory impairments.

Consolidation

Lesions of the hippocampal formation do not appear to impair preexisting semantic memory, but there is some loss of episodic memories from the time before the lesion, and more recently stored information appears to be affected more strongly – a phenomenon termed temporally graded retrograde amnesia. This suggests that the hippocampus mediates the gradual formation of neocortical memory representations. Models of the formation of semantic memory demonstrate that gradual, interleaved learning of new episodic information with existing semantic representations is essential to prevent distortion of previously stored semantic representations. Thus, the hippocampus may provide a temporary store for associations which then gradually modify neocortical representations.

The potential effect of the loss of hippocampal training on semantic memory has been investigated in studies of children with perinatal damage to the hippocampus. These subjects show a profound impairment of episodic memory, and as might be expected from the model, their development of semantic memory requires extensive training over a longer period – the external world must take the place of an internal mechanism for interleaved learning. The phenomenon of temporally graded retrograde amnesia does not appear consistently in all behavioral tasks, but in the case of human subjects, temporally graded retrograde amnesia appears to be particularly true for patients with damage selective to the hippocampus proper.

Potential physiological mechanisms for a two-stage model of memory formation have been proposed. The initial encoding in the hippocampus has been proposed to occur during theta rhythm dynamics, and the subsequent transfer to the neocortex to occur during sharp waves in quiet waking and slow-wave sleep. The dramatic decrease in acetylcholine levels during slow-wave sleep could contribute to these different dynamical states, as it will greatly enhance the strength of excitatory feedback in the hippocampus. This two-stage system allows rapid encoding of episodic memories, with slower consolidation of more complex semantic representations.

The hippocampus has long been a major focus of neuroscience research, in large part due to its highly distinctive cytoarchitecture and its widely accepted functional role in learning and memory. Analysis of gene expression in the hippocampus has been a popular means to understand the cellular diversity of the hippocampus and genetic underpinnings of phenotypic properties of these cells. These approaches range from global genomic analyses of hippocampus in its entirety to cellular resolution immunocytochemical analysis.

Genomic Analysis of Total Hippocampal Gene Expression

The availability of methodologies for large-scale transcriptional analysis has allowed genome-scale profiling in the complete hippocampus or in subdivisions of the hippocampus, most notably using serial analysis of gene expression (SAGE) and DNA microarrays. These approaches have yielded insight into the types and relative abundances of genes expressed in the hippocampus and also the genetic relationship between the hippocampus and other brain regions. Based on these techniques, at least half of known genes are expressed at detectable levels in the hippocampus. Less than 0.5% of these genes, largely composed of mitochondrial genes and genes involved in energy metabolism, make up >20% of the total mRNA transcripts in the hippocampus. A wide variety of neurotransmitter receptors, G-protein-coupled receptors, ion channels, and synaptic components representing neuronal gene expression are expressed at lower levels. Gross analysis of the entire hippocampus also reflects nonneuronal populations such as oligodendrocytes and astrocytes since these cell types are intermingled with or adjacent to the major neuronal populations.

Global patterns of gene expression in adult brain regions bear the imprint of their developmental origins. Hippocampal gene expression is most similar to that of other forebrain regions such as the neocortex and amygdala, less similar to the evolutionarily older brain stem regions, and even more dissimilar to regions such as the retina and pituitary gland. Interestingly, global gene expression patterns in different subfields of the hippocampus are more similar to one another than to other brain regions, despite the major differences in predominant neuronal types between hippocampal subfields (pyramidal vs. granule) and apparent morphological similarities of cell types in different brain regions (e.g., pyramidal cells in the hippocampus and neocortex).

Histochemical analysis of gene localization in the hippocampus has produced a wealth of cellular resolution gene expression data in the hippocampus. Centralized databases have become available that provide detailed gene expression data on a genomewide scale as well, allowing a global approach to correlating underlying gene expression to the unique phenotypic properties of particular cell types in the brain.

Subregional Gene Expression in Excitatory Hippocampal Neurons

The contemporary delineation of the hippocampus includes the dentate gyrus and Ammon's horn (cornu ammonis), which is divided into four subfields – CA1–CA4 – based on the nomenclature originally proposed by Lorente de Nó. CA4, now generally referred to as the hilus or polymorphic layer. The dentate gyrus is composed largely of small, densely packed granule neurons, whereas the CA fields are dominated by a dense band of pyramidal neurons that vary in their morphological and physiological characteristics from field to field. There is some debate regarding the distinct nature of the CA2 subfield in the rodent because it is not possible to delineate boundaries on the basis of cytoarchitecture alone, whereas single neurons in CA2 bear a strong resemblance to neurons in either CA3 or CA1.

Many studies have demonstrated striking regional gene expression in the different subfields of the hippocampus, discovered either on a gene-by-gene basis or through targeted profiling using DNA microarrays on microdissected hippocampal subregions. Pyramidal cells in CA1–CA3, hilar neurons, and dentate gyrus granule cells are each uniquely delineated by expression of individual genes (Figure 1). A fairly large number of genes expressed selectively in CA2 (or specifically excluded from CA2) have bolstered the argument for its identity as a discrete hippocampal subfield, although no distinct function has been ascribed to it. Visualized with specific markers, CA2 forms a thin, uniform band between, and nonoverlapping with, both CA1 and CA3 throughout the entire septotemporal extent of the hippocampus (Figure 2). Interestingly, co-expression of genes in CA2 and CA3 occurs more frequently than expression in either region separately, indicating that pyramidal cells in these regions are functionally very similar to one another.

Anatomical and functional heterogeneity within hippocampal subregions has been described at a number of levels that are likely to be reflected at the level of gene expression. First, efferent, afferent, and intrahippocampal connections are topographically organized along both the septotemporal and the proximal–distal planes. Several members of the Ephrin family, demonstrated to mediate the formation of

topographically specific connections in other structures, are expressed in gradients along the septotemporal axis of the hippocampus. There is also a functional differentiation along the septotemporal axis of the hippocampus, with the dorsal portion being more tightly linked to spatial learning and the ventral portion more closely linked to anxiety-related behaviors. Dorsal–ventral (septotemporal) variation in CA1 gene expression has been described that may correlate with these functional differences.

Genes that display regional specificity within the hippocampus are enriched for certain types of molecular functions. Signal transduction, transcriptional regulation, ion channels or transporters, and cytoskeletal or structural molecules are highly represented, as are growth factors and calcium-binding proteins. These classes of genes are likely to give rise to the different morphological and dynamic signaling properties that differentiate excitatory hippocampal neurons. Subfield-specific splice variance of ion channel subunits has also been described, adding another level of complexity to the relationship of gene expression to the electrophysiological properties of specific hippocampal neurons.

Gene expression at the regional and cellular level is highly complex and combinatorial. At the gene level, few genes are expressed in a single subfield. The majority of genes differentially regulated in the hippocampus are expressed in more than one subfield, and all possible combinations of subfields are seen for particular genes. At the cellular level, neurons in each subfield express unique combinations of genes that overlap strongly but differentially with neurons in the other subfields. Ultimately, it will be necessary to understand larger genetic interactions between cohorts of co-expressed genes at the cellular level to predict the full spectrum of phenotypic differences between different cell types in the hippocampus.

Hippocampal Interneurons

Inhibitory interneurons that use γ-aminobutyric acid (GABA) as their neurotransmitter form a diverse set of hippocampal cell types. At least 16 subtypes of interneurons exist in CA1 alone, with a remarkable diversity of morphological and physiological properties as well as distinct patterns of connectivity. For example, axo-axonal cells innervate the axon initial segment of large numbers of pyramidal neurons, putting them in position to strongly modulate action potential generation in those neurons. Several other cell types selectively innervate other interneurons, presumably evoking disinhibition in their target neurons.

Different interneuron subtypes are also distinguished by differential gene expression. Calcium-binding proteins, neuropeptides, and certain neurotransmitter receptors in particular are robustly and differentially expressed in different interneuron populations. CA1 expression patterns for most of the defined interneuron markers are shown in Figure 3, illustrating specificity of somal locations in the different sublaminae of CA1 but with highly overlapping patterns. Few, if any, interneuron classes are uniquely identified with current genetic markers, however, and are typically distinguished by a combination of characteristics including soma location, axonal and dendritic patterns of connectivity, and physiological response properties in addition to marker expression. These findings indicate, as for excitatory neuronal populations, that cellular phenotype is the product of the expression of complex combinations of gene products. Although it is possible that there exist single genetic markers that specifically delineate different interneuron populations, it seems highly likely that a set of genes may be necessary to identify a particular neuronal class.

Nonneuronal Cell Populations

In addition to the neuronal populations of the hippocampus, several prominent nonneuronal populations exist in the hippocampus (Figure 4). Oligodendrocytes and astrocytes comprise the major glial populations. Oligodendrocytes are found mainly in the fimbria and alveus, with smaller numbers in stratum lacunosum-moleculare and the dentate gyrus (the mossy fiber pathway from the dentate gyrus to CA3 is unmyelinated). Oligodendrocytes express very high levels of myelin-associated genes, including myelin basic protein and proteolipid protein, which are among the highest expressing hippocampal genes identified by SAGE analysis of total hippocampus. Astrocytes are more uniformly distributed throughout the hippocampus, with some enrichment in stratum lacunosum-moleculare. There appears to be some diversity among astrocyte populations defined by molecular markers, as demonstrated by the different expression patterns of glial fibrillary astrocytic protein and the gap junctional protein connexin-43, two well-characterized markers for astrocytes (Figure 4).

The hippocampus also contains dense vasculature. Vascular endothelial cells making up the vascular walls express a distinct set of genes, such as vascular endothelial protein tyrosine phosphatase, whereas hemoglobin expression in red blood cells is prominent in nonperfused tissue preparations.

Finally, the subgranular zone of the dentate gyrus is a region of intense study as one of two regions in which neurogenesis persists in the adult brain. This zone contains a precursor population that continues

to divide and generate new granule neurons that migrate into the overlying granule cell layer of the dentate gyrus. Cell cycle-associated genes such as mKi67 are specifically expressed in these dividing cells, and they are detectable as sparse cells in the subgranular zone as well as in dividing cells in the walls of the lateral ventricles.

Developmental Hippocampal Gene Expression

Gene expression profiling has also been applied to hippocampal development, identifying stage-specific genetic programs associated with hippocampal neurogenesis, differentiation, and maturation. For example, at prenatal ages, genes involved in cell cycle, histone regulation, and DNA replication are expressed at high levels, correlating with the period of neurogenesis. Later, genes associated with neuronal maturation are expressed at high levels, including actin and tubulin isoforms. Finally, in later development genes associated with synaptogenesis are upregulated. Subregion-specific gene expression provides useful markers to track the specification of hippocampal cell types. For example, the subfields of the hippocampus can be differentiated by region-specific gene expression as early as embryonic day 15.5, prior to the arrival of major hippocampal afferents.

Summary

Despite its apparent cytoarchitectural simplicity, the hippocampus contains a wide variety of neuronal and nonneuronal cell populations. This cellular diversity is reflected at the level of gene expression, which provides the genetic substrate for phenotypic differences between these cell classes. The availability of techniques for global gene expression analysis holds great promise for understanding structure–function relationships within the hippocampus, particularly as they begin to be applied to specific cellular populations. Genome-scale cellular resolution gene expression data are now available as well, holding the promise of defining comprehensive molecular taxonomies at the cellular level.

Histamine Receptors and their Ligands: Mechanisms and Applications

H Timmerman and H van der Goot, Amsterdam, The Netherlands

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Histamine was known as a chemical before its presence in biological systems was confirmed. In 1907 Windaus and Vogt described the synthesis of 2-(imidazole-4-yl) ethylamine; much later this compound received the name histamine (Greek *histos*, 'tissue'), because of the relatively high concentrations found in tissues. In 1910 Dale and Laidlaw isolated the compound from animal tissues, but originally it was thought to be there just as a metabolite of histidine, having no physiological significance of its own. During the 1920s it became clear that histamine evokes several pharmacological activities, resembling very much the actions of the (at that time) not well-defined 'H substance,' a more or less hypothetical compound thought to be released from injured tissue. Eventually it was found that H substance was a complex mixture of compounds, of which histamine was only one, playing a major role in anaphylaxis. Because of the role of histamine in anaphylaxis an intensive search for histamine blocking agents was started; the first so-called antihistamines were found in the late 1930s, and in the 1940s the antihistamines were introduced as antiasthmatics and as antiallergics in general.

Very many antihistamines, of which diphenhydramine may be considered as being the archetype, have been developed since. They are all of limited use in asthma, but are quite effective in treating other allergic responses, such as hay fever and skin rashes. For many years it remained unclear why certain effects of histamine (e.g., stimulation of gastric acid secretion or increased heart rate) were not blocked by highly active antihistamines. In the 1960s Ash and Shild proposed that a second type of histamine receptor might exist in heart and stomach tissues. Subsequently, in 1974, Black et al. reported for the first time on selective blockers of the actions of histamine in both the heart and the stomach. The new type of receptor was named H_2; the receptor discovered earlier was designated H_1 from then on. As with the antihistamines – now renamed H_1 blockers – several selective H_2 blockers followed the first H_2 antagonist burimamide; cimetidine and ranitidine, antigastric ulcer agents, have become blockbuster medicines (Tagamet and Zantac, respectively).

In the 1980s it became clear that histamine not only has the characteristics of a local hormone, but is a neurotransmitter as well. Shortly thereafter, Schwartz and group in Paris identified a third class of histamine receptors. These H_3 receptors occur mainly as presynaptic receptors, functioning both as auto- and heteroreceptors by regulating the release of histamine (autoreceptor) and other neurotransmitters (heteroreceptor). Pretty soon thereafter a large number of selective H_3 agonists and antagonists were found; so far none of these compounds has been developed for clinical application; several antagonists, however, are undergoing clinical testing for different central nervous system (CNS)-related diseases.

During a search for new G-protein-coupled receptor (GPCR) genes, using the sequence of the H_3 receptor gene as template, a fourth type of histamine receptor was found in the early 2000s. This H_4 receptor is present especially in peripheral organs, on immunoactive cells, where it likely mediates the proinflammatory properties of histamine. Histamine-induced inflammation is not blocked by H_1, H_2, or H_3 antagonists. There is a low level of homology between the H_1, H_2, and H_3/H_4 receptor proteins. The latter pair has a relatively high degree of homology, explaining why imidazole-derived ligands of the H_3 receptor typically have a considerable affinity for the H_4 receptor as well; the reverse is also true. Selective nonimidazole H_3 and H_4 ligands are available, though.

In the following sections, the several ligands of the four histamine receptors are discussed, regarding both their medicinal (or potential medicinal) application and their use as tools in pharmacological research. Although it is beyond the scope of this article to discuss the many pharmacological technologies applied to characterize the different ligands, the most frequently used tests are summarized in the final section.

The Histamine H_1 System

The Receptor, Mechanisms, and Role in Physiology and Pathology; H_1 Blockers as Medicines

Originally the H_1 receptor was known as 'the' histamine receptor, and its ligands were viewed as (anti) histamines. Like all identified histamine receptors, the H_1 receptor belongs to the large family of G-protein-coupled receptors. The receptor is via a G_q-protein coupled to phospholipase C; receptor stimulation leads to the hydrolysis of phosphatidylinositol 4,5-bisphosphate, yielding increased levels of inositol 1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol and eventually of increased Ca^{2+} levels and activation of protein kinase C.

The receptor is present in many tissues, both in peripheral organs and in the CNS. The first

described function of the H_1 receptor was its role in allergy-related conditions – contraction of soft tissue (in airways) and increased permeability of the capillaries of the cardiovascular system. It was known that histamine release from mast cells occurred during allergen–antibody reactions; thus the idea emerged that H_1 antagonists would be effective antiallergics. These expectations were not completely fulfilled, especially because histamine is only one of the factors released in allergic responses and also because side effects (sleepiness) occur at H_1 blocker doses lower than needed for an antiallergic effect. The several H_1 blockers that reached the market are, however, of use in conditions such as hay fever, but are only weakly effective in treating asthma.

Although sleep-inducing properties of H_1 blockers were seen for virtually all of the many compounds that were marketed during the 1950s and 1960s, it had not been proved that these effects were related to the H_1 blockade. There were intensive efforts to develop so-called non-sleep-inducing H_1 blockers, without any true success, though. The application of so-called *ex vivo* experiments using radiolabeled ligands showed a very good correlation between occupation of H_1 receptors in the brain and induction of sleep in animals, suggesting that the induction of sleep by H_1 blockers is caused by H_1 blockade. When, moreover, later on it was found by molecular biology approaches that H_1 receptors in peripheral tissues are identical with the receptors in the CNS, it became obvious that nonsedating H_1 blockers could only be based on the absence of penetration of a given compound into the CNS.

Early attempts to reduce brain penetration by making less lipophilic derivatives failed. In the 1980s, rather by chance, a number of less CNS-penetrating H_1 blockers were found (terfenadine, cetirizine, and loratadine are examples); these compounds led to a new class of a second-generation non-sleep-inducing (or less sleep-inducing) antiallergic medicines that were quite active, especially in hay fever patients. The warning 'no driving when using this medicine,' applicable to the early antihistamines, could be rescinded for the new medicines.

During the 1990s a cardiotoxity, a prolongation of the QT interval, was observed for some members of the new class of medicines. This serious side effect, caused by a blockade of K^+ channels of the human *eag*-related gene (HERG) type on cardiac tissue, led to the removal from the market of a few medicines (e.g., the first successful second-generation blocker, terfenadine), but the cardiotoxicity was found not to be a class effect. From animal experiments it became clear that some of the early H_1 blockers – and even those available as over-the-counter medicines – showed signs of the same toxicity, but such compounds remained freely available. In addition, there is ample evidence that histamine plays a role via H_1 receptors in seizures and epilepsy, and Japanese investigators published data on the proconvulsant activity of H_1 blockers. These observations have not, however, led to serious concern about this potential side effect of the H_1 blocking agents.

As is the case for many receptor systems, the H_1 receptor shows constitutive activity; this means that under certain conditions the receptor is in an active conformation, thus producing the second messenger intracellularly, in the absolute absence of an agonist. Equally important is that histamine blocking agents should be considered as being either true antagonists (binding only to the receptor; no intrinsic activity) or as inverse agonists (reducing the constitutive activity upon binding to the receptor). All clinically applied H_1 blockers tested for these properties have been identified as inverse agonists.

Compounds; Structure–Activity Relationships

H_1 agonists Histamine has a very simple chemical structure (Figure 1). The compound has a low affinity for the H_1 receptor (K_D around 4.5 nM), and as the ED_{50} is around 6.5 nM, there is a high spare receptor capacity; only about 1% occupation of the receptor leads to the maximal level of receptor activation.

Figure 1 Histamine and some representative selective H_1 agonists.

The agonistic activity is very much dependent on the structure. Introduction of even small substituents, either in the side chain or at the imidazole nucleus, causes a strong reduction in activity, except at position 2 of the imidazole ('between the two nitrogens') group. At this position certain substitutions favor the activity. Especially aromatic groups and ω-benzhydryl alkylene groups at this C2 position may lead to compounds with a much higher (and, moreover, more selective) H_1 activity (see Figure 1). As a rule of thumb it may be said that H_1 agonism may be expected from heteroaromatic compounds in which an ethylamine moiety is placed on the aromatic nucleus at a position adjacent to a nitrogen atom. Recently, our group identified the ergot derivative lisuride, a compound with a potent H_1 agonistic activity and an unexpected structure.

H_1 blockers During the late 1930s the first experimental H_1 blockers were found during random screening procedures. The intravenous LD_{50} of histamine was determined in untreated mice; when mice were pretreated with a test compound, the LD_{50} was found to be higher, thus a histamine blockade was established and a blocker was identified. Though not the first H_1 blocker to be used therapeutically, diphenhydramine became the archetype of the very many derivatives that appeared in the scientific literature, several of which were marketed. Figure 2 depicts the structures of a number of H_1 blockers.

The H_1 blockers compounds reaching the marketplace since the late 1940s and the 1950s have been much less successful than anticipated. Besides their lack of activity, the high incidence of CNS-related side effects (sedation to a level which made them attractive as sleeping pills, thus ruling out their use when driving) limited their usefulness. Many researchers have tried to design so-called nonsedating H_1 blockers. Originally it was thought that the sedation induction had nothing to do with H_1 blockade, and nonsedating compounds were searched for more or less at random among series of H_1 blockers. When it was eventually found that the sedation is a consequence of H_1 receptor blockade in the CNS and that these CNS receptors are not different from the ones found in peripheral systems, the focus became the identification of compounds that do not penetrate into the brain. Attempts to reach this objective by selecting hydrophilic blockers were unsuccessful. The goal was finally reached by chance, when the diphenhydramine derivative terfenadine was found to be an active H_1 blocker, but did not penetrate into the CNS. This first example of this new class of second-generation (nonsedating) H_1 blockers was followed by a number of other effective derivatives, including loratadine and cetirizine (Figure 2). Only later was it found that the beneficial property (no CNS penetrance) is a result of the property of these compounds to be substrates of the permeability glycoprotein (PgP) transporter system. A number of these second-generation compounds have achieved major market status as antiallergic medicines.

H_1 Ligands as Research Tools

For any molecular pharmacology study, the availability of selective ligands as tools is essential. In this section and in subsequent sections on H_2, H_3, and H_4 receptors, ligands that afford such utility are presented.

H_1 agonists Until rather recently very few selective H_1 agonists were available, and those that were had an activity level much lower than that of the nonselective histamine, making them of limited use only. The most widely used agonists have been the 2-thiazolyl and the 2-pyridyl analogs (Figure 3). The histamine derivatives shown in Figure 1, when carrying on position C2 an aromatic group with an alkylene linker (Figure 3), have greatly improved the matter; compounds such as histaprodifen and superhistaprodifen have become important tools for studying the role of H_1 receptors in physiology and pathology.

H_1 antagonists; chiral ligands Although many selective H_1 antagonists have been described, only a few have been selected as tools for experimental studies; these compounds are shown in Figure 4. The most frequently used compound is likely mepyramine, but triprolidine and chlorpheniramine offer certain advantages. The structure of triprolidine is interesting in that it forms two geometric isomers. The E-isomer (triprolidine) is about a 1000 times more active (as measured in guinea pig ileum) than the Z-isomer, which makes triprolidine very useful for studying the binding mode of the compound to the receptor and the reason why it is frequently used in molecular modeling studies.

Chlorpheniramine, having a chiral structure, is also very suitable for many pharmacological studies. One of its two isomers is a much more potent H_1 blocker than the other one; thus the two isomers can be used to determine whether an effect of an H_1 agonist is caused by an interaction with the H_1 receptor. A nice example of such an application has been given by Leurs and colleagues, in studies proving that a binding site for mepyramine on liver cells was not an H_1 receptor but rather was a P450 enzyme.

Radiolabeled ligands Studying the affinity of ligands for any binding system can best be done by experiments

Figure 2 Representative blockers of first-generation (sedating) and second-generation (nonsedating) antihistamines.

in which the replacement of a selective, radiolabeled ligand, bound to that binding system, is measured. These radiolabeled ligands are also very useful for studying the distribution and localization of H_1 receptors throughout biological systems. Several H_1 blockers labeled by a radioactive isotope have been developed and are readily available. [^{3}H]Mepyramine is widely used, and [^{3}H]doxepin is used to a lesser extent. More useful, however, because of a higher specific radioactivity, are ^{125}I-labeled ligands; compounds of this type include [^{125}I]iodobolpyramine and [^{125}I] iodoazidophenpyramine (Figure 4).

Figure 3 H_1 agonists used as pharmacological research tools.

Ligands for positron emission tomography studies The introduction of positron emission tomography (PET) made it possible to study the interaction of ligands with their binding sites in human experiments. For histamine H_1 blockers this technology has been used to prove that the sedating effect of H_1 blockers is directly related to their binding to receptors. For this purpose the physicochemical properties of the ligands need to fulfill precise requirements: good penetration into the particular biosphere is crucial. A number of derivatives have been developed: [^{11}C]doxepin and [^{11}C]mepyramine have been successfully used to study the role of histamine receptors in brain functions.

The Histamine H_2 System

The Receptor, Mechanisms, and Role in Physiology and Pathology; H_2 Ligands as Medicines

The H_2 receptor is a G_s-protein-coupled receptor; upon receptor stimulation, through activation of an adenylyl cyclase, the intracellular concentration of c-AMP is increased. For about two decades after the introduction of antihistamines (i.e., H_1 blockers) for therapeutic purposes, it remained unexplained why active blockers antagonized the effects of histamine in the soft tissues (e.g., the airway system and blood vessels), but not the effects of histamine in the heart (increase in rate) and stomach (gastric acid production). After the success story of the distinction of α- and β-adrenergic receptors by Ash and Schild, and following the introduction of selective ligands for these receptors, Ash and Schild proposed the theory of the existence of two classes of histamine receptors. Subsequently, Black (who also worked on selective ligands for the β-receptors) proved that this concept was right, by identifying selective ligands for the two types of receptors; from then on these receptors were called histamine H_1 and H_2 receptors. The classical antihistamines were found to be selective blockers of the H_1 receptors, which were identified in the airway system and on small blood vessels; via these receptors histamine causes bronchoconstriction and an increased permeability of capillaries of the vascular system. Black's concept became generally accepted when his group synthesized selective H_2 blockers; later on, most of these compounds were identified as inverse agonists.

Histamine H_2 agonists have some medicinal application for inducing gastric acid production in patients with an achlorhydria; the potential use of H_2 agonistic impromidine analogs as cardiac stimulants (see later), as an alternative for β-agonists, has not moved beyond experimental status. The major obstacle is the intrinsic side effect of an increase in gastric acid secretion; some selectivity (heart vs. stomach) has proved possible, though. Another problem is caused by a species difference in receptor affinities of the analogs, making the selection of the best candidate for clinical evaluation difficult.

Histamine H_2 blockers are very effective in reducing gastric acid secretion. As antiulcer medicines (cimetidine, ranitidine, famotidine) they achieved major market blockbuster status in the 1980s, having the highest sales ever for a single type of drug during that time. In the 1990s this status was taken over by the

Figure 4 H_1 blockers used as pharmacological research tools.

proton pump inhibitors and anti-*Helicobacter* agents. Collectively, the highly effective antiulcer agents have more or less definitely solved the problem of gastric ulcers, and surgery is no longer necessary.

Histamine H_2 blockers do not influence heart rate; histamine does not play an important physiological role in this respect. Although H_2 receptors are present in several CNS areas and whereas brain-penetrating H_2 blockers have been found, no useful property for medicinal application in brain diseases has been identified for H_2 blockers.

The H_2 receptors show constitutive activity and it has been found that most H_2 blockers are inverse agonists, with burimamide, the first H_2 blocker reported, being an exception; this derivative is a true, neutral antagonist, antagonizing both H_2 agonists and H_2 inverse agonists with the same level of activity.

Compounds; Structure–Activity Relationships

Agonists Histamine has a low affinity for the H_2 receptor (K_D around 4.5 nM); as has been seen for H_1, activity is observed at much lower concentrations, with a pD_2 of about 6.2 at heart H_2 receptors, causing a high incidence of spare receptors at H_2 (the pD_2 value is the negative log of the molar EC_{50} value of an agonist). Again, as established for H_1 agonism, the structure of the physiological stimulant of the

H_2 receptor is very sensitive to changes. A certain selectivity over H_1 and H_3 (but not H_4; see later) with a minimal loss of agonistic efficacy has been reached by introducing a methyl group on position 5 of the imidazole nucleus (Figure 5). Empirically it was established that the tautomeric equilibrium of the imidazole nucleus is favorable for H_2 stimulatory activity (Figure 6). Derivatives with a substituent on the imidazole shifting the tautomeric equilibrium to one side have much reduced H_2 agonistic properties; 5-NO_2-imidazole is an example. It was proposed that upon binding of the agonist to the receptor, this equilibrium induces a proton shift in the receptor protein subsequently causing a change in receptor conformation and finally activation of the receptor.

By empirical approaches several H_2 agonists were established and have become important research compounds. The first two were dimaprit and impromidine (Figure 7). Both compounds fulfill what was considered an important criterion – that a tautomeric equilibrium would be needed for H_2 agonism. When the isothiourea group of dimaprit was 'closed,' thiazole derivatives were obtained, which on proper substitution, yielded a new class of selective H_2 agonists, of which amthamine became an important research tool in pharmacology (Figure 7). The agonistic activity of compounds like amthamine was reason to abandon the 'proton shift' theory. In contrast with histamine, no spare receptor capacity has been found for amthamine; this finding shows nicely that

Figure 5 The influence of substituents (histamine derivatives) on H_2 agonistic activity.

Figure 6 The tautomerism of the imidazole nucleus of histamine for activating the H_2 receptor.

Figure 7 Histamine and selective ($H_2 > H_1$) H_2 agonists.

a spare receptor capacity is a property of a compound and not of a receptor system.

The molecular structure of impromidine is of particular interest; at regions I, II, and III (Figure 8)

Figure 8 The different regions of the impromidine molecule and their roles in activating the H_2 receptor: I is for binding to a negative locus at the receptor, II is for activating, comparable to the imidazole nucleus of imidazole, and III contributes extra affinity for binding.

tautomeric equilibriums are possible; by structural modifications it has been established that region II is essential for H_2 agonism. This observation has led several investigators to modify region III in such a way that compounds with dual activity are obtained, yielding H_2 agonists with an extra (e.g., an H_1 blocking) property (Figure 9).

Histamine H_2 blockers Whereas H_1 blockers were initially found by applying random screening procedures, H_2 blockers were first identified by a more rational approach. Black et al. had found β-adrenergic antagonists by masking the hydroxyl groups in adrenaline. A comparable attempt using histamine led to inactive derivatives; when Black and group then changed the side chain of histamine, they eventually found a class of H_2 blockers, of which

Figure 9 Impromidine derivatives with additional pharmacological properties (PDE, phosphodiesterase).

cimetidine (Figure 10) was the first to reach the market as an antiulcer agent. The development of cimetidine was based on the assumption that the imidazole part of the molecule was crucial to the blocking properties; this assumption was not true, as became clear when it was found that nonimidazole ligands such as ranitidine and famotidine (Figure 10) had higher H_2 blocking activities, and this became important as an active principle regarding medicines effective against stomach ulcers. Because the imidazole group – as in cimetidine – causes an interaction with P450 enzymes, the favored market position of cimetidine, which had become rapidly a blockbuster medicine, was gradually taken over by the nonimidazole agents.

H_2 Ligands as Research Tools

H_2 agonists When compounds such as dimaprit, impromidine, and amthamine became available, the classic histamine derivatives (e.g., 5-methylhistamine) became obsolete as H_2 agonists. In addition to an H_2 agonistic effect, both dimaprit and impromidine also have an affinity for the H_3 and the H_4 receptors, and the selective amthamine offers advantages for pharmacological studies. Amthamine has no or very weak effects on other receptor systems; for example, the compound shows no adrenergic effect *in vitro* or *in vivo*.

H_2 blockers Compounds such as cimetidine, ranitidine, and famotidine are attractive therapeutically and are very valuable research tools. The compounds are rather selective, having no significant affinity for the other three histamine receptors. There is no example available of an active H_2 blocker carrying a chiral center.

Radiolabeled ligands When the H_2 system had been identified, there was an immediate need for a radiolabeled blocker for pharmacological studies. Cimetidine was labeled with tritium, but this ligand was unsuitable as a research tool due to extreme levels of aspecific binding, not only to proteins but also to glass surfaces. Tritium-labeled tiotidine (Figure 11) was somewhat better, but far from ideal. A very useful derivative came from a new class of blockers synthesized by Schunack and group; iodoaminopotentidine, labeled with ^{125}I, has a very high H_2 affinity (pK_D around 9.5) and a low level of specific binding. Interestingly, the iodoazido analog is an irreversible H_2 blocker and is also useful in receptor studies.

Ligands for PET studies As no use has been found for H_2 ligands in the CNS, no H_2 PET ligand has been developed.

The Histamine H_3 System

Receptors, Mechanisms, and Role in Physiology and Pathology; Potential Therapeutic Applications of H_3 Ligands

The histamine H_3 receptor was first identified during the last years (the early 1980s) of the pregenomic era, by classical pharmacological investigations, as a presynaptic autoreceptor, influencing both histamine synthesis in and release from histaminergic CNS neurons. It was subsequently found that the receptor occurs also as a heteroreceptor on other types of neurons (e.g., those releasing dopamine, serotonin, acetylcholine) in the CNS. The CNS H_3 receptors reach in high densities in distinct areas (basal ganglia, hippocampus, and cortex) but occur in certain peripheral systems as well (gastrointestinal tract, blood vessels, and airways).

After the receptor was described, it took relatively long before the H_3 gene was cloned. The gene was

Figure 10 Selective H_2 blockers.

Figure 11 Radiolabeled ligands of the H_2 receptor.

identified by researchers at Johnson & Johnson using an expressed sequence tag (EST) database. The receptor belongs to the GPCR family, being linked to $G_{i/o}$, leading to a lowering of the intracellular cAMP levels. Relatively high degrees of species differences have been established, making predictive pharmacology complicated. This became very apparent when it was found that the H_3 receptor shows constitutive activity. Indeed, agonists, inverse agonists, and (true) antagonists are available. Certain ligands are classified as so-called protean agonists, meaning that in some test systems they are agonists and in others they are inverse agonists. An example is proxyfan (Figure 12). Given all of these different aspects, the prediction of clinical applications for both agonists and antagonists is extremely difficult; this matter has been nicely reviewed by Letavic and colleagues. Interestingly, in this case inverse agonism has been shown to also occur *in vivo*. In animal experiments, both thioperamide and clobenpropit act as inverse agonists. Various isoforms of the H_3 receptor have been identified in guinea pigs, rats, and humans. These isoforms, resulting from alternative splicing, show distinct expression in several brain nuclei and signaling routes.

An extremely wide variation of biological effects mediated via H_3 receptors emerged when selective ligands for the new receptor became available. Based on the pharmacological effects, many potential therapeutic applications have been proposed, but despite intensive research programs by a large number of pharmaceutical companies, no H_3 ligand has yet reached the market as a medicine. Agonists have been

Figure 12 Proxyfan, a protean H_3 agonist.

suggested as having potential benefits in treating asthma, pain, and insomnia; antagonists are thought to be of value in treating cognitive problems, obesity, neuropathic pain, allergic rhinitis, narcolepsy, and schizophrenia. Maikel Wijtmans and colleagues have recently published a comprehensive survey on therapeutic roles that have been proposed for H_3 ligands.

Ligands of the H_3 receptor carrying an imidazole moiety likely also have considerable affinity for H_4 receptors. Although this should be seriously considered in experimental studies, the implications for potential therapeutic use seem to be limited, as H_3 ligands are targeted mainly to the CNS, and so far no role for H_4 in the CNS has been reported. However, the search for nonimidazole ligands has been very intensive and successful; because such compounds are less likely to interact with P450 enzymes, there is major interest in continuing research on their therapeutic application.

Compounds; Structure–Activity Relationships

H_3 agonists Comparing the activity of histamine on H_3 receptors with its activities on H_1 and H_2 receptors indicates that H_3 activity occurs at relatively

low concentrations of histamine; the observed pD_2 is about 7.5, being a log unit higher than the comparable parameters for H_1 and H_2 (the pD_2 values were measured as a reduction of the outflow of histamine upon electrical stimulation from isolated neuronal tissue). Even more striking is that substitutions in the side chain of histamine with small alkyl groups, which reduce both H_1 and H_2 agonistic properties, strongly increase H_3 agonism. Surprisingly, a basic moiety is not required for H_3 agonism: several 4-alkyl-substituted imidazoles have a moderate H_3 receptor-activating property. From the data of Table 1 it is apparent that H_3 agonists have no or low spare receptor capacities, a feature of many H_1 and H_2 agonists. The H_3 agonist α-methylhistamine has a pD_2 value of about 8.5. An additional feature of the latter compound is the presence of a chiral center, making this derivative very useful as a pharmacological tool (see later).

[b]Inhibition of cAMP production in β-galactosidase assay (SK-N-MC cells expressing human H_3 receptor).

Following identification of α-methylhistamine as a research tool (the compound has, however, also been investigated in several disease models), many other agonists selective over H_1 and H_2 were identified, several with a high level of activity; the most interesting ones are summarized in Table 1 and Figure 13. Because of its selectivity (H_3 over H_4), immethridine is of particularly great interest, as is methimepip. All of the listed compounds are substituted imidazoles and thus are not attractive as medicinal agents, because of poor brain penetration capacities and, even more importantly, because imidazole moieties are likely to interact with P450 enzymes, with consequences for drug–drug interactions. The poor brain penetration has been overcome by making a prodrug of α-methylhistamine (Figure 14); designed by Walter Schunack and group (Berlin), BP 2-94, upon oral administration in animals, reaches active levels of the parent α-methylhistamine in the CNS. In animals, the compound also has interesting anti-inflammatory and antinociceptive effects (no clinical data are available).

H_3 antagonists Shortly after the identification of the first H_3 agonists, reports of a number of active antagonists were published. The archetype H_3 antagonist is thioperamide (Figure 15), introduced by Jean-Charles Schwartz and co-workers in 1987.

Figure 13 Examples of selective H_3 agonists.

Soon thereafter many other H_3 blockers appeared on the scene. A recent review has been published by Wijtmans et al. All early compounds were imidazole derivatives, causing the same limitations for practical use as mentioned previously for the agonists. Highly potent blockers eventually became available, with K_D values in the low nanomolar range. A selection of such ligands is shown in Figure 15.

The H_2 agonists dimaprit and impromidine (Figure 7) both show appreciable H_3 blocking effects. The route of synthesis of the impromidine structure is complicated, whereas dimaprit analogs are easy to prepare; consequently, large numbers of the latter type of compound have been investigated and many highly active derivatives have been identified (Figure 15). The active compounds share a high level of lipophilicity; this feature, together with the presence of the imidazole nucleus and an isothiourea moiety (known to be toxic), make this type of compound unattractive for therapeutic application. These compounds have proved to be highly useful research tools, though. It is again striking that no basic group is required in the side chain. An H_3 blocker with a somewhat unusual structure is the compound known as GT-2331 (Figure 16). This derivative resulted from an optimization program screening potential lead compounds from natural sources; it was tried as a blocker in CNS indications, but failed. The cause of the failure is likely due to species differences; the compound was identified in rats as a blocker, but in humans it functions as an H_3 agonist.

For obvious reasons many nonimidazole H_3 blockers are under development and are being intensively investigated for several (mainly brain) disorders; comprehensive reviews by Wulff and Wijtmans are available. Most interesting are the nonimidazole derivatives; a selection of representative examples is shown in Figure 17. There is also a certain interest in ligands which have both H_1 and H_3 antagonistic properties; such compounds are thought – on the basis of their pharmacological profile – to be of use in certain allergic conditions. An example is the compound shown in Figure 18, which has nanomolar affinities for both H_1 and H_3 receptors.

BP 2–94

Figure 14 The potent H_3 agonist (*R*)α-methylhistamine prodrug, BP 2-94.

Figure 15 H_3 antagonists of the imidazole type.

A very complicating feature of several ligands is the extreme level of species differences; some compounds (impentamine, for example, or the already mentioned GT-2331) identified in rat studies as antagonists appear to be agonists on the (cloned) human receptor; currently the human receptor is used as the standard model for establishing an H_3 profile.

H_3 Ligands as Research Tools

H_3 agonists As already discussed, a large number of active and selective (H_3 over H_1 and H_2) agonists is available. A striking feature of the structure–activity relationship of the agonists is the role of chirality. The availability of pairs of active and almost inactive ligands such as (*R*)α-methylhistamine and (*S*)α-methylhistamine has been very instrumental in unraveling the several roles of H_3 receptors. Other widely used H_3 agonists in pharmacological studies are immepip and imetit.

GT-2331

Figure 16 GT-2331, an H_3 antagonist with an unusual structure.

H_3 antagonists Blockers of the H_3 receptors are also readily available. Compounds such as thioperamide, clobenpropit, and ciproxifan (Figures 15 and 16) are frequently used as highly potent H_3 blocking agents. Pairs of active and inactive enantiomers of H_3 blockers are not available, but this has not hampered pharmacological investigations of the H_3 system.

Radiolabeled H_3 ligands Soon after the identification of α-methylhistamine as an H_3 agonist, a tritium analog, labeled at the methyl group, was introduced as an attractive tool for ligand displacement studies. The N^{α}-methyl derivative with a tritium label in the methyl group also became available, but [^{3}H] (*R*)α-methylhistamine became the standard ligand

(Figure 19). The use of an agonist as radiolabeled ligand in ligand displacement studies has an important disadvantage that the agonistic activities may cause induction of different activation states (high and low affinity) of the receptor. Several research groups have therefore tried to identify, for the purpose of radiolabeling, suitable H_3 blockers. Successful compounds include the ^{125}I analogs of iodophenpropit and iodoproxyfan (Figure 19) (complicating this effort, iodoproxyfan has been found to be an agonist for human H_3 receptors). Besides having the advantage of being antagonists, these compounds are of great use because of the high specific radioactivity of the iodo label; a disadvantage of these compounds is their high level of lipophilicity, causing nonspecific binding to biological preparations. Both ^{125}I derivatives have also been applied to visualize H_3 receptors in the CNS. Nonimidazole inverse agonists have also been radiolabeled (tritium) for use in receptor characterization studies.

Figure 18 An H_3 blocker with additional H_1 blocking activity.

H_3 PET ligands There was an early demand for suitable PET ligands to study the pharmacology of H_3 ligands and to identify their potential medical applications. It proved difficult to find ligands that fulfill the criteria of high affinity, good CNS penetration, fast on/off kinetics at the receptor, and a 'doable' route of synthesis; there were several failures in pursuit of these characteristics. Recently, however, an interesting ligand was reported by research teams at Johnson & Johnson and the Vrije Universiteit Amsterdam. This derivative (Figure 20) could become an attractive tool to further unravel the role of H_3 receptors in healthy brains and in pathological conditions, as it fulfills all of the aforementioned criteria.

The Histamine H_4 System

The H_4 Receptor, Mechanisms, and Role in Physiology and Pathology; Potential Use of Ligands as Medicines

The newest histamine receptor to date, H_4, was not first identified by pharmacological means, as the other three receptors were. The gene for the H_4 receptor was found in 2000 by Tamaki Oda and colleagues by searching a gene bank using the sequence of the H_3

Figure 19 Radiolabeled ligands of the H_3 receptor.

Figure 20 A positron emission tomography (PET) ligand of H_3 receptors.

gene; they subsequently identified H_4 as a new type of histamine receptor. The receptor is linked to a $G_{\alpha i/o}$ signaling system, inhibiting intracellular cAMP synthesis. In eosinophils and mast cells H_4 activation leads to increased intracellular Ca^{2+} levels through a phospholipase-mediated process. As for the other three histamine receptors, constitutive activity is observed for H_4.

The H_4 receptor (protein) shows a relatively high level of homology with the H_3 receptor. Comparable to what has been observed for H_3, spliced isoforms occur for H_4, and as is the case for H_3, important species variation characterizes the H_4 system; consequently, ligand activities vary from species to species. As an example, histamine is about 25 times more active on the human receptor than on the rat H_4 receptor. As a consequence of the H_3/H_4 homology, several H_3 ligands show effects on H_4 as well (this is especially true for imidazole derivatives); the opposite also applies.

The H_4 receptor is especially expressed in bone marrow and peripheral leukocytes; the mRNA is found in eosinophils, mast cells, spleen, and, at a lower level, in the small intestine. Perhaps because methods of analysis are not absolutely reliable, conflicting results have been published on the distribution of the mRNA. It has long been recognized that histamine has proinflammatory properties; some, but not all, H_3 blockers antagonize to a certain extent the histamine-induced inflammation, but no effect is observed from H_1 or H_2 blocking agents. From these observations and based on the H_4 receptor distribution, it is attractive to consider this receptor as being the pathway by which histamine obtains its proinflammatory properties. So far, pharmacological data are available only for H_4 ligands.

There is ample evidence from *in vitro* experiments that H_4 receptors mediate processes playing a role in inflammation. It is quite remarkable that the CC chemokine ligand CCL16 also interacts directly with H_4 receptors. The pathways involved seem to be very complex and are not yet completely understood. There are also indications from pharmacological experiments that H_4 receptors may be viewed as targets for medicines to be used in inflammatory bowel disease, rheumatic arthritis, and asthma. Whereas H_1 blockers are intensively applied for treating itching, such preparations are effective only in allergy-induced itching, and not when other mechanisms are involved. In a mouse model in which itching is induced by histamine or an H_4 agonist, H_4 blockers show efficacy.

There is increasing evidence that H_4 receptors mediate chemotaxis for cells that play important roles in allergy and inflammation. H_4 receptor-mediated chemotaxis has been described for mast cells and eosinophils.

A role for histamine in malignant cell growth has long been proposed. The presence of H_1, H_2, and H_4 receptors has been confirmed on cancer cells from the colon. For example, in Caco-2 cells, histamine induces an upregulation of cyclooxygenase (Cox-2) expression which can be antagonized by H_2 and H_4 blockers; based on a prostaglandin E2 assay (PGE2), it is speculated that production of vascular endothelial growth factor and tumor growth may be influenced by a mechanism regulated by H_2 and H_4 receptors.

Compounds; Structure–Activity Relationships

H_4 agonists The reported structural resemblance of the H_3 and H_4 proteins explains a remarkable overlap in affinities of ligands for the two receptors. Most, if not all, H_3 ligands of the imidazole-type derivatives also have affinities for the H_4 receptor. As an example, the H_3 blocker thioperamide also blocks the H_4 receptor, whereas the H_3 blocker clobenpropit behaves as an agonist at H_4 receptors.

A very remarkable, nonselective H_4 agonist is clozapine, a compound that behaves as an antagonist at a variety of GPCRs. Clozapine also blocks the H_1 receptor; the clozapine analog VUF 6884 (Figure 21) is also an H_4 agonist, having a tenfold higher affinity for H_4 compared to clozapine. 5-Methylhistamine is a selective H_4 agonist; this compound was previously described as a moderately active but selective H_2 agonist. The selectivity for H_4 over H_2 is, however, at least 100-fold, with a reported K_i of 50 nM.

Compounds with a dual H_4 and H_3 agonistic activity have been found in a series of dimaprit analogs, originally developed as H_2 agonists. The guanidine analog of dimaprit, VUF 8430 (Figure 21), has comparable affinities for H_3 and H_4, having only very weak affinities for H_1 and H_2, and differs therefore in this sense from 5-methylhistamine; VUF 8430 may serve as an interesting tool in pharmacological research.

H_4 antagonists Soon after the identification of the H_4 receptor it became clear that the imidazole type

Figure 21 Selected H_4 agonists.

of H_3 ligand binds to the H_4 receptor as well. From the beginning, the search for selective H_4 blockers has therefore been focused on nonimidazole derivatives – in this way avoiding some other disadvantages of imidazoles. Highly active compounds have been found among a series of indoles and benzimidazoles, but other heterocyclic compounds (quinoxalinones, aminopyrimidines) have also been reported; some selected compounds are shown in Figure 22. Most of the published data are available so far in patent literature only, and it is therefore as yet difficult to decide on the practical value of these compounds.

H_4 ligands as tools The pharmacological approaches in H_4 research are rather special, as no simple and easy functional model is available and selective ligands are scarce as well. Cell lines with the expressed human H_4 receptor are the most frequently used model to establish either agonistic (with a reporter gene system) or blocking properties. For confirming agonistic effects, a blockade with an antagonist as JNJ 7777120 (Figure 22) may be applied.

To establish affinity, a ligand displacement technique is used, with tritium-labeled histamine as the hot ligand. This aselective ligand is applied to a population of cells expressing H_4 receptors, but lacking other histamine receptors. In general, an antagonist is preferred as the hot ligand; a study using an H_4 antagonist with a radiolabel has been published, but there is only limited information on this ligand available so far.

Pharmacological Methods to Characterize Selective H_1, H_2, H_3, and H_4 Ligands

The way in which ligands for the four histamine receptors have been identified illustrates in a very nice way the evolution that experimental pharmacology has undergone during the twentieth century – namely, from whole animal pharmacology, through molecular pharmacology with isolated organs, through radioligand displacement technology, to application of cells with expressed (human) receptors, including reporter gene technologies for measuring functional activity. In the following sections the most frequently used methods are briefly presented.

H_1

When the role of histamine in allergy became accepted in the 1930s, and when the idea emerged that histamine blocking agents might be beneficial for treating allergic patients, an intensive search for so-called antihistamines was initiated. The intravenous LD_{50} of histamine was used as a study parameter: any test compound that increased the LD_{50} was considered

Figure 22 Selected H_4 antagonists.

to be an antihistamine. Because acute death caused by histamine is mediated via H_1 receptors, only H_1 blocking agents were identified; these compounds are currently known as H_1 blockers.

When pharmacology went molecular (1950s and 1960s), the isolated gut of guinea pigs, contracted by histamine, became the standard for pD_2 values, and pD_2 (together with 'intrinsic activity') and pA_2 values became the typical parameters for agonists and antagonists. Somewhat later, isolated cells, first with endogenous receptors and later (1990s) with expressed receptors, became the standard for screening for affinity; functional activity remained to be done with the isolated organ technique. Because the radioligand mepyramine became the standard, the measured affinities, however, were independent of the applied radioligand. Currently, the functional activity of H_1 receptor ligands can be measured on isolated cells by measuring the production of the second messenger IP_3 or Ca^{2+}; a reporter gene (nuclear factor-κB) approach is also available.

H_2

The theory of the existence of more than one class of histamine receptors was originally tested on organs on which histamine was known to exert influences (the heart, increased rate; the stomach, enhanced acid secretion) but which were unaffected by the available antihistamines. Isolated organ preparations of heart and stomach, especially from the rat, have thus been used for a relatively long time and prior to availability of radioligands for reliable ligand displacement studies. The problem with the organ studies was that most H_2 blockers proved to have a high level of aspecific binding, even to the glass of the test tubes used experimentally. The problem was solved with the introduction of radiolabeled aminopotentidine (Figure 11). Another method for functional activity determinations on isolated cells involves cAMP measurement; here too a reporter gene assay (CRE) has been applied.

H_3

H_3 agonism by histamine was first identified by measuring the reduction of the outflow of (radiolabeled) histamine from neuronal tissue, preloaded with radiolabeled L-histidine. Upon stimulation by K^+, antagonism was established by measuring a reduction of the influence of the agonist. As this setup is somewhat tedious, it was replaced by a method in which the relaxation of a piece of isolated gut (guinea pig) contracted by electrical stimulation, as induced by an agonist, is established. For *in vivo* experiments, the reduced outflow of histamine, following application of an agonist in a microdialysis setup, proved to be very useful. The same is true for a method in which the reduced outflow of histamine, achieved by applying an agonist, is followed by measuring the concentration of the level of the major metabolite of histamine, N^{τ}-methylhistamine.

For ligand displacement studies the tritium-labeled agonist α-methylhistamine is widely used; the radiolabeled antagonists (^{125}I label) iodophenpropit and iodoproxyfan are also often applied. Due to the large species differences seen for this receptor, the cells with expressed human H_3 receptors have a strong preference. Currently, determination of functional activity is

often accomplished using an assay in which the binding of GTPγS is measured.

H_4

The specific distribution of the H_4 receptor constitutes a specific problem, especially for screening procedures. In such screening procedures cells with expressed H_4 receptors are widely used; in ligand displacement studies, labeled histamine is applied as hot ligand. For establishing agonistic activity, a reporter gene assay is available; in this approach an increased level of β-galactosidase is used as the parameter. Other pharmacological effects are of a rather specific nature and not very suited for screening systems. A reporter gene assay using a G_i-coupled CRE gene, with increased production of cAMP being the parameter, is applied as well. Functional activity can be established by GTPγS binding.

History of Neuroscience: Early Neuroscience

C G Gross, Princeton University, Princeton, NJ, USA

© 2009 Elsevier Ltd. All rights reserved.

Ancient Egypt

The first written description of the cerebral cortex and the first indications that the site of brain injury can determine the nature of neurological symptoms are found in the Edwin Smith Surgical Papyrus. Written in about 1700 BCE, it is a copy and gloss of a much older treatise dating back to about 3000 BCE. Legend ascribes the original treatise to Imhotep, grand vizier of the 3rd dynasty pharaoh, Zoser, and later deified as an Egyptian god of medicine.

In describing a case of skull fracture, the author noted the pulsations of the exposed brain and compared the surface of the brain to the rippling surface of copper slag (which indeed has a gyral–sulcal pattern). The laterality of injury was related to the laterality of symptom, and both aphasia ("he speaks not to thee") and seizures ("he shudders exceedingly") after head injury were described.

Overall, the treatise is a coolly empirical and practical handbook, perhaps for a battlefield surgeon. It contrasts with most subsequent ancient Egyptian medical writings, which are amalgams of mysticism, superstition, and elaborate speculation. In them, the heart, not the brain, is the most important organ, the seat of the mind and the center of intellectual activity. This hegemony of heart over brain was the prevailing view in the Ancient Near and Far East, and advocates of this opinion can be found in Europe into the seventeenth century.

Classical Greece and Rome

Formal, self-conscious science began in the sixth century BCE. with the naturalistic Ionian philosophers (such as Thales and Anaximenes) and the more mystical Pythagoreans. The Ionians, particularly, were responsible for the idea that the universe could be understood by reason: that it consisted of a set of mechanisms that worked in a consistent fashion according to fixed rules.

Several of these pre-Socratic philosophers, such as Empedocles and Democritus, were particularly interested in the sense organs and perception. However, the pre-Socratic most important for the history of neuroscience was Alcmaeon of Croton. He was the first writer to champion the brain as the seat of the senses and the central organ of intellect. According to ancient authorities, he believed.

> the seat of sensations is in the brain. This contains the governing faculty. All the senses are connected in some way with the brain; consequently they are incapable of action if the brain is disturbed . . . the power of the brain to synthesize sensations makes it also the seat of thought: the storing up of perceptions gives memory and belief and when these are stabilized you get knowledge.

Alcmaeon dissected the eye, described the optic nerves and Eustachian tubes, and recognized arteries and veins as blood vessels. More generally, he stressed that health was the state of harmony and disease that of discord of the elements composing the body.

Perhaps the most famous treatise of the Hippocratic corpus and certainly the most relevant one for neuroscience is *On the Sacred Disease* written in the fifth century BCE. The so-called sacred disease is epilepsy, but the author is clear about its natural origins:

> I do not believe that the sacred disease is any more divine or sacred than any other disease, but, on the contrary, has specific characteristics and a definite course . . . It is my opinion that those who first called it sacred were the sort of people we call witch-doctors, faith-healers, quacks and charlatans . . . By invoking a divine element they . . . conceal their ignorance of its nature.

The author is equally clear about the importance of the brain:

> It ought to be generally known that the source of our pleasure, merriment, laughter, and amusement, as of our grief, pain, anxiety, and tears, is none other than the brain. It is specially the organ which enables us to think, see, and hear, and to distinguish the ugly and the beautiful, the bad and the good, pleasant and unpleasant . . . It is the brain too which is the seat of madness and delirium, of the fears and frights which assail us . . . it is there where lies the cause of insomnia and sleep-walking, of thoughts that will not come, forgotten duties, and eccentricities.

The Hippocratic doctors did not practice dissection, and their knowledge of anatomy was slight. Although they made many perceptive observations and even devised some reasonable treatments, their conception of mechanisms was largely a mixture of false analogy and speculation. Epilepsy, for example, was believed to be caused by phlegm (one of the four humors) descending from the brain and preventing pneuma (roughly, 'vital air') from entering the blood vessels.

The influence of both Plato and Aristotle on the development of neuroscience was essentially negative, but in different ways.

Plato (427–247 BCE) argued against every kind of science, preferring pure reason over observation and experimentation, seeking divine principle rather than

natural law, and advocating the study of ideas or ideal forms rather than actual objects. His cosmological schema of the universe and the body, particularly as set forth in the *Timaios*, had a particularly strong and nefarious influence. In it the soul is divided into three parts. The immortal soul, responsible for reason, resides in the head. The superior part of the mortal soul is in the heart, which receives input from sense organs and is the executor of reason. The inferior part, controlling animal desires and emotions, is placed in the liver. This concept of localization of mental functions continued to reverberate for about 2000 years.

Aristotle (384–322 BCE) was the greatest biologist of antiquity, the founder of comparative anatomy, the first embryologist, the first evolutionist, and the first systematic student of animal behavior. Yet he dismissed the brain as wet and cold and devoid of sensation. Rather, the heart was the center of sensation, intellect, and movement. Why did Aristotle reject the views on the hegemony of the brain held by his predecessors such as Alcmaeon, his contemporaries such as Hippocrates, and even his collaborator and successor as head of the Lyceum, Theophrastus (371–287)? Aristotle produced physiological, comparative, embryological, and introspective arguments for his view of brain function. But the crucial approach in his time was the study of brain-injured humans. Both Alcmaeon and the Hippocratic writers were practicing physicians and their evidence on brain function was strictly clinical. Perhaps because Aristotle's father was a physician and he had been slated to become one himself, medicine was one of the few intellectual endeavors in which Aristotle never showed any interest, and clinical medicine was the key to brain function in fourth-century Greece.

The great Museum at Alexandria has been compared to the National Institutes of Health. The Museum was a vast state-supported institute for research including an astronomical observatory, a zoo, botanical gardens, dissecting and operating rooms, more than 100 professors and that wonder of the ancient world, the Library. In two ways it was a continuation and expansion of Aristotle's Lyceum. First, the founder and chief patron of the Museum was the first Ptolemy, who had been, together with his boyhood friend Alexander, a young pupil of Aristotle. Second, its main scientific founders were Demetrios and Strato, who had been students of Theophrastus at the Lyceum. Strato himself was interested in the brain and taught that it and not the sense organs (let alone the heart) was the seat of sensation.

The Greek reverance for the body had made human dissection impossible, or at least illegal, in Athens, but in Alexandria, where dissection of the dead for embalming had been practiced for centuries, this restriction was absent and the systematic study of the human body flourished.

The two great neuroanatomists at the Museum were Herophilos and Erasistratos (both second century BCE). Herophilos distinguished the cerebrum and the cerebellum, described the meninges and sinuses, and provided the first clear description of the ventricles. He believed all nerves originated in the brain and traced their courses to sense organs and muscles. Herophilos distinguished sensory and motor nerves by noting that damage to the former produced loss of sensation and damage to the latter loss of movement.

Erasistratos continued Herophilos's anatomical work and was particularly interested in the application of contemporary physical ideas to the study of neural function. He attributed human superior intelligence to the greater number of convolutions in brain and seems to have carried out experiments on the living brain, perhaps including the human brain. He believed the psychic pneuma entered the brain through hollow sensory nerves providing sensation and that movement was caused by the expansion of muscles due to pneuma carried to them from the brain through the motor nerves. Both views were dominant well into the eighteenth century.

Galen (129–199) was the most important figure in Classical medical science. He represents its culmination, and his views on the body and brain dominated Western thought for more than 1500 years. Galen's work on the nervous system included detailed dissections of the brains of a variety of animals, extensive clinical investigations, and a series of systematic studies of the effects of experimental lesions of various parts of the nervous system.

Galen regarded the brain as the site of sensation and thought and the controller of movement. The sensory nerves were 'soft' and came from the anterior portions of the brain, whereas the motor nerves were 'hard' and came from the posterior portions, particularly the cerebellum. Thus, sensation was a 'central process,' and the characteristics of nerves derived from their central connections.

Galen's studies of the cranial nerves and spinal cord were outstanding. He described seven of the cranial nerves and experimentally determined the functions of several of them. He studied the effects of transections of the spinal cord at various levels and concluded that the spinal cord was an extension of the brain and the conduit of sensory signals from and motor commands to the body below the head. He noted that specific spinal nerves controlled specific

muscles, and had the idea of the reciprocal action of muscles. For the next advance in understanding spinal function we must await Bell and Magendie in the nineteenth century.

Galen's writings on mental and nervous diseases, although often bizarre from our point of view, were no less influential. Mental diseases were attributed to the obstruction of the passage of pneuma in the brain by one of the four humors or sometimes to an excess of a particular humor. For example, melancholia was due to an excess of black bile and epilepsy to an excess of phlegm. He attempted to attribute particular nervous diseases to dysfunctions of specific brain regions. Epilepsy was supposed to involve the posterior ventricles and apoplexy the posterior cerebral matter itself. He ridiculed Erasistratus's correlation of intelligence with the cerebral convolutions, and in general, minimized the importance of the cerebral cortex, a view that remained prevalent until Gall. Although Galen believed the ventricles were important for the passage of pneuma, he vigorously denied that the soul was situated in them, because animals and humans could survive damage to the ventricles.

After his death, Galen's ideas became frozen dogma. Rather than extend his discoveries and experimental innovations, his successors in Europe accepted as undisputed and indisputable his views in every branch of medicine.

Medieval Europe

The advances in understanding the brain in medieval Europe are easy to summarize: there were none. The central feature of the medieval view of the brain was the localization of the mental faculties in the ventricles of the brain. The church fathers were very much concerned with the nonmaterial nature of the soul. Thus, rather than localize the soul, they ascribed loci for Aristotle's classifications of its functions, namely, the functions of the mind such as sensation, reasoning, and memory. Furthermore, they felt that brain tissue was too mundance to act as an intermediary between the earthly body and the heavenly soul, so they placed the mental faculties in the empty spaces in the brain – the ventricles. Sensation was assigned to the anterior ventricle because according to Galen, the anterior cerebrum was soft and impressionable. Cognition and reason were in the middle ventricle, an appropriate central place for the 'digestion' of the sensations. Memory was in the posterior ventricle, as that region of the brain was hard and thus a good place for storage.

During the European Middle Ages, however, much of Classical medicine was kept alive and further developed in Islamic civilization. Thus, the writings of Hippocrates, Galen, and other Greek medical figures usually came to Europe through Syrian, Persian, Hebrew, or Arabic translations and then into Latin.

Vesalius and the Rebirth of Neuroscience

The first person to break the stronghold of Galen and rekindle neuroscience was Andreas Vesalius (1514–64) – the founder of modern anatomy and, with Nicholas Copernicus (1473–1543), the initiator of the scientific revolution. By the beginning of the sixteenth century, the foundations for Vesalius's achievement were well under way. Galen's original works had become available, and the invention of movable type helped disseminate them, as well as more recent anatomical studies. Naturalism in Renaissance art had generated interest in at least superficial human anatomy. Public dissections of the human body in medical schools, originally for forensic purposes, were common and drew large audiences.

Those dissections, however, were largely demonstrations, if not ceremonial celebrations of Galenic anatomy, not investigations of the human body. Indeed, only gradually did even Vesalius realize, and then only partially, that Galen's descriptions tended to be of the brain and body of the ox or barbary ape, rather than of humans. It is only with Vesalius's great work, *On the Fabric of the Human Body* (1543), that the structure of the human body began again to be studied systematically and directly.

Vesalius ridiculed the crude medieval drawings of ventricular localization of mental function, saying, "Such are the inventions of those who never look into our Maker's ingenuity in the buildings of the human body." Although largely accepting Galen's pneumatic physiology, he was modest about the potential of anatomy for understanding brain function: "How the brain performs its functions in imagination, in reasoning, in thinking and in memory ... I can form no opinion whatsoever. Nor do I think that anything more will be found out by anatomy."

The Reflex: From Descartes to Marshall Hall

René Descartes (1596–1650) combined Galenic physiology with a conception of the body as a machine to provide the first idea of reflex action. Within a nerve, Descartes thought, there are thin threads attached at one end to the sense organs. External stimuli pull on the threads to open little gates to the ventricles allowing pneuma to flow back out of the ventricles (reflected) through the same hollow nerves, causing movement by inflating the muscles. The flow of the pneuma is

directed by the pineal gland, extending from the midline into the ventricles. In animals this is a strictly mechanical process. However, in humans, who unlike animals have a soul, the soul interacts with the body at the pineal gland and thus can influence the flow of pneuma to the muscles.

Thomas Willis (1621–75), anatomist, physician, and Oxford professor, took this idea further and related it to actual brain structures. His *Cerebri Anatome* (1664), illustrated by Christopher Wren (1632–1723), was the most complete description of the brain to that date. Sense impressions, Willis speculated, were carried by pneuma within the nerves to the *sensus communis* in the corpus striatum and then on to the corpus callosum and the cerebral cortex, where they were perceived and remembered. However, some were 'reflected' back to the muscles by way of the cerebellum. Thus, voluntary movement was controlled by the cerebrum and involuntary, or 'reflex,' movement by the cerebellum.

The first actual experiments on neural mechanisms of reflexes were carried out by Robert Whytt (1714–66) of Edinburgh. Using frogs, he showed that the spinal cord, indeed only a segment of the cord, was necessary and sufficient for reflex responses to stimulation of the skin. He also demonstrated that the pupillary reflex was dependent on the midbrain. He stressed, more than Descartes had, the protective function of reflexes. Whereas movement was strictly mechanical for Descartes, Whytt believed it was dependent on 'sentient principle,' even when involuntary or reflex, an idea that persisted into the nineteenth century.

The modern concept of a reflex largely began with the English physiologist and physician, Marshall Hall (1790–1857). He used Charles Bell (1774–1842) and Francois Magendie's (1783–1855) distinction of sensory and motor roots to develop the idea of the reflex arc. Reflexes were now, by definition, dependent on the spinal cord, independent of the brain, and strictly unconscious and involuntary. Hall also described the excitation or inhibition of reflex movements by various drugs. Finally, he was the first to use reflexes in medical diagnosis and treatment. The next significant development was CS Sherrington's (1857–1952).

Bioelectricity: From Frog's Legs to Action Potential

By the middle of the eighteenth century the stage was set for Galvani and the beginning of electrophysiology. The Leyden jar as a source of electricity and the electroscope to measure electricity had been invented, the electrical nature of lightning was known, and ideas about animal electricity were widespread among the intelligentsia. Using his frog nerve–muscle preparation, Luigi Galvani (1737–98) produced muscle contraction by stimulation with an electrostatic machine, by atmospheric electricity, by hanging the frog's legs by brass hooks on an iron railing, and by placing the cut end of a nerve on the muscle. He interpreted these observations as reflecting intrinsic animal electricity. Alessandro Volta (1745–1827), on the other hand, in a long and acrimonious controversy with Galvani, explained these and similar results as due to electricity produced by currents generated by two dissimilar metals and quite independent of any animal electricity.

Frederick von Humboldt (1769–1859) finally sorted out the controversy and demonstrated that Galvani was dealing with two independent phenomena, intrinsic animal electricity and bimetallic electricity. Carlo Matteucci (1811–68) went a step further to detect current flow in muscle both with an electroscope and another nerve muscle preparation.

Soon after, Emil du Bois-Reymond (1818–96) differentiated nerve from muscle current. Du Bois-Reymond's theory of electromotive particles lined up along the surface of nerve and muscle was further developed by his student Julius Bernstein (1839–1917) into the beginning of the modern membrane theory of the action potential. Further development awaited JZ Young's (1907–97) discovery of the squid giant axon and AL Hodgkin (1919–98) and AF Huxley's (1917–) brilliant use of it to elucidate the biophysical basis of the action potential.

From Globules to Neurons

Cells were first described (in plants) by Robert Hooke (1635–1703) and in what he called nerve fibers by Anton van Leeuwenhoek (1632–1723), but it was not until the development of achromatic lenses and methods of embedding and staining in the middle of the nineteenth century that the study of the fine structure of the nervous system could begin. Until then, and even somewhat after, nerves were considered to be hollow as Galen had suggested, gray matter was made up of 'globules,' and the relationship between the fibers of white matter and globules was unclear.

Although MJ Schleiden in 1838 pointed out that cells were the basic unit of plant life and T Schwann in 1839 extended this idea to animals, the nervous system resisted an interpretation in terms of their cell theory for at least another 60–70 years. Even after RA Von Kolliker (1817–1905) demonstrated that nerve fibers came from nerve cells and OFK Deiters (1834–63) distinguished axons from dendrites, the nervous system was thought to consist of an

interconnected network. Nerve cells were thought to be nodes of this reticular structure and the fibers originating from them to anastomose completely. J. Gerlach (1820–96) is usually considered the founder of this reticular doctrine, and Camillo Golgi (1844–1920) its most famous advocate. Yet, by using Golgi's silver stain the great Spanish anatomist Salvadore Ramón y Cajal (1852–1936) was able to demonstrate that each nerve cell with its dendrites and axon is an independent unit. This extension of cell theory to the nervous system is known as the 'neuron doctrine'. Cajal further demonstrated that neurons come in a great variety of specific shapes that are characteristic of their location and often constant from animal to animal and species to species. When they shared the Nobel Prize in 1906, Golgi and Cajal's addresses were violent attacks on one another, and the reticular concept did not entirely disappear for a few more decades. Indeed, the definitive disproof of the reticular doctrine and confirmation of the neuron doctrine had to await the electron microscope.

> Fitting theoretical equations to biological processes is often not a very profitable business, but in this case Huxley and I had a particular reason for carrying out such an analysis. (AL Hodgkin, *The Sherrington Lectures VII*, 1964)

Introduction

In 1963, Alan Lloyd Hodgkin and Andrew Fielding Huxley shared the Nobel Prize with Sir John Carew Eccles for their efforts to elucidate the electrical process by which neurons process information and then send signals down their axons as action potentials. Hodgkin and Huxley's contribution specifically involved the first clear elucidation of the ionic mechanisms underlying the action potential (Figure 1). The methods they employed involved a combination of precise and carefully controlled biophysical experiments and a careful mathematical and statistical analysis of the data. The results of these biophysical experiments were then captured in a series of nonlinear differential equations, now commonly referred to as the Hodgkin–Huxley model for action potential generation. Although first developed in the context of the movement of sodium (Na) and potassium (K) ions through the cell membrane of the squid giant axon, the basic structure of these equations has been used to represent a broad range of ion membrane conductances found not only within cells of the nervous system but also in many other electrically active cell types (e.g., the heart and kidney). Although alternatives to the Hodgkin–Huxley model have been proposed for specialized modeling purposes, Hodgkin and Huxley's basic equations have provided the foundation for literally tens of thousands of computational studies, and their achievement is arguably the foundation for computational approaches to biological systems.

Historical Context

Hodgkin and Huxley's quantitative description of membrane currents and their application to conduction and excitation in nerves was published in the *Journal of Physiology* in 1952 as the fifth in a series of papers, the first four of which were experimental. The biophysical studies that formed the foundation for the theoretical model were conducted in the giant axon of the squid, whose unusually large size allowed electrodes to be placed inside its cell membrane. The potential value of the squid giant axon for these types of studies was first suggested by JZ Young in 1936, and Hodgkin and Huxley first demonstrated the ability to record electrical potentials from inside the axon in a short report in the journal *Nature* published in 1939. Interrupted by World War II, Hodgkin and Huxley returned to their biophysical studies at the Marine Biological Station in Plymouth, UK, following up their original description of the squid action potential with a longer paper in the *Journal of Physiology* in 1945. These studies and those of their American peers, Kenneth Cole and Howard Curtis, put to rest the view that the action potential was due to the simple breakdown of the cell membrane, and they laid the groundwork for a series of papers suggesting that the electrical properties of nerves were active and not passive. Hodgkin and Huxley's five papers in 1952 were the capstone to this effort.

The first of the five papers provided a description of the electrical behavior of the membrane of the squid giant axon under control conditions. The second paper examined the effect of changing the concentration of Na on the action potential, providing evidence that the ionic currents' association with the action potential could be resolved into those related to Na flowing into the cell and K flowing out of the cell. The third paper reported on voltage clamp techniques (first applied by Cole and Curtis in 1947) used to demonstrate the effects of rapid changes in membrane potential on these ionic conductances. The fourth paper described the conduction inactivation process that they had discovered applied to the Na conductance. The final paper reassembled all these pieces together into a set of mathematical equations whose principal parameters were fit with experimental data on the voltage- and time-dependent permeability of the membrane to Na and K.

Hodgkin and Huxley's efforts represent not only arguably the first but also the gold standard for computational studies in biology. They demonstrated that a series of equations tuned using data obtained by artificially isolating and controlling the electrical response of the squid axon could, without further tuning, reproduce the naturally occurring action potential. Thus, the action potential was an emergent property of equations tuned to replicate individual ionic conductance data. In their words, these equations predicted

> with fair accuracy many of the electrical properties of the squid giant axon: the form, duration, and amplitude of the spike, both 'membrane' and propagated; the

conduction velocity; the impedance changes during the spike; the refractory period; ionic exchanges, subthreshold responses; and oscillations.

The Hodgkin–Huxley Equations

This section describes the set of Hodgkin–Huxley equations in the context of what was known about the biology of the squid axon and neuronal processes at the time. Although the key step in parameterizing the equations involved curve fitting experimental data, the form of the equations was strongly influenced by the researchers own intuition and speculations regarding the underlying physical mechanism.

The Membrane

Biologists at the time knew that cell membranes had passive electrical properties that could be characterized using basic equations derived from the physics of electrodynamics and electrical circuits. Thus, in the Hodgkin–Huxley model, the membrane of the squid axon is represented by an electrically equivalent circuit with values for membrane resistance, R_m, and capacitance, C_m. In addition, they knew that cell membranes maintain a difference in potential between the inside and the outside of the axon. Accordingly, the electrical equivalent for the membrane includes a battery (Figure 2(a)). By their own convention, the resistance is in units of $[1/G_m] = [R_m] = \text{ohm} \times \text{cm}^2$, $[C_m] = \text{F cm}^{-2}$, $[V] = \text{mV}$, and $[I_m] = \text{A}$. It was also known, of course, that the membrane potential of the axon changed with time, and that this change in time involved both the movement (or conductance) of ions through the membrane and a capacitive component due to the membrane. Thus, the overall flow of current was represented by the following form:

$$I_m = G_m(V - V_m) + C_m(\mathrm{d}V/\mathrm{d}t) \quad [1]$$

Note that according to this equation, holding V constant (thus, $\mathrm{d}V/\mathrm{d}t = 0$) allows a direct measure of I_m, which was the critical insight for the experimental use of the voltage clamp technique.

Figure 1 The action potential is the electrical discharge of a neuron. Action potentials are usually generated in the area connecting the soma and the axon (axon hillock). The plot shows the calculated voltage values of an implementation of the Hodgkin–Huxley model in which the axon was stimulated with a constant step current of 0.025 nA starting at $t = 0$.

Membrane Currents

In the Hodgkin–Huxley formulation, ionic currents are modeled as conductances (g_i) in parallel to a leak conductance through the membrane as shown in Figure 2(b) [eqn 2.1]:

$$I_m = g_m(V - V_m) + C_m \frac{\mathrm{d}V}{\mathrm{d}t} + \sum_i g_i(V - V_i) \quad [2.1]$$

$$g_i = \bar{g}_i f_i(V, t) \quad [2.2]$$

Equation [2.2] shows the net conductance given the constant $\bar{g}_i$, which represents the maximum conductance of the channels, and V_i, which is the

Figure 2 The membrane of a neuron has electrical properties. (a) The passive membrane properties include the constant negative voltage that the membrane keeps between the inside and the outside of the cell, modeled by a battery (V_m). The membrane also acts as a capacitor by separating different concentrations of charges on both sides (C_m), and the membrane allows the flow of current, characterized by a membrane resistance (R_m) or conductance ($G_m = 1/R_m$). (b) The active properties of a membrane are modeled similarly as the passive properties using conductances that depend on time and membrane voltage for each individual modeled channel. Note that each active current has a different reversal potential (V_{Na} and V_K).

reversal potential for the respective currents. Using the voltage clamp technique, Hodgkin and Huxley determined how g_i varied as a function of voltage and time, and fitted a biophysical model to $f_i(V, t)$. This function is also a function of temperature, but here we focus on its temporal and voltage dependence.

Adding Ion Currents

It was known at the time that the action potential was certainly associated with the flow of Na into the cell and K out of the cell. What was not well known was the specific biophysical mechanism of these conductances or their detailed relationship to time, voltage, or each other.

Potassium current Using voltage clamp techniques and manipulating ion concentrations, Hodgkin and Huxley showed that the K conductance generated during an action potential was turned on by depolarization and remained on as long as the stimulation remained constant. They modeled this K conductance as a first-order differential equation. The actual mathematical model they chose was based on kinetic reaction equations that had been intensely studied during the early nineteenth century by Leonor Michaelis, Maud Menten, and others. Using this form, if n is the kinetic variable, the reaction is described by eqn [3.1], with n having values between 0 and 1, and with α_n and β_n being rate functions dependent on voltage. To properly curve fit the experimental results, the activation term was raised to the fourth power, although Hodgkin and Huxley also provided a possible physical interpretation for this value (see below):

$$\frac{dn}{dt} = \alpha_n(1-n) - \beta_n n \qquad [3.1]$$

$$f_k(V) = n^4 \qquad [3.2]$$

Using the voltage clamp technique to fix the voltage of the axon at a specific value, two parameters were measured: the final value of the conductance and the time constant required to reach that value, with the rate functions then expressed as in eqns [4.1] and [4.4] (**Figures 3(a) and 3(b)**):

$$\text{Steady state: } 0 = \alpha_n(1-n_\infty) - \beta_n n_\infty \qquad [4.1]$$

$$n_\infty = \frac{\alpha_n}{\alpha_n + \beta_n} \qquad [4.2]$$

Temporal response, α_n and β_n constant

$$n_\tau = e^{-t(\alpha_n+\beta_n)} + \frac{\alpha_n}{\alpha_n + \beta_n} \qquad [4.3]$$

With time constant

$$\tau_n = \frac{1}{\alpha_n + \beta_n} \qquad [4.4]$$

The total current passing through the membrane associated with K was therefore described by

$$I_m = g_m(V - V_m) + c_m \frac{dV}{dt} + \bar{g}_k n^4 (V - V_k) \qquad [5]$$

Sodium current Hodgkin and Huxley discovered that the other conductance associated with the action potential – that due to Na – was somewhat more complex. Unlike the K conductance, the Na conductance does not maintain a continuous level with maintained depolarization but instead appears to decrease on its own after a period of time. Hodgkin and Huxley therefore postulated that in addition to a K-like activation, the Na conductance also had an intrinsic inactivation phase related to time. To describe the Na conductance, Hodgkin and Huxley therefore had to introduce two voltage-dependent variables, one for activation (m) and one for inactivation (h), as shown in eqn [6.1]:

$$f_i(V, t) = m^3 h \qquad [6.1]$$

$$\frac{dm}{dt} = \alpha_m(1-m) - \beta_m m \qquad [6.2]$$

$$\frac{dh}{dt} = \alpha_h(1-h) - \beta_h h \qquad [6.3]$$

As in the equations for K (eqns [4.2] and [4.4]), the kinetics of these variables were governed by the rate variables m_∞ and h_∞, with a reverse dependence with respect to depolarization voltage for activation (m) kinetics and inactivation (h) kinetics (**Figures 3(c)–3(f)**). Accordingly, the values of m_∞ increase as voltage rises, whereas the values of h_∞ decrease (**Figures 3(d) and 3(f)**). The multiplication of both variables ensures that the sodium current is only active in a small window of voltage and time after depolarization, and the inactivation term means that the conductance decreases even in the presence of a sustained depolarization (generated, for example, by the voltage clamp). Combining the Na and K conductance terms, the final form of the Hodgkin–Huxley model is

$$I_m = g_m(V - V_m) + C_m \frac{dV}{dt} + \bar{g}_k n^4 (V - V_k) + \bar{g}_{Na} m^3 h (V - V_{Na}) \qquad [7]$$

Figure 3 Rate functions used to reproduce the action potential in the Hodgkin–Huxley model. (a) Forward (α_n) and backward (β_n) rate constants used to model the potassium conductance: $dn/dt = \alpha_n(1-n) - \beta_n n$. (b) An alternative way to describe the kinetics of the model that allows measuring their values experimentally is to use the steady-state value of the rate variable, $n_\infty = \alpha_n/(\alpha_n + \beta_n)$, and time constant, $\tau_n = 1/(\alpha_n + \beta_n)$. (c–f) The sodium current requires two particles, one of which models the fast activation (m) and the second one models the inactivation (h). Note that the inactivation particle behaves inversely as a function of voltage compared to the activation particle.

Emergent Properties

Although the ability of this equation to replicate an action potential "agreed satisfactorily with the time course of the action potential recorded experimentally" was the evidence cited as support for the model in the original 1952 paper, another measure of the success of their efforts was in the other properties of axons and neurons which this equation also illuminated (and replicated). These are discussed next.

Firing threshold and firing frequencies One way to determine the minimum current required to generate an action potential in the model and the experiments is to inject a step current of different amplitudes. Figure 4 shows that for low levels of current amplitude, the model does not generate action potentials (black trace). When the amplitude of the step current is approximately 0.02 nA, the model produces only one action potential. A single action potential is evoked by stimulation between 0.02 and 0.045 nA. After 0.045 nA, the model generates an uninterrupted train of action potentials. After that, the increase in firing frequency with increased current injection follows a logarithmic function. Thus, overall, a constant current of sufficient amplitude, injected into a neuron and the model, results in repetitive firing after reaching a threshold. However, the Hodgkin–Huxley model also accounts for the fact that the onset of firing is dependent on the rate of depolarization of the membrane. As shown in Figure 4, two types of current stimulus induce different current threshold for firing. The red trace shows a similar simulation in which the step current was preceded by a 100 ms ramp. Note that not only has the threshold for generating a repetitive train of action potentials been shifted to higher currents (0.08 nA) but also there is no generation of a single spike for lower values of stimulation. The same is true for voltage. Figure 5 shows that an instantaneous depolarization of the membrane results in a voltage threshold between 6 and 7 mV. If, instead of a sudden instantaneous depolarization, the membrane voltage is clamped to a ramp, then the threshold to generate an action potential varies as a function of the duration of the ramp. If the duration of the ramp is longer than 10 ms, then no action potential is evoked. The model suggests that this is due to the increasing inactivation of the sodium conductance under this type of stimulus. Thus, an action potential is generated at a

Figure 4 Action potential frequency and threshold as a function of injected current. The model was stimulated with different constant values of current starting at $t = 0$ for 1000 ms (black). We then recorded the number of action potentials generated during that period and calculated the firing frequency. The red curve shows the average firing rate calculated over the same window of time as the black curve but preceded by a ramp current over 100 ms.

Figure 5 The Hodgkin–Huxley model does not have a fixed voltage threshold. (a) Response of the model to increasing instantaneous depolarizations. At $t = 0$, the voltage is fixed at different depolarizing values for a single time step (0–8 mV). The threshold is between 6 and 7 mV. (b) The voltage threshold depends on the stimulus. We simulated several voltage clamp experiments in which the axon was depolarized following a ramp function starting at $t = 0$ for three different windows of time. After the voltage clamp ramp reached the target final voltage, the simulation was allowed to continue freely. The final voltage was 5, 20, or 30 mV. Depending on the length of the ramp stimulation, the axon never generated an action potential.

different level of depolarization for a step voltage pulse than for a voltage current. In this sense, Hodgkin and Huxley demonstrated that neurons do not, in fact, have a fixed threshold for firing, but both the timing and the rate of firing depend on the type of depolarization.

Refractory period After an action potential is generated, there is a window of time in which an identical stimulus fails to generate a second action potential. The Hodgkin–Huxley model suggests that this refractory period is due to the combination of the inactivation of Na channels and the activation of K conductances (Figure 6).

Propagation velocity Hodgkin and Huxley related eqn [7] to the speed of action potential propagation by noting that the membrane current (I_m) is proportional to the speed of voltage change:

$$I_m = \frac{a}{2R_a v^2}\frac{\partial^2 V}{\partial t^2} \qquad [8]$$

where v is the propagation velocity, a the fiber diameter, and R_a is the cytoplasmic axial resistance. Hodgkin and Huxley found that only the correct value of v makes the shape of the action potential stable. Using an iterative method, they calculated the value of v that was within 10% of the experimentally found value.

Anode break A feature of many neurons is that an action potential is generated after being hyperpolarized. In the Hodgkin–Huxley model, this is due to the sudden change in voltage and the fast time constant of the sodium channels. Combined, they are capable of allowing a sudden influx of current that results in an action potential (Figure 7).

Figure 6 The action potential has a refractory period. The plot shows an identical simulation as shown in Figure 5(a), where the model was instantaneously stimulated at $t = 0$ to 8 mV, generating an action potential. At different times after the initial stimulus, a second identical stimulation was delivered ($t = 7$, 10, and 15 ms). The plots show that it is not until the second stimulus is 15 ms apart that a full-blown action potential is evoked.

Figure 7 Anode break response or excitation after release from inhibition. The model generates an action potential after being voltage clamped at relative negative potentials (−20, −10, and −5 mV) for 50 ms and then allowed to continue freely without any further external stimulation.

Physical Interpretations of the Hodgkin–Huxley Equations

Rigorously, the Hodgkin–Huxley equations are not a model of action potential generation since their derivation does not start from an actual biophysical model of the components (now known to be actual channels in the membrane) that are responsible for current flow. This was recognized by the authors in their original paper when they noted that "an equally satisfactory description of the voltage clamp data could no doubt have been achieved with equations of a different form, which would probably have been equally successful in predicting the electrical behavior of the membrane."

There is no question, however, that the choice of the form of the equations Hodgkin and Huxley used reflected their own guess as to the mechanisms involved. In particular, Hodgkin and Huxley knew from their previous experimental work that the movement of ions through the membrane was an active process and not, as had previously been thought, simply a general breakdown of the membrane. Therefore, it was natural for them to suggest that some active agent, in this case transporter particles, might be responsible for actively facilitating the movement of ions through the membrane. Hodgkin and Huxley interpreted the exponents in the rate equations (n^3, m^4, and h) to reflect the number of particles necessary to move a single ion.

Today, we know that Na and K conductances (and almost all ion conductances) are dependent on actual

physical channels that can have multiple open and closed states. The actual flow through these channels is not facilitated; once the channel opens, the ions flow along their concentration and potential gradients. However, the fact that Hodgkin and Huxley constructed their equations based on first-order reaction kinetics allowed multiple mechanistic interpretations to be applied, including the probability of open and closing of a 'gate' in the channel. The fact that the form of the equations was so well matched to the form of the experimental data also meant that Hodgkin and Huxley captured the dynamics, independent of the specific mechanism.

Modern Interpretation of Hodgkin–Huxley Equations

It is another tribute to Hodgkin and Huxley's work, and the close interaction between their experimental and theoretical efforts, that the form of their equations can be reinterpreted in the context of modern channel data, even though the authors did not know about channels. Specifically, we now know that current flows along the electrochemical gradient of a pore created by a membrane channel. The opening and closing of a channel is a stochastic event that depends on membrane voltage and time. Each channel is composed of internal states. For example, the exponent of the activation particle of the K conductance (n^4) is now interpreted to mean that each ion channel has four independent internal states, and it is only when the four states are in the active position that ions actually flow through the membrane. Similarly, for the Na conductance, a single channel requires three internal states to be in the open position (m^3) and the inactivation variable to be closed (h) for Na to flow. The rate functions α_i and β_i determine the transition between open and closed states.

Limitations in the Hodgkin–Huxley Formulation

Although the Hodgkin–Huxley model has been tremendously successful, there are limitations. The fact that Hodgkin and Huxley found it expedient to work in the squid giant axon, for example, has had consequences for our understanding of the biophysics and evolution of ion channels. Specifically, the squid giant axon is a highly specialized biological device whose sole purpose is to rapidly and reliably activate the muscles of the squid's mantle to generate its jet propulsion mechanism. As a result, the ion conductances of the axon have evolved for speed and consequently are less complex than those found in many other neurons. We now know that most other neurons are much more complex, especially with regard to the number and diversity of potassium conductances. Nevertheless, these more complicated conductances are still generally represented computationally using a Hodgkin–Huxley formulation.

With an interest in reducing the computational complexity of their models, others have argued that the Hodgkin–Huxley formulation is more complex than necessary to replicate the basic phenomenon it describes. In their original 1952 paper, Hodgkin and Huxley made the point that there might be other equations which capture the dynamics of the action potential. In 1961 and 1962, Fitzhugh and Nagumo introduced one such formulation, which is now used extensively in simplified neural network-type models to represent the spiking behavior of neurons. This simplified model is computationally more compact than the Hodgkin–Huxley model, although it loses several of the subtleties of the Hodgkin–Huxley form, including the precise reproduction of the shape of the action potential; however, it preserves the timing of firing when stimulated by a constant current.

With respect to real biological mechanisms, there is good evidence that the Hodgkin–Huxley formulation may not be complex enough. It has been known for some time, for example, that the Hodgkin–Huxley equations cannot in their traditional form account for the variability of spike initiation or the speed of the rising phase of the action potential, especially in mammalian cortical neurons. One explanation for these two properties relies on reconsidering the fundamental assumption of the Hodgkin–Huxley equations that individual ionic conductances act independently of each other. There is now evidence, although controversial, for cooperativity among sodium channels which appears to account for the variability and speed of the action potential but requires a new form of equations.

Thus, since its original introduction, the Hodgkin–Huxley model has been changed by some to be less complex and by others to be more complex. Yet, for more than 50 years these equations have provided the basis for the majority of modeling efforts in neuroscience. The close and quantitative connection Hodgkin and Huxley made between careful experimental studies and intuitively driven mathematical structures continues to provide the foundation for computational neuroscience and our evolving understanding of the function of the nervous system.

Holoprosencephaly

J A Golden, Children's Hospital of Philadelphia and the University of Pennsylvania School of Medicine, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Holoprosencephaly is a dramatic central nervous system (CNS) malformation highlighted by a partial or complete failure of the brain to separate into right and left hemispheres, forming a continuum of cortex and other structures across the midline. Patients with this anomaly frequently exhibit specific craniofacial anomalies, including midline facial clefts, cyclopia, and nasal anomalies. Although relatively rare, holoprosencephaly is the most common anomaly involving the brain and the face, with an incidence of approximately 0.48–0.88 per 10 000 live-born children with normal chromosomes and an estimated 40 per 10 000 cases among human abortuses, indicating a high rate of fetal loss. The identification of mutations in multiple genes coupled with advancements in understanding neural tube induction and patterning have provided a somewhat unique opportunity to begin understanding the neurodevelopmental basis of a human malformation. This article reviews the pathology, genetics, and current understanding of neural development as it relates to holoprosencephaly.

Classification and Associated Anomalies

The cardinal feature of holoprosencephaly is a single telencephalic ventricle with continuity of the cerebral hemisphere across the midline (Figure 1). Holoprosencephaly is conventionally divided into three subtypes, lobar, semilobar, and alobar, based on the extent of the malformation. In reality these three subtypes represent a continuous spectrum rather than clearly distinguishable forms of the same disorder. In addition to the CNS anomalies, specific craniofacial abnormalities are associated with holoprosencephaly and together constitute the holoprosencephaly sequence or syndrome. Similar to the brain anomalies, the craniofacial anomalies vary in extent, from the most severe, cyclopia with a single proboscis (nasal anlagen) located above the midline eye, to the mildest facial abnormality, consisting of a single midline maxillary incisor. While some correlation exists with the extent of the brain anomaly to the severity of the craniofacial anomalies, there is not a perfect association.

Environmental Causes of Holoprosencephaly

An outbreak of cyclopia in lambs in the early 1960s led to the identification of cyclopamine, a steroidal alkaloid, as the causative agent. Ewes grazing on *Veratrum californicum*, a plant species containing large amounts of cyclopamine, were found to give birth to malformed offspring. Further studies determined that cyclopamine and a related compound, jervine, can cause a similar spectrum of anomalies in chickens, rats, mice, hamsters, and rabbits. The pathogenetic mechanism through which these alkaloids exert their effect was linked to molecular signaling along the sonic hedgehog (SHH) pathway, a signaling pathway involved in many developmental processes, including neural induction and the pathogenesis of holoprosencephaly.

Genetics

Approximately 25% of patients with holoprosencephaly have a recognizable syndrome. As will be discussed, the Smith–Lemli–Opitz syndrome, which is due to a defect in cholesterol biosynthesis at the level of 3β-hydroxy-steroid-Δ^7-reductase, is of particular interest because it also has a link to the SHH signaling pathway. A number of nonrandom chromosomal abnormalities have also been found in patients with holoprosencephaly. Chromosomal anomalies have been reported in 24–45% of live-born infants, the most common of which is trisomy 13. Based on nonrandom cytogenetic rearrangements, at least 12 chromosomal regions on 11 chromosomes may contain genes that play a role in the pathogenesis of holoprosencephaly.

Positional cloning studies, cloning of translocation sites, and candidate gene screenings have resulted in the identification of mutations in six genes associated with holoprosencephaly. The first identified was *SHH*; subsequently, mutations in *SIX3*, *ZIC2*, *TGIF*, *PTCH1*, *GLI2*, and *TDGF1* have been identified (Table 1). All but one of these genes can be placed in a complex signaling pathway, suggesting a common pathogenesis for holoprosencephaly (Figure 2).

Confirmation that *SHH* plays a role in the pathogenesis of holoprosencephaly has come through the generation and analysis of mice that are homozygous mutant for *Shh*. These mice show cyclopia and CNS features that resemble holoprosencephaly. Why only homozygous null mutant mice have features of the holoprosencephaly sequence, whereas humans heterozygous

Figure 1 Alobar, semilobar, and lobar holoprosencephaly. (a) Frontal view of the brain from a 20-week fetus with alobar holoprosencephaly; note there is no fissure separating the two hemispheres. (b) Brain from an adult with alobar holoprosencephaly, showing continuity of the gray matter across the dorsal midline. This patient had minimal ventral abnormalities, which is atypical for most cases of alobar holoprosencephaly. (c) Semilobar holoprosencephaly with a small cleft partially separating the dorsal–caudal cerebral hemispheres (caudal view, 19-week fetus). (d) Brain from a full-term child with semilobar holoprosencephaly. The diencephalic structures show an abnormal structure spanning the midline and there appears to be a sagittal fissure; however, gray matter is seen crossing the midline and no corpus callosum is present. (e) Brain of a 20-week fetus with lobar holoprosencephaly. The cerebral hemispheres appear separated in both anterior (top) and posterior (bottom) sections, although the diencephalon shows a massively enlarged massa intermedia or an abnormal developed midline structure (bottom section). (f) Coronal section from the same brain as in (e), showing a continuum across the midline in the frontal cortex only.

Table 1 Holoprosencephaly genes

Gene	*Abbreviation*	*Chromosomal location*
Sonic hedgehog	*SHH*	7q36
Patched-1	*PTCH1*	9q22.3
Sine oculis homeobox homolog 3	*SIX3*	2p21
ZIC family member 2	*ZIC2*	13q32
5′-TG-3′-interacting factor	*TGIF*	18p11.3
GLI-Kruppel family member GLI2	*GLI2*	2q14
Teratocarcinoma-derived growth factor 1	*TDGF1*	3p21.31

Figure 2 Cellular signaling pathways implicated in holoprosencephaly. Schematic representation of two cells (pink and blue), with the nucleus (yellow) highlighted in one cell. All factors shaded in black have known mutations correlating to holoprosencephaly (see text). SHH, sonic hedgehog; SHH-N, N-terminal of SHH; DLP, Dally-like protein; PTCH, Patched; SMO, Smoothened; CDO/BOC, cell adhesion molecule-related/downregulated by oncogenes/brother of CDO; GLI2, GLI-Kruppel family member 2; ZIC2, ZIC family member 2; RA, retinoic acid; RAR, retinoic acid receptor; RXR, retinoid X receptor; CRBPII, cellular retinol-binding protein 2; SIX3, sine oculis homeobox homolog 3; HIP1, hedgehog-interacting protein 1; BMP, bone morphogenetic protein; Type I, BMP receptor type I; Type II, BMP receptor type II; SMAD, mothers against decapentaplegia; R-SMAD, receptor SMAD; P, phosphorylation; FAST1, forkhead activin signal transducer 1 (forkhead box H1); TGIF, 5′-TG-3′-interacting factor.

for mutations in *SHH* show holoprosencephaly, remains unknown. Presumably, point mutations in the human *SHH* gene result in haploinsufficiency. Further studies will be required to sort out this discrepancy. The analysis of other mouse mutants also supports the role in holoprosencephaly, although this was not true for at least one mouse model (*Tgif*), confusing its role in the pathogenesis. Interestingly, extreme heterogeneity exists in the clinical expression of the holoprosencephaly sequence within families with known mutations. In some of these families, rare polymorphisms or mutations in a second holoprosencephaly gene have been identified, supporting a complex genetic origin in some cases.

Neuropathology

Hans Kundrat first designated this class of malformation as arrhinencephalies, considering the absence of the olfactory bulbs and tracts as the cardinal feature. Paul Yakovlev later pointed out that these malformations were not of the rhinencephalon (end of the forebrain) alone, but instead were a defect of the entire telencephalon. Recognizing the single telencephalic ventricle, which Yakovlev called a holosphere, he named this class of malformation 'holotelencephaly.' The subsequent recognition that the thalamus and other diencephalic-derived structures were also affected in these patients led William DeMeyer to coin the term 'holoprosencephaly' to account for a defect in the entire prosencephalon. Holoprosencephaly has since been the preferred terminology.

In all forms, the brain is small, averaging less than 100 g at full term for the alobar and semilobar forms of holoprosencephaly. The classification of alobar, semilobar, and lobar forms of holoprosencephaly is primarily based on the presence or absence of a midline fissure separating the two cerebral hemispheres and the extent of the fissure. In reality, these three forms are really a spectrum of the same entity, and this classification is useful for anatomic and pathologic purposes but does not appear to have clinical relevance.

In alobar holoprosencephaly, no midline fissure separates the two cerebral hemispheres that morphologically exhibit one holosphere (**Figure 1**). The Sylvian fissures are not formed and there is often no distinction between the lobes of the cerebral hemisphere. In infants and older individuals, the gyri are usually well developed; however, the course of the gyri does not resemble the normal surface anatomy. Instead, there are frequently sets of medial and paramedial gyri. The most medial gyri frequently contain the hippocampus and entorhinal cortex and course along the lateral aspect of a cystlike membrane located in the dorsal–posterior aspect of the brain. The posterior aspect of the cerebrum is shaped like a horseshoe with the posterior–dorsal rim is composed of the thin, cystlike membrane. This membrane is actually the posterior roof of the single telencephalic ventricle. The basal ganglia and thalamus are immediately under the cystlike membrane and vary from distinct left and right structures to disorganized masses that span the midline. The corpus callosum and anterior commissure are usually absent; however, occasionally rudimentary callosal plates may be identified. Of interest, Probst's bundles have not been identified in the brains of patients with holoprosencephaly, which may reflect the absence of normal cortical projections (see later). The brain stem and cerebellum are most often grossly normal, although the corticospinal tracts are usually hypoplastic or absent.

Semilobar holoprosencephaly represents an intermediate degree of the same CNS malformation. The distinction between semilobar and alobar holoprosencephaly is the presence of a partial interhemispheric fissure separating the posterior extent of the cerebral hemisphere (**Figure 1**). In semilobar holoprosencephaly, the midline fissure does not extend to the rostral end of the brain and on cross sections; at the level of the midline fissure, cerebral cortex crosses the midline in continuity. Again the gyral pattern is disorganized.

The lobar form of holoprosencephaly is generally considered the least severe in the spectrum and is characterized by an interhemispheric fissure that divides virtually the entire brain, with the exception of the most rostral and ventral regions of the frontal lobes. Despite the apparent interhemispheric fissure, cerebral cortex is still found crossing the midline along virtually the entire anterior–posterior axis. Occasionally, a small part of the most posterior region of the brain will have a complete separation of the cerebral hemispheres and may even show a well-developed corpus callosum in the region of the separated cerebral hemispheres. The lobes of the cerebral hemispheres may become recognizable in the mildest cases, along with the semblance of a normal gyral pattern. Cross sections of the brain continue to show the single telencephalic ventricle (holosphere) with disorganized basal ganglia, commonly restricted to the most rostral region, forming a single structure across the midline. The thalami may be less involved, although an enlarged massa intermedia is quite common.

Some controversy exists regarding the cytoarchitecture of the cerebral cortex. All cytoarchitectural areas of the cerebral cortex have been identified in some cases, whereas others have reported the

organization of the cerebral cortex to be markedly disrupted. Large periventricular and/or white matter glioneuronal heterotopia are encountered in occasional cases. The defects in cortical organization that are more frequently observed may represent secondary injury to the cerebral cortex or an abnormality in connections into and out of the cerebral cortex. The pia overlying the cerebral hemisphere often shows extensive glioneuronal rests that form a 'crust' over the surface of the brain. This is not ordinarily seen at midgestation, but is common in late gestation and postnatally, suggesting a secondary change or late-developing anomaly.

The hippocampus is virtually always present, although most often developmentally incomplete or abnormal, particularly in its medial structures. The histopathology of the basal ganglia and the thalamus varies, frequently in direct proportion to the severity of the cerebral hemispheric malformation. In the most severe cases (alobar holoprosencephaly), the basal ganglia may be unidentifiable or recognized only as a midline mass with disorganized cytoarchitecture that has only a superficial resemblance to the caudate or putamen. The globus pallidus is often not recognizable. In less severe forms of holoprosencephaly, all components of the basal ganglia are present, although the head of the caudate may be a single structure spanning the midline and the septal region is not identifiable as such. The cerebellum may show various degrees of cortical dysplasia and/or heterotopia. This is particularly true for those cases associated with trisomy 13 and other cytogenetic abnormalities. Abnormalities of the brain stem are frequently limited to hypoplastic or absent corticobulbar and corticospinal tracts.

The olfactory bulbs and tracts are absent in virtually all of the cases. The optic nerves are often hypoplastic, while the remaining cranial nerves are usually normally formed. The course of middle and anterior cerebral arteries is usually abnormal. Most often, a disorganized cluster of vessels (rete mirable) extends from the region of the internal carotid arteries anteriorly over the ventral and frontal regions of the brain. A single anterior cerebral artery may be found coursing along the midline over the rostral aspect of the cerebral hemispheres. A variety of other less commonly associated anomalies of the brain (e.g., encephaloceles, myelomeningoceles, arachnoid cysts, porencephaly) may be seen in occasional cases of holoprosencephaly.

Pathogenesis

When the arrhinencephalies were first defined as a distinct entity, the embryologic origin was postulated to be a failure of the most rostral forebrain and the olfactory bulbs and tracts to develop. This remained the prevailing theory until 1959, when Paul Yakovlev first postulated that these anomalies resulted from a failure of the simple rostral neural tube to cleave into two cerebral hemispheres. In humans this was believed to occur shortly after neural tube closure, approximately 38–45 days postfertilization. The failure-of-cleavage hypothesis was later amended to include the possibility that the two cerebral hemispheres either represented a failure of cleavage of the simple neural tube, or that the two cerebral hemispheres failed to grow out from the neural tube. This suggested a failure in regional cell proliferation or potentially excessive cell death. Given that brains showing holoprosencephaly are always very small, averaging less than 100 g at full term, a failure to grow, or increased cell death, appeared to be a reasonable hypothesis. Over the past decade, the focus of the anomaly has shifted from the failure of cleavage or outgrowth of the rostral neural tube to a defect of the prechordal mesendoderm and the mediobasal forebrain. These data have led to the refined hypothesis that holoprosencephaly results from a primary defect of induction and patterning of the rostral neural tube, occurring in the first 4 weeks of gestation.

The classic experiments of Spemann and Mangold demonstrated that the neural tube, and, in fact, the entire body axes, could be induced by a small region of embryonic tissue, which has become known as the Spemann organizer. At the site of induction, an organized process of cell movement known as gastrulation occurs, resulting in the formation of a primitive streak and the migration of a population of cells to form the notochord. The notochord induces the overlying ectoderm, fated to become the neuroectoderm, to become the ventral neural tube. At the level of the spinal cord, the induction is mediated through the secreted protein SHH. First expressed by the notochord, SHH induces the midline of the overlying neural plate to become a specialized region of the neural tube known as the floor plate. The floor plate, once induced, also expresses SHH, leading to the induction of several transcription factors in the adjacent ventral columns. In turn, these give rise to the various classes of ventral interneurons and motor neurons, with each class dependent on the expression of specific transcription factors.

Development of the dorsal neural tube appears to be regulated by molecules produced initially in the adjacent nonneural ectoderm and later by the dorsal midline (roof plate). The molecular regulators of this process include bone morphogenetic proteins (BMP) and WNT proteins. Multiple members of the *BMP* and *WNT* gene families are expressed in the dorsal midline of the CNS. Loss-of-function studies

for several members of the *WNT* family and BMP signaling through the BMP receptors support a role for these proteins in dorsal neural tube development.

In contrast to the pathways that are being elucidated for dorsal–ventral patterning in the more caudal regions of the neural tube, study of the molecular basis for dorsal–ventral patterning of the rostral neural tube are more complex and less complete. Similar to the spinal cord, SHH participates in ventral patterning of the midbrain and the forebrain. SHH is expressed in two domains of the prosencephalon; initially it is restricted to the tuberal and mammillary hypothalamic primordia, and later to a small region in the rostrobasal telencephalon. Ectopic expression studies in the forebrain indicate that SHH is sufficient to induce gene markers of the tuberal and mammillary hypothalamus and basal telencephalon. Mice homozygous mutant for *Shh* lack ventral forebrain development and have cyclopia and holoprosencephaly. *Shh* has also been shown to be necessary and sufficient for forebrain development in zebra fish, complementing the data from mammals.

The genetic pathway(s) involved in dorsal induction and patterning of the prosencephalon are beginning to be understood, although they are currently less well defined than those for ventral induction. Similar to more caudal regions of the neural tube, BMPs also appear to participate in dorsal forebrain patterning. *In vitro* studies with forebrain tissue explants indicate that BMPs can induce genes that are expressed in the roof plate, such as *Msx1*, and repress *BF1*, which is expressed in the dorsal lateral forebrain. Ectopic localization of recombinant BMP5 or BMP4 into the chick embryo prosencephalon also results in holoprosencephaly, cyclopia, and a proboscis. Evaluation of these embryos has shown that dorsally expressed genes are still expressed in the forebrain. However, genes normally expressed in the ventral (mediobasal) forebrain are not seen or their expression is markedly reduced. Further evaluation of these embryos reveals evidence of cell death in the ventral (mediobasal) forebrain alone. Development of the holoprosencephaly sequence in these chick embryos is of further interest because the recombinant BMPs were introduced after the normal timing of prechordal plate induction on the forebrain.

In summary, the data on dorsal and ventral patterning of the forebrain are beginning to shed light on the molecular basis of holoprosencephaly. Development of this malformation may result from an initial failure of the prechordal plate to induce the overlying neuroectoderm to become the ventral forebrain. Some have hypothesized that the underlying defect in this malformation is the prechordal plate. Support for this concept comes from the *Shh* homozygous mutant mice, in which signaling from the entire notochord and prechordal plate fails to induce ventral markers and cell types, although these mice still express dorsal markers. Studies of two zebra fish mutants, *Cyclops* and *one-eye pinhead*, also support a primary defect in signaling from the prechordal plate as the pathogenesis of this malformation. The *cyclops* mutant has recently been shown to represent a defect in either nodal-related protein Ndr1 or Ndr2. The Nodal family of proteins are members of the transforming growth factor-β (TGF-β) superfamily, similar to the BMPs. The zebra fish *cyclops* mutants have mutations in *Ndr1* or *Ndr2* and show abnormal maintenance of the prechordal plate cells. In another mutant, *one-eyed pinhead*, the notochord develops but not the prechordal plate. The *one-eyed pinhead* mutant fish have cyclopia and are missing the ventral forebrain. A novel epidermal growth factor (EGF)-like molecule was recently identified as the *one-eyed pinhead* gene product. These data all support a primary defect of ventral forebrain induction by the prechordal plate. Data from ectopic localization of BMPs in chick embryos suggest that the holoprosencephaly sequence can occur in the presence of normal prechordal plate signaling if the responding cells (ventral forebrain) are absent. Further work will be required to define the pathogenesis of this sequence and the many genes involved. These data are likely to come from reverse genetics, experimental embryology, and the identification and characterization of additional mutant from multiple species.

Recent work has demonstrated that the holoprosencephaly sequence can arise not only from abnormal dorsal–ventral patterning of the forebrain, but also from defects in cholesterol biosynthesis. These abnormalities in cholesterol biosynthesis may have effects on the SHH signaling pathway. SHH is synthesized as an approximately 45 kDa precursor that undergoes an autocatalytic processing event that produces an approximately 19 kDa N-terminal product (SHH-N) and an approximately 25 kDa C-terminal fragment (SHH-C). SHH-N is responsible for all signaling by binding to Patched (PTCH), the primary receptor for SHH signaling. Binding of SHH-N to PTCH results in the suppression of PTCH, which normally functions to suppress SHH pathway activity. SHH-C's function is to perform the autocatalytic cleavage of the precursor protein and mediate the covalent modification of the N-terminal fragment by cholesterol. A second lipid modification subsequently results from attachment of palmitate at the N-terminus of SHH-N. Through this pathway it can be seen how cholesterol is required for normal SHH signaling. A second role for cholesterol is in the translocation of Smoothened (SMO) upon derepression

from PTCH. How this occurs is less clear but may depend on specialized lipid rafts. Lipid rafts have also been postulated to regulate other membrane components of SHH signaling, such as hedgehog interacting factor (HIF) and Dispatched (DISP) (see Figure 1).

Given these apparent roles for cholesterol in SHH processing, it is reasonable to speculate on the observed experimental overlap between SHH signaling and perturbations in the cholesterol biosynthesis pathways. As already noted (see discussion of environmental factors), blockers of cholesterol biosynthesis by naturally occurring compounds or specific drugs give rise to experimental animals with cyclopia and, in some cases, holoprosencephaly. It has also been shown that disruptions in genes involved in cholesterol transport can also phenocopy mutations in SHH. Furthermore, holoprosencephaly may occasionally be seen in the Smith–Lemli–Opitz syndrome, which is caused by defective cholesterol biosynthesis and can result in severe hypocholesterolemia. While it is enticing to implicate the cholesterol modification of SHH as the mechanism causing the phenocopy of SHH signaling abnormalities and cholesterol biosynthesis defects, the pathogenesis remains unknown. In fact, experimental blockage of the cholesterol biosynthesis pathway in mice resulted in cyclopia but not in the sterol modification of SHH-N. In contrast, tissues treated with these same compounds were unresponsive to cholesterol. This has led to the hypothesis that the cholesterol biosynthesis is primarily important for the response of target tissues (i.e., effects on SMO).

Finally, it is worth at least speculating on the pathogenesis of the frequently associated craniofacial and CNS anomalies. As discussed previously, the prechordal plate plays essential roles in induction of the ventral forebrain. SHH, which is expressed in the prechordal plate, appears to mediate this induction. SHH also appears to directly participate in craniofacial development, and the initial signaling for this is also likely to come from the prechordal plate. Eye development is also under the control of SHH, and this signaling is absent in cyclopic zebra fish. Normal eye development requires repressing the midline of a single eye field, which results in two lateral eye fields and thus two lateral eyes. The midline repression appears to be under the control of the prechordal plate. In the absence of this repression, a single eye field remains and results in the development of a single midline eye. Given that this eye field is located ventral to the site of nasal placode induction, the location of a proboscis above a single midline eye seems intuitive. Whether this is the embryologic origin of the craniofacial features in some cases of holoprosencephaly remains speculative at this time.

Homeostasis at Multiple Spatial and Temporal Scales

Introduction

For neural circuits to function normally, many properties of the nervous system require precise regulation. Temperature, pH, and ionic gradients, for instance, need to be maintained at relative constant levels, despite fluctuations in the cellular environment. Complex homeostatic mechanisms are at work to keep them at their desired values. In general, a property is said to be under homeostatic control if a desired output is restored after a perturbation. Typically, homeostatic control is characterized by a desired output level (the set point), sensors that report a mismatch between the actual output and the set point, and mechanisms that restore the output to the set point level.

Like temperature and pH, neural activity appears to be under homeostatic control to prevent activity in neural circuits from becoming too high or too low. Throughout life, neural circuits are constantly perturbed by changes in synaptic strength, connectivity, morphology, sensory input, and protein turnover. When left unchecked, these disturbances may alter neural activity levels beyond the range in which neural circuits can operate properly. For example, for controlled activity propagation in feed-forward networks as well as stable ongoing activity in recurrent networks, synaptic strengths should be just so that each action potential triggers on average one action potential in another neuron; otherwise, activity will explode or die out. Without normalizing mechanisms, changes in synaptic strengths – brought about by Hebbian synaptic plasticity, for example – will thus destabilize network activity.

Changes in Neural Circuits during Development and Adulthood

During development, the number and strength of synapses alter dramatically. Once initial synaptic connections are established during the early stages of development, refinement of connections takes place by elimination of axons that project to the wrong targets and further elaboration of axons that project to the correct targets. This process of fine-tuning connectivity thus involves both synapse elimination and continued synapse formation. In many cases, the net effect is that the total number of synapses onto a postsynaptic cell increases during the period in which elimination occurs. For example, during the elimination of polyneuronal innervation in the neuromuscular junction, the total synaptic area on the muscle endplate becomes larger. Similarly, during the refinement of connections onto the lateral geniculate nucleus and cortex that creates ocular dominance columns, the number of synapses onto postsynaptic cells increases considerably. Despite these changes in synapse numbers during development, neural circuits have to remain functional.

In adulthood, synaptic strengths are also not constant but increase or decrease as a result of activity-dependent synaptic plasticity. In neural network models, correlation-based synaptic plasticity rules have been shown to lead to a hyperexcitable network without a stabilizing mechanism such as, for example, conservation of the average level of neural activity.

Likewise, the number of neurons is not constant but changes as new cells are generated (neurogenesis) and existing cells die (apoptosis). Neurogenesis occurs not only during development but, in brain areas such as the dental gyrus of the hippocampus, also in adulthood. Homeostatic mechanisms will therefore be necessary to regulate the changes in neural activity resulting from the insertion or deletion of neurons.

During development, neurons can experience a great amount of structural growth, which will affect their electrophysiological properties. The neural circuits in which they operate nevertheless have to remain functional. This requires that activity-dependent regulatory processes, targeting, for example, synaptic or intrinsic properties, must tune circuits to maintain their appropriate patterns of network activity during periods of neuronal growth.

Other changes during development that can affect electrical activity include switches in the subunit composition of neurotransmitter receptors. For example, the γ-aminobutyric acid $(GABA)_A$ receptor, the main inhibitory receptor in the mammalian brain, shows a subunit switch in the neonatal visual cortex around the time of eye opening. As a result of this switch, the duration of the inhibitory postsynaptic current decreases, effectively reducing the level of inhibition.

Experimental Evidence for Homeostasis of Neural Activity

Several experimental observations support the idea of homeostatic regulation of neural activity. First, in neuronal cultures, firing rates are restored after manipulation of the global level of activity or the

activity level in single cells. In cultured cortical networks composed of excitatory and inhibitory neurons, application of bicuculline (which reduces inhibition) initially raises the activity. After 2 days in bicuculline, however, activity returns to control levels. Conversely, blockade for 2 days of spiking activity with tetrodotoxin generates a hyperactive network when tetrodotoxin is removed. In this network, the firing rates of both excitatory and inhibitory neurons are increased. Suppressing activity in a single hippocampal neuron by overexpressing an inward rectifier K^+ channel initially reduces firing rates. After a few days, however, the activity of the neuron is restored to control levels. Second, at the neuromuscular junction, changes in presynaptic efficacy induce compensatory changes in postsynaptic efficacy and vice-versa, effectively keeping neuromuscular transmission at a relatively constant level. For example, reducing the number of synapses causes a compensatory increase in the postsynaptic response to a single vesicle of neurotransmitter. Conversely, hyperpolarization of muscle fibers induces an increase in presynaptic release. Third, the removal of neuromodulatory synaptic inputs to stomatogastric ganglion (STG) neurons initially slows or abolishes the typical STG pyloric rhythm of alternating bursts of activity. However, after a period of days, normal rhythmic burst firing resumes. The presence of a wide variety of activity-dependent mechanisms that counteract changes in activity forms further evidence for the homeostatic control of neural activity.

The Set Point

In the context of homeostatic control of neural activity, the set point represents the desired level of neural activity to which neurons or neural networks strive to return after experiencing a perturbation. There are, however, many open questions regarding the nature of such a set point:

1. What is the spatial scale of the set point? Do neurons or perhaps subneuronal structures (such as neurites) have their own individual set points, or is the set point specified at the level of neuronal populations? Under some conditions, homeostasis of neural activity can be a cell-autonomous process. Hyperpolarizing single hippocampal pyramidal cells in neuronal cultures by overexpressing an inward rectifier K^+ channel initially decreases firing rates, but after a few days, firing rates are restored to normal levels. The scaling of excitatory synapses on inhibitory neurons is dependent on the activity-dependent release of brain-derived neurotrophic factor from nearby pyramidal neurons, which perhaps suggests that homeostasis of neural activity in interneurons is not cell-autonomous. An important question is whether cell-autonomous homeostatic processes are capable of achieving homeostasis of activity at the network level. Some studies suggest that this may indeed be the case, but there are also examples showing that synaptic and cellular homeostatic rules do not achieve homeostasis of neural activity at the network level, at least under some conditions (see the section titled 'Discussion').

2. Does the set point involve activity as it occurs over the entire day or only during certain periods of the day? The temporal range of the set point may span long periods of ongoing activity or perhaps only periods during which a neuron or a neural circuit actively processes particular synaptic inputs. Another possibility is that the set point involves only neural activity during sleep. In neuronal cultures, homeostasis appears to involve ongoing activity. At the neuromuscular junction, peak depolarization is precisely restored after postsynaptic activity manipulations, suggesting that the set point involves an adequate response to synaptic input.

3. What aspects of neural activity are under homeostatic control? At the level of individual neurons, the possibilities that have been suggested include a temporal average of firing rate, membrane potential, intracellular Ca^{2+} concentration, amount of excitatory synaptic receptor activation, or a particular pattern of spiking activity. At the level of neuronal populations, a spatial average of firing rate or a particular spatial pattern of activity could be under homeostatic control. In STG neurons the set point may involve a precise pattern of burst firing. In neuronal cultures the set point may involve the average firing rate of neurons. Furthermore, perhaps there is not a single set point but a range of activities that is allowed.

4. How is the set point encoded? The set point may be encoded as an explicit cellular property, or alternatively it could come about as an emergent property of a large number of interacting processes. Although it may not be explicitly encoded as such, the attractor state of a complex system may function as a set point. For example, spike timing-dependent plasticity (STDP) contributes to stabilizing neural activity levels, but it does not contain an explicit set point. In this form of long-term synaptic plasticity, presynaptic action potentials that precede postsynaptic spikes strengthen a synapse, whereas presynaptic action potentials that follow postsynaptic spikes weaken it. STDP has the effect of keeping the total synaptic input to the neuron roughly constant, independent of the presynaptic firing rates. In the Bienenstock, Cooper, and Munro model, the set point of postsynaptic activity is not explicitly specified but arises as a

result of the local synaptic learning rule. If the threshold value of postsynaptic activity above which long-term potentiation of synapses occurs increases faster than linearly with the average postsynaptic activity, the synaptic strengths will adjust to keep the postsynaptic activity near a particular value.

5. How are differences between the actual activity and the set-point activity level sensed? Many experimental studies indicate that intracellular Ca^{2+} concentration is a good indicator of neural activity, and cells appear to be capable of sensing the difference between actual and desired Ca^{2+} levels. The intracellular Ca^{2+} concentration increases in response to activity (e.g., through enhanced influx through *N*-methyl-D-aspartate channels and voltage-sensitive Ca^{2+} channels) and decreases during inactive periods. Intracellular Ca^{2+} is an important messenger signal for a wide variety of cellular processes and can modulate, for example, levels of gene expression. Different firing patterns, such as bursting or regular spiking, result in different temporal profiles of Ca^{2+}. These profiles can be captured by integrating Ca^{2+} on different timescales.

Mechanisms Contributing to the Homeostasis of Neural Activity

A variety of mechanisms operating at different spatial and temporal scales have been suggested to contribute to the homeostasis of neural activity.

Synaptic Scaling

In cortical cultures, changing the level of network activity causes dynamic adjustments in the relative strengths of excitatory and inhibitory connections. Raising activity results in reduced feedback excitation and increased feedback inhibition onto pyramidal neurons. Lowering activity produces the opposite set of changes. A few days of pharmacological activity blockade in cortical cell cultures increases the amplitude of miniature excitatory postsynaptic currents (mEPSCs) and evoked EPSCs in pyramidal cells. Conversely, prolonged enhanced activity reduces the amplitude of mEPSCs. Similar bidirectional activity-dependent changes in mEPSC size have been observed in spinal cell cultures. It is interesting that activity blockade scales down the amplitude of miniature inhibitory postsynaptic currents (mIPSCs), in the opposite direction of excitatory currents. The expression site of homeostatic excitatory synaptic plasticity in cortical cultures is a controversial issue. Synaptic scaling of mEPSCs occurs in part postsynaptically by changes in the number of glutamate receptors, but also presynaptically by changes in release probability. The pre- or postsynaptic expression site has recently been shown to depend on the time neurons have spent *in vitro*. Synaptic scaling of mIPSCs is accompanied by a change in the number of $GABA_A$ receptors clustered at synaptic sites. Chronic suppression of activity in a single hippocampal neuron increases excitatory synaptic strengths on the neuron, but not sufficiently to alter inhibitory synaptic strengths.

It remains to be explored whether homeostatic synaptic plasticity operates *in vivo* and in cell cultures similarly. Recent evidence suggests that excitatory synapses in intact rodent visual cortex are upregulated after sensory deprivation. Two days of monocular deprivation scales up mEPSC amplitudes by 15–30% in a layer- and age-dependent manner. However, these changes are smaller than those seen in culture. One possible explanation is that sensory deprivation only partially reduces activity compared with the complete activity block in cultures.

An important issue is the conditions under which homeostatic synaptic plasticity can cause the network to settle into a desired activity level. It seems rather obvious that an individual neuron in isolation may be able to keep its activity close to a set point value by increasing synaptic excitation and decreasing synaptic inhibition. Neurons in the brain, however, are not isolated but embedded in circuits with recurrent synaptic connectivity. Such neural networks are known to be very sensitive to the balance of synaptic excitation and inhibition. An altered balance of excitation and inhibition may affect synchrony in the network and in extreme conditions result in hyperactivity or other nonphysiological oscillatory states. Thus, scaling excitatory and inhibitory synaptic strengths in opposite directions may have undesirable effects for the stability of network activity. This is an important issue that can be explored in neural network models.

Intrinsic Excitability

Intrinsic excitability is also regulated by activity. Chronic activity blockade in cortical cell cultures enhances Na^+ currents and reduces K^+ currents in pyramidal cells, resulting in an enhanced responsiveness to current injections. Fast Na^+ conductances in pyramidal cells are upregulated by approximately 30% and K^+ conductances (of the delayed rectifier and a persistent outward current) are downregulated by about 30–60% after 2 days of activity blockade. Inhibitory neurons also display an increased excitability after chronic activity blockade, but through a different mechanism. In somatostatin-positive inhibitory neurons, the densities of a passive leak current and the hyperpolarization-activated (H-) current are downregulated, which increases excitability mostly

through a decrease in membrane input conductance. Intrinsic excitability may also be modified in an adaptive manner at the very short timescale of minutes. In hippocampal CA1 pyramidal neurons, an increase in H-current can be observed within tens of minutes of enhanced activity, which reduces firing rates in response to current injections. Reducing background activity results in an increased excitability within tens of minutes through a decrease in a sustained K^+ conductance.

In model neurons (and networks) with activity-dependent regulation of maximal conductances of ionic currents, conductances may adjust to restore a given pattern of electrical activity following a perturbation. For example, in a multicompartmental model neuron, regulation of some of the maximal conductances (of the fast Na^+ current, the delayed rectifier K^+ current, and the transient K^+ current) by the local intracellular Ca^{2+} concentration acts as a gain control mechanism to restore the neuron to its optimal firing range after potentiating a set of synapses. Another example concerns a model of a bursting STG neuron, in which the maximal conductances of seven voltage-dependent membrane currents are regulated by Ca^{2+} sensors acting on different timescales. When the electrical activity of this model neuron is perturbed, such as by changing the reversal potential for the K^+ currents or by applying hyperpolarizing current, the maximal conductances adjust to restore the original bursting pattern. Under some conditions, activity-dependent regulation of intrinsic excitability, operating at the level of individual neurons, may stabilize network activity in models of synaptically connected neurons. In a model of the neocortex, neurons fire initially asynchronously and at low firing rates. Removing the external synaptic inputs strongly reduces the firing rates of all neurons. Activity-dependent regulation of some of the maximal conductances in pyramidal cells (of the fast and persistent Na^+ currents and two types of K^+ current) restores an irregular state with low firing rates comparable to that in the intact model. Another example concerns a three-neuron network model of the pyloric circuit of the STG. The small network model recovers rhythmicity after blockade of neuromodulatory synaptic inputs using activity-dependent regulation of some of the maximal conductances (of a K^+ current and a Ca^{2+} current).

Structural Plasticity

Neurite elongation and branching are under the control of the growth cone (a specialized structure at the tip of a growing neurite) and are sensitive to the Ca^{2+} concentration inside the growth cone. Electrical activity in general increases the Ca^{2+} influx through voltage-gated Ca^{2+} channels. In neuronal cultures, raising the level of neural activity has been found to cause retraction of neurites, whereas lower levels allow further outgrowth. Model studies have shown that this activity-dependent neurite outgrowth will contribute to the homeostasis of neural activity, both in purely excitatory and in mixed networks of excitatory and inhibitory cells. In purely excitatory networks, for example, when the level of activity is too high, the neuron will withdraw neurites and, consequently, lose connections with other neurons, resulting in a decrease in neural activity. Conversely, when the activity is too low, neurites will grow out and new connections will be formed, resulting in an increase in neural activity. Experimental work on the Xenopus retinotectal system suggests that neuronal activity, via activation of Ca^{2+}/calmodulin-dependent protein kinase, slows the outgrowth of axonal and dendritic arbors and controls synapse formation. In the developing spinal cord, the intracellular Ca^{2+} in growth cones has been found to regulate axon elongation, with the rate of axon elongation being inversely proportional to the frequency of Ca^{2+} transients. Many experimental studies have demonstrated considerable structural plasticity in the adult brain, including synapse formation and elimination and remodeling of axons and dendrites, which might be influenced by activity. Large-scale changes in dendrites can occur in response to environmental enrichment and with pharmacological manipulations. In the superior cervical ganglion of the spinal cord, highly dynamic dendritic branches have been found. Recent long-term imaging studies in the *in vivo* adult neocortex have found high levels of structural plasiticity of axonal branches and boutons. In addition, *in vivo* and *in vitro* studies have revealed rich dynamics of postsynaptic dendritic spines, including spine formation, retraction, and shape changes. Changes in spine number are likely to indicate synapse formation and elimination.

If the size of the dendritic tree increases or decreases, then the activity of the neuron can change not only as a result of loss or formation of synaptic connections, but in principle also directly as a consequence of altered morphology. In many cell types – including pyramidal cells in visual cortex, somatosensory cortex, prefrontal cortex, and hippocampus – firing patterns (both spike frequency and spike pattern) are correlated with dendritic morphology. Results from modeling studies suggest a causal relationship between dendritic morphology and firing patterns. For example, models of neocortical neurons that have the same channel densities and kinetics but differ in their dendritic shape and size can generate firing patterns ranging from regular spiking to bursting when stimulated at the soma with a fixed current

injection. Both dendritic size and dendritic branching structure may influence firing patterns, especially the cell's propensity for generating bursts (the occurrence of clusters of spikes with short interspike intervals).

Number of Inhibitory and Excitatory Cells

Insertion of new excitatory neurons into adult neuronal networks, as takes place in the dentate gyrus of the hippocampus, requires the existence of homeostatic mechanisms to regulate the resulting changes in neural activity. One of the possibilities, for which there is some experimental evidence, is that not all the newly generated neurons become excitatory granule cells but that some take on features typical of inhibitory GABAergic basket cells. A related mechanism is the conversion of preexisting granule cells to the GABAergic phenotype. Into maturity, granule cells express low levels of the inhibitory transmitter GABA.

Discussion

Besides keeping neural activity in the range where neural circuits can operate properly, homeostasis of neural activity has been postulated to lead to some additional beneficial properties. For example, homeostatic synaptic plasticity may prevent the runaway of synaptic strengths during Hebbian modifications or facilitate the competition between synapses during development.

Modeling studies have shown that homeostatic activity-dependent neurite outgrowth leads to a number of interesting emergent phenomena, including a transient phase of high network connectivity during development, size differences between the spatial extent of neurites of excitatory and inhibitory neurons, and compensatory sprouting of remaining cells following cell death. Furthermore, activity-dependent neurite outgrowth has been found to construct networks with a critical connectivity level in which the frequency of spontaneous network bursts of activity shows a power law relationship with burst duration and size. This critical connectivity has been shown to optimize information transmission while preventing runaway network excitation.

It is generally believed that homeostatic synaptic plasticity acts to restore a target pattern of activity in networks after a perturbation. However, under some conditions, rather than restoring a desired activity state, homeostatic plasticity rules may instead lead to pathological forms of neural activity. In a computer model of the neocortex with a biologically based homeostatic plasticity rule that operates to maintain firing rates, pathological neural activity has been found to develop after complete cortical deafferentation (such as may occur after severe head trauma). Homeostatic synaptic plasticity increases the network excitability to a level at which only synchronized bursting activity becomes possible.

Under some conditions, model networks consisting of excitatory and inhibitory cells in which individual neurons adapt their intrinsic excitability may become unstable. The stability of the adaptation at the network level critically depends on the relation between the cellular adaptation rates of both neuron populations, combined with their respective gains. If input–output relations of both excitatory and inhibitory cells have equal gain, the inhibitory cells need to adapt more slowly than the excitatory cells for a network to remain stable and attain its target state. If this condition is not met, the activity level in the network keeps increasing until the network abruptly falls silent, after which activity gradually builds up again.

Models exploring the consequences of homeostatic, activity-dependent neurite outgrowth have shown that networks with both excitatory and inhibitory cells can under some conditions develop into a pathological network state. This state, in which the average activity is still at set point level, is characterized by a high level of network connectivity and fast, epileptiform oscillations in electrical activity. Blocking electrical activity in the network for a certain period of time during development can induce the network to evolve into this state. It is interesting and perhaps counterintuitive that the higher the level of inhibition (e.g., the number of inhibitory cells) during the early stages of development, the more likely the network is to end up in the pathological state. As a consequence of the interactions between excitation, inhibition, and outgrowth, too much inhibition prevents the normal pruning of exuberant connections, resulting in a network with epileptiform activity. This model result may shed light on experimental observations that in rat pups with hypoxic–ischemic encephalopathy, epileptiform activity later on in life appears to be due to the preferential survival, not loss, of inhibitory elements.

Homology and Homoplasy

A B Butler, George Mason University, Fairfax, VA, USA

Introduction

The word 'homology' literally translates as 'the study of sameness.' In biology, it refers to the relationship of a character in one species to what is believed to be the same character in another species. A character can be any definable attribute, such as an organ, part, feature, trait, structure, developmental process or pathway, or morphogenetic field. In 1843, the British comparative anatomist Richard Owen proposed the concept of homology and defined it as "the same organ in different animals under every variety of form and function." Thus, although the original definition recognized that the 'same' character could vary in both its morphology and function across species, it did not specify the criteria for recognizing sameness. Our concept of homology has therefore changed in step with advances in understanding the processes by which morphology is generated.

Phylogenetic Homology

Owen's definition of homology preceded the announcement of the Darwin–Wallace theory of evolution by 16 years. The concept of homology was subsequently linked to the Darwinian perspective, and those studying phylogeny, or systematics, redefined Owen's original notion. The criteria for recognizing homology became phylogenetic: homologous characters were those that had been inherited from a common ancestor. A commonly cited definition in the current literature is that of Edward Wiley:

> A character of two or more taxa is homologous if this character is found in the common ancestor of these taxa, or, two characters (or a linear sequence of characters) are homologous if one is directly (or sequentially) derived from the other(s).

Thus, the character must have been expressed in the phenotype of the common ancestor and been present in all subsequent members of each descendant lineage. This type of homology is now referred to as phylogenetic, or historical, homology. It is the opposite of homoplasy, which is the independent evolution of apparently similar characters and comprises three types: parallelism, reversal, and convergence.

Analysis of phylogenetic homology is particularly challenging for the study of the nervous system, since most neural structures do not fossilize. Only some surface features of the brain can be detected from fossilized endocast material. For inferring the phylogeny of internal brain structures, the most common method, called cladistic analysis, is to examine the distribution of a character across the members of a taxon for which the phylogenetic relationships have been established by nonneural characters. If the neural structure in question is present in all or most members of the taxon, then it is presumed to have been present in the common ancestor, according to the principle of parsimony. All living species are a mosaic of characters, some of which were present in a common ancestor and thus are plesiomorphic (primitive, or ancestral) characters and some of which are more recently evolved and thus are apomorphic (specialized, or derived) characters.

Shared apomorphic characters (synapomorphs) are used to recognize sets of species that are more closely related to each other than to other species that lack these characters. This method is called outgroup comparison and is used to establish phylogenies as well as to hypothesize homology. Neural characters can be evaluated across such phylogenies. For example, consider a character that occurs in the brains of reptiles and birds but is absent in the brains of mammals. Was this character present in the common ancestor of all amniotes and subsequently lost in the ancestral line to mammals, or was it gained only in the common ancestor of reptiles and birds after the mammalian line diverged? Presence of the character in the brains of amphibians, as the outgroup to amniotes, would indicate the former, while it absence in amphibians would indicate the latter.

For recognizing a character in the first place as being the 'same' character in different species, multiple criteria can and should be used. Similar features are most commonly used to identify potentially homologous characters. The probability that the character is the same across species increases with the number of points of similarity. Homologous genes and developmental pathways that produce the characters are of great current interest in this regard, but it is important to weigh other points of similarity as well. For neural structures, location, cellular architecture, histochemical traits, and afferent and efferent connections are all informative. Also, the basis of the homology needs to be specified unless the specification is implicit and unambiguous. When comparing one nucleus with another nucleus, for example, the specification is implicit: the two nuclei are being compared as nuclei. In many other cases, the specification needs to be stated: the wing of a bird and the wing of a bat are not homologous as wings; they are, however, homologous as forelimbs.

Homoplasy

Since similarity can arise from several different causes, one must distinguish between similarity due to inheritance from a common ancestor and similarity gained independently of such ancestry. The term 'homoplasy' was coined by Lankester in 1870 to refer to the latter circumstance – the independent gain of similar characters in different members of a taxon. It is the opposite of phylogenetic, or historical, homology. Homoplasy traditionally comprises three types: parallelism, reversal, and convergence. George Gaylord Simpson also distinguished analogy, mimicry, and chance similarity, although these are most often considered as different instances of convergence. Recent advances in our understanding of the relationship of embryological development to evolution have necessitated a reevaluation of the adjective 'independent,' particularly concerning parallelism and reversal, as further discussed in the following text.

Homoplasy presents a challenge to the task of reconstructing the evolutionary history of neural structures. Since, as already noted, the internal components of the nervous system do not fossilize, one cannot utilize the fossil record in order to find out what neural structures the ancestor of any extant lineage had or whether a particular structure has been phenotypically expressed with consistency along a lineage. The degree of similarity may help in some situations to differentiate convergence from phylogenetic homology, but, as will be further discussed, among closely related species, either parallelism or reversal could easily be mistaken for phylogenetic homology.

Convergence was defined by Edward Wiley as "the development of similar characters from different preexisting characters." It is usually assigned to cases of similarity in animals with only a remote common ancestry, and the similarity is usually superficial, such as with the resemblance of the wing of a bird to the wing of a bat. Both are aeronautically suited to flight, but the use of feathers versus membrane and different modifications of the bony elements of the hands belie the overall, superficial similarity. Comparison of the anatomical features makes it difficult to imagine a common ancestral condition that could have given rise over evolution to the two different types of wings, and of course the fossil record confirms that the common amniote ancestor had an upper limb that then independently evolved into the two types of wings in the two separate lineages. While the wings of bats and birds are phylogenetically homologous as upper limbs, they are convergently homoplaseous as wings. Likewise, the wings of flying fishes, derived from their forelimbs, are convergent, as are the wings of insects, which demonstrate extreme differences in their anatomical components. The study of convergence addresses how similar selective pressures can result in the evolution of similar solutions that are truly independently arrived at.

In contrast to characters evolved by convergence, characters that result from parallelism and reversal exhibit minute and extensive similarities. Parallelism has been defined by Edward Wiley as "the independent development of similar characters from the same plesiomorphic [i.e., ancestral] character." Likewise, David Wake has defined parallelism as "the production of apparently identical traits by the same generative system." Parallelism usually occurs in closely related animals, although in some instances extensive similarity occurs for characters scattered across wide phylogenetic gaps. Reversal is the reacquisition within a single lineage of a developmental or structural character of its ancestral condition, with the intermediate member(s) of the lineage having lacked the character or exhibited a different condition.

Homoplasy is generally considered to be the result of adaptive evolution, with different lineages responding in similar ways to similar adaptive pressures. However, the similarities seen in cases of convergence, parallelism, and other instances of homoplasy may also be the result of limits of design. For example, only a circumscribed set of options exists for creating a wing surface that will permit flight – the feathers of birds and the membranous surfaces of bats, flying fishes, pterosaurs (the extinct, flying reptiles), and insects. Extending the body surface by limb extension and/or the deployment of membranous structures is also used for parachuting or gliding by other animals, including flying squirrels and some lizards, but solutions other than membranes or feathers have not appeared.

The most frequently used tests to distinguish homoplasy from phylogenetic homology are evaluating the degree of similarity and determining whether congruence occurs, that is, whether the distribution of the character in question is congruent with a phylogeny established using other characters not related to the character in question. Cases of convergence fail both of these tests. In contrast, some cases of parallelism may exhibit extensive similarity but fail the test of congruence. Cases of parallelism in closely related lineages as well as cases of reversal often pass both the similarity and congruence tests and can thus be mistaken for phylogenetic homology if the fossil record cannot be used to illuminate the situation.

Evolutionary-Developmental Approaches to Homology

New information on the genetic bases for characters and the stunningly widespread distribution of many

of the patterning genes across almost all lineages of multicellular animals has challenged the dictum that homology must be phylogenetic and meet the requirements of Edward Wiley's definition. The concept of homology has been reexamined in light of the new synthesis of evolutionary and developmental biology. While embryological development does not recapitulate evolution *per se*, the sequence of development is from the general to the specific, as Karl Ernst von Baer recognized in the nineteenth century, so that the early steps in the developmental sequence are those that are shared across all groups within a large taxon, while the later steps produce the more specialized characters that uniquely characterize a particular genus or species.

Almost all characters that are phylogenetically homologous are produced in the phenotype as the result of the same genes and generative pathways that were inherited from a common ancestor. In some instances, a different generative event can be substituted for the inherited one in part of the pathway for production of the character. The evolution of generative pathways is of great interest in regard to how characters become stabilized and conserved within a taxon and how they vary so that selection can act on them. Günter Wagner's concept of biological homology for characters that share a set of developmental constraints (specified by the generative pathways) addresses these mechanisms. Biological homology seeks to understand the patterns of character diversification and thus focuses on the mechanisms of character evolution; in most cases, it overlaps with phylogenetic homology.

The issue of shared genes and generative pathways as a basis for comparison is a pivotal one, since it has long been recognized that instances of parallelism and reversals are both the result of the inheritance of a shared generative basis, inherited with continuity from the common ancestor. Various other terms for parallelism (which is more frequently encountered than reversals) thus have been offered to denote this situation. Gavin de Beer proposed the term 'latent homology' for characters that have a high degree of similarity but occur only within some members of a taxon. Latent homology implies a 'genetically based homology' that allows for the expression of the character in selected descendant species or groups of species, even though the character itself was not a 'visible phenotypic' character in the common ancestor or in many of the descendant taxa. Likewise, the terms 'homoiology,' or 'deep homology,' apply to similarity evolved from a homologous base through parallel evolution. For example, the wings of birds, bats, and flying fishes – even though often cited as examples of convergence – are homoiologous, since they all exhibit the 'tendency' of the vertebrate upper limb to form extended surfaces usable for flight, presumably using a shared genetic basis for at least part of this morphological evolution, in contrast to the much more phylogenetically distant wings of insects. The more information comes to light about the commonalities of patterning genes across all multicellular animals, the more cases of parallelism and reversal and even some apparent cases of convergence fail the criterion of being 'independent.' Even between taxa as diverse as insects and mammals, some of the same patterning genes specify the dorsoventral and rostrocaudal divisions of the brain, for example.

Thus, in contrast to cases of true convergence, it is now clearly acknowledged that most cases of phylogenetic homology as well as parallelism and reversal share the evolutionary commonality of inherited genetic basis. Due to this recent illumination of the processes for the distribution of various characters and the shared genetic basis in many cases of homoplasy, the previous lumping of the process of convergence with the processes of parallelism and reversal under this rubric has become conceptually untenable. Parallelism and reversal are distinguished from phylogenetic homology only by the distribution of the character across the taxon. A concept that unites these three ways of generating sameness is that of generative homology, or syngeny, which literally means 'same genes' or 'same genesis.' Syngeny comprises all instances of characters produced by the same genes, regardless of phylogenetic distribution. It applies to characters that are produced by generative bases inherited from a common ancestor, whether the character was expressed in the common ancestor (and with continuity along a lineage of descent) or not. In contrast, the complementary concept of allogeny (meaning 'different genes' or 'different genesis') is the basis for true cases of convergence.

Syngeny comprises almost all cases of phylogenetic homology, as well as situations where the phylogenetic expression of a character is sporadic, either across a taxon of extant species or along a lineage. For example, eyes occur in several very distantly related groups of animals – arthropods (including insects such as flies), cephalopods (octopus, squid, etc.), and vertebrates. The structure of these eyes varies considerably, but the same patterning gene, *Pax6*, is one of a few essential genes for initiating the generative cascade that produces the eyes in both fruit flies and mammals (and presumably in cephalopods as well). This gene is known to be expressed in all light-detecting, rostrally lying structures examined to date, from the eye spots of planarian worms and those along the mantles of clams to the compound eyes of flies and the retinal eyes of

mammals. While the large, whole eyes of flies and mammals cannot be considered homologous in the phylogenetic sense, they are, however, syngenous – homologous in the generative sense – as whole eyes initiated by *Pax6*. In contrast, the finer details of these eyes – ommatidia in flies versus the retinal eye of mammals – to the extent that these features are truly independently evolved, result from the actions of different patterning genes and are thus allogenous.

The concepts of biological and generative homology, as well as those that more specifically recognize a genetic basis for parallelism and reversals, are aligned with the new approaches to evolution that integrate developmental and evolutionary perspectives. As noted by Axel Meyer,

> The biological basis for these seemingly disparate kinds of 'sameness' in evolution [including all forms of homoplasy] may in some, or even most, instances not be all that different and may be based on the same principle – the long evolutionary retention of genes, gene interactions and developmental mechanisms. . . . Therefore, the biological basis of both [historically] homologous traits (those that are evolutionarily always expressed) and homoplasious traits (those that are not always 'on,' but are 're-awakened' during evolution) might not be so different, and the distinction between homology and some forms of homoplasy may be somewhat artificial.

Other Applications of the Homology Concept

Several other applications of the concept of homology – whether phylogenetic, biological, or generative – need to be mentioned here. The concept of field homology has enjoyed a renewed interest recently, particularly in regard to comparisons of some sets of neural populations across different vertebrate taxa. Hobart Smith defined field homology as the "derivation of structures, however similar or dissimilar, from a common anlage." Anlagen, or morphogenetic fields, are defined by Scott Gilbert as "discrete [modular] units of embryological development . . . produced by the interactions of genes and gene products within specific bounded domains . . .[and]. . . the morphogenetic field . . . is seen as a major unit of ontogeny whose changes bring about changes in evolution [and] homologous morphogenetic fields can exist . . . between different organisms." Some opponents of applying this concept in neurobiology argue that it compares adult characters in one taxon to embryonic ones in another. Those that find the concept useful consider it to compare a set of adult characters to another set of adult characters, each set derived from a specified homologous morphogenetic field. Specification of the field in question allows for this concept to apply broadly to a large set of structures, such as all parts of the forelimb as derivatives of the forelimb morphogenetic field, or to a much more restricted set, such as the digits as derivatives of the morphogenetic field for the hand.

Serial, or iterative, homology is also a generally recognized concept, albeit not universally accepted. Some take the position that iterative structures are not homologous but simply iterative. The concept applies to similar units, such as segments, that repeat along an axis of the body. Vertebrae are an excellent example of iteration or serial homology. Concerning development, Scott Gilbert has noted that "homologous morphogenetic fields can exist within the same organism (serial process homology)." It is important to note, however, that this phenomenon is not simply pleiotropy, the actions of a gene in multiple tissues. Many of the patterning genes that are shared across most multicellular animal taxa are involved in more than one role at different levels of the body. A single patterning gene may be involved in specifying clearly different structures, such as parts of the nervous system in the head and the heart in the thorax, but that does not confer any homologous or even iterative relationship for such disparate structures. Only structures with multiple points of similarity that repeat along an axis within an individual are candidates for serial homology.

The question of whether homology can be partial is a hotly debated one. David Wake convincingly defends the case for partial homology, citing the system of *Hox* patterning genes. He notes that "all homology among genealogical entities is partial at some level, except between the closest relatives." The concept of partial homology dovetails with the concepts of syngeny and allogeny, since, like eyes, virtually all structures across members of a taxon will have some genes and generative pathways in common and be syngenous, as specified, in that regard and at the same time have some genes and generative pathways that differ, causing the finer levels of variation among them, and be allogenous, as specified, in that regard.

Finally, the concept of homology has been applied to behaviors, with particular import to the field of neuroethology. Some would assert that only those behaviors that are generated by homologous structural characters could be themselves homologous, but others have argued that the inheritance and continuity of a behavior itself can be preserved in some cases even though it is generated by nonhomologous structures. This situation is similar to that of substitutions of part(s) of the generative pathways for the production of homologous structural characters in the phenotype.

Our understanding of homology – at all levels – is crucial to our appreciation of how the nervous system has evolved in its many different guises across the kingdom of multicellular animals. As David Wake has stated, homology is "the central concept for *all* of biology." The new insights into the interactions of embryological development and evolution continue to challenge and redefine our comprehension of sameness.

Hormonal Signaling to the Brain for the Control of Feeding/Energy Balance

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

Energy homeostasis – the balance between energy intake and energy expenditure – is the key principle underlying weight fluctuation in humans. Until the mid-1990s, very little was understood about the regulation of energy homeostasis. However, since the discovery of leptin in 1994, a network of hormonal mechanisms has been unraveled that links the control of appetite and energy expenditure to feeding behavior and adiposity. A host of signals produced in the digestive system, adipose tissue, and brain interact to modify behavior and physiological responses. Malfunctions in this delicately balanced system can lead to metabolic disorders and obesity.

Major Hormones Involved in Appetite Regulation

Leptin

Leptin was the first hormone shown to have a direct role in the regulation of food intake. It was quickly recognized as a circulating index of peripheral energy stores that could directly signal hypothalamic neurons in a position to effect appropriate adjustments in energy intake and expenditure. Long before its discovery in 1994, researchers had been using a homozygous mutant strain of mice called *obese* (*ob*/*ob*), which was characterized by excessive eating (hyperphagia) and obesity. When the *ob* gene was cloned, it was found to encode a circulating hormone, which was named leptin, secreted by adipocytes. The absence of leptin in *ob* mice was proposed to cause their characteristic phenotype since injections of recombinant leptin restored them to normal. Furthermore, the injection of leptin into wild-type mice resulted in fasting (hypophagia) and weight loss, leading to the proposal that leptin signals to the brain when excess fat is stored and promotes a reduction in food intake. In support of this conclusion, plasma leptin levels are usually proportional to total fat content, and the amount of leptin entering the central nervous system (CNS) is proportional to circulating levels.

The leptin receptor gene encodes a protein with six known isoforms, but only one of these (LepRb) has been shown to have an active intracellular signaling domain. Leptin receptors are richly expressed in the hypothalamus, which is the primary brain area responsible for energy homeostasis. This discovery correlated well with the results of earlier surgical experiments showing that lesions and electrical stimulations in different parts of the hypothalamus had a strong impact on food intake. Lesions in the ventromedial hypothalamus (VMH) and arcuate nucleus, or electrical stimulation of the lateral hypothalamus (LH), produce animals that tend toward morbid obesity and hyperphagia, whereas LH lesions or stimulation of the VMH produces unusually lean animals that are reluctant to eat. Such experiments formed the basis of Stellar's dual-center model, in which the LH acts as the feeding center and the VMH as the satiety center. Leptin receptors are expressed in all these regions, as well as in the dorsomedial hypothalamus. There are extensive reciprocal connections among these brain regions and with other parts of the brain, including the nucleus tractus solitarius (NTS) and various higher brain centers.

Since the discovery of leptin and other hormones that regulate appetite and food intake, the dual-center model has been progressively refined to include multiple hypothalamic nuclei and hormonal signaling pathways, as well as multiple roles for many of the regulators. For example, more-recent work with leptin has shown that its role is more complex than initially understood since it is also an indicator of general nutritional health and has a specific role in sexual development and the onset of fertility.

Research on leptin has focused on the arcuate nucleus, a structure within the mediobasal hypothalamus, adjacent to the third ventricle and the median eminence. This placement is probably significant since it makes the arcuate nucleus especially sensitive to leptin and other energy homeostasis regulators and indicators. The arcuate nucleus has the highest density of leptin receptors in the brain, and injections of leptin directly into this structure result in profound hypophagia, an effect which can be completely ameliorated by surgical ablation. Two groups of neurons have attracted particular interest, those containing neuropeptide Y (NPY) and those containing proopiomelanocortin (POMC). Centrally projecting NPY neurons, found in the most ventromedial part of the nucleus, project to the LH and paraventricular nucleus (PVN). Activation of these neurons stimulates the appetite, and they are acutely sensitive to leptin and ghrelin (see the section titled 'Ghrelin'). Centrally

projecting POMC neurons have widespread projections to many brain areas, including all hypothalamic nuclei. Activation of these neurons suppresses the appetite, and they are also responsive to leptin and ghrelin. There are direct projections between the NPY and POMC neurons.

Insulin

Insulin is a pancreatic hormone that regulates blood glucose levels by stimulating the conversion of glucose to glycogen. In addition to this role in carbohydrate metabolism, insulin suppresses the appetite, as shown by the effect of direct insulin injections into the brain. Insulin receptors are distributed in the hypothalamus and NTS and are particularly concentrated on NPY and POMC neurons in the arcuate nucleus, where their distribution is similar to that of the leptin receptor. This additional role for insulin may be related to its function in lipid homeostasis since, as well as promoting the storage of carbohydrates, insulin promotes the storage of fats. Overall levels of insulin correlate with the degree of adiposity in a manner similar to the correlation shown by leptin.

Ghrelin

Ghrelin was first identified as a growth hormone-releasing peptide (hence its name) but was later found to also have a role in energy homeostasis. Ghrelin is a circulating hormone and acts on the arcuate nucleus and hypothalamus in a manner antagonistic to leptin. Consistent with this role, injection of ghrelin either directly into the brain or into the blood results in increased food intake, and co-injection of ghrelin and leptin attenuates the effects of leptin. Ghrelin is produced by the empty stomach, specifically by P/D1 cells, and stimulates food intake. Levels of ghrelin fall when the stomach is full after a meal. However, it appears that ghrelin release is inhibited, not by stretching of the stomach, but by the presence of energy-rich food. Strategies to combat obesity such as gastric bypass work not only by limiting the capacity of the stomach but also by reducing the amount of circulating ghrelin. A treatment for obesity recently developed by the Scripps Research Institute is based on the use of antibodies against ghrelin to prevent its uptake by the CNS.

The ghrelin receptor is expressed in the arcuate nucleus and is found on both NYP and POMC neurons. It is also expressed strongly in the VMH.

NPY

Injections of NPY into the brain result in ravenous feeding, weight gain, and obesity, indicating that NPY is a potent appetite stimulator. In addition, NPY reduces sympathetic impulses to brown adipose tissue, thus reducing the metabolic rate and increasing energy efficiency. NPY is produced by neurons in the arcuate nucleus, which project strongly to the LH and PVN. The synthesis and release of NPY by these neurons is strictly regulated according to the energy balance, and hypothalamic neurons have NPY receptors, indicating a complex feedback system is in place to control this pivotal component of energy homeostasis.

Surprisingly, knockout mice lacking the ability to produce NPY appear to feed normally both under typical conditions and after a period of fasting, and they respond normally to chemical treatments that induce obesity. In *ob/ob* mice, NPY deficiency results in significant weight loss (although not a complete restoration to wild-type feeding behavior), which indicates that NPY may have a role in balancing the activity of leptin and may contribute to the obesity phenotype when leptin is absent. This is supported by the exaggerated effects of leptin injections in *npy/npy* mice.

Five major subtypes of NPY receptors have been described. Studies with antagonists suggest that NPY receptors 1 and 5 are the main receptors involved in the stimulation of food intake, although the putative autoreceptors 2 and 4 are also highly expressed in the hypothalamus, including both arcuate NPY and POMC neurons. Paradoxically, mice lacking the NPY1, NPY2, or NPY5 receptors have mild obesity phenotypes and varying degrees of hyperphagia. The failure to see a lean phenotype after the removal of a potent stimulator of feeding such as NPY suggests that the pathways involved in the control of food intake, like other hypothalamic systems, are sufficiently redundant to compensate for the loss of a major signaling system.

Alpha-Melanocyte-Stimulating Hormone

The *POMC* gene encodes a precursor polypeptide that gives rise to multiple peptides in different cell types, depending on the way it is cleaved. In the arcuate nucleus, the main products of pro-opiomelanocortin are two melanocyte-stimulating hormones (αMSH and γMSH) and the opioid β-endorphin. Only αMSH has a major role in energy homeostasis, and it acts as a potent inhibitor of food intake when injected into the brain. Furthermore, the effects of αMSH on sympathetic outflow to brown adipose tissue are opposite those of NPY; that is, it increases energy expenditure and results in net weight loss. Mice expressing an antagonist of αMSH are morbidly obese, and several genetic forms of human obesity have been linked to mutations in the *POMC* gene.

There are five melanocortin receptors, and it appears that the effects of αMSH are mediated mainly through MC4R. This has been deduced primarily by studies of *mc4r* knockout mice, which are severely hyperphagic and obese, but it is also apparent that approximately 5% of cases of childhood-onset obesity are associated with mutations in the human *MC4R* gene. It is likely that αMSH may be partly responsible for the loss of appetite seen in chronic illnesses such as cancer, since *mc4r* knockout mice with cancer appear to feed normally, as do mice expressing an antagonist of αMSH.

The specific role of MC4R, as opposed to the other receptors, is shown in experiments in which *mc4r* knockout mice are treated with αMSH agonists, which would increase signaling through the other receptors but still fail to influence feeding behavior. A mild obesity phenotype is seen in *mc3r* knockouts, but this is accompanied by feeding aversion, suggesting the underlying effect concerns energy utilization rather than food intake.

Major Control Circuits Involved in Appetite Regulation

The NPY and POMC neurons in the arcuate nucleus represent the primary integration site for circulating hormones and central signals involved in energy homeostasis (Figure 1). They carry a similar repertoire of receptors for the regulatory molecules discussed above, and they also project into many of the same brain regions, including the LH, PVN, and NTS, but they have antagonistic effects through the activities of NPY and αMSH. In addition to their nominal roles, NPY neurons produce agouti-related peptide (AGRP), which is an endogenous antagonist of the melanocortin receptors, and the inhibitory neurotransmitter γ-aminobutyric acid. POMC neurons also produce cocaine- and amphetamine-regulated transcript (CART).

Although NPY and POMC neurons have receptors for the major regulatory hormones, the effect of hormone signaling is distinct in each case. Leptin acts to

Figure 1 Simplified representation of the core regulatory circuit in energy homeostasis. AGRP, agouti-related peptide; CART, cocaine- and amphetamine-regulated transcript; NPY, neuropeptide Y; POMC, pro-opiomelanocortin.

reduce food intake by stimulating POMC neurons (thus causing the release of αMSH) while inhibiting NPY neurons (and limiting the release of NPY). Conversely, ghrelin treatment stimulates the production of NPY and AGRP but has no impact on *POMC* messenger RNA (mRNA) levels. This is thought to reflect different intracellular signaling responses in each cell type. In the case of leptin signaling, binding to the leptin receptor activates the immediate early gene c-*fos* in POMC neurons, but not in NPY neurons. The activation of c-*fos* generally correlates with neuronal excitation. The ability of leptin to increase the activity of POMC neurons and decrease the activity of NPY neurons has been confirmed directly through electrophysiological recordings.

There are also reciprocal connections between the NPY and POMC neurons, indicating they may directly modulate each other's ability to release peptides. However, there is a further control mechanism mediated through the release of AGRP by NPY neurons. Like NPY, AGRP stimulates food intake and is thought to do so by blocking the effects of melanocortins. Thus, the release of both NPY and AGRP by NPY neurons has two simultaneous effects: a direct effect on downstream targets through the activity of NPY and indirect effects through the inhibition of αMSH and any other melanocyte-stimulating hormones released by POMC neurons.

The PVN is a major candidate downstream target of the POMC and NPY neurons since both NPY and αMSH have been shown to influence food intake following direct injections into this structure, and thyrotropin-releasing hormone neurons located therein express the pivotal αMSH receptor, MC4R. It is possible that the inhibitory effects of αMSH on food intake are mediated by direct signaling to these neurons and the stimulatory effects of leptin reflect at least in part the blocking of melanocortin activity via AGRP. Regulation of thyrotropin-releasing hormone and other PVN neurons would regulate both the pituitary and the thyroid axes, thereby providing a mechanism by which leptin and the melanocortin system may modulate both food intake and energy homeostasis. Other potential downstream targets of the POMC and the NPY neurons are discussed in the next section.

Downstream Factors Involved in Appetite Regulation

Factors That Promote Food Intake

A number of additional hormones and regulators have been shown to promote feeding when administered to rodents, and research over the past few years has allowed many of these to be slotted into the primary control circuit involving leptin, ghrelin, NPY, and αMSH. Some of these factors are likely to be directly involved in energy homeostasis, while others have peripheral roles, such as general roles in arousal or in mediating the rewarding aspects of food intake.

One of the principal downstream targets of NPY is the release of melanin-concentrating hormone (MCH), a potent stimulator of feeding when injected directly into the brain. *MCH* mRNA levels increase during fasting and decrease after meals (and after the administration of leptin). The hormone is found exclusively in so-called MCH neurons in the LH, which project to other hypothalamic nuclei as well as to the NTS and cortex. These neurons are likely to be targets of the NPY and POMC neurons in the arcuate nucleus, as discussed earlier, and possibly act as a relay system in the NPY circuit. Tampering with gene expression levels artificially has predictable effects: transgenic mice overexpressing the *MCH* gene are hyperphagic and obese, while *mch*/*mch* knockouts are hypophagic and lean. This contrasts with the phenotype of *npy*/*npy* mice and suggests that the functional redundancy exhibited in the NPY system is not present in its downstream target, MCH.

Another possible target for NPY is the release of galanin, a 30-amino-acid neuropeptide, from discrete populations of neurons in the arcuate nucleus, dorsomedial hypothalamus, and PVN. Galanin neurons project to multiple areas of the hypothalamus and other brain regions involved in food intake, and they have synaptic links with both NPY and POMC neurons. Galanin levels increase during fasting, and the injection of the mature galanin peptide into the PVN, LH, VMH, and NTS stimulates food intake in rodents, although not to the levels seen with NPY injections. The precise role of galanin remains unclear since *gal*/*gal* knockout mice are neither obese nor unusually lean.

Finally, it is likely that some of the effects of leptin are mediated by endogenous cannabinoids, at least two of which, anandamide and 2-arachidonoylglycerol, are normally present in the hypothalamus. Supportive evidence includes the increased levels of endogenous cannabinoids in the hypothalami of *ob*/*ob* mice and the reduction in levels that follows administration of leptin. Also, injections of cannabinoid agonists stimulate feeding, whereas mice lacking the CB1 cannabinoid receptor are hypophagic after fasting (although without fasting they eat normally). Research has focused on the CB1 receptor because prolonged administration

of a CB1 antagonist also results in hypophagia and leanness. Rimonabant (Acomplia) is a cannabinoid receptor antagonist which has been prescribed as an appetite suppressant in the countries of the European Union since 2006.

Factors That Inhibit Food Intake

A number of additional factors have also been described which inhibit feeding and generate a negative energy balance, and again it is possible to slot many into the central regulatory circuit controlling energy homeostasis. CART is a neuropeptide co-expressed with αMSH in POMC neurons of the arcuate nucleus. Like αMSH, CART can inhibit food intake when injected directly into the brain. CART expression is also dependent on leptin, which marks it out as an important component of the energy homeostasis network. However, mice deficient in the expression of this peptide show no significant changes in feeding behavior or body weight, indicating that whatever role CART plays in the system, it can be replaced by a redundant component. CART is expressed in several additional sets of neurons that do not express POMC, so it is possible these neurons have secondary roles in appetite control.

While CART is expressed in the CNS, cholecystokinin (CCK) is a satiety factor expressed primarily in the gut. CCK is secreted by the gut after a meal, and its release stimulates CCK receptors located on the vagal nerve, which transmits the satiety signal through the NTS. There are two classes of CCK receptor, and studies using specific antagonists show that the satiety signal is transmitted primarily through the class A (CCKA) receptor. Such antagonists inhibit feeding after a period of fasting. Injections of CCK result in sudden but short-lived food aversion, which is enhanced in the presence of leptin. Additional studies have shown that CCK and its receptors are also produced in the brain, indicating a central role through direct action on neurons in the NTS and hypothalamus. The precise role of CCK is clouded by different results from studies in different animals. For example, CCKA knockout mice show no obvious feeding phenotype, whereas rats with the orthologous gene knocked out show mild obesity. Another gut peptide with activity similar to CCK's is bombesin, and mice lacking the receptor BBR3 are obese. Finally, enterostatin is a peptide, produced by the pancreas and gastrointestinal tract, which reduces insulin secretion, increases sympathetic outflow to brown adipose tissue, and stimulates adrenal corticosteroid secretion. The overall impact of enterostatin secretion is a sensation of fullness leading to a selective reduction in fat intake. It is not yet clear how this peptide interacts with the other components of the energy homeostasis system.

Several other peptides are known to inhibit food intake following direct injection and to be regulated by leptin but to have little effect on feeding in rodents with the corresponding genes knocked out. Corticotropin-releasing hormone (CRH), for example, is produced mainly by neurons in the PVN and has a number of diverse effects, including the release of adrenocorticotropic hormone (another product derived from POMC) from the pituitary gland. CRH levels are regulated by leptin, and injections of CRH into the brain reduce food intake, even after induction by NPY, and stimulate thermogenesis via sympathetic pathways, but mice lacking the corresponding receptors, CRHR1 and CRHR2, have normal weight and feeding behavior. Urocortin is a related peptide which has a more potent anorexigenic effect than CRH's when injected, but because it signals through the same receptors as CRH and there is no impact on feeding when these receptors are missing, its precise role is unclear. Another potent anorectic is glucagon-like peptide 1 (GLP-1), a gastrointestinal peptide that is released in response to food intake. GLP-1 plays an important role in glucose homeostasis by inhibiting the secretion of glucagon and augmenting glucose-induced insulin secretion. In the context of this article, GLP-1 is also proposed to act as a satiety factor. Consistent with this hypothesis, peripheral administration of GLP-1 inhibits food intake. In addition to being produced in the intestine, GLP-1 is expressed at hypothalamic sites, the caudal portion of the NTS, and the forebrain. Central administration of GLP-1 inhibits food intake through actions in the hypothalamus, including the PVN. Conversely, GLP-1 antagonists stimulate feeding in satiated rats. GLP-1 antagonists also attenuate the effects of both leptin and CCK to inhibit food intake. Leptin has been shown to increase hypothalamic GLP-1 levels and to activate GLP-1 neurons in the NTS, providing further evidence of a role for GLP-1 in food intake and energy homeostasis. However, mice lacking the GLP-1 receptor do not show any feeding abnormalities.

Summary

The regulation of appetite and food intake is a complex process. It involves a coordinated response to many orexigenic and anorexigenic factors in multiple brain regions. Significant progress has occurred during the past decade, including the discovery of the adipostatic hormone leptin and some of the pathways required for its actions. Leptin produces its effects in part by a coordinated action to simultaneously

activate POMC and inhibit NPY neurons in the arcuate nucleus to alter food intake and energy homeostasis. Downstream targets of the NPY and POMC neurons include specific neurons in the PVN, LH, NTS, and other brain regions. However, much is still unknown, and it is likely that some critical appetite factors remain to be discovered. Furthermore, as is the case with other functions regulated by the hypothalamus, there appears to be some redundancy between these appetite factors.

Introduction

There are some stimuli encountered by animals to which the most appropriate response is invariant. If a large predator appears, seeking refuge almost always benefits a foraging rodent. Then there are other stimuli and situations to which the most appropriate response is dependent on the internal state of the individual. A hungry animal, for example, may consume food that a well-fed animal would ignore. There are many such internal or physiological variables that influence animals' behavior, and some change rapidly, whereas others change more slowly. Using the example of feeding, in addition to the difference in behavior between an animal that has just fed and an animal that has not fed for several hours, two animals with equally full stomachs may behave differently if one is fat and the other is lean. Furthermore, some of these physiological factors change unpredictably, whereas others change cyclically across a range of timescales from minutes to years. Such cyclic variability is typical of the reproductive states of many animals – for example, the ovarian cycle of most vertebrates.

For many of these phenomena, changes in a particular physiological parameter are associated with changes in the levels of one or more signaling molecules produced by the body. For several kinds of behavior, described in this article, it has been possible to show that a particular signaling molecule or hormone is the critical agent inducing the behavior appropriate for the physiological state associated with that hormone. Hormones, in other words, can be thought of as messengers that inform the brain of the state of the rest of the organism and enable the appropriate behavior. This article presents an overview of current knowledge about the relationships between environment, hormones, and the brain. Then, for three particular kinds of behavior (i.e., copulatory behavior, affiliative behavior, and feeding behavior) it describes in more detail the endocrine and neural systems that are thought to underlie these relationships.

Research

To say that a hormone influences a behavior is to say that an organism in one hormonal state responds to a given stimulus with one response, whereas the same organism in a different hormonal state exhibits a different response to the same stimulus. The elucidation of this relationship involves the following questions:

- What are the hormonal states involved, in terms of chemical identity, concentrations, and timing of hormonal exposure?
- What is the stimulus?
- What are the alternative behavioral responses?
- Which cells in the nervous system are involved in conveying information about the stimulus to the effectors that mediate the responses?
- On which of these cells does the hormone(s) have its effect?
- What kinds of receptors in these cells bind the hormone?
- Following hormone receptor binding, what kinds of changes occur in each cell, in terms of second-messenger activation, gene expression, and so on?
- How do these changes in each cell produce changes in cell-to-cell neurotransmission so that the stimulus–response relationship is altered?

Hormones

Historically, for a substance to be considered a hormone, it had to satisfy three criteria: synthesis by a specified kind of cell or tissue, release into and transport by the blood, and action on a specified target cell or tissue type(s). With increasing appreciation of physiological signaling systems, the second of these criteria has been become more complicated, and a system of adjectives has been developed to describe signaling molecules that act at various distances. Molecules that act within the cell that produces them are called intracrine signals, those that are secreted but act on the secreting cell are called autocrine, and those that act on adjacent cells are called paracrine. This article deals principally with endocrine systems – that is, those involving signaling molecules secreted from the producing cell into the intracellular fluid and exerting a physiological effect on other cells. However, several kinds of signaling molecules satisfy this definition that are not thought of as hormones. In particular, signaling molecules such as dopamine that are released by neurons and influence large numbers of other neurons are known as neuromodulators and not as hormones. Furthermore, some substances such as the cytokines modulate interactions between various components of the immune system and satisfy all three criteria perfectly well but are not called hormones, perhaps because

they are the historical purview of immunologists rather than endocrinologists.

Most of the well-studied hormones belong to one of four chemical classes, and as a result of their biochemical properties, members of a particular class tend to serve similar functions and engage similar transduction machinery in their target cells.

Steroids

Steroids, such as the gonadal hormones estrogen, progesterone, and testosterone, and the adrenal steroids corticosterone and aldosterone are synthesized from cholesterol and have a four-ring structure similar to the estrogen molecule shown in Figure 1. Their hydrocarbon-dominated structure makes their solubility in water low and that in lipids high. Consequently, they pass easily though cell membranes, and a steroid secreted in one part of the body will gain access to all tissues. The concentration of hormone reaching target tissues, however, is limited by the low carrying capacity of the blood, although for many steroids, this is augmented by specialized carrying proteins. Many of the effects of steroid hormones on behavior are mediated by proteins belonging to the nuclear receptor family that dimerize on binding ligand and then associate with the DNA of regulatory regions of genes to influence gene transcription. There is also accumulating evidence that steroids sometimes interact with membrane-associated receptors, and such effects are generally more rapid than the hours or days during which the nuclear receptors manifest their influence.

Prostaglandins

Prostaglandins are signaling molecules derived from fatty acids and are common mediators of physiological processes. Evidence of direct involvement in vertebrate behavioral regulation is not abundant, but, for example, prostaglandin E has been implicated as a key component of the developmental process of masculinization of the brain and subsequent behavior.

Figure 1 17β estradiol. Estradiol and other sex steroids share the basic structure of three six-carbon rings and one five-carbon ring, and they are interconverted by modifications of the substituent groups. Estradiol, for example, is formed from testosterone by the aromatization of the first six-carbon ring and the reduction of the ketone group on this ring to the hydroxyl shown here.

Monoamines

Monoamines, such as epinephrine, serotonin, and melatonin, are small molecules derived from single amino acids. They generally exert their effects through membrane-bound receptors with an extracellular ligand-binding site, often a G-protein-coupled receptor (GPCR), whose action on ligand binding is often to influence the production of a second messengers such as cyclic AMP.

Peptides

Peptide hormones are polymers of small numbers of amino acids (from fewer than ten to a few hundred); in other words, they are small proteins. Like monoamines, they generally utilize membrane-bound receptors, often GPCRs. The complexity of peptide hormones means that they often show variation in exact structure according to the organism examined. Steroids and monoamines are chemically identical from species to species (e.g., testosterone in a fish is identical in structure to testosterone in a human), although there are species differences in the nature and pattern of synthesis and release of the hormone (e.g., in many male fish 11-ketotestosterone is the dominant circulating androgen and is produced by steroidogenic enzymes not present in humans).

Behaviors Influenced by Hormones

Sexual Behaviors

There are three very important roles for hormones in modulating reproductive behavior. First, males and females have different roles in reproduction, and gonadal sex steroids tell the brain whether male-typical or female-typical behavior is appropriate. Second, animals do not reproduce throughout their lives but, rather, have a reproductively quiescent period before puberty, and, according to the species, sometimes breeding and nonbreeding seasons; hormones serve to encode reproductive status of the animal. Third, in females, sexual behavior is often restricted to narrow windows of the ovarian cycle, which are also associated with particular hormonal states. In general, testicular androgens enable the expression of male-typical behaviors such as competitive aggression, mounting, and intromission, whereas ovarian hormones, particularly estrogen, enable the display of female-typical sexual behaviors such as estrous and maternal behaviors. However, the hormones do not

act as simple on/off switches but, rather, are players in a complicated program of interaction between the developing animal and the environment, acting at multiple time points in both the brain and the periphery to coordinate the critical function of reproduction.

Development A central concept in the behavioral neuroendocrinology of reproduction is the organization–activation hypothesis. This idea was originally formulated to describe the development of the peripheral reproductive organs. Mammalian embryos are initially bipotential, possessing gonadal and genital primordia of both sexes. Working with rabbit embryos *in utero* in the 1940s and early 1950s, Alfred Jost recognized that early in development, castration of a male embryo would result in the development of the female-appropriate genital tract and the disintegration of the male genital tract, whereas a similar operation on an embryonic female did not affect the development of the female genital primordia or the disintegration of the male genital tract. This organization (i.e., the irreversible selection of which sexual structures are retained and which are lost) is irreversible and is restricted to a critical developmental time period. Later, once puberty occurs and levels of sex steroids increase again, the sexual structures develop further from their prepubescent state to their reproductively functional state. This activation of the previously organized structures is generally reversible, and in seasonally breeding animals it is commonly executed and reversed each breeding season.

Experiments conducted by William C Young's group in the 1950s suggested that the same kind of relationship between embryonic and adult effects of hormones might hold in the brain. Female guinea pigs that had been exposed to androgens *in utero* were much more likely to express male-like copulatory behavior when exposed to androgens as adults, and they were also less likely to express female-typical receptive behavior when treated with estrogen and progesterone. These two effects of prenatal androgenization, known as masculinization and defeminization, together constitute the process of behavioral organization and are experimentally separable by the timing of the critical developmental window and the nature of the hormones involved. During normal development, it appears that both components are mediated by circulating testosterone, although according to the species involved, the local conversion (i.e., at the site of action in the brain) of testosterone to estrogen, or aromatization, may be more or less critical. In rats, for example, administering an aromatase inhibitor prenatally can block masculinization. A schematic depiction of the development of sexual dimorphisms in anatomy, physiology, and behavior related to reproduction is presented in Figure 2. In addition to the behavioral motor patterns of copulation, such as female-typical receptivity and male mounting and intromission, other aspects of sexually dimorphic behavior can be subject to the organizational effects of embryonic hormone exposure. Examples include sex-typical play patterns, aggressiveness, and adult preference for sexual partners of the opposite sex.

Site of action It is presumably not a coincidence that the same hormones that control the development of reproductive organs also control the expression of behaviors utilizing those organs. In vertebrates of both sexes, the gonadal steroids that regulate the production of gametes also enable mating behavior, a kind of pleiotropy with obvious adaptive significance. More subtly, a given hormone will often have many sites of action within the brain for two reasons. First, expression of one kind of behavior may be associated with suppression of another kind of behavior. For example, the rise in progesterone associated with early pregnancy in female rabbits not only induces nest-building behavior but also suppresses mating behavior. Second, behavioral responses involve many different areas of the brain. A large number of experiments have identified specific nuclei of the limbic forebrain to be critically involved in the display of sexual behavior. Furthermore, various methods reveal these to be reciprocally interconnected, to contain sex steroid hormone receptors, and to be sexually dimorphic in their volume and synaptic organization as a consequence of the nature and frequency of sex steroid hormones secreted perinatally. Importantly, these properties appear to be evolutionarily conserved. Furthermore, these limbic nuclei form integrated circuits that are sensitive to both somatosensory and hormonal stimuli with overlapping functions that subserve all sex steroid hormone-modulated social and reproductive behaviors. In this manner, social and reproductive behaviors emerge from the activity of a unitary neuroanatomical framework rather than being the product of activity of a single brain area.

Interaction with the environment With increases in our understanding of the genetic determination of gonadal sex, it is becoming possible to map out, albeit with gaps, a pathway from the sex chromosomes an individual inherits, through the development of gonads, the secretion of sex-typical patterns of hormones, the sex-typical development of the brain, to the expression of sex-typical behavior. However, an individual vertebrate is not a hormone-driven automaton, blindly executing whatever behavioral program its gonads dictate, any more than the shape of its

Figure 2 Sex steroids act in various ways throughout development to coordinate physiology and behavior. This figure is a schematic depiction of important events in the development of female and male mammals, illustrating the interaction between the three organ systems (gonad, peripheral sex organs, and brain) and ultimately between the two sexes. In mammals, the sex is fixed at conception, and a molecular cascade will determine the sexual fate of the gonad. Secretions of the fetal gonad are then principally responsible for determining the sexual phenotype of the other two systems. This includes the accessory sex structures where testosterone maintains the Wolffian duct and enables them to develop into the epididymis and vas deferens, whereas Müllerian inhibiting substance (MIS), a protein signaling molecule secreted by the testis, induces the disintegration of the Müllerian ducts, which otherwise (i.e., in the developing female) develop into the uterus, cervix, and parts of the vagina. Fetal testosterone is also responsible for masculinizing (i.e., enabling future masculine) and defeminizing (i.e., disabling future feminine) behavior by its actions on the developing brain. At puberty, the body and brain thus organized during fetal development are activated by increasing levels of sex hormones, and animals of either sex become physiologically capable of reproduction and behaviorally able to mate. Arrows signify the actions of secreted molecules. E, estrogen; P, progesterone; T, testosterone.

development is determined entirely by its genome. Rather, each individual develops and behaves in continual interaction with other individuals and with other aspects of its environment. Such environmental influences on the development of the hormone–behavior relationship include hormone exposure *in utero* from mother and siblings, postnatal interaction with mother and siblings, the type and availability of food, and sexual and aggressive interactions with other individuals in adulthood, all of which can act to increase, decrease, or qualitatively change the expression of sex-typical as well as sex-atypical behaviors.

Copulatory behavior Mammalian male sexual behavior is dependent on testicular androgens so that castration eliminates the behavior in the majority of individuals, and administration of exogenous testosterone will reinstate it. In naturalistic settings, the expression of male sexual behavior is generally determined by the sexual behavior of females. Female sexual behavior is largely under the control of ovarian steroids and is therefore tightly linked to the ovarian cycle, of which a schematic is presented in Figure 3. In the rat, the cycle is usually 4 days long, with estrogen levels rising continuously until ovulation on the afternoon of the fourth day and then falling back to baseline, whereas progesterone levels remain low except on the day of ovulation. The periovulatory increase in progesterone following a period of sustained estrogen exposure is the hormonal antecedent to behavioral estrus, including increased attractivity, receptivity, and proceptivity, and can be mimicked in ovariectomized rats by an injection of estrogen, followed 48 h later by an injection of progesterone. In the wild, this cycle is unlikely to persist for long since behavioral estrus will normally involve mating and pregnancy, and the sustained high levels of progesterone

Figure 3 Hormonal changes across the ovarian cycle. Levels of three hormones are shown, scaled arbitrarily on the vertical axis and plotted against the time of the ovarian cycle. The horizontal axis would thus represent 4 days for a rat, or 28 days for a human. Luteinizing hormone (LH) is shown because it is a reliable marker of ovulation, rather than for its behavioral importance. In rodents, the rise in estrogen (E) levels before ovulation followed by a rise in progesterone (P) levels are critical determinants of estrous behavior.

originating from the corpora lutea suppress further ovarian cycles until gestation is complete. Other species have cycles of different lengths, but the general pattern of estrogen levels rising gradually before ovulation and then progesterone levels rising during and after ovulation is conserved. There are also some species such as cats, in which there is no regular ovarian cycle but, rather, ovulation is induced by copulation.

In 1976, Frank A Beach proposed that the sexual behavior of female mammals could generally be thought of as including three components, namely attractivity, proceptivity, and receptivity. The attractivity of a female (many aspects of which are obviously nonbehavioral) represents the degree to which a male will seek and elicit copulation with her. Proceptivity is the degree to which she will actively seek out a sexual partner and attempt to initiate copulation. Receptivity is the degree to which a female will allow the courtship and intromission of a male that attempts to copulate with her. These three components are still extremely useful heuristically in describing the copulatory sequence of mammals.

In rats, attractivity is assessed largely through olfactory and pheromonal cues (Figure 4(a)). Little is known about the neural mechanisms by which females assess a male's value as a mate, but the neuroanatomy underlying male processing of female pheromonal signals is known in some detail (Figure 5(a)). Volatile odorants are detected at the olfactory epithelium and larger, less volatile pheromones by the vomeronasal organ. These sensory structures project respectively to the main and accessory olfactory bulbs and then via the amygdala (particularly medial division) and the bed nucleus of the stria terminalis to the medial preoptic area (MPOA). The MPOA plays a

Figure 4 Characteristic behaviors in the rat mating sequence. Rat social interactions of all kinds, including sexual, often involve mutual olfactory examination, particularly of the facial area (a). When the interaction involves an estrous female and a suitable mate, she will express a suite of proceptive behaviors that signal her sexual status to the male, including rapid approach and withdrawal, hopping and darting, and rapidly moving her ears (b). A sexually active male will follow and mount her (c). If receptive, she will express the flattened posture of lordosis, with head and rump elevated and back depressed, enabling him to intromit, thrust, and ejaculate. Illustrations by Lauren Munchrath.

particularly important role in integrating male-typical copulatory behavior, especially the hormonal gating thereof. Although prolonged systemic exposure to androgens is necessary for the development of sexual structures such as the penis, it seems that expression of copulatory behavior as an adult is simply determined by exposure of a small number of brain areas to hormone, particularly the MPOA.

An estrous female will solicit the male's attention with proceptive behaviors such as approaching him and rapidly withdrawing with a characteristic dart-hopping movement, ear wiggling, and other behaviors (Figure 4(b)). Comparatively little effort has been made to elucidate the neuroanatomical substrates of this behavior as distinct from those subserving the receptive behavior that follows.

A sexually active male will follow a proceptive female and attempt to mount her. The stimulation from his snout and forepaws on her rump and flank induces the estrogen- and progesterone-dependent reflexive receptive posture known as lordosis shown in Figure 4(c), and whose neural substrates are schematized in Figure 5(b). The essential reflex arc flows

Figure 5 Neuroanatomical pathways mediating copulatory behavior. Brain nuclei known to be important in the expression of the various behaviors are depicted as square boxes, and the projections between them (of which some are excitatory and some inhibitory) are shown as arrows. Sensory and effector organs are shown as rounded boxes. Brain nuclei critical for hormonal control over behavior are shown as bold boxes. The neuroanatomy involved in processing sexually relevant chemosensory information has been well studied in the male rodent (a) and involves the pathway from the main and accessory olfactory bulbs to the amygdala, particularly the medial division, and thence via the bed nucleus of the stria terminalis and an alternative route via the ventral amygdalofugal pathway to the medial preoptic area. Exactly what happens to this information once it reaches the medial preoptic area is unknown, but it is presumed to result in the decision to attempt to mount. Once the mount is established, events in both the female and the male involve reflex arcs mediated by well-characterized neural circuits, shown by bold arrows. (b) Lordosis in the female involves the transfer of sensory information from the male's mounting and thrusting movements to the lumbar spinal cord, whence it ascends to the brain stem motor nuclei responsible for integrating the muscular motor pattern of lordosis. Descending control over this reflex arc is exerted by the ventromedial hypothalamus via the periaqueductal gray and the midbrain reticular formation. The medial preoptic area plays an inhibitory role. (c) Erection and ejaculation in the male are spinal reflexes, albeit subject to descending influences from higher in the brain, whereas other motor patterns of male-typical copulation are mediated by brain stem motor areas. The periaqueductal gray exerts an inhibitory influence on these lower copulatory reflexes, and a major role played by the medial preoptic area is probably disinhibition achieved by inhibiting the periaqueductal gray.

from the sensory receptors on the skin via the pudendal nerve to the lumbar spinal cord. Then it is relayed to the brain stem motor centers of the lateral vestibular nuclei and the nucleus paragigantocellularis of the medullary reticular formation. These motor centers project back to the lumbar spine and orchestrate the motor pattern of lordosis via their control over the musculature of back and pelvis. Hormonal control of this behavior is achieved by higher centers in the brain, particularly the ventromedial hypothalamus, which influences the nucleus paragigantocellularis via the periaqueductal gray. A similar system of nuclei mediates the motor and other physiological responses of the mounting male (**Figures 4(c) and 5(c)**). Sensory information from the penis is relayed via the pudendal nerve to the sacral and lumbar spinal cord. Some important components of the male sexual response, such as erection and ejaculation, are spinal reflexes and are observed even in rats spinally transected above the thoracic level. Sensory information, however, is conveyed to the medullary reticular formation, whose nucleus paragigantocellularis integrates reflexive motor patterns such as thrusting, and then via the thalamus to higher areas in the brain. Descending signals from the MPOA reach the nucleus paragigantocellularis directly or via the periaqueductal gray. Other aspects of female sexual behavior, such as mate choice, the rewarding properties of copulation in various different contexts, copulation for other reasons than reproduction, and an individual's preference for one particular mate over others, are also beginning to be studied.

Aggression The ecology of sexual aggression is complex, with a number of factors influencing which individuals are aggressive to which others under which circumstances in which species. This complexity in the nature of the behavior is reflected in the relationship between the behavior and its hormonal antecedents, and general principles are difficult to extract. However, with respect to the endocrinology of male reproductive aggression, observations from a number of species can be reconciled in a conceptual framework known as the 'challenge hypothesis,' originally elaborated by John Wingfield and colleagues to explain some of the available observations concerning testosterone and aggression in songbirds. This hypothesis posits that testosterone levels are low during nonreproductive periods, rise to intermediate levels during breeding to support reproductive physiology such as spermatogenesis and copulatory behavior, and increase to especially high levels during periods characterized by frequent agonistic interactions with other males, sometimes apparently as a result of such agonistic interactions.

Again, possibly because of the complexity of the phenomenon, the neuroanatomical substrates of aggression have been less thoroughly elucidated than those subserving copulatory behavior, but some kinds of aggression seem to involve the lateral septum and the nucleus accumbens, in addition to the amygdala and various subdivisions of the hypothalamus. These areas express androgen and/or estrogen receptors and also various types of serotonin receptor. Serotonin appears to occupy a central role in the control of aggressive behavior, with reduced levels of serotonin receptor activation being associated with increased aggressiveness in a range of contexts in a range of species. This is not a completely valid generalization, however, since maternal aggression is associated with increased serotonin levels.

Parental behavior Parental behavior obviously includes both maternal and paternal behaviors, but since paternal behavior is not common other than in birds and certain fish taxa, this discussion is largely limited to females. Once again, rats have been the main focus of research, and important kinds of maternal behavior in this species include nest building, licking and grooming, nursing, pup retrieval, and maternal aggression. These behaviors are exhibited at different points in the reproductive cycle (or at least exhibited at different frequencies), and their expression is partly dependent on the endocrine events associated with pregnancy, lactation, and birth. The end of pregnancy is characterized in rats by high estrogen levels, plunging progesterone levels, and a sharp spike in prolactin levels, whereas the event of parturition is associated with a peak of oxytocin secretion. All of these hormonal parameters appear to be involved in the onset of maternal behavior. Expression and maintenance of the behavior is not only partly controlled by hormones but also largely dependent on stimulation from the young so that nursing female rodents are not exceptionally aggressive except in the presence of their pups.

Pair bonding In some species, males and females form stable reproductive pairs in order to raise young. Oddly, the neuroendocrine mechanisms underlying this behavioral phenomenon have received little attention in birds, in which the behavioral pattern is common, and instead have been most extensively investigated in microtine rodents. These studies have implicated corticosteroids and the peptide hormones oxytocin and vasopressin in mediating pair-bond formation in these animals. In the prairie vole, socially naive animals will form monogamous pairs with the partners with whom they first mate. The genesis of this pair bond is

dependent on copulation-induced oxytocin release in females and on a combination of vasopressin and corticosterone in males.

Other Hormonally Influenced Behavior

Feeding is important, but there are times, such as when an animal has a full stomach, that it is inappropriate or, when the animal is fat, that it is less important than other activities such as reproduction. Accordingly, vertebrates have evolved a network of signaling systems that keeps the brain informed about the animal's short-term and long-term state of nutrition and enables appropriate feeding behavior. In addition to direct neural pathways to the brain, the gastrointestinal tract produces a range of peptide hormones that encode information about the quantity and quality of food being ingested and processed. The majority of these hormones, such as cholecystokinin and glucagon-like peptide 1, appear to be satiety inducing, rising after feeding and reducing food intake when administered exogenously. An interesting exception is ghrelin, which appears to peak before (i.e., in anticipation of) feeding and increases food intake. Just as other behaviorally important hormones often mediate nonbehavioral aspects of the processes with which they are associated, these gastrointestinal peptides are intricately involved in the regulation of gut function in addition to their role in regulating feeding behavior.

In the longer term, the brain receives information about nutritional status via adiposity signals such as leptin secreted by adipocytes and insulin from the pancreas. In the central nervous system, the arcuate nucleus appears to play a central role in regulating feeding via projections to the lateral, paraventricular, and ventromedial nuclei of the hypothalamus. The various peripherally generated nutrition-related signaling molecules reach the arcuate nucleus via the median eminence and are transduced into two kinds of signals – either suppressing food intake and involving the expression of pro-opiomelanocortin and cocaine- and amphetamine-related transcript or augmenting food intake and involving the expression of neuropeptide Y and agouti-related peptide.

It is important to recognize the degree to which separate hormone–behavior systems are interrelated. For example, in some species (e.g., elephant seals), males do not feed during the mating season, and in most species the onset of puberty is dependent on nutritional status.

Summary

Several kinds of behavior are dependent on or influenced by circulating hormones. Many, but not all, of these are related to reproduction and are accordingly influenced by the same suite of steroid and peptide hormones that serve to regulate the other aspects of reproductive physiology. Sex differences in vertebrate hormone metabolism occur throughout the development of the individual, from the differentiation of the fetal gonad until death. For much of this period, these hormonal differences have effects, both subtle and profound, on the brain and on behavior. In many cases, the systemic hormonal antecedents to particular behaviors in adults are well known, although in the brain, the localized release of various peptide hormones and the localized metabolism of steroids make it a much more difficult task to identify which hormone is contributing how much to which effect in which target cell. For some behaviors, particularly those such as rodent lordosis in which the stimulus–response relationship is a simple one, the anatomy of the neural circuits responsible for responding transducing hormone–behavior relationships is fairly thoroughly elucidated. In others, such as female proceptive behaviors, the neural substrates are more of a mystery. In almost all cases, our knowledge of neural structure stops at the level of anatomical connectivity. Despite the fact that the first sex difference in neural structure was reported at the ultrastructural level, we still know very little about how hormones alter the flow of information from one neuron to another, which is presumably a prerequisite for changing behavior. This last lacuna in our knowledge of hormone–behavior relationships is perhaps the most inevitable, given that the same problem exists throughout behavioral neuroscience, and for the same reason it is one of the most challenging.

Hormones and Memory

Background

Compelling neurobiological evidence from animal models suggests that estrogen and testosterone influence the structure and function of brain regions important for memory. These regions include the hippocampus, amygdala, basal ganglia, and prefrontal cortex, all of which have traditional androgen or estrogen receptors or have what are considered to be rapid 'membrane mechanisms' of hormone action. A variety of physiological changes occur in these regions when sex hormone levels are manipulated. These findings have shaped studies of sex hormone actions on memory in humans; however, findings from human studies are as yet ambiguous. The literature can best be characterized as the 'the good, the bad, and the ugly.' There are several situations through which hormone action in humans has been studied. These include effects on memory of hormone changes across the menstrual cycle, age and menopause-related hormone loss, hormone therapy in healthy men and women, hormone supplementation in neurodegenerative disease, and hormone loss for prostate cancer treatment in men. Recent studies of memory effects from these models will be briefly reviewed here with attention to the specific forms of memory affected. That is the good news. Most studies of animal models use 17-β-estradiol, testosterone, or a metabolite of these sex steroids. Human studies must utilize medications and application methods approved for human use. Thus, the studies reviewed examined effects from a variety of medications that modify the hormonal milieu of the brain including estradiol, conjugated equine estrogen, testosterone, gonadotropin-releasing hormone agonists, administered by pill, injection, patch, gel, or after surgical oopherectomy. Differences in memory effects among these different methods of hormone intervention are not well established in the literature. That is the bad news. Finally, data come from naturalistic, cross-sectional, and placebo-controlled trials. Thus, differences in effects or lack of effects among studies may well be due to the difference in medications, sample, and design. That is ugly, but part and parcel of the constraints of human studies.

Estrogen and Declarative Memory

Effects of Estrogen on Memory during Normal Menstrual Cycling

Definitive studies of memory effects during menstrual cycling and their relationship to sex hormone levels in young women are sparse. The phase of the menstrual cycle (e.g., high estradiol and progesterone in the luteal phase versus low sex hormones in the menstrual phase) does not modify memory in women with mild or severe premenstrual symptoms nor does it modify cortisol-induced memory impairments. Similarly, explicit verbal memory is not affected by menstrual phase in healthy young women despite effects in other cognitive domains including visual priming and mental rotation. Visual memory is poorer at the low estrogen menstrual phase as opposed to the luteal phase, but other measures of memory are unaffected. Factors that qualify studies in the literature are the lack of confirmation of menstrual phase with estradiol levels, very small sample sizes, and oral contraceptive use by women in some studies. The lack of definitive effects of estradiol modulation, particularly of verbal memory in younger women, is in contrast to effects in aging.

Effects of Estrogen in the Perimenopausal Period

During the transition to menopause, estrogen production gradually declines and women report memory difficulties. This transition causes physiological symptoms, such as hot flushes and sleep disturbances. Estradiol therapy relieves these physiological symptoms. Studies suggest that women on estrogen therapy to relieve symptoms of the menopause and particularly after surgical menopause, when hormone levels drop precipitously to negligible levels, have superior recall of verbal information. What is still unclear is whether this is a critical period for long-term estrogen effects in aging, or whether the critical factor is the severity or rate of hormone loss. A placebo-controlled trial showed that women (mean age 51.2 years) on conjugated equine estrogen for 21 days had numerically higher verbal memory performance than controls, but this did not reach significance when scores were corrected for general intelligence differences among treatment groups. Furthermore, five other randomized clinical trials show that women under the age of 65 receiving estrogen are more likely to show better verbal memory performance later in life than those not on estrogen. In addition, a novel intranasal estradiol

preparation administered for 2 years did improve women's perception of their memory in a dose-dependent manner. These studies are in contrast to no effects or poorer performance in studies where hormone therapy is initiated late in life, after the age of 65. Verbal memory does not differ in women at different stages of the menopausal transition, nor between current versus past hormone users in a population-based observational study. Similarly, a placebo-controlled study finds that the severity of menopausal symptoms, their relief, or estradiol treatment during the transitional phase of natural menopause affects memory. However, a significant association occurs such that those who began hormone use during the menopausal transition have better memory subsequently than those who begin hormone use only after the final menstrual period. Neither verbal nor nonverbal memory differed among women who were never, current, or past users of hormone therapy when the data were adjusted for age, education, and other cognitive performance differences among hormone-use groups in another cross-sectional study. Together these studies suggest that verbal memory is affected by estrogen when it is begun during but not after the menopausal transition and this may be a narrow window. Thus, there may be a critical period during which the influence of estrogen on memory, particularly verbal memory, is most significant. Similar temporally limited effects of estrogen replacement after gonadectomy are found in rodent models. This would suggest that memory areas change in their responsiveness to estradiol depending on age or the prior hormonal milieu of the brain.

Effects of Estrogen on Older (Postmenopausal) Women

Hormone therapy in older postmenopausal women may have a protective effect against age-related memory decline, and/or the promotion of memory performance over and above age-related changes in memory. For instance, an early randomized controlled study found that a year of estradiol therapy improved performance on the Wechsler memory scale as compared to a placebo control group or pretreatment performance in older women confined to a nursing home. In contrast, recent data from women in their 70s find that there is no effect of estrogen in combination with progesterone on verbal or nonverbal (figural) memory approximately 3 years after initiation of hormone therapy. However, estrogen and progesterone treatment are negatively associated with verbal memory and positively associated with nonverbal memory rates of change over the approximately 3-year follow-up interval. Estradiol alone for a shorter duration (20 weeks) in a similar sample of older women does not affect cognition. Blinded controlled data on the long-term effects of estradiol alone are as yet not available. The female advantage for verbal memory tasks remains when older men and women with similar estradiol levels are examined. This suggests that sex differences are not dependent on circulating estradiol levels in adulthood.

Case-control studies compare women who are users versus nonusers of hormone therapy and who are matched for a variety of other demographic variables. This is the only method that is available to understand whether estradiol has effects in older women when used over much of their postmenopausal life. Healthy, older postmenopausal women on estrogen therapy perform significantly better than nonusers of estrogen on word-list recall and on both immediate and delayed paragraph recall. Users of hormone therapy had better visual memory on the Benton visual retention task as compared to women not using hormone therapy. Visual memory, as measured by the visual reproduction test of the Weschler memory scale, is also significantly better in women on hormone therapy. However, not all studies find such effects. For instance, users of hormone therapy perform similarly to never users of hormone therapy on a test of story memory in a large sample of healthy older women. Hormone use is not related to rate of memory decline in older women over a 2-year study period, and in fact hormone users have a numerically faster rate of memory decline compared to never users.

Estradiol levels are positively related to verbal memory in elderly women (age 61–91 years) even if they are not on hormone therapy but are not associated or are negatively associated with visual memory. The negative association of estradiol levels and visual memory in hormone users as opposed to the positive effects observed in hormone users suggests that there may be a threshold over which estradiol has positive effects on nonverbal memory in elderly women.

Brain activity during memory tasks is also associated with hormone therapy in older women. For example, measurements of blood flow (using positron emission tomography (PET)) in brain regions that subserve verbal and nonverbal memory processing, including the parahippocampus and right frontal regions, are higher in women using hormone therapy as compared to women without hormone therapy. A 2-year follow-up PET study finds increases in regional cerebral blood flow (rCBF) in estrogen users as compared to nonusers in areas associated with a verbal recognition memory test, including the hippocampus, parahippocampus, and middle temporal lobe. This parallels findings of improved memory performance over an 18-month period in hormone users as compared to nonusers.

Estrogen and Working Memory

Estrogen does not affect working memory performance in middle-aged women (mean age 50.8 years) but does result in increased brain activity in the inferior parietal lobe during storage of verbal information and decreased brain activity in the same region during storage of nonverbal material. Another placebo-controlled study finds no influence of estrogen therapy on working memory in older women using the subject-ordered pointing test. Cross-sectional studies find middle-aged women on estrogen perform better than nonusers on working memory tasks comprised of both verbal and spatial components. Young women have better verbal working memory (span task) during the high estrogen phase as opposed to the low estrogen phase of the menstrual cycle as inferred by body temperature, while the performance of women on birth control, and estradiol levels, do not vary but remain constant.

Estrogen and Implicit Learning

Higher estradiol levels or performance at the high estrogen phase of the menstrual cycle in young, premenopausal women is related to faster motor dexterity on the grooved pegboard task, and motor sequence learning, but not simple reaction time using a task associated with the striatum. Visual priming may be lessened at the high estrogen phase, although this was confounded with the order of testing across menstrual phase.

Sex Hormone Effects in Men

Testosterone supplementation is most commonly used to treat hypogonadism in older men. In addition, testosterone can be converted to estrogen in the brain. Thus, studies using inhibitors to block the metabolism to estrogen, or studies of complete blockade of the androgen pathway, as is a common treatment to prevent the progression of prostate cancer, will result in very low estradiol in men. Very high-dose estradiol has also been studied as a novel treatment for prostate cancer. Studies using these models show that significant changes of testosterone or estradiol levels affect memory in older men. Testosterone deprivation results in poorer verbal memory in younger men, as well as older men on hormonal therapy for prostate cancer. Replacement with very high-dose estradiol, that also maintains an androgen blockade, results in improved verbal memory in men with prostate cancer. Similarly, testosterone supplementation in hypogonadal men results in improved verbal memory, while dihydrotestosterone, an androgen that does not metabolize to estradiol, results in improved spatial memory. Blocking the conversion of testosterone to estradiol blocks the enhancement of verbal memory in older men. Together these studies suggest that estradiol is important for verbal memory enhancement, at least in older men. Memory is not affected by testosterone supplementation in men with congenital disorders that cause hypogonadism. Very brief testosterone supplementation by a single injection or dose does not affect memory in younger men, although object location memory is improved in younger women.

Working memory as assessed with the subject-ordered pointing test is improved with testosterone supplementation in older men, and cross-sectional studies show that higher free (unbound) testosterone levels are related to lower rates of decline in verbal and nonverbal memory as well as a working memory measure, Trails B, performance as men age. The relationship between testosterone levels and memory performance gets stronger as men age. Like estrogen, cross-sectional studies suggest that low free testosterone is a premorbid risk factor for Alzheimer's disease in men and is associated with poorer performance on screening measures for dementia in women. Together these studies suggest that testosterone or its metabolites may play a role in maintaining brain health in aging.

Concluding Comments on Sex Hormones and Memory

Estradiol does not affect declarative memory in younger cycling women, and the effects on memory in older women are unclear. The timing, dose, and form of sex hormones influence the outcome of studies. Still unclear is whether these hormones activate memory performance or have a neuroprotective role when cognition declines. If it were the latter, then effects would only be seen with comparisons among people with age-related or disease-related cognitive decline. These lifetime factors complicate the ability to study effects in humans versus effects found in animal models. Regardless, the effects in humans are subtle as compared to the effects of gonadectomy and hormone replacement in animal models. This suggests that the day-to-day role of sex hormones in humans is to modulate memory formation, while severe and sudden hormone deprivation, particularly in critical periods for age-related decline, may amplify memory impairments and risk for neurodegenerative disease.

Hox Genes Expression

Introduction

What Are *Hox* Genes?

Hox genes encode a family of homeodomain-containing transcription factors required for patterning regional properties along the rostral–caudal (R/C) axis during embryogenesis. The *Hox* gene family is highly conserved in organisms ranging from *Drosophila* to humans. In most vertebrates, except ray-finned fishes, there are 39 members segregated into four tightly clustered gene arrays (A–D) on four separate chromosomes (Figure 1). The *Hox* complexes are believed to have arisen by tandem duplication of a single gene to create a cluster, followed by duplication and divergence of the ancestral cluster associated with large-scale genomewide duplications in vertebrate evolution. This gene family is defined by sequence conservation, their genomic organization, and the presence of a homeobox or homeodomain motif within the protein. This domain is a helix–turn–helix protein motif responsible for sequence-specific DNA binding. These genes were initially identified in fly mutant screens as genes important in regulating segmental identity. One of the most famous examples is a gain-of-function mutation of the *Antennapedia* (*Antp*) gene, which transforms fly antenna into legs (Figure 2). Further investigation led to the discovery of 8 Hox proteins in *Drosophila*, each with roles in patterning and R/C-restricted patterns of expression.

Hox Gene Expression

Initial experiments demonstrating dramatic phenotypes associated with *Hox* gene deficiencies stimulated exploration of their expression patterns in *Drosophila* and other organisms. Surprisingly, developmentally regulated, nested and ordered patterns of expression were observed during embryogenesis. This further elevated interest in this family as developmental regulators because their patterns of expression along the embryonic R/C axis correlated with their gene order along the chromosome, suggesting they might provide a molecular means of defining head from tail or different structures from a common tissue. In the mouse, *Hox* gene expression begins at approximately embryonic day 6 (E6), one-third of the way through mouse development, after gastrulation has begun and the R/C axis has extended and become patterned. During the middle third of mouse development, *Hox* genes are highly expressed in the developing neural tube, often in dynamic patterns. The pattern of expression of individual *Hox* genes generally correlates both temporally and spatially with the location of the gene within its complex, a phenomenon called collinearity. Genes at the 3′ end of the complexes (paralog group 1) are expressed earliest with the most rostral boundaries of expression, and these two characteristics progressively change in successive genes in the complex, such that the most 5′ genes (paralog group 13) are only expressed caudally and have a delayed onset of expression compared to 3′ genes (Figures 1, 3 and 4). Although the spatial/temporal aspects of expression patterns progressively change between adjacent paralog groups, within paralog groups expression characteristics and even protein functions are often similar. Although the focus of this article is on the role of *Hox* genes in R/C patterning, they are expressed and have important functions in many other tissues. *Hox* genes have roles in hematopoiesis; lung, thyroid, parathyroid, kidney, breast, and muscle development; and in development of the structure of the head and neck and in the gastrointestinal and urogenital systems, where they have at least partially collinear patterns of expression. A common feature of *Hox* genes is that they provide a means of specifying different regional properties along the axis of a tissue. Within these systems they can do so by regulating a broad range of cellular activities, such as proliferation, differentiation, migration, patterning, adhesion, and cell death. In fact, part of the excitement about *Hox* genes is that they provide insight into the cellular and molecular mechanisms that use common building blocks to create different tissue structures (leg vs. antenna, hindbrain vs. spinal cord, and rib vs. tail bone).

Hox Gene Function

Since their initial discovery and analysis in *Drosophila*, Hox proteins have been demonstrated to be crucial molecules in regulating R/C patterning and defining segmental identity in vertebrates as well. Targeted mutagenesis of *Hox* genes in the mouse or manipulation of *Hox* gene expression in chickens via *in ovo* electroporation often alter segmental identity in the hindbrain and spinal cord as demonstrated by changes in motor neuron differentiation and identity. For instance, when either *Hoxa1* or *Hoxb1* is deleted by gene targeting, it perturbs the development of rhombomere-specific motor neuron populations as evidenced by altered motor neuron migration and/or projection patterns. When either of these is ectopically expressed in rhombomere 1 (normally a region devoid of *Hox*

expression), it triggers ectopic development of motor neuron types typically found in more posterior segments. Similar experiments manipulating *Hox* gene expression in the developing chick spinal cord have shown that the products of *Hox* genes are the primary factors defining motor neuron pool subdivisions which innervate specific limb muscles. These studies emphasize that within the hindbrain and spinal cord, Hox proteins play a pivotal role in developmental patterning by defining segmental identity and controlling segment-specific structures and cell types. Pharmacological studies also support this role in that agents that perturb *Hox* regulatory pathways result in corresponding shifts in *Hox* expression profiles and regularly lead to alterations in segmental identity. Hence, detailed knowledge of the mechanisms of *Hox* gene regulation is fundamental to understanding how segmental identity is established and maintained. The following sections summarize the current understanding of basic mechanisms of *Hox* gene regulation within the hindbrain and spinal cord and provide specific examples to demonstrate key points.

Figure 3 Expression patterns of *Hox* gene regulatory transcription factors and *Hox* genes are indicated by colored bars above and below the schematic of the developing mouse hindbrain at E9.5. Color gradients indicate relative expression levels or caudally regressing patterns of expression. r1–r7, rhombomeres 1–7; MB, midbrain; SC, spinal cord. Dashed lines indicate rhombomere boundaries.

Figure 4 Expression patterns of caudally expressed *Hox* genes between E11.5 and E12.5. Spinal cord regions and associated segments are indicated on the left. The blunt ends of arrows indicate expression boundaries and the pointed ends signify that expression continues rostrally or caudally in the direction of the arrows. Expression patterns that have both anterior and posterior boundaries within the limits of the diagram are indicated as boxes.

Signaling Pathways Are Important Regulators of *Hox* Gene Expression

The retinoic acid (RA) and fibroblast grow factor (FGF) signaling pathways regulate significant aspects of *Hox* gene expression patterns. Manipulation of either of these pathways results in both alterations in *Hox* gene expression patterns and changes in R/C segmental identity. This has been demonstrated by adding exogenous RA or FGF, generating vitamin A-deficient (VAD) embryos, employing chemical agonists/antagonists, or expressing dominant negative FGF receptors. Additionally, mice engineered to be deficient in Cdx transcription factors, one of the integrators of FGF signaling, also display phenotypes which are strikingly similar to mice bearing homozygous *Hox* gene deficiencies. The teratogenic effects of RA exposure on human development and the similarity of the results to those of experiments done in mouse, chick, frog, and fish model systems corroborate the importance of *Hox* genes in segmental identity and the importance of RA in *Hox* gene regulation.

Regulation of *Hox* Genes by RA

RA, the active form of vitamin A, is produced by an enzymatic pathway that culminates in the conversion of retinaldehyde to RA by retinaldehyde dehydrogenase (RALDH). Lipophilic RA then diffuses or is transferred into surrounding tissues and cells so that it is able to bind to retinoic acid receptors (RARα, -β, and -γ and RXRα, -β, and -γ). These nuclear receptors exist as heterodimers that together bind retinoic acid response elements (RAREs) within the genome and modulate gene transcription. The binding of RA to these receptors converts these bound heterodimers to transcriptional activators via increasing their affinity for coactivators and decreasing their affinity for co-repressors. RA signaling relevant for R/C patterning of the hindbrain and spinal cord is initially regulated by controlling RA production via *Raldh2* expression in somitic mesoderm. After RA has been produced, local concentrations are modulated by cytoplasmic retinoic acid binding proteins (CRABP1 and -2), clearance by the blood, isomerization from 9-*cis* to the less potent all-*trans* RA, and, finally, degradation via the Cyp26 family of enzymes. This provides a complex metabolic mechanism to ensure the levels of this important signal are very carefully modulated in a tissue-specific and temporally specific manner. A transgenic mouse line bearing an RA responsive marker gene shows that these mechanisms synergize to produce substantial RA signaling in the eye, telencephalon, and throughout the spinal cord and adjacent mesoderm/somites from the level of the caudal hindbrain throughout the majority of the trunk, with the lowest levels at the node and tailbud at later stages.

RA Response Specificity and Diversity

Many *Hox* genes have been shown to be RA responsive, and several functional RAREs have been identified near *Hox* genes demonstrating that they are direct targets of the signaling pathway. Multiple DR5 (direct repeat + 5-base pair spacer; i.e., AGGTC AnnnnnAGGTCA) and DR2 RAREs have been identified within the *Hox* clusters and associated with either activation or repression of one or more neighboring genes. For example, transcription of both *Hoxb3* and *Hoxb4* is activated by a single DR5 RARE located in the intergenic region between these two genes. *Hoxb1*, on the other hand, is associated with three separate RAREs, all of which have distinct influences on its expression. A DR5 RARE 5′ of *Hoxb1* mediates repression of *Hoxb1* in rhombomeres 3 and 5, whereas a DR2 RARE and a DR5 RARE 3′ of *Hoxb1* both activate expression of *Hoxb1* but in different spatial patterns (**Figure 5**). Several other 3′ *Hox* genes not mentioned here also have RAREs with similar organization and function as those mentioned previously. Thus, RA affects a broad range of *Hox* expression patterns, and although these responses can be regulated both directly and indirectly, it is clear that *Hox* genes are often direct targets of RA activity. Additional modes of regulation continue to be investigated.

FGF Regulates *Hox* Expression

FGFs are also important regulators of *Hox* gene expression. FGFs are an expanding family of secreted signaling molecules that includes more than 20 members. After secretion, these soluble proteins bind to transmembrane tyrosine kinase receptors, FGFR1–4. These ligand-bound receptors dimerize, autophosphorylate themselves, and transduce intracellular signals via mitogen-activated protein kinase, phosphatidylinositol 3-kinase, or protein kinase C/protein lipase C (PLCγ), among others. Activation of these pathways can result in a broad spectrum of responses depending on the context; however, activation of *Cdx1–4* homeobox gene expression is one of the primary modes of influencing *Hox* gene expression. Cdx homeodomain transcription factors, homologs of the *Drosophila* caudal protein, are capable of binding *Hox* gene enhancers and directly regulating *Hox* transcription. Hence, FGFs activate *Hox* gene expression indirectly via the *Cdx* family of genes. FGF8 expressed in the isthmus (a thin region that separates the midbrain from the hindbrain) and the node (a signaling center and region of posterior

Figure 5 RA regulation of *Hoxb1*. *Hoxb1* has three retinoic acid response elements (RAREs) indicated by blue boxes. Two of these activate expression of *Hoxb1* (green arrows) and one mediates repression (red line). The *Hoxb1* autoregulatory *Hox* response elements are indicated as gray squares and circles. DR2 and -5, direct repeat 2- and 5-base pair spacers.

elongation) has significant patterning influences on the R/C axis. FGF8 from the node influences *Hox* gene expression throughout much of the spinal cord during elongation of the axis. Isthmic sources of FGF8 are critical for maintaining the identity of rhombomere 1, the first hindbrain segment, but its role in *Hox* gene repression in this uniquely Hox-free region is poorly understood.

FGF and RA Regulate Opposing Groups of *Hox* Genes

Although both RA and FGF exhibit dose-dependent activation of *Hox* gene expression, they display opposing preferences for which *Hox* genes are activated by each. RA preferentially activates *Hox* genes in the 3′ portion of the complex (*Hox1–5*) and has little influence on the expression of 5′ genes (*Hox6–13*). For instance, expression of a dominant negative RAR diminishes *Hoxb4* expression in the developing spinal cord but does not alter *Hoxb9*. Functional RAREs responsible for this preferential activation have been identified in the 3′ portions of the complexes. In contrast, FGF preferentially influences *Hox* genes in the 5′ portion of the complex (*Hox6–13*) and can expand their rostral boundaries of expression. FGF specificity appears to be determined, in part, by *Cdx* expression domains, which supports the hypothesis that Cdx proteins play an important role in integrating FGF signaling. FGFs are capable of activating expression of both 5′ and 3′ *Hox* genes and expanding their expression domains, but activation of 3′ *Hox* genes in the hindbrain is limited by the availability of Cdx. Whereas exogenous FGF can extend the expression of *Hoxb9* from its caudal boundary up to the level of the otic vesicle, *Hoxb4* expression that normally terminates just posterior to the otic vesicle cannot be expanded by additional FGF alone. Ectopic expression of a dominant active Cdx (XcadVP16) in the presence of exogenous FGF, however, can expand both *Hoxb4* and *Hoxb9* expression past the otic vesicle and into the hindbrain.

FGF and RA Generate Opposing Gradients

RA and FGF signaling oppose each other on multiple levels. They preferentially influence opposing groups of *Hox* genes and also positively and negatively cross-regulate the opposing pathway. For example, FGF can activate transcription of RARs, activate expression of *Cyp26* (the enzyme responsible for RA degradation), and block expression of *Raldh2* and thus attenuate RA production. Conversely, RA can activate *FGFR* expression, block expression of fgf8, block expression of *Cdx1*, and stimulate its own degradation by upregulation of *Cyp26*. These diverse mechanisms work together to produce opposing gradients of FGF and RA signaling activity, which allows a wide range of concentration-dependent, segmentally restricted responses to FGF and RA, including their regulation of *Hox* gene expression (Figure 6).

Additional Signaling Pathways

Although FGF and RA appear to be the most influential signaling pathways regulating *Hox* genes, other pathways do appear to impinge upon *Hox* gene expression to a lesser extent. Gdf11, a secreted transforming growth factor-β homolog, can influence *Hox* gene expression and sensitize neural tube progenitors to FGF8 emanating from the node. The Wnt signaling pathway is another critical signal that influences regional character. Wnts can modulate Cdx1 activity and have an indirect input on *Hox* expression via this route. This further illustrates the importance of understanding Cdx regulation because it appears to integrate RA, FGF, and Wnt signaling in the regulation of *Hox* gene expression in the developing central nervous system and axial skeleton.

Regulation of *Hox* Genes by Transcription Factors

Regulation by transcription factors serves to establish, stabilize, and define the boundaries of *Hox* gene

Figure 6 FGF and RA form opposing gradients through cross-regulation. (Top) Regulatory relationships between elements of the FGF and RA pathways. Activation is indicated by green arrows and repression by red lines. (Bottom) FGF (blue) and RA (purple) gradient formation along the rostral–caudal axis of the developing mouse embryo.

expression initiated by the previously mentioned signaling systems. Some of these upstream transcription factors activate *Hox* gene transcription in a defined way, limited by the boundaries of their own expression. Many of the transcription factors that regulate *Hox* gene expression, however, are ubiquitously expressed and presumably rely on association with additional proteins to achieve specificity. Exploring these cooperative mechanisms of specificity is an important area of current investigation.

Four spatially restricted and developmentally regulated transcription factors have been shown to be important regulators of *Hox* expression patterns: Krox 20, Kreisler (MafB), and Sox/Oct. *Krox 20* encodes a zinc finger transcription factor expressed in rhombomeres 3 and 5. Binding of Krox 20 to its target sequences upstream of *Hoxa2* and *Hoxb2* and between *Hoxb3* and *Hoxb4* activates expression of these genes in rhombomeres 3 and 5. *Kreisler,* encodes a bZIP leucine zipper containing transcription factor expressed in rhombomeres 5 and 6, is required to activate transcription of *Hoxa3* and *Hoxb3*. Two other transcription factors important in stem cell maintenance, Sox2 and Oct4, may form a complex and participate in regulating *Hoxb1* in rhombomere 4.

Polycomb group (PcG) proteins and trithorax group (TrxG) proteins are two classes of chromatin-modifying proteins that epigenetically regulate *Hox* gene expression. These groups form multiprotein chromatin remodeling complexes that either repress transcription (PcG) or activate transcription (TrxG). Although these complexes are ubiquitously expressed and regulate many genes and cellular behaviors, mutations in members of both of these groups can alter *Hox* gene expression patterns and compromise R/C patterning in ways similar to both *Hox* gene deficiencies and abnormal FGF or RA signaling. PcG regulation of *Hox* expression may be direct because the PcG protein Phc2 can bind directly to the *Hoxb8* promoter. Additional regulation of this system appears necessary, however, because Phc2 can be observed at the *Hoxb8* promoter in tissues with high *Hoxb8* expression and also in tissues with low *Hoxb8* expression levels. PcG mutations also alter *Cdx* expression, and thus may have additional indirect inputs into *Hox* regulation. Several other ubiquitous transcription factors have been shown to be capable of regulating *Hox* genes. Factors such as YY1, Sp1, USF, NFY, and AP2 can modulate *Hox* expression in some contexts. The mechanism by which these ubiquitous transcription factors regulate specific aspects of *Hox* gene expression remains unclear; however, it may be related to their association with other factors. Sp1 can interact with AP2 and indirectly cooperate with Hox proteins

themselves. USF and NFY can interact with each other, and YY1 and Plzf can both interact with PcG components, although the roles of these interactions *in vivo* remain poorly characterized.

Auto-/Cross-Regulation

In addition to regulation by numerous other transcription factors, *Hox* genes also exhibit extensive autoregulation. Hox proteins can bind to *Hox* responsive elements (HREs), which consist of a *Hox* target site and usually include an adjacent binding site for one or more cofactors, such as Pbx, Prep, or Meis. Among the numerous possibilities, HRE-mediated *Hox* regulation usually functions in three main ways to refine and maintain *Hox* expression: *Hox* genes may maintain their own expression (autoregulation), activate expression of other *Hox* genes expressed in the same segment (cross-activation), or have antagonistic interactions in which one gene represses the expression of another *Hox* gene (cross-repression). These are all important processes in constructing and maintaining the complement of *Hox* genes expressed at each axial level and in defining boundaries between adjacently expressed genes.

The most extensively studied HRE is that of *Hoxb1*, which contributes to its expression in rhombomere 4. This element contains multiple Hox/cofactor binding sites and exhibits both autoregulation by Hoxb1 and cross-activation by Hoxa1. RA signaling and RAREs are directly responsible for the initial activation of *Hoxb1* expression. However, at later stages of development the HRE assumes regulatory control of *Hoxb1* transcription and Hoxb1 maintains its own expression. Genetic studies in mouse reveal that both the *Hoxa1* and *Hoxb1* genes are required for normal expression of *Hoxb1* in rhombomere 4. HREs have been identified either functionally, by sequence comparison, or inferred by transcriptional responses to *Hox* overexpression and are associated with the regulation of at least one-fourth of all *Hox* genes. Auto- and cross-regulatory interactions between the *Hox* genes appear to be fundamental mechanisms for modulating Hox transcriptional activity. Although both autoregulatory and cross-activation functions of the *Hoxb1* HRE can be clearly demonstrated, these regulatory interactions become less distinguishable for *Hox* members more 5′ in each complex because of the increasing number of *Hox* genes expressed at more posterior levels and the potential for indirect relationships. For 5′ *Hox* genes, it is likely that HREs are utilized to produce defined boundaries between different *Hox* gene expression domains by cross-repression. Such relationships have been demonstrated for *Hoxc5–Hoxc8*, *Hoxc6–Hoxc9*, and *Hox4–Hoxa7* such that ectopic expression of one gene of the pair represses the expression of the second gene, producing precise boundaries between expression domains of the two genes. Many of these relationships have not been demonstrated to be direct; however, several of the *Hox* genes involved are associated with functional HREs (Figure 7).

Hox Cofactors

Although isolated Hox proteins show sequence-specific binding to a 4-base pair A/T-rich target site (ATTA or TAAT), their affinity for this site is usually low and the length of the site allows little specificity in target site selection. It is thought that associations with cofactors may confer specificity to the Hox proteins in target site selection. HREs that contain both a Hox binding site and cofactor target sites can dramatically increase affinity of Hox + cofactor complexes for the site, specificity of the response, and the ability of the complex to stimulate transcription. The primary Hox cofactors are of the Meinox/TALE (three amino acid loop extension) family of proteins which include Pbx1–3, related to Drosophila Extradenticle (Exd), and Prep1-4/Meis1-3, related to *Drosophila* Homothorax (Hth). Pbx proteins directly bind to Hox proteins via a hexapeptide motif, X (Y/F) (P/D) WM (K/R), N-terminal to the Hox homeodomain, whereas a C-terminal portion of the homeodomain participates in stabilizing this association. The interaction of Hox and Pbx expands the target site specificity to a consensus ATGATTNATNN, where the Hox protein binds to the TNATNN portion of the half site

Figure 7 *Hox* gene auto-/cross-regulatory relationships. Regulatory relationships between paralog groups are indicated by green arrows, indicating positive loops, or red lines, indicating repressive relationships.

and Pbx binds to the ATGAT element. The binding selectivity of a Hox–Pbx target site is determined, in part, by site preferences conferred by the identity of the Hox protein present in the heterodimer. Prep/Meis cofactors initially bind to Pbx, which subsequently binds Hox proteins to form a ternary complex. These ternary complexes bind expanded target sites and activate transcription at a level higher than Hox/Pbx dimers and to a much greater extent than Hox proteins alone. Hox paralogs 1–10 can bind Pbx or Pbx–Prep/Meis heterodimers, paralogs 9 and 10 can bind Meis in the absence of Pbx, and groups 11–13 lack the Pbx interacting motif but can form complexes with Prep/Meis. Pbx/(Prep/Meis) heterodimers may also bind HREs in the absence of Hox and repress transcription. Both *in vitro* biochemical experiments and *in vivo* mouse deletions of these cofactors demonstrate their importance in *Hox* gene regulation and the function of HREs. Whereas the formation of Hox–Pbx heterodimeric complexes is DNA dependent, the formation of Pbx–Prep/Meis heterodimers is not. Pbx–Prep heterodimers can form in the cytosol and heterodimerization facilitates the nuclear localization of Pbx. Understanding these protein complexes and the events that modulate Hox/cofactor interactions is important in building a clear understanding of how Hox proteins find and act on their target sites *in vivo*.

Although the functional significance of Hox protein interactions is only beginning to be explored, several other developmentally important transcription factors have been shown to be capable of physically interacting with Hox proteins and these may also be relevant *in vivo* as cofactors or modulators. Modulation of Hox protein function may explain additional aspects of Hox protein target site specificity and switch Hox transcriptional activity between activation and repression. The transcription factors Sp1, Btg1, Smads, and members of the Maf family can interact with Hox proteins in some contexts. Although many of these interactions were investigated in artificial systems, these proteins were capable of interacting with Hox proteins and affecting their ability to transactivate reporter expression. Sp1 and Hoxa13, known regulators of BMP4, cooperate in activating transcription from the BMP4 promoter. Btg1 and-2 have been identified as Hoxb9 interacting proteins by the yeast two-hybrid assay and work together to activate transcription from a *Hoxb9* response element-driven reporter. Although Maf proteins have been shown to interact with several Hox proteins, these experiments did not reveal the function of these interactions. Kriesler, a member of this Maf family of proteins, has been shown to both regulate *Hox* gene expression and be involved in R/C patterning of the hindbrain; thus, it seems unlikely that these interactions would be without functional consequence during hindbrain development. These potential Hox cofactors participate in many different systems, but the importance of their interaction with Hox proteins remains unknown.

Initiation Versus Maintenance

Regulatory influences on *Hox* gene expression often result in expression patterns controlled in two separate phases, an early initiation phase and a later maintenance phase. Many of the 3′ *Hox* genes are regulated primarily by a combination of retinoic acid response elements and autoregulatory HREs. RA functions early in initiating expression in the absence of active *Hox* gene expression, and as Hox proteins accumulate within cells, the HREs may then assume regulatory influence over these genes. This mechanism is critical in maintaining *Hox* expression because expression patterns of *Cyp26* expand to encompass much of the hindbrain, reducing RA there and decreasing RARE-mediated *Hox* gene expression. Experiments in which the DR2 RARE 3′ of *Hoxb1* was deleted demonstrate this phenomenon very clearly. They show that the DR2 RARE 3′ of *Hoxb1* is required for correct temporal and spatial initiation of *Hoxb1* expression, and the remaining autoregulatory elements are capable of directing accurate *Hoxb1* spatial expression patterns at later time points.

Competition and Sharing

Unlike most other genes, *Hox* genes are organized into dense arrays/clusters. Nine to 11 genes are clustered within each ~130 kb genomic locus and are all transcribed off the same DNA strand. Mechanisms that actively isolate individual *Hox* genes from the influences of other nearby *Hox* gene enhancers have been found in the *Drosophila* HOM-C cluster; however, such elements do not appear to be present, as a general rule, in vertebrates. Additionally, in mouse, an entire *Hox* cluster is approximately the size of a single *Hox* gene, such as *Antp* in *Drosophila*. As a consequence of this close proximity, adjacent *Hox* gene promoters often appear to share or compete for enhancers. Transgenic mouse experiments exploring the regulatory landscape around *Hoxb4* and *Hoxb5* revealed that enhancer sharing, selectivity, and competition are all mechanisms regulating the expression of these two genes. Multiple elements between *Hoxb4* and *Hoxb5* participated in the regulation of both genes, which is largely responsible for overlapping *Hoxb4* and *Hoxb5* expression domains. One control element, equally capable of activating *Hoxb4* and *Hoxb5*, was preferentially recruited to

activate the *Hoxb4* promoter compared to that of *Hoxb5* when given a choice. Although few additional examples of promoter competition exist, either because of their rarity or because of their experimental in tractability, enhancer sharing appears to be common between neighboring *Hox* genes. In the case of *Hoxb3* and *Hoxb4*, at least two distinct elements in the intergenic region between these genes influence the expression of both genes. Similarly, shared elements have also been identified between *Hoxb5* and *Hoxb6*. The compactness of the *Hox* complexes and the absence of insulator elements blocking the influence of nearby regulatory elements suggest that enhancer sharing must be a common feature of *Hox* gene regulation.

Posttranscriptional Regulation of *Hox* Genes

Although mRNA levels and spatial/temporal localization are normally good indicators of protein distribution, it is becoming clear that they may be misleading in relation to Hox protein distribution. Because antibodies to Hox proteins have been particularly difficult to produce, expression analysis has often relied on *in situ* detection of mRNA. Several cases in which immunodetection of Hox protein has been achieved have demonstrated that protein expression domains often do not encompass the entire domain in which mRNA is expressed. Careful analysis of the regulation of the *Hoxb4* gene allowed the observation of a difference in reporter gene expression patterns dependent on whether the reporter utilized the endogenous *Hoxb4* 3′untranslated region (UTR) and polyadenylation signal or used an exogenous polyadenylation signal. Although the *Hoxb4* 3′ UTR was present in each of these reporter constructs, its inclusion into the mRNA transcript produced altered patterns of expression. This clearly demonstrated that *Hoxb4* was posttranscriptionally regulated and identified the domain responsible for this regulation. Similarly, mRNA expression and protein levels of some of the *Hoxc* genes in the spinal cord have been shown to be discordant, indicating that translational regulation may indeed be an additional mechanism modulating Hox expression.

Concurrent with these observations, microRNAs (miRNAs) (small regulatory RNAs that can mediate both pre- and posttranscriptional regulation through sequence-specific binding to target mRNAs) were being investigated as *Hox* regulatory molecules. Multiple miRNAs have been identified embedded within *Hox* complexes. mir-196a1/a2/b, which are located 5′ of the *Hox9* paralog in *Hox* B, C, and A clusters, respectively, are predicted to target *Hoxa7*, *Hoxb8*, *Hoxc8*, and *Hoxd8* transcripts for degradation. Verification of miRNA targets *in vivo* and assessment of their relevance has just begun; however, degradation products resulting from mir-196 targeting of *Hoxb8* have been isolated from mouse embryos, demonstrating that this process is functional *in vivo*. *Hox* genes have been identified as the targets of these and other miRNAs. Posttranscriptional regulation may be a consistent mechanism by which *Hox* genes are regulated; however, the importance of miRNAs in this process has not been demonstrated.

Global Regulatory Elements

By far the most elusive *Hox* gene regulatory process is the mechanism by which collinear expression of *Hox* genes is achieved. One hypothesis focuses on long-range elements outside of the complex (global regulatory elements) that mediate processive regulatory influences on *Hox* genes that travel along the DNA through the *Hox* complex. Experiments in which a *Hoxb1* reporter was inserted 5′ of *Hoxd13* showed that some aspects of the reporter expression were affected by the location of the reporter in the complex which were not seen when the reporter was inserted randomly, suggesting that location within the complex could influence expression pattern. Separate experiments showed both a sequential de-compaction of *Hox* complexes during development and partial collinearity of 'active' chromatin marks spreading through the *Hoxb* locus during differentiation, further supporting the global element plus spreading model. Although some elements capable of long-range influences on multiple *Hoxd* genes have been identified for the limb expression, global elements capable of long-distance, sequential regulation of entire complexes in most other sites of *Hox* expression have yet to be identified. In contrast, local elements capable of specific and ordered expression for many of the individual genes have been well characterized. Thus, it remains possible that many aspects of collinear expression could be achieved through the collective activity of locally positioned internal elements rather than through a single global modulator of each cluster. Clearly, if global control regions are a common feature regulating collinear *Hox* gene expression, they are not solely responsible for this phenomenon. Rather, it seems likely that diverse mechanisms are used to open the clusters to make them available for transcription that vary at different times and locations. A variety of locally recruited activators and repressors (including the Hox proteins) may work in concert with local and long-range chromatin remodeling complexes to impart the ordered domains of *Hox* expression.

Conclusions

Hox proteins play a fundamental role in the development of R/C identity in diverse tissues in addition to many less appreciated roles in organogenesis and cell differentiation. They participate in giving R/C segments of the hindbrain and spinal cord their unique identity through their nested expression patterns within these structures. The host of Hox proteins present at each axial level then conveys identity onto that segment observable by segment-specific gene expression patterns, neuronal phenotypes, and cell migratory behavior. Appreciation of Hox gene collinear expression patterns and their regulation are essential aspects of understanding mechanisms of R/C polarity within the hindbrain and spinal cord. *Hox* genes are regulated on multiple levels. Expression is initiated by transcription factors and secreted molecule signaling systems and is subsequently maintained via Hox-mediated auto- and cross-regulatory mechanisms. Experiments have begun to unveil an additional level of *Hox* gene regulation that functions posttranscriptionally; however, the full significance of this has yet to be determined.

A burgeoning area of exploration is the role of Hox cofactors and other interacting proteins. These experiments open the possibility of an additional level of modulation of Hox protein binding, activation/repression, and target site selection. Although much of these data have yet to be shown relevant *in vivo* during development, they could vastly expand our understanding of the role of Hox proteins and their mechanisms of action. More attention must be directed toward this avenue of investigation, but it promises to be an exciting future for Hox gene study.

Although it is clear that Hox proteins play a critical role in R/C patterning and identity, several questions remain about how this occurs. Altering *Hox* gene expression patterns within the hindbrain and spinal cord often results in dramatic alterations in cell identity or behavior; however, how Hox proteins regulate target genes to achieve these effects is largely unknown. A few downstream target genes activated or repressed by Hox proteins have been identified, but our understanding is too limited to create a picture of the pathways under Hox regulation that impose diverse regional characters. This is an exciting area for future study. Systems biology approaches and genomic analyses are all aimed at understanding how the alteration of one gene can impact on the outcome of cell behaviors to result in differences such as a leg versus an antenna. This is an elusive basis of morphogenesis, and understanding these mechanisms and their outcomes opens the possibility of a wealth of knowledge about the genetic programs that control normal development, how they are perturbed in human diseases, and how they might be involved in producing diversity. *Hox* genes have fundamental roles in these processes and provide an opportunity for exciting insight into the mechanisms responsible for building the basic body plan of animals.

The language of the nervous system and its building blocks, the neurons, is that of changing electrical potentials. The opportunity to record this activity directly inside the human brain is, however, limited to a few clinical situations. The newer methods of neural imaging, such as functional magnetic resonance imaging (fMRI), though immensely popular, are indirect ways of imaging neuronal activity and are based on measurements of regional hemodynamic changes in the brain. The major limitations of the fMRI technique are its spatial and temporal resolutions: Although fMRI has provided a wealth of information about brain regions, it cannot demonstrate how individual neurons and small neuronal assemblies contribute to cognitive processes, and it lacks the millisecond resolution which is often important in probing the timing of neuronal activity. This article describes the contributions of a technique that allows investigators to observe the activity of individual neurons deep within the human brain. This relatively small area of scientific investigation is situated between animal extracellular neurophysiology, a technique that allows investigators to observe single neuron activity during behavior, and the human neuroimaging techniques that provide images of neuronal activity from whole brains. Extracellular neurophysiology in animals, however, cannot inform science about cognitive processes that are unique to humans and accessible via conscious report, whereas fMRI has limited resolution and is an indirect measure of neural activity. Depth electrode recordings in humans have two primary advantages: unlike fMRI, recordings have excellent spatial and temporal resolution and they provide a direct measure of neuronal activity; unlike animal extracellular neurophysiology, recordings are performed on conscious subjects who can describe their experiences.

Methodological Considerations

Invasive depth electrode recordings are only performed for clinical reasons, predominantly in patients with movement disorders (e.g., Parkinson's disease (PD)) or pharmacologically resistant epilepsy. In these contexts, depth recordings are used to diagnose disorder subtypes and define appropriate treatment in particularly difficult cases. Today's electrodes can measure both local field potentials, which provide information on the averaged dendrosomatic synaptic activity of large cell assemblies, and action potentials of individual neurons isolated with embedded microelectrodes. Both types of information are useful, and each is discussed in this article. Depth electrode recordings in humans, then, allow investigators to compare neural activity in human brains with the wealth of information garnered from recordings in other animals and to evaluate the validity of animal models with respect to human brain function.

Depth Electrodes in the Basal Ganglia and Related Structures

We begin with a discussion of the major findings stemming from direct recordings in patients with movement disorders. Today, the most common use of depth electrode recordings in the context of movement disorders is to localize the target sites for therapeutic lesions or, more commonly, for the placement of a deep-brain stimulating (DBS) electrode. In patients with PD, DBS electrodes are used to inhibit the overactive cells in the globus pallidus (GP) or subthalamic nucleus (STN) that are normally inhibited by dopaminergic cells in the substantia nigra. Since PD is caused mainly by the degeneration of the substantia nigra, DBS electrodes relieve symptoms by acting directly on the GP or STN. In patients with PD, surgeons may implant recording electrodes in the GP or STN to aid the implantation of DBS electrodes. While the surgeons are targeting these two regions, they have the capability of observing neural activity at the target sites. Patients remain fully conscious throughout the surgery, allowing surgeons to test their motor functions and to observe the effects of electrical stimulation in the targeted regions.

Local Field Potentials Recorded from the Basal Ganglia and Related Structures

In one study using depth electrode recordings, in patients who were not on medication and were in the akinetic 'off' state (i.e., they were in the process of showing symptoms of PD), neural activity coherence between the basal ganglia structures and other cortical regions was found to be dominated by tremor (3–8 Hz) and beta-band (15–30 Hz) frequencies. In previous studies using noninvasive recordings, investigators had failed to find the putative source of neural activity in the tremor frequencies, thought to underlie the resting tremor seen in PD patients.

Furthermore, stimulation of those sites where beta-band coherence was the highest yielded the greatest reduction in PD symptoms. Similar approaches have allowed investigators to evaluate the effects of certain drug treatments on these coherence peaks in the hope of finding new pharmacological treatments for PD and other movement disorders.

Insights from Single-Unit Recordings in Subcortical Structures

Recordings from single units in the STN in particular provide a unique complement to electrophysiology in animals. For example, single-unit depth electrode recordings in humans have delineated the somatotopic organization of the STN, previously only described in animals. In addition, the cellular correlates of resting tremor have also been described: cells that show synchronous rhythmical discharges associated with tremor have been found in the external pallidum, GP and STN, and motor thalamic nuclei. These findings support a model in which the tremors that characterize PD are driven by a central pacemaker which may be modulated by sensory inputs, thereby providing a model for how sensory stimuli may alleviate PD symptoms.

Single-cell recordings have also provided support for a 'dynamic' model of basal ganglia function. This model posits that neurons oscillate at tremor frequencies and in the beta band and that these firing patterns tend to be synchronized along the basal ganglia loop, leading to abnormally patterned firing in motor cortex. The model further suggests that the normal dopaminergic system supports a functional segregation of subcircuits in the basal ganglia. A breakdown of this independent processing leads to abnormal temporal coupling and the emergence of the symptoms of PD. The existence of such oscillatory neurons and the synchrony in their firing patterns has been confirmed using invasive depth electrode recordings.

Combining the findings from local field potentials (LFPs) and single units in the basal ganglia has resulted in a model in which the basal ganglia, thalamus, and cortex interact in different frequency bands, modulating basal ganglia functions in a task- and state-dependent way. For example, slow oscillations at tremor frequencies or in the beta band that result from dopamine depletion may disrupt normal motor function.

Future Directions

As our understanding of the neural basis of movement disorders such as PD becomes more complete, more effective treatments can be devised. Until then, however, depth electrode recordings in these regions have provided critical information concerning the functions of brain regions underlying movement. Future studies may include the application of DBS to other diseases, such as major depression, obsessive–compulsive disorder, and epilepsy, as invasive electrode recordings uncover the ways in which DBS can affect brain function. Moreover, modified DBS could become effective treatment for people afflicted with paralysis and motor coordination problems.

Depth Electrode Recordings in Patients with Pharmacologically Resistant Epilepsy

Patients with intractable epilepsy can benefit from surgical resection of the small area implicated in seizure onset. If scalp electroencephalogram (EEG) recordings fail to definitively localize the seizure focus, patients may be implanted with depth electrodes for further monitoring. Most of these patients have foci in the medial temporal lobe (MTL), which includes the hippocampus, amygdala, entorhinal and posterior parahippocampal cortices, as well as other extratemporal lobe sites. Electrodes are generally implanted bilaterally so that physicians can monitor the spread of seizures and thus confirm the putative focus. Once implanted, patients are monitored on the ward for several days and sometimes weeks. During this time, patients may consent to participate in behavioral experiments that provide invaluable information about single- and multiunit activity in many aspects of brain function. These neurons can also be monitored during different states of consciousness, such as sleep or during seizures. In general, several types of electrophysiological data can be obtained from depth electrodes. Most depth electrodes used in epilepsy have contacts for recording of intracranial EEG along the shaft of the electrodes at distances of 5–10 mm between adjacent contacts. If behavioral paradigms are used as well, event-related potentials (ERPs) can then be recorded with respect to timed stimuli or behavioral events. In some centers, depth electrodes are also fashioned with the capability of recording local field potentials and multi- and single-unit activity via microelectrodes, usually microwires, which are situated either at the tip of the electrode or along the shaft of the electrode (Figure 1).

In addition to chronic recordings with depth electrodes, EEG and even single-unit activity can be recorded acutely during epilepsy surgery via electrodes placed on the surface of the cortex or inserted into the cortex. Acute single- and multiunit recordings in conjunction with language and memory tasks have been performed during epilepsy surgery under local anesthesia, mainly by Ojemann and colleagues. This

Figure 1 Placement of depth electrodes. Some electrodes are fitted with microwires that are capable of recording electrical activity at the level of single neurons. (a) MRI and CT scans may be fused in order to localize the anatomical placement of electrodes. (b) A Nissl-stained image of the MTL shows how protruding microwires may be arranged. Reproduced from Bragin A, Wilson CL, Staba RJ, Reddick M, Fried I, and Engel J Jr. (2002) Interictal high frequency oscillations (80–500 Hz) in the human epileptic brain: Entorhinal cortex. *Annals of Neurology* 52: 407–415, with permission.

article, however, focuses on data obtained from implantation of depth electrodes for chronic recordings over a period of several days while patients are monitored in a hospital ward environment for spontaneously occurring seizures and can perform behavioral tasks outside the acute environment of the operating room.

LFPs in Patients with Epilepsy

In addition to single- and multiunit activity, depth electrodes in the MTL can be used to record LFPs or, when observed during behavior, ERPs. These ERPs are commonly recorded from EEG contacts along the shaft of the electrode – the same contacts that are also used to monitor seizure onset and spread patterns. Historically, ERP studies have used noninvasive scalp recordings in healthy participants to correlate behavior with changes in neural activity. Many of these studies have investigated changes in scalp ERPs during memory processes. One reliable finding is the presence of the P3 component (the third positive peak after stimulus onset, also called P300 to denote that it occurs approximately 300 ms after stimulus onset) thought to represent the end of a salient event and the updating of information in working memory. The origin of this component, however, cannot be precisely defined using scalp EEG. Instead, depth electrode recordings have shown that P3 is generated in the hippocampus, superior temporal sulcus, and the amygdala, indicating that polymodal association areas interact with the limbic and memory systems in order to produce this marker of working memory function. A similar methodology has been used to investigate the origin of averaged ERPs as it reflects the activity of underlying neural assemblies. Depth electrode recordings have shown that two processes operate to generate late ERP components in cognitive tasks: event-related activation of neural assemblies and phase resetting of ongoing activity. These two mechanisms may serve cognitive processes in different ways, and they need to be further investigated as potentially independent signals.

LFP insights into cognitive processes Another body of work has shown that the formation of declarative memories, or consciously retrievable memories for facts and events, correlates with phase synchronization of rhinal–hippocampal EEG activity in the gamma range (~40 Hz) and an increased EEG coherence in the low-frequency range. Specifically, the process generated by the rhinal cortex, which occurs within 300 ms of stimulus onset, precedes the hippocampal process, occurring approximately 300 ms later. Furthermore, the rhinal process correlates with semantic preprocessing, whereas the hippocampal process correlates with a purely mnemonic operation. Current knowledge about phase synchrony in gamma activity suggests that synchronization facilitates communication between the rhinal cortex and the hippocampus, whereas decoupling terminates this communication. This phase synchrony may accomplish Hebbian synaptic plasticity, as neurons that fire in synchrony become associated, and establish the initial memory trace.

Another controversy in neuroscience has been the precise function of theta (3–8 Hz) oscillations in the MTLs. A hypothesis concerning the function of theta oscillations, or neural synchrony in general, is known as the sensorimotor integration hypothesis, which suggests that theta oscillations provide constantly updated feedback from sensory regions to voluntary motor regions to ensure correct motor output and performance of a task. Findings from depth electrodes have shown that theta oscillations in the neocortex increased when patients were actively engaged in a virtual reality game, supporting the sensorimotor integration hypothesis.

Findings from Single-Unit Recordings in the Human MTL and Other Regions

In a small number of hospitals, depth electrodes are fitted with microelectrode wires (40 μm) protruding from the tips, allowing investigators to record individual cells. Recordings from single units deep within various regions have provided insights into various aspects of brain function, including basic mechanisms of epilepsy, sleep, memory, perception, and other aspects of cognition and motor function. Because many of the patients undergoing implantation of depth electrodes are suspected of having temporal lobe epilepsy originating in the MTL, the MTL has been most accessible to investigations at the single-unit level.

Insights into basic mechanisms of epilepsy and sleep behavior From a clinical standpoint, recordings from isolated single neurons have provided important information regarding seizure physiology. For example, neurons in epileptogenic regions show higher baseline firing rates, more bursting and stronger synchrony during slow-wave sleep, yet show no differences from cells in nonepileptogenic regions during awake behaviors. It may be that during wakefulness, epileptogenic neurons show higher firing rates and more bursting when there is synchronous firing of neighboring cells, indicating that there may be a difference in synchrony during sleep and wakefulness that influences seizure activity.

In addition, rodent epilepsy models suggest a central role for fast ripple oscillations (200–500 Hz) in seizure activity. In humans, investigators have observed both fast ripple oscillations and ripples (80–200 Hz) chiefly during non-rapid-eye-movement sleep (NREM). Whereas ripples represent normal activity in the human hippocampus, fast ripple oscillations have been shown to be more prevalent in epileptogenic areas than in healthy tissue. Furthermore, the highest rates of fast ripple oscillations have been found during NREM sleep. These findings support the view that fast ripple oscillations are the product of pathological neuronal hypersynchronization associated with seizure-generating areas.

Insights into memory function Studies of patients with epilepsy have provided some of the most significant findings concerning the neural basis of memory. Beginning with the patient H.M., who had bilateral MTL resection to treat his seizures, numerous studies have identified the critical role that this brain region plays in consciously accessible memory for facts and events. Therefore, invasive depth electrode recordings in the MTL can provide information about the manner by which memories are represented at the level of individual neurons.

Early single-unit studies found that cells in the hippocampus responded with changes in firing patterns to specific items during word or picture recognition tasks. During repeated performance of the task, however, many of these cells changed their 'preferred' stimulus, suggesting that neurons are flexible in terms of their response patterns and may only temporarily represent an item during learning or encoding. These early studies also failed to find a correlation between individual firing patterns and performance.

As the technology used to record cells improved, studies have dramatically increased sample sizes, and a link between neural firing and memory performance has indeed been made. In the hippocampus, for instance, responses during encoding have been shown to predict whether patients subsequently remembered word pairs, whereas in the entorhinal cortex correct performance was predicted by activity during retrieval. Depth electrode recordings have also shown that neurons in the MTL are capable of detecting novelty or familiarity immediately on the second presentation of a stimulus. In addition, a substantial number of cells in the hippocampus and amygdala respond to conjunctions of features rather than individual stimuli. In order to interpret these results, a discussion of current models of MTL function in memory is warranted.

Memories are composed of a set of associations between different elements in the original sensory representation. The pattern of activation that underlies the set of associations is strengthened as the elements of which it is composed 'fire together' and create Hebbian-style synapses (named for the neuroscientist who first envisioned the process). During retrieval, when a subset of elements is reactivated, the entire pattern is retrieved, strengthening associations between elements. The number of connections that this model requires between elements quickly escalates to a biological implausibility. Furthermore, as new associations are created, they may disrupt existing ones or result in overlapping representations. If the number of overlapping representations becomes large, the reactivation of a particular pattern may no longer be unique. This situation is called catastrophic interference. Given the problem of catastrophic interference, the models propose that a separate processor, namely the hippocampus, could rapidly store the events and facilitate gradual transfer of these memories to the neocortex. To enable this rapid storage and avoid interference, it has been proposed that only a very small subset of cells encode any given element; this is called sparse coding. Strikingly, in one study, a few cells in both the hippocampus and the parahippocampal cortex responded to novel stimuli with an

Figure 2 Cells coding mnemonic properties of stimuli. This figure shows raster plots and firing frequency histograms for four individual neurons sorted by the mnemonic property of the stimuli. (a and b) Responses of two hippocampal cells that decrease firing from baseline to repeated stimuli. (c) The response of a novelty preferring cell in the entorhinal cortex and (d) the cell in the entorhinal cortex that is sharply tuned to the second presentation of scenes. Reproduced from Viskontas IV, Knowlton BJ, Steinmetz PN, and Fried I (2006) Differences in mnemonic processing by neurons in the human hippocampus and parahippocampal region. *Journal of Cognitive Neuroscience* 18: 1654–1662, with permission.

increase in firing (excitation). However, on the second presentation of a stimulus, neurons in these regions already showed very different firing patterns; whereas in the parahippocampal region there was a dramatic decrease in the number of cells responding to the stimuli, in the hippocampus a large subset of neurons showed inhibitory responses (firing decreased from baseline) (Figure 2). Therefore, in line with this view, wide-scale inhibition observed by depth electrode recordings in the hippocampus may provide a mechanism by which cells in the human hippocampus increase the signal-to-noise ratio, allowing those few cells that represent a given item to be 'heard' by higher cognitive regions, thereby supporting sparse coding in memory processes.

Another role for the hippocampus: Human spatial navigation The discovery of 'place cells' in the rodent hippocampus led to the theory that this structure is involved in spatial navigation. Place cells respond with a change in their firing patterns when the animal is in a particular location in space. Single-unit depth electrode recordings in humans have confirmed the presence of place cells in the human hippocampus as well (Figure 3). In these studies, patients engaged in a virtual-reality computer game in which they could 'move' through a town. Investigators found that certain cells responded in highly reproducible ways when the patient was 'in' a specific location in the town. Importantly, place cells were more likely to be in the hippocampus than in the surrounding parahippocampal cortex, and a subset of place cells were modulated by the patient's goal in navigation. For example, some cells would only respond with excitation if the patient was in a particular place and had a specific goal in mind, such as locating a virtual person. By contrast, cells in the parahippocampal cortex were more likely to respond

Figure 3 'Place' cells. (a) Firing rate map of a hippocampal cell showing significant place selectivity. Red lines indicate the subject's trajectory, and black-rimmed squares indicate regions of significantly high firing rate (all examples, $p = 0.01$). (b) Place-responsive cells were clustered in the hippocampus (H) compared with amygdala (A), parahippocampal region (PR), and frontal lobes (FRS). (c) Regions of high firing included high numbers of traversals in different directions. The distribution of firing rate differences across these traversals was centered on zero and normal. (d) Firing rate map of a right hippocampal cell showing significant place selectivity when searching for shop SC but no such specificity when searching for other goals. (e) Areas with two traversals were excluded. (f) This cell similarly showed no effect of viewing specific targets. P, viewing passengers; N, a control background view. Reproduced from Ekstrom AD, Kahana MJ, Caplan JB, et al. (2003) Cellular networks underlying human spatial navigation. *Nature* 425: 184–188, with permission.

predictably when the patient was viewing a specific landmark, even if that landmark was viewed independently of the person's 'location' in the game. Thus, these results confirm the presence of place cells in the hippocampus but also underscore another functional difference between the hippocampus and its surrounding cortices. Moreover, findings from this study suggest that although some aspects of MTL function in humans are highly similar to those in nonhuman animals, there are important differences which single-unit recordings in humans can help define.

Visual perception Another remarkable finding that has been reported from depth electrode recordings in human MTL is the existence of category-specific cells and cells that respond to a particular concept, such as a person or a landmark (e.g., Bill Clinton or the Sydney Opera House), even when the sensory stimuli that represent the concept are dissimilar (e.g., a pictorial and a semantic cue). In the case of a category such as specificity, neurons were found that responded exclusively to visual images of animals, human faces, outdoor scenes, or inanimate objects such as cars or foods. Even though the actual pictures that represented the category items were quite dissimilar, the neurons were capable of separating and classifying the percepts, developing firing patterns specific to a single category. Furthermore, the investigators found that category-specific cells would respond even when the patients were asked to 'imagine' a stimulus within the cell's preferred category. This finding, as well as findings from another study using flash suppression, suggest that MTL cells respond to a percept rather than to the image falling on the retina.

Figure 4 Cell responding to images and the name of Halle Berry. This cell showed an increase from baseline firing when the patient viewed images of Halle Berry but not other celebrities. Reproduced from Quiroga RQ, Reddy L, Kreiman G, Koch C, and Fried I (2005) Invariant visual representation by single neurons in the human brain. *Nature* 435: 1102–1107, with permission.

In addition to a remarkable specificity of responses, such as the ability to respond preferentially to a particular person but not to hundreds of other people, MTL cells also exhibit invariance in their responses; that is, they show the same response to strikingly different exemplars of the same preferred stimulus (Figure 4). This property suggests that single neurons code for an abstraction of the stimulus rather than its physical characteristics.

Perception of speech and music Intracranial depth electrode recordings have also been used in investigations of auditory perception. Neurons in the primary auditory cortices have been shown to respond to human speech, music, and other sounds. For example, auditory-evoked potentials in the auditory cortex (Heschl's gyrus) have been shown to display greater phase-locked synchronous activity during the perception of dissonant chords, such as minor and major seconds, than during the perception of consonant chords, such as octaves and major fifths, thus replicating findings in monkeys. Ojemann and colleagues have also used single- and multiunit recordings in the operating room to show specific neuronal responses to language, music, and visuospatial stimuli in temporal neocortex.

Findings related to emotional processes In addition to models of cognitive processes, depth electrode recordings have also been applied to the study of the neural

basis of emotional processes. Two independent groups have reported that stimulation of the pre-supplementary motor area via depth electrodes results in feelings of mirth and laughter. In another study of emotional processes, investigators found that individual neurons in the ventral and medial prefrontal cortex, in both hemispheres, responded selectively to aversive, pleasant, or neutral stimuli, yet most of the neurons that showed responses in these regions preferred aversive stimuli. At the local field potential level, investigators using depth electrode recordings have also found a preference for aversive stimuli in the amygdala – a finding that supports a large body of animal work implicating the amygdala in fear responses.

Motor planning and execution Occasionally, depth electrodes need to be placed in the medial frontal lobe. Placement in this region represents an opportunity to record neuronal activity related to motor planning. Recording from medial frontal cortex, investigators have found neurons that responded selectively to specific features of a motor plan, such as which hand performed the motor activity or the complexity of the sequence. These results support the notion that the medial frontal cortex is involved in the temporal organization and planning of movement in humans, and that individual neurons can distinguish different aspects of a particular actions.

Investigating the relationship between the blood oxygen level-dependent signal and neuronal activity Another important use for depth electrode recordings has been the investigation of the extent to which the blood oxygen level-dependent (BOLD) response used in fMRI correlates with actual neural activity. fMRI uses a measure of cerebral blood flow and the assumption that neural activity is accompanied by increased blood flow to the active area. The extent to which this assumption is valid in the human brain, however, remains under debate. Depth electrode recordings in the human auditory cortex have shown that the BOLD signal is in fact highly correlated with activity even at the level of single neurons. Data from this study showed that when patients viewed a 9 min movie clip several times, neurons in the auditory cortex (Heschl's gyrus) showed reproducible firing patterns in response to the auditory stimulation. Furthermore, the fMRI BOLD signal that was recorded in the auditory cortex of a different set of healthy participants who watched the same movie clip showed a high correlation with both activity recorded from signal neurons and high-frequency local field potentials in the same region. This study demonstrates the value of depth electrode recordings in bridging the gap between neuronal activity and the signals measured by fMRI. Additional studies using recordings from other brain regions should be performed to further investigate these issues, because the BOLD signal and the neural code underlying various cognitive processes may vary among different-regions. For instance, correlation between single-unit activity, LFPs, and the BOLD signal may be different for regions and cognitive processes dominated by sparse versus distributed coding.

Conclusions and Future Directions

Depth electrode recordings represent a unique approach to understanding how neural activity supports human brain function at multiple levels. It is important to keep in mind, however, that these studies are performed in patients with neurological disorders. Nevertheless, they represent the only opportunity in modern-day neuroscience to probe human cognitive function at the level of the single neuron. Therefore, it is important to use this rare opportunity in conjunction with paradigms which are based on well-established findings from the animal and nonhuman primate literature in particular. At the same time, the opportunity to record neural activity directly in humans challenges us to extend our investigations to include questions which cannot be answered using animal studies, especially those paradigms in which conscious behavioral reports are invaluable. Although experimental design should be comparable to work in animal neurophysiology, investigators should also consider findings from studies performed in humans using fMRI, scalp-recorded ERPs, and magnetoencephalography.

The opportunities to record intracranial signals at the single neuron and neuronal assembly level include mainly the surgical treatment epilepsy and movement disorders. The rapidly evolving field of clinical investigation of brain–machine interfaces may, however, provide more opportunities. Already, several studies point to the feasibility of decoding movement and percepts from neural activity at the single- and multi-unit level and at the level of LFPs. Closed-loop devices utilizing intracranial EEG to deliver targeted stimulation to stop epileptic seizures are also under development and in clinical trials. Therefore, the role of brain-derived signals from depth electrodes is likely to play an important role not only in understanding basic mechanisms of cognition but also in designing neural prostheses and other clinically relevant devices.

Human Haptics

Haptic Perception of Surface and Object Properties

People use their hands to obtain information about a variety of physical properties of surfaces and objects. They are particularly effective at haptically processing dimensions that pertain to the materials used in the construction of surfaces and objects. The most notable dimensions relate to texture, compliance, thermal qualities, and weight, the last being a hybrid of material and geometry. People are considerably less effective at haptically evaluating and discriminating an object's geometric features, such as orientation, shape, and size. In the following sections, we discuss research on the principal dimensions of haptic perception.

Roughness

To date, most research on haptic texture perception has focused on the perception of surface roughness. Provided there is relative motion between skin and surface and that both speed and force are equated, roughness perception is equivalent whether the hand is stationary and the surface moves or vice versa. Thus, cutaneous information is critical for perceiving roughness. Perceived roughness of very fine surfaces (i.e., those with spatial periods of less than ~200 μm in size) is likely based on intensive coding of vibration by Pacinian or fast adapting type II (FAII) peripheral tactile units. For spatial periods ranging from ~200 μm to 2 mm, perceived roughness is neurally represented by the stochastic variation in the spike rates of slow-adapting type I units (SAI) innervated by Merkel complexes. Beyond a spatial period of ~2 mm, perceived roughness is processed spatially by SAI tactile units.

Compliance

Considerably less is known about the perception of compliance or other related physical properties, such as elasticity and viscosity. Early research investigated how expert bakers perceived four primary dimensions of dough: stickiness, elasticity, firmness or toughness, and extensibility (i.e., the extent to which dough may be stretched before it breaks). The bakers were most sensitive to variation in stickiness, an attribute judged to be quite unpleasant; however, they were relatively insensitive to changes in either elasticity or viscosity.

More recent research has shown that cutaneous information alone is both necessary and sufficient to judge the relative softness of rubber specimens with deformable surfaces. The discharge rate of SAI units increases with increasing average pressure during indentation and, thus, could serve as a peripheral neural code for perceived softness independent of the velocity of indentation. Because single-fiber response depends on indentation velocity as well as on surface compliance, this code must be based on a population response, particularly in SAI units. To differentiate the stiffness of compliant objects with planar rigid surfaces, cutaneous cues on their own are insufficient and must be combined with kinesthetic cues. Figure 1 shows the two different kinds of compliant stimuli used in this work.

Thermal

The resting temperature of the skin (25–36 °C) is usually higher than the ambient temperature of materials in the environment. Thermal cues, which are sensed by peripheral populations of thermoreceptors (warm and cool), may potentially contribute to the haptic identification of different materials by producing different thermal transients as the skin interacts with the material during contact. People can identify materials such as copper, stainless steel, granite, and foam merely by contact, but not equally well. Perceptual confusions among materials are probably the result of similar thermal transients.

Weight

Weight is optimally perceived when the observer actively lifts the object away from a supporting surface, thereby providing information from both cutaneous and kinesthetic mechanoreceptors, as well as from the associated neural correlates of the descending motor commands. Humans use more than object mass to haptically assess weight. For example, a small object feels heavier than a large object of the same mass, a very powerful illusion known as the haptic size–weight illusion.

Opinions vary as to the nature of the processing involved in haptic weight perception. Some researchers have argued that haptic observers use cognitive expectations based on prior experience of the correlation between weight and size (or density) to judge object weight. Others suggest that observers incorporate sensory cues (cutaneous and/or kinesthetic) to object volume into their weight judgments. Still others argue that weight, both veridical and illusory,

Figure 1 Schematics of apparatus for experiments: (a) with transparent rubber specimens of variable compliance; (b) on deformable objects with planar rigid surfaces. In (a), the specimen is mounted on the spring-loaded plate projecting out of a computer-controlled tactile stimulator. The plate is in contact with a force transducer that is able to measure forces of contact between the specimens and finger pads under active or passive touch conditions. The contact regions are videotaped using a dissection microscope fitted with a video camera. Shown in (b) is a spring cell mounted on the same spring-loaded plate and in longitudinal section. Each specimen consisted of two telescoping hollow cylinders such that the inner cylinder could move freely within the outer cylinder. Four springs glued to the bottom plate of the outer cylinder and connected to the inner cylinder determined the compliance of the specimen. Reproduced from LaMotte MA and Srinivasan RH (1995) Tactual discrimination of softness. *Journal of Neurophysiology* 73(1): 88–101, with permission from American Physiological Society.

is assessed more directly in terms of differences in the magnitude of the moments of inertia, that is, resistance to rotational forces produced as the observer wields an object. This last interpretation constitutes an example of dynamic touch, a haptic subsystem that uses deformations of muscles, tendons, and ligaments to perceptually judge the attributes of objects wielded in the hand (e.g., length, weight, width, shape of the object tip, and the orientation of the hand and object relative to one another).

Curvature, Angle, and Orientation (Tilt)

Humans can haptically detect curvature over a wide range of spatial scales and haptic sensory inputs, according to the size of the explored object. The relative contribution of the cutaneous and kinesthetic signals varies with the spatial scale of the curved surfaces.

Humans are capable of haptically differentiating 2-D angular differences of 5.2° between pairs of relatively large angles with an accuracy level of 75%, with performance depending on both cutaneous and kinesthetic (shoulder) inputs.

Finally, haptic perception of orientation has been measured by requiring that a test bar be positioned parallel to a reference bar presented together within a planar (horizontal) work space. The perception of orientation within this peripersonal space is systematically biased by several factors, particularly the location of the bars within the plane (e.g., distance from the midline of the body).

Shape of Two- and Three-Dimensional Forms Larger than a Fingertip

Spatial patterns that fit within the fingertip are sensed on the basis of cutaneous cues alone, and are thus not discussed further here. Humans haptically process relatively ineffectively 2-D and 3-D shapes of larger objects that are made of a single material. At this time, little is known about the underlying neural codes.

Purposive manual exploration critically influences how objects and their properties are haptically processed and cognitively represented. More specifically, the spatially restricted inputs derived from contacting objects with multiple fingers impose constraints on spatial integration. Furthermore, the sequential nature of manual exploration renders it slow to perform, creating notable demands on memory and

temporal integration. Humans initially process an object haptically more by its local features than by its global shape, particularly when exploration time is limited.

Size

To date, most research has focused on the haptic perception of object length or width, as opposed to its area or volume. Haptic perception of the length of rods statically held at their ends between the two index fingers varies in a 1:1 fashion with physical length. Unlike most other sensory judgments, then, there is excellent correspondence between the percept and the physical property. However, in some cases the haptic perception of size may be systematically distorted. For example, people are haptically susceptible to a variant of the horizontal–vertical illusion, in which a vertical line is perceived to be longer than the same line oriented horizontally, in both T- and L-shaped configurations of this illusion. The horizontal–vertical illusion is believed to consist of two separate components resulting from bisection and radial–tangential effects. The bisection effect consists of the bisecting line being overestimated relative to the bisected line. However, the radial–tangential effect is an anisotropy of haptic space in which radial movements toward and away from the observer's body are overestimated relative to those that are tangential to the body.

Haptic Space Perception by Sighted and Blind Observers

How spatial locations are coded haptically and which errors are induced by the coding system adopted are issues that have been extensively investigated. The focus here is on space within human reach, that is, manipulatory space. Do people represent the location of their hands in space by the kinesthetic posture needed to place them there or by some extrinsic spatial framework? A posture-matching strategy is adopted in tasks wherein the observers' hands are passively moved to a location to which they must reach again. If this strategy is prevented, for example, by having the observer reach the second time with a pointer, performance by posture matching becomes relatively error-prone and variable.

A frame of reference may also be defined extrinsically with respect to the body when space is haptically explored. For example, observers who attempt to match the tabletop position to which one hand is moved by placing the other hand in the corresponding location underneath the table (Figure 2) appear to make spatial errors consistent with using an extrinsic frame of reference in which the haptic egocenter (origin) is located at the shoulder of the arm used to mark the position on the tabletop. The position of this haptic egocenter is not fixed; for example, it reverses when the roles of the hands are switched.

Still other research has shown that spatial coding can also occur using an extrinsic spatial frame of reference outside the body. For example, consider when an observer's left or right finger is passively guided to a specific location. The observer must then actively reach to that location with the right hand. Systematic biases (constant errors) shift the endpoints outward laterally along the frontal plane and compress them sagittally and vertically. More significantly, variable errors are essentially independent of whether the observer uses the same hand or switches hands between initial exposure and test. The postures for the responding (right) arm depend little on the arm that originally locates the target. Therefore, target position after passive kinesthetic exposure can be represented in an amodal frame of reference that is not referred to reaching postures; rather, it is defined by extrinsic space and is shared by vision and kinesthesis. This representation is not always observed when relatively few target locations and responses are used.

It has been further proposed that multiple spatial representations are formed after haptic exposure in a temporal cascade. These begin with kinesthetic reference frames and proceed to extrinsic frames that might be egocentric or environmental.

Once spatial locations are encoded by means of reaching, they can be updated when people move in the absence of vision. Studies investigating nonvisual updating in manipulatory space have found that sighted and blind observers can update their representation of touched locations after moving their finger to a new reference location or after walking to a new location. However, updating is superior when observers can actually touch the target at the updated location rather than just point to it, suggesting that a specifically haptic code is updated more successfully during movement than is an abstract representation of location.

Haptic Recognition of Objects

Humans are remarkably effective at recognizing common objects using only their hands. When asked to identify them, participants attain close to 100% accuracy, most often within only 2–3 s.

Role of Hand Movements

Active manual exploration may play a critical role in the normal development of somatosensory perception in mammals. Nonetheless, as long as there is

Figure 2 Locating the haptic egocenter: (a) top view; (b) front view. One hand places a stylus on the target on the upper table surface, and the other hand attempts to match up underneath the table in the corresponding location. Reproduced from Wolfe JW, Levi D, Kluender K, Bartoshuk L, Herz R, Klatzky RL, and Lederman S (2005) *Sensation and Perception*. Sunderland, MA: Sinauer, with permission from Sinauer Associates, Inc.

relativemotion between the surface and the skin, for fingertip-size stimuli such as Braille characters and textures, it is not critical whether the hand moves over a stationary surface or the surface moves across the stationary hand.

Manual exploration contains the key to understanding why humans are so skilled at recognizing common objects haptically. People manually explore such multi-attribute objects and surfaces in highly systematic ways by executing a number of stereotypical hand-movement patterns know as exploratory procedures. Each procedure is voluntarily selected in association with one or more object properties to which the person is selectively attending.

The exploratory procedures that have most frequently been the focus of scientific investigation are shown in Figure 3 in association with the property (ies) with which they have been most closely linked. Lateral motion involves a back-and-forth shearing motion across a surface and provides the most precise information about the textural properties of a surface. Pressure involves the application of force normal to a surface or a torque about some axis of the object and provides the most precise information about properties relating to compliance. Static contact, as its name implies, involves making simple static contact with a surface and is used to extract optimal information about thermal qualities. Unsupported holding involves lifting the object away from a supporting surface, often jiggling it, to learn best about its weight. Enclosure involves molding the fingers to the object's contours

Figure 3 Six haptic exploratory procedures and the object property(ies) with which each is most closely associated: (a) lateral motion, texture; (b) pressure, hardness; (c) static contact, temperature; (d) unsupported holding, weight; (e) enclosure, global shape and volume; (f) contour following, global shape and exact shape. Reproduced from Lederman SJ and Klatzky RL (1987) Hand movements: A window into haptic object recognition. *Cognitive Psychology* 19(3): 342–368, with permission from Elsevier Ltd.

Figure 4 Costs and benefits as influenced by three relative performance characteristics of haptic exploratory procedures: precision of information (chance, sufficient, optimal, or necessary), breadth of sufficiency or generality, and average execution duration. EP, exploratory procedures; Temp, temperature; Unsupp., unsupported; Vol, volume; Wt, weight. Reproduced from Lederman SJ and Klatzky RL (1987) Hand movements: A window into haptic object recognition. *Cognitive Psychology* 19(3): 342–368, with permission from Elsevier Ltd.

and provides the most precise information about an object's size and general shape. Finally, contour following involves tracing around an object's edges or contoured surfaces and provides the most precise spatial details about an object.

These six exploratory procedures have been further compared in terms of four different performance characteristics: precision of information, breadth of object property information, average duration, and co-executability. A summary of the first three relative performance characteristics is presented in Figure 4.

Relative precision of information The empty cells indicate that the designated exploratory procedure (row) does not provide any information about the target property (column). Such is the case when unsupported holding is used to provide information about texture. The gray cells indicate that the designated exploratory procedure provides only coarse information about the target property, such as when pressure is used to extract texture information. The blue cells indicate that the designated exploratory procedure provides the most precise information about the target property, as is the case when lateral motion is used to extract texture. Finally, the red cell indicates that the designated exploratory procedure not only provides the most precise information about the target property (exact shape) but that this information is necessary for the haptic perception of fine shape details.

Breadth of property information The exploratory procedures also vary in terms of the number of properties about which information is made available, minimally at a coarse level. Thus, lateral motion and pressure, the least general hand-movement patterns, provide only three types of property information that are all related to an object's material. In contrast, enclosure and contour following each offers information about both material and geometric object properties.

Duration Most exploratory procedures are relatively quickly performed, as is the case for those that provide relatively precise information about material. In contrast, although relatively quickly executed, enclosure provides only coarse information about an object. Contour following takes notably longer to perform than any other exploratory procedure.

Co-executability A fourth relative performance characteristic relates to the extent to which exploratory procedures can be co-executed. To the extent that this is possible, the observer gains information that each exploratory procedure is not only optimal (or necessary), but also sufficient, at providing.

Implications for Haptic Object Classification

The relative performance characteristics of exploratory procedures just discussed have both costs and benefits for the haptic perception of the physical

properties of the concrete world and for object recognition and identification.

First, material properties of objects tend to be more salient (i.e., more active) in our conscious experience than others. Consider what happens when observers are biased by instructions to focus on either haptic or visual information when sorting multi-attribute objects into several piles. The most similar objects are to be placed within the same pile. When objects are constructed so that material (e.g., texture and compliance) and geometric (e.g., shape and size) dimensions vary in perceptually equivalent (i.e., discriminable) ways, the importance of material properties for people's judgments of object similarity increases when they are given haptic-bias instructions compared to when they are given vision-bias instructions (Figure 5). The reverse occurs for the importance of geometric properties when people are given vision-bias (as opposed to haptic-bias) instructions. This result may be explained by the relative efficacy with which people perform material, as opposed to geometric, exploratory procedures.

Second, when vision is available during object recognition, humans tend to use their sense of touch primarily when the most diagnostic object property relates to material, as opposed to geometric, properties (e.g., sandpaper vs. spoon, respectively). As shown in Figure 6, when people are instructed to make difficult discriminations between pairs of common objects whose most diagnostic property is based on material (e.g., texture and compliance) or geometry (e.g., shape complexity and size), they choose to also haptically explore the objects for which material differences are most diagnostic. This is much less the case for highly discriminable pairs, presumably because information is semantically available.

Figure 5 Relative cognitive salience of geometric (shape and size) and material object properties. Subjects were instructed to sort multi-attribute objects into piles based on cues available from haptic (H) or haptic + visual (HV) exploration. The salience score (out of 8) were calculated on the basis of subjects' sorting judgments Based on Lederman S, Summers C, and Klatzky RL (1996) Cognitive salience of haptic object properties: Role of modality-encoding bias. *Perception* 25(8): 983–998.

Third, when people haptically recognize an object, manual exploration proceeds in a stereotyped way that is determined by the relative breadth of property information afforded by exploratory procedures and by their associated durations. Thus, humans begin their manual exploration by grasping (enclosure) and lifting (unsupported holding) the object. Both movement patterns provide information about many object properties and are relatively quickly executed. This highly standard routine is followed, albeit less frequently, by executing the exploratory procedure that provides optimal information, that is, that offers the most precise information about the property that is highly diagnostic of the object.

Fourth, humans may capitalize on the fact that multiple properties often predict an object's identity. For example, a pencil is long and narrow; in addition, it frequently has a section at one end consisting of an interior metal band adjacent to a rubber end. With the haptic system, the perceptual gain resulting from property redundancy(ies) is potentially constrained by manual exploration. The addition of a second predictive property does not reduce the time needed to categorize objects if the two exploratory procedures that are optimal for those properties cannot be co-executed, either because of biomechanical constraints or because the second property is available at a region that cannot be explored simultaneously with the first.

Consequences of Constraining Manual Exploration in Space and/or Time

Restricting manual exploration helps to reveal how object properties are haptically encoded. More specifically, limiting spatial access to objects highlights the significance of both shape and material information

Figure 6 Frequency of touching objects during haptic discrimination of various object properties when vision is available. Temp, temperature. for object identification. Limiting temporal access speaks, rather, to the sequence in which object properties emerge.

Spatial constraints Small-scale, cutaneous spatial constraints may be imposed by covering the fingertip in a rigid sheath. Without the spatially distributed force array that is normally available, observers can access only the summed forces stimulating receptors in the skin, muscles, tendons, and joints. Under such circumstances, they retain their ability to sense vibration and remain sensitive to coarse pressure differences; however, they are unable to discriminate fine spatial patterns within the scale of the fingertip.

It is also possible to constrain larger-scale spatial variation in objects that are typically explored using contour following and/or enclosure exploratory procedures. Consider, for example, what happens when observers are required to identify a set of common objects selected because they are all rigid, fairly smooth, and fixed to a supporting surface. A thick glove is worn to reduce the cutaneous information from the spatially distributed deformation patterns and vibrations normally created during contact. Under such circumstances, kinesthetically derived shape information becomes critical for object identification. Performance may be compared across gloved haptic exploration conditions that vary in the extent to which the kinesthetic inputs from muscles, tendons, and joints are spatially constrained. For example, the kinesthetic cues may remain intact. Alternatively, kinesthetic information may be reduced by wearing finger splints to prevent any flexion at the joints or by restricting the number of fingers used during exploration. By comparing performance across conditions, we can assess the extent to which reduced kinesthesis impairs object recognition when cutaneous sensing is minimized. Regardless of the method used to reduce kinesthetic information, performance declines, and it worsens as the number of exploration constraints is increased. When a rigid interface (i.e., sheath) between hand and object or a rigid, pencil-shaped probe is used, performance declines still further.

Temporal constraints The costs and benefits of exploratory procedures imply that features become available at different points in time, depending on the duration of haptic exploration and the processes (e.g., intensive and spatial) used to encode the explored features. Haptic access to information pertaining to material, to the presence of edges, and to geometric features has been shown to differ in terms of the relative availability of information about these feature subclasses over time. More specifically,

material attributes and edges, which are processed intensively, emerge earlier than do the spatial arrangement of an object's geometric features, even when those features lie within the span of a fingertip.

Applications

The results of studies based on the scientific investigation of human haptic processing of surfaces, objects, and their properties have been applied to a number of application domains. Examples include the design of tangible graphics displays (maps, drawings, graphs, etc.) for the blind that are apprehended by hand as opposed to eye, the design of haptic and multisensory interfaces for exploring and acting on remote real and virtual environments, and haptic art for the blind and sighted. Several examples are presented in Figure 7.

Introduction

Psychophysical methods have been developed by researchers in an attempt to determine how the mind encodes and represents environmental events – that is, to determine the relationship between the mind ('psycho') and the world ('physics'). To investigate such relationships, methods were developed in which observers were required to make judgments concerning the presence or absence of stimuli, or the sensory relationship of one stimulus to another (e.g., whether stimulus one is brighter than stimulus two). These judgments were then used to determine how the stimulus is encoded and represented in the minds of the observers. Note that the nature of this representation is inferred from behavioral judgments. Hence psychophysical methodology is a way of indirectly investigating how information about the physical world is organized and represented in the nervous system.

Although these methods were initially used to investigate the relationship between a physical aspect of the stimulus and how it is experienced by the observer (e.g., how the loudness of a sound is related to its physical intensity), they are now used to investigate how information in general is encoded and represented. Hence, psychophysical methodology can be, and is, used not only to investigate how a psychological attribute varies as a function of some physical variable, but also to determine, among other things, the psychological utility of objects, the prestige of various occupations, or the discriminability between classes of words previously presented to observers and semantically related words that were not previously presented. Note that in these latter three examples, the psychological property under investigation is not directly related to any specific physical aspect of the stimulus.

In approaching psychophysical methodology we begin here by describing the theory upon which many of these methods are based. We then describe the range of psychophysical methods that have been developed to assess how information is encoded and represented, along with examples of their application.

Theoretical Concepts

Representation of Information

Psychophysical methodologies assume that the activity a stimulus evokes in the nervous system can be represented as a point in an n-dimensional space. Consider, for example, a pure tone, which has four physical dimensions, intensity, frequency, duration, and phase. If each of these dimensions had a psychological counterpart, we would need four dimensions to represent the manner in which an observer experiences that tone. However, because observers are not sensitive to monaural phase, it is likely that there are only three dimensions to the psychological experience: loudness, pitch, and perceived duration. In Figure 1, the loudness, pitch, and perceived duration evoked by single presentations of each of three tones are indicated as points in a three-dimensional (3-D) space. Because a stimulus will not give rise to exactly the same experience each time it is presented (because of the presence of external noise or intrinsic variability in the nervous system), repeated presentations of a stimulus are depicted as giving rise to a cloud of points clustered around a mean position in this 3-D space.

To better illustrate the degree of variability in the evoked experience, Figure 2 plots the probability density functions that result when three pure tones having different intensities and frequencies, but identical durations, are presented repeatedly to an observer. (Because the mean perceived duration is the same for all three tones, variation along the perceived duration dimension is not illustrated.) As in Figure 1, variations in loudness and pitch are assumed to be independently and normally distributed with standard deviations of 1.0. In this example, because the tones are closely spaced together, the distributions exhibit some degree of overlap.

It is important to note that, theoretically, we could assume any two-dimensional probability function for the stimuli in this space, and we need not assume that all probability density functions are equally variable. However, the default assumption is usually that the distributions are normal or Gaussian in shape, and that the variation of stimuli along any one dimension is constant. (In Figure 2 the variances are shown as equal across the two dimensions.) In addition, in the vast majority of cases in which psychophysical methods are employed, it is assumed or shown that the stimuli being judged can be represented along a single

Figure 1 Each tone is presumed to evoke a sensation of loudness, pitch, and perceived duration. The subjective experience corresponding to a tone presentation is represented as a point in a 3-D perceptual space with axes of loudness, pitch, and perceived duration. Because of variability in the stimulus, and the presence of internal noise, the location of a point varies from trial to trial, even when the stimulus remains the same. In generating a cluster of points for a tone, it was assumed that the loudness, pitch, and perceived duration values were independently and normally distributed with a standard deviation equal to 1.0. Shown here are hypothetical clouds of points resulting from 20 repetitions of three tones. The mean locations of the three tones, for loudness (L), pitch (P), and perceived duration (PD), are depicted as follows: red ($L=1$, $P=1$, PD$=1$), green ($L=5$, $P=8$, PD$=8.5$), and purple ($L=7$, $P=4$, PD$=4.5$).

Figure 2 Probability density functions for three tones having identical perceived durations but different loudness and pitch values. Loudness (L) and pitch (P) values are as follows: tone 1 ($L=3$, $P=6$), tone 2 ($L=7$, $P=5$); and tone 3 ($L=5$, $P=3$). The loudness and pitch values for each of the tones are assumed to be independently and normally distributed with standard deviations equal to 1.0.

psychological dimension. For example, were we to restrict our set of pure tones to have the same mean pitch and perceived duration, so that they differed reliably only in loudness, we would choose to represent

Figure 3 Hypothetical distributions of loudness values for four pure tones in the equal-variance Gaussian model.

their density functions along a single psychological dimension, such as the one shown in Figure 3. Here, the Gaussian probability density functions for all tones have the same variance, and differ only in their mean values. We refer to this situation as the unidimensional, normally distributed, equal-variance case. In describing the various psychometric methods, we restrict our discussion herein to this case.

Relationship to the Goal of Psychophysics

As mentioned in the Introduction, psychophysical methods were developed to explore how sensory information is structured in the mind, and to relate this structure to the physical world. For instance, if Figure 3 truly represented how the loudness of four different tones was experienced, then one could relate the mean loudness values of these stimuli to their physical intensities, thereby establishing a psychophysical relationship. Psychophysical methods, based on observers' judgments, were developed to establish how the physical properties of stimuli were experienced, so that psychophysical relationships, such as the one between loudness and sound intensity, could be established. However, these methods can be used to determine how other psychological phenomena are represented, such as the utilities of a collection of objects, even though it may be difficult to determine exactly how the utility of an object is related to its physical properties. In all cases, these psychophysical methods are based on judgments about relationships among stimuli. Here we consider different types of judgments and what can be learned from them.

Psychophysical Methodologies

Detection Experiments

In many instances, the experimenter wants to know the minimum value of a stimulus that can be detected. For example, a vision scientist might want to know

the smallest degree of contrast that can be detected in a sinusoidal grating (see Figure 4, top row), and the simplest way of determining this is to ask the observer to report the presence or absence of contrast on a trial. There are two classes of psychophysical methods that have been developed for the detection experiment, the Yes/No method and the *m*-interval forced-choice method.

The Yes/No method In the simplest version of this method there are *n* trials and a single stimulus. The occurrence of a trial is signaled in some fashion, and there are two types of trials: those in which a stimulus appears and those in which no stimulus is presented. For example, consider an experiment in which the stimulus is a low-contrast sinusoidal grating (Figure 4, top row), and the observer's task is to detect the presence of this stimulus when it is added to a field of Gaussian noise (Figure 4, middle row). The occurrence of a trial is signaled by the presentation of a fixation cross in the middle of the screen, and a trial of fixed duration begins either shortly after the fixation cross occurs, or shortly following a button press by the observer. The trial consists of a presentation of the noise field alone (N trial; Figure 4, middle row), or the sum of the sinusoidal grating (S) and the noise field (signal + noise, or SN, trial; Figure 4, bottom row). The probability of an SN trial, $p(\mathrm{SN})$, is fixed throughout the session, and the observer's task to indicate whether there is a signal present (a Yes response) or not (a No response). Correct detection of a signal is typically referred to as a Hit (H); responding Yes when there is no signal is referred to as a False Alarm (FA). If there are $n(\mathrm{N})$ noise trials and $n(\mathrm{SN})$ signal trials, the critical data in this experiment are the proportion of Hits, $n(\mathrm{H})/n(\mathrm{SN})$, versus the proportion of False Alarms, $n(\mathrm{FA})/n(\mathrm{N})$. These two proportions are used to estimate the detectability of the sinusoidal grating, assuming that the N and SN stimuli give rise to two different distributions of events along a unidimensional decision axis (e.g., perceived contrast). As mentioned previously, it is usually assumed that these two distributions are Gaussian and have equivalent standard deviations (see Figure 5(a)).

Interpretation of the results of this experiment, however, depends on whether or not one assumes that the threshold for detecting a grating is fixed or variable. Figure 5 illustrates what we would expect if the threshold was fixed. Here, the observer would report the presence of a grating whenever the occurrence of a trial produced an event along the decision

Figure 4 Images of signals and noises. (Top row): Signals; vertically oriented sine wave gratings (four cycles/image). The leftmost image has a contrast of 0 (no grating, i.e., uniform gray); the contrasts of the other images in the row increase from left to right. (Middle row): Noises; five independent samples of Gaussian noise. (Bottom row): Signal + noise; here, the gratings in the top row have been added to independent samples of noise. Note that there is no sinusoidal grating in the leftmost square of this row. Hence, this is technically a noise trial. The other four squares constitute signal + noise events.

Figure 5 (a) Noise (N) and four signal + noise distributions (1, 2, 3, 4) along a unidimensional decision axis; T represents the point on the decision axis corresponding to a fixed threshold. (b) The portion of the N distribution that exceeds threshold. (c–e) The corresponding portions of the first three signal + noise distributions (1–3) that exceed threshold. (f) Probability of a Yes response as a function of stimulus intensity. This function assumes that the mean location of a stimulus event along the decision axis is linearly related to stimulus intensity. If the relation mapping stimulus intensity onto the decision axis is nonlinear, the shape of this function will change accordingly.

axis (the neural representation of contrast) to the right of the threshold, T. The area under an SN distribution to the right of the threshold would correspond to the probability of a Hit in an SN trial. Increasing the degree of contrast would shift the mean of the SN distribution to right, thereby increasing the proportion of the distribution to the right of T (compare areas to the right of T for Figures 5(b)–5(e)). Hence, by presenting different stimulus contrasts over successive experimental sessions one could map out a psychometric function relating the proportion of Yes responses to the degree of visual contrast as indicated in Figure 5(f). Note that as visual contrast approaches 0, p(H) approaches p(FA). The reason for this is that the N distribution extends to the right of T, so occasional events occur along the decision axis that exceed this fixed threshold even in the absence of a stimulus. Hence, p(FA) provides a floor for p(H), as stimulus contrast becomes smaller and smaller.

Note that if the threshold is fixed, the probability of a False Alarm will be independent of the stimulus contrast in the signal. Therefore, rather than varying stimulus contrast across sessions (where each session consists of N and SN trials), it would be more efficient to simply vary stimulus contrast within a session, with one of the several contrast values being zero (an N trial). This method is called the 'method of constant stimuli,' and the asymptotic value of the psychometric function obtained when stimulus magnitude approaches zero is sometimes referred to as the 'probability of guessing.' Under fixed-threshold theory, it would be interpreted as a measure of the location of the threshold relative to the null event (no stimulus presentation).

Assuming a fixed threshold and a unidimensional decision axis, one can measure the location of each of the stimuli along the decision axis with reference to the null event, measured in standard deviation units. Assume for the moment that we use the method of constant stimuli (in which one of the stimuli was the null stimulus) to map out a psychometric function relating p(Yes) to stimulus contrast. To do this we first rescale the x axis so that all distributions have a standard deviation of 1.0. Second, we determine the z-score corresponding to the location of the threshold T with respect to the mean, μ_N, of the N distribution ($z_{N,T} = \mu_N - T$). Third, we determine the z-score for T relative to the mean for an SN stimulus (e.g., $z_{SN1,T} = \mu_{SN1} - T$). Note that p(FA) (see Figure 5(b)) is the probability that an event elicited on an N trial, $z_{N,}$, exceeds $z_{N,T}$ – that is, $p(FA) = p(z_N > z_{N,T})$ – and that p(H) on an SN_1 trial (see Figure 5(c)) is the probability that an event elicited on an SN_1 trial, z_{SN1}, exceeds $z_{SN1,T}$ – that is, $p(H) = p(z_{SN1} > z_{SN1,T})$. Hence, p(FA) and p(H) can be used to find $z_{N,T}$ and $z_{SN1,T}$, respectively. Now if we subtract $z_{N,T}$ from $z_{SN1,T}$ we obtain $(\mu_{SN1} - T) - (\mu_N - T) = \mu_{SN1} - \mu_N$. Hence, the difference between the z-transformation of p(H) when SN_1 is presented, and the z-transformation of p(FA), is an estimate of the distance between the means of the two distributions when the abscissa has been rescaled so that all distributions have a standard deviation of 1.0. This difference between the two means is called d' (d prime). Therefore, we can determine the separation between the means of the signal distributions with respect to the mean of the N distribution in units of d'. Note that to do this, we need to assume that the decision axis is unidimensional and that the distributions corresponding to different stimuli are equal-variance normal distributions. Increasing the separation between the distributions in Figures 5(a)–5(e) will increase d' and the rapidity of the growth of the function in Figure 5(f). An individual who has a large value of d' has good resolving power – a good ability to discriminate between presentations of N and of SN.

Note that up to this point we have assumed a fixed threshold. A number of experiments have suggested that the location of the decision point along the decision axis is variable and can be set by the observer. For example, in a simple Yes/No experiment, we can vary the probability of an SN trial across sessions and/or we could create variable rewards for Hits and penalties for False Alarms. If the threshold is truly fixed, then p(FA) and p(H) should be independent of both p(SN) and the payoff structure of the experiment. However, in general they are not, and there is every indication that observers can adjust location of the decision point (the 'criterion') to improve outcomes in the experiment.

Consider the case in which the probability of an SN trial is 0.5, and the observer is penalized \$2.00 for every False Alarm, and rewarded with \$1.00 for every Hit. Assume that the N and SN distributions are separated by 1.5 standard deviation units ($d' = 1.5$). Figure 6 shows five different possible locations (panels a–e) of the criterion along the decision axis. Each of these criterion locations will give rise to different proportions of False Alarms and Hits in an experiment. Assume 1000 (500 N and 500 SN) trials. The amount of money that a person will earn is $\$1.00 \times n(\text{H}) - \$2.00 \times n(\text{FA})$, where n(H) and n(FA) are the numbers of Hits and False Alarms. The amount of money earned for each of the criterion locations is also shown in Figures 6(a)–6(e). Figure 6(f) shows how the expected payoff for this experiment varies as a function of criterion location. Observers in this experiment will maximize their payoffs if they locate their criterion approximately 5/6 of the way between the mean of the N distribution and the mean of the SN distributions. Clearly, if possible, observers should position their criterion to maximize payoff. A similar argument holds when p(SN) is varied.

By convention, the unbiased condition occurs when the observer locates the criterion midway between the two distributions. Under these conditions, p(FA) will equal $1 - p$(H). Changing the location of the criterion away from the unbiased location will change p(FA) and p(H) in a systematic way, but will not change d'. A plot of p(H) versus p(FA) for a constant d' is called a 'receiver operating characteristic' (ROC). Figure 7 shows ROCs for $d' = 0$ (the diagonal line), $d' = 0.5$, $d' = 1$, $d' = 1.5$, and $d' = 2.0$.

Figure 6 (a–e) Different criterion (C) locations for detecting a signal in noise, where d' between the noise (N) and signal + noise (SN) distributions is 1.5. The dollar amount is the expected payoff if the observer is given \$1 for each hit and penalized \$2 for each false alarm (number of trials = 1000). (f) The expected payoff for this experiment as a function of criterion location.

Figure 7 Receiver operating characteristics for a Yes/No paradigm, assuming that repeated presentations of noise give rise to a normal distribution of events along a decision axis, and that repeated presentations of signal + noise give rise to another normal distribution of events along the decision axis with the same variance as that of the noise distribution. The probability p of a Hit is plotted as a function of the probability of a False Alarm in this paradigm for four different values of d'. Each curve is generated by determining and plotting p(Hit) and p(False Alarm) as the location of the criterion is swept along the decision axis.

It is important to note that signal-analysis techniques based on the Yes/No paradigm can also be applied to neural data. For instance, suppose a researcher is measuring the response rate of a single unit in visual cortex that is sensitive to luminance contrast. Using the method of constant stimuli, the researcher could repeatedly present the each of the five gratings shown in the top row of Figure 4 an equal number of times, and record the response rate during that presentation period. Distributions of response rates could then be determined for each of the stimuli, and a threshold response could be set by the experimenter. This would be equivalent to setting the location of T in Figure 5. The experimenter could then determine the area under each distribution to the right of the threshold criterion and then plot this area (proportion of times threshold is exceeded) as a function of stimulus contrast, thereby mapping out a function like the one shown in Figure 5(f). In this way, the experimenter can determine the shape of the function relating d' to physical contrast. Note, however, that in this kind of application, it is the experimenter, rather than the subject of the experiment, who is setting the location of the criterion.

The advantage of a signal-detection analysis of a Yes/No experiment is that it allows the experimenter, in analyzing the data, to separate shifts of criterion location (also referred to as response biases) from sensitivity. Both changes in d' and shifts of criterion location will affect both $p(\mathrm{H})$ and $p(\mathrm{FA})$ – the observer's performance will be sensitive to both. However, to estimate both accurately requires the collection of enough data to plot an ROC curve. Often, experimenters are primarily interested in sensitivity measures (such as d') and not interested in determining response criteria. In such circumstances, an m-interval or m-alternative forced-choice paradigm is typically used.

***m*-Interval forced-choice method** In an m-interval forced-choice paradigm, a trial consists of the presentation of m intervals separated by a short but constant interinterval time period. Most experimenters prefer to use two intervals only, and two stimulus values (N and SN), so that this method is referred to as a two-interval, two-alternative, forced-choice (2I2AFC, or sometimes just 2IFC) procedure. In a 2IFC paradigm, SN is randomly assigned to one of the two intervals, with N occurring in the other. Hence, there are two types of trials, N_SN and SN_N, with the probability of each trial type typically being set to 0.5. The observer's task is to decide which type of trial it is. The ideal strategy is for the observer to note the value of the event that occurs along the decision axis in each of the intervals and subtract one from the other. Let the difference between the means of the N and SN distributions be d'. Suppose the observer subtracts the observation in interval one from the observation in interval two. On N_SN trials, this strategy will give rise to a normal distribution with a mean of d' and a standard deviation $= \sqrt{2}$. On SN_N trials, this strategy will give rise to a distribution with a mean $= -d'$ and a standard deviation of $\sqrt{2}$. If these two distributions are then normalized so that their standard deviations are 1.0, the separation between the means of these two distributions is $\sqrt{2}d'$. The distribution of this difference score is shown for N_SN and SN_N presentations in Figure 8, where the d' value separating the original N and SN distributions in the Yes/No task is 1.0. Note that if the observer chooses to respond that the signal is in interval 2 if the observation in interval 2 is greater than the observation in interval 1, this places the location of the criterion, C, for deciding which type of trial type occurred, midway between the distributions for N_SN and SN_N (i.e., the decision is unbiased). Provided that the two types of trials occur equally frequently and the payoff for correct identification of both kinds of trials is unbiased, there is every reason to believe that observers will set their criterion to zero, i.e., to the unbiased position. Hence, the 2IFC is said to minimize the possibility of the occurrence of response biases. Because the expectation in a 2IFC experiment is that the observer is unbiased, d' values

Figure 8 Shown here are hypothetical distributions of events along a normalized decision axis in a two-interval forced-choice experiment. For noise (N) and signal + noise (SN), both the SN_N distribution (signal in first interval, noise in the second interval) and the N_SN distribution (noise in the first interval, signal in the second) were generated by assuming that the observer subtracts an observation along the decision axis during the first interval from an observation along the decision axis during the second interval on both kinds of trials. In other words, the observer responds that the signal is in the second interval when this difference observation is >0. The two distributions of difference judgments corresponding to the two types of trials (SN_N and N_SN) have been normalized to have unit variances, with the separation between the means of the N and SN distributions along the original decision axis being equal to 1 ($d'_{\mathrm{Yes/No}} = 1$); C, criterion location.

are typically not computed, and experimenters usually plot percent correct identification as a function of stimulus intensity.

A very significant advantage of the 2IFC procedure is that it is amenable to adaptive techniques in which the intensity of the signal is changed from trial to trial in an attempt to rapidly converge to the stimulus intensity corresponding to a particular point on the psychometric function relating percent correct to stimulus intensity. Consider the following rule for adjusting the stimulus contrast on successive trials in a 2IFC task. If the observer is correct on three successive trials, lower the contrast. However, if the observer makes a mistake on a trial, increase the contrast. Typically, the amount by which the contrast is increased or decreased becomes smaller each time there is a reversal in direction. Figure 9 plots the performance of an observer in such a task when the initial stimulus contrast was set to 50%, and the first step size is a 10% change in contrast, with the step size decreased by one-half with each reversal of direction, until a minimum step size is reached. The session is usually terminated after a certain number of reversals have occurred, and the threshold is estimated by averaging the last few reversals in intensity. For an attentive observer this '3 down, 1 up' rule will converge on the 79% point of the psychometric function.

Many different algorithms have been developed, including some based on maximum-likelihood procedures, to achieve efficient and unbiased convergence on the targeted point on the psychometric function using the 2IFC procedure. In general, the algorithms that provide the most rapid convergence are sensitive

Figure 9 Performance of a hypothetical observer in a method of adjustment paradigm employing a '3 down, 1 up' procedure in a two-interval forced-choice experiment paradigm. In this procedure, three correct responses in a row (a correct response is denoted by the numeral 1) reduce the contrast by a fixed amount on the next trial. If an incorrect response (0) occurs, the contrast is incremented on the next trial. On each reversal of direction of change, the size of the increment is halved on the next trial until a minimum step size for a contrast change is reached. The session is terminated when performance has stabilized.

to lapses in attention. Therefore, the appropriate method to choose will depend on the motivation and attentiveness expected of the observers.

Vigilance paradigm In Yes/No and 2IFC methods, the trial periods are discrete and usually short. In the vigilance paradigm, there is usually one long trial period, during which stimuli are occasionally and infrequently presented. In order to perform well on this task, the observer has to remain focused on the task (i.e., remain vigilant). The dependent measure is the proportion of times the observer detects the presentation of the signal. The vigilance paradigm is typically employed in an attempt to simulate situations in which constant monitoring is required, and the occurrence of signals is unpredictable and infrequent (e.g., monitoring a radar screen to detect intruder aircraft).

Tracking techniques In the techniques just described, stimulus presentations are usually brief, intermittent, and under the control of the experimenter. One can determine the threshold value of a stimulus, however, by using a tracking technique in which stimulus intensity is controlled by the observer. For instance, observers can be told that as long as they press down on a button, the intensity of a tone will continue to decrease and will increase only when the button is released. They are then told to hold down the button when they can hear the tone and to release it when the tone becomes inaudible. In this way, the threshold can be tracked during the course of a session.

Discrimination Experiments

In addition to determining the detectability of a stimulus, one often wants to determine how discriminable pairs of the stimuli are. Here, rather than having a no-signal condition (with or without external noise) versus a signal condition (again, with or without noise), the two conditions become stimulus 1 versus stimulus 2 (S1 and S2). Because of inherent variability in the nervous system, repeated presentations of the two stimuli are assumed to give rise to dispersions of events along a decision axis (even in the absence of external noise), presumably with Gaussian distributions. Hence, by simply substituting S1 for N, and S2 for SN, stimulus discriminability can be investigated using either the Yes/No or the 2IFC method.

Scaling Experiments

In many cases the experimenter would like to know how a dimension of stimulus experience is represented in the nervous system. Two classes of procedures exist for determining this: direct scaling methods and indirect scaling methods. In direct scaling methods the

observer is asked to directly report, say, on the loudness of a sound by assigning a number to it, or by indicating where the loudness of that sound would lie along some scale. The most commonly used direct methods require observers to assign numbers to the stimuli that reflect the magnitude of a sensory property of a stimulus. For example, one could present observers with pure tones ranging from 40 to 100 dB, and ask them to assign numbers to these tones such that the numbers are directly proportional to the loudness they experience (magnitude estimation). Or, one could ask them to assign a number that represents the ratio of the loudness of one tone to another (ratio estimation), or the difference in loudness between two tones (interval estimation), or one could ask them to rate loudness on a 1 to 10 scale (category estimation). The assumption in such techniques is that observers can assign numbers in such a way that they are proportional to sensory experience – that is, $N_L = k \times L$, where N_L is the numerical estimate of loudness generated by the observer, and L is the magnitude of the psychological loudness experience evoked by the stimulus. These techniques are easy to employ, require relatively few trials, and typically generate reliable and replicable relationships between numerical estimates and stimulus intensity. Their weakness is that they assume that observers can accurately, and without bias, assign numbers to reflect stimulus qualities.

Indirect scaling methods derive sensory scales without assuming that the observer can directly assign numbers to sensory experience. For example, consider a set of 12 pure tones differing only in intensity. Suppose each tone gives rise to a value along a unidimensional loudness scale, these 12 tones form $12 \times 11/2 = 66$ distinct pairs. Suppose the observer is asked, when presented with two pairs of tones, to indicate whether the loudness difference between the tones in pair 1 was larger or smaller than the loudness difference between the tones in pair 2, and these judgments are based on a comparison of the psychological distance between the tones in pairs 1 and 2. It turns out that there is sufficient information in the comparisons of pairs to permit the experimenter to recover the location of the tones along this subjective dimension such that the recovered locations, P, are related to the loudnesses of the tones, L, by $P = k \times L + b$. In Figure 10, 12 points were randomly chosen along the line segment from 0 to 1. The 66 interpoint differences between the points were then computed and used to decide which of two intervals was larger. These binary comparisons of intervals were used to recover the location of the original points along a line segment from 0 to 1. Figure 10 plots the recovered locations of the points as a function of their original values, and shows that a comparison of intervals contains sufficient information to recover the original points, such that $y = k \times x + b$, where y is the recovered value of the point, and x is the original value of the point. When 12 stimuli are involved, and the observer can accurately judge which interval is larger, agreement between the recovered and original points is almost perfect.

Figure 10 Five simulations of the application of a nonmetric scaling procedure to recover the location of a set of 12 points, randomly sampled from the line segment (0, 1), from comparisons of the intervals between pairs of points. Different colors are assigned to the five different sets of 12 points. In each simulation, all pairwise distances were determined among the set of 12 points. These distances were then used to determine whether the interval between a pair of points (a, b) was greater than, equal to, or less than the interval between another pair of points (c, d). These inequality judgments served as input to a nonmetric scaling program, which returned the best fitting locations of the points along the line segment (0, 1). These recovered points are plotted as a function of the original points. The squared correlation coefficients between the recovered and original points exceed 0.999 in all five cases.

The frontal lobes comprise roughly a third of the human cerebral cortex. Through evolution this brain region has increased disproportionately, and as a result of this expansion it has been viewed as the basis for human intellect and thought. Studies of individuals with brain injury have suggested that frontal lobe damage affects many aspects of cognition, including attention, memory, language, problem solving, emotion, and decision making. Yet, its role as the seat of human reasoning and thought became suspect, as findings indicated that frontal lobe damage did not grossly affect measures of general intelligence. Now, there is general consensus that the frontal lobes – or more specifically the anterior portion of the frontal lobes identified as the prefrontal cortex (PFC) – contributes to the regulation or control of mental processing.

The PFC can be parceled into five general regions – the dorsolateral (dlPFC), ventrolateral (vlPFC), posterior (pPFC), anterior (aPFC), and ventromedial (vmPFC) prefrontal regions. These first four regions are spatially located as north, south, east, and west regions within the PFC when the left hemisphere is viewed from the side (i.e., laterally). The fifth region, vmPFC, refers to the lowest and medial (i.e., inner) portions of the PFC. These regions are intricately connected to regions outside the PFC (i.e., in the posterior cortex) and also have interconnections among themselves. These regions are distinct both in terms of anatomical and functional characteristics. In particular, functional neuroimaging techniques, such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), have been successful in demonstrating that these brain regions play different roles in the control of cognitive (and emotional) processes. With respect to memory, the dlPFC, vlPFC, and aPFC have been most associated with control processes associated with encoding, organizing, and retrieving memory.

Consider the following question: What did you eat for dinner 3 days ago? It is unlikely that you were able to answer this question immediately. However, with some time and searching through your memory, you may have been able to retrieve the information. Most of us would begin by trying to figure out the day of the week. "Let see, today is Wednesday, three days ago would be Tuesday, Monday, Sunday... yes Sunday, what was I doing on Sunday...." If you ultimately retrieved the information – or even if you tried but were unsuccessful – you likely engaged in a variety of mental processes, particularly those involved in selecting, maintaining, organizing, and ultimately retrieving the desired memory. These processes enabled you to guide and control your mental path toward successful retrieval. In psychological terms, these functions enabled executive control, a process that is critically dependent on the PFC. By analogy, the PFC is your brain's chief executive – it functions to select information, monitor its use, disregard irrelevant information, make decisions, and initiate actions. Without it, your memory – just like a poorly run business – is disorganized, inefficient, and more susceptible to disruptions.

Stimulus Overload and Working Memory

One reason for the necessity of executive control is that we cannot possibly hold in mind everything that we know or perceive. Indeed, it would be an inordinate load on our cognitive system if we even attempted to consider everything that we experienced at any given moment. Because of this stimulus overload, we need to select certain information to be analyzed. Other information is filtered or ignored. For instance, at this moment you are reading and presumably paying attention to this sentence. Yet, pause briefly and pay attention to other sensory information. Perhaps, you can now hear surrounding noises such as a fan or people talking. You can direct your attention to other things, such as the rhythmic changes of pressure on your chest as you breathe. Clearly, at any given moment we experience a multitude of sensations. Not only can we select aspects from the environment, we can select and consider a plethora of memories. It almost seems incredible that in the midst of this information overload, we are able to select, maintain, and control what to bring into our realm of consciousness. The term working memory is used to describe the information that we choose to keep in mind at any given moment. Working memory is transient, and executive control is the dynamic process by which information is selected, maintained, updated, and organized in working memory.

Patients with damage to the PFC (more specifically damage to dlPFC and vlPFC) exhibit a syndrome in which executive control is severely impaired. These patients have problems in paying attention, holding things in mind, organizing thoughts, and retrieving memories. They experience particular problems when

confronted with multiple sensations or choices and must decide which ones to select and which ones to disregard. One particular problem concerns their ability to hold information in mind. A simple task to test this ability is the digit span test, in which individuals are asked to report a short string of digits immediately after presentation. Most individuals can hold about six or seven digits in mind, just as we might when we have to hold a phone number in mind before placing a call. Patients with PFC damage have reduced digit span – they have difficulty keeping information in mind. This deficit pervades many domains, including the ability to maintain locations, colors, or sounds in mind.

Neuroimaging studies have confirmed the role of the PFC in working memory. When individuals must hold or maintain information in mind for a brief delay, prefrontal activity is increased. Interestingly, different prefrontal regions appear to be responsible for maintaining different kinds of information. For example, increased activity in left vlPFC is observed when individuals are asked to hold names of objects in mind, whereas increased activity in right vlPFC is observed when individuals are asked to keep spatial locations in mind. In many instances, these prefrontal activations are linked to activations in posterior regions of the brain, suggesting that the holding of information in working memory involves a brain circuit that includes the information to be activated (presumed to be stored in posterior cortex) and the executive control process that keeps the information active (presumed to be established by PFC).

In addition to its role in maintaining information in mind, the PFC is also involved in updating and manipulating information in working memory. In many everyday situations, it is necessary to rearrange or update information in mind. In laboratory studies, this aspect of working memory has been investigated by asking individuals to reorganize information, such as putting a random string of letters in alphabetical order. Another manipulation task is called the self-ordered pointing task in which individuals are presented with an array of stimuli (e.g., eight objects) and asked to point to one of the stimuli. On subsequent trials, the same objects are shown in different positions, and individuals are asked to point to a different object on each presentation. This task not only requires the holding of objects in mind but also remembering which objects have already been selected. Thus, after each presentation, the contents in working memory must be updated or reorganized to include another item. Patients with PFC damage have difficulty performing this task. Also, neuroimaging studies suggest that the dlPFC is particularly active during such manipulations of information in working memory compared to conditions in which only the maintenance of information is required. Taken together, findings suggest that the mere maintenance or holding of information involves the vlPFC, whereas the manipulation of that information additionally recruits the dlPFC.

Encoding Memories

Executive control is also critical for efficient learning – that is, the encoding of new memories. For example, how would you learn the following series of words: peach, bus, shirt, car, apple, socks, train, shoe, pear? Perhaps, you continually repeated the words in your mind. Alternatively, you may have noticed that the words could be grouped into three meaningful categories: vehicles, fruits, and clothing. In fact, when learning such word lists, many people organize words during encoding and then report the words by grouping all of the words in each category – such as reporting the vehicles first, then fruits and clothing. This kind of organizational strategy would involve maintaining, manipulating, and updating items while they are being presented. Thus, efficient encoding of memories would depend critically upon the kind of executive control processes involved in working memory tasks, such as digit span and the self-ordered pointing task.

Patients with frontal lobe lesions exhibit poor organizational strategies during learning. They fail to elaborate information, such as grouping information into meaningful categories. Moreover, long-lasting memory formation requires the integration of the new information with existing knowledge. This interchange between new and existing information is called elaborative encoding and depends upon the PFC for efficient analysis. Neuroimaging studies corroborate the role of the PFC in elaborative encoding. For example, the left vlPFC has been shown to be particularly active when individuals are asked to consider the meaning of items, such as determining whether a word is concrete (e.g., dollar) or abstract (e.g., freedom) compared to conditions in which they determine superficial features, such as the number of vowels in a word.

The extent of PFC activity during encoding can predict the success of later retrieval. In neuroimaging studies, activations during the initial encoding of items were analyzed separately on the basis of whether the items were later remembered or forgotten. Remembered items were associated with greater prefrontal activity (generally in left vlPFC) during encoding compared to forgotten items. That is, if you recruited PFC during the encoding of an item, you increased your chances of later remembering that item. These findings further support the notion that

efficient encoding depends upon prefrontal activation during learning. The method of backsorting brain activations during learning in terms of whether items are subsequently remembered or forgotten offers a useful means by which to relate efficient encoding strategies to long-lasting memory retrieval.

Another aspect of executive control is related to the suppression of distracting or irrelevant information. In such situations, multiple activations of information place heavy demands on updating and manipulating information in working memory. Proactive interference is the term used to describe instances when earlier information impedes or interferes with the encoding of new information. For example, in memory tests individuals are asked to learn word associates, such as thief–crime, which are then tested by presenting the first word in a pair and asking for the second word, such as theif– ? Proactive interference is assessed by presenting a second learning phase involving the same cues but different responses (e.g., thief–bandit). Patients with PFC damage exhibit particular impairment when they try to recall the second set of responses. That is, they exhibit heightened proactive interference due to the learning of the first set of associates. Evidence for interference is demonstrated by the fact that these patients make many intrusion errors – that is, they use words from the first set during testing of the second set. These problems can be explained by a lack of inhibiting or suppressing the activation of related but now irrelevant information. With respect to executive control, the mitigation of proactive interference requires selecting and updating relevant information. The importance of the PFC in inhibitory control of distracting information has also been demonstrated in fMRI analyses using similar learning paradigms. For example, when individuals are asked to learn word associates such as dog–boxer then later dog–Labrador, they exhibit increased left dlPFC activity when attempting to learn the second related word pair.

Selecting Semantic Memory

A hallmark feature of PFC damage is a problem in searching through memory and selecting specific information. This deficit can be demonstrated in the verbal fluency task, in which individuals are given a minute to retrieve words from a specific semantic category (e.g., 'animals') or retrieve words that begin with a specific letter (e.g., 'A'). This task requires a search through semantic memory – that is, our database of memory for facts and knowledge. Similar to tasks involving the manipulation of working memory or the encoding of new information, efficient retrieval involves the development of strategies to control what words are generated. For example, after trying to come up with just any animal, it would be useful to consider subcategories of animals, such as pets, farm animals, or reptiles. Such strategies are efficient because they facilitate the selection of different words and prevent the report of words already generated. Patients with PFC damage have difficulty controlling their memory searches on this task. They report only 10–12 animal names in a minute, whereas most individuals would be able to retrieve twice as many animal names. Moreover, patients with PFC damage tend to repeat words over and over, as if they have difficult in suppressing the activation of words that were already selected.

The verbal fluency task appears to be a rather easy one, though it is important to appreciate the role of executive control in selecting and updating such information. Not only is it necessary to generate and select information, it is also necessary to monitor responses so that one avoids repeating the same word. Thus after each response all prior responses must be kept in mind so that they will not be repeated. As such, this task has some similarities with the self-ordered pointing task and tasks associated with proactive interference, in which prior information interferes with current performance. In these tasks, it is necessary to monitor and control the activation of previously relevant but currently irrelevant information.

In neuroimaging studies, vlPFC is particularly active during the generation and selection of semantic knowledge. One often-used task to assess retrieval from semantic memory is the verb generation task, in which individuals are presented a noun cue (e.g., 'nail') and asked to generate an associated verb (e.g., 'pound'). As in the verbal fluency task, verb generation requires a search and selection process through one's semantic database. Also, it is necessary to control competing or interfering items during retrieval. In fact, vlPFC activity increases to the extent that there are many competing responses from which to choose. Such regulation of semantic retrieval extends to other linguistic tasks, such as making decisions about the conceptual relatedness between items or interpreting difficult or ambiguous sentences.

The retrieval of general factual knowledge can be assessed by tests of remote pubic events (e.g., "Who shot John Lennon?" [answer: Chapman]). In one study, patients with PFC lesions and control subjects were asked to recall public events or faces of famous people. These tests assessed recent to very remote semantic knowledge. Thus, exposure to these events and people occurred well before the onset of neurological damage. As such, it can be presumed that deficits in performance are due to problems in retrieval rather than encoding. Patients with PFC damage exhibited

recall impairment that was similar across all time periods tested. However, the patients were not impaired on tests of recognition memory, in which they selected the correct answers from several choices. The disproportionate impairment on tests of recall compared to recognition memory suggests that the PFC is involved in controlling the search through semantic memory rather than impairment in the knowledge itself. That is, selecting, updating, and manipulating information in working memory play a significant role in strategic retrieval of information, such as recalling a public event or a famous face. Such retrievals require searching through semantic knowledge, generating relevant information, and disregarding irrelevant information. Recognition memory can be based on a familiarity judgment. That is, on recognition tests it is simply necessary to determine which choice seems most closely related or familiar.

Another example of the distinction between impaired in control of semantic memory and damage to semantic memory itself can be demonstrated in other analyses of recognition versus recall. Consider again the verbal fluency task, in which patients are asked to generate animal names. This task requires recall of information, and patients with PFC damage are impaired. Yet, these patients exhibit intact semantic knowledge of animals when asked to make recognition judgments of animal characteristics. In one study, patients were shown three animal names, such as dog, cow, and pig, and asked to determine which two animals go together. They were told that there were no correct answers and to simply make decisions based on which two go together. The patients exhibited intact semantic memory ability in that they based their decisions on appropriate subcategories of animals, such as associating farm animals (e.g., indicating that cow and pig go together in the example above). In such studies, executive control is minimized by having individuals make simple choice decisions rather than searching, updating, and organizing self-generated retrievals.

Retrieving Autobiographical Memories

Another aspect of memory that requires extensive executive control is the retrieval of autobiographical memory – that is, recollecting an event or experience from the past. The opening exercise of remembering what you had for dinner 3 days ago is an example of retrieving autobiographical memory. Closely related to this form of memory is the notion of source recollection, in which individuals are asked to recollect specific time and place features of an event, such as when an event occurred or who was present during an event. Remembering such information requires executive control in that it is likely that you will have to make a guided analysis to reconstruct an autobiographical memory.

Neuropsychological studies have also demonstrated a prominent role of the PFC in mediating aspects of autobiographical retrieval. Although patients with PFC damage do not exhibit severe amnesia, they are impaired when asked to recollect past experiences. As in the retrieval of semantic knowledge, patients with PFC damage exhibit a particular impairment of recall compared to recognition memory. With respect to source recollection, patients with PFC damage exhibit particular impairment in remembering details of a learning event, such as where and when some information was presented. Such findings are consistent with disorders in memory for the temporal order of events, a common disorder in patients with PFC damage.

In neuroimaging studies, the dlPFC and aPFC are particularly involved in retrieval of autobiographical memory. Studies of autobiographical memory have assessed brain activity during the reminiscence of life experiences, reexperiencing spatial locations in virtual realities, and recognizing photographs taken by oneself or others. Such retrieval tasks have implicated both right and left PFC along with a host of other brain regions, including parietal cortex, medial temporal cortex, and retrospenial cortex. Similarly, studies of source recollection have shown similar brain activations. In such studies, individuals are asked to recollect features of a learning event, such as the color a stimulus, its spatial location, or its temporal order. In studies of source recollection, left PFC appears to be more active than right PFC.

To the extent that the PFC is involved in the control of autobiographical retrieval – rather than in the actual storage of such information – it is necessary to demonstrate that this kind of retrieval places particular demands on executive control. That is, it must be demonstrated that the selecting, maintaining, updating, and organizing of memory is particularly important for retrieval of details about one's past experiences. This issue was addressed with a task that facilitated executive control in patients with PFC damage. Individuals were presented objects and were asked to perform an action with each one (e.g., bounce the ball). This manipulation was presumed to increase sensorimotor activation during encoding and thereby increase the distinctiveness of stimuli. Memory for the temporal order of items was assessed by presenting pairs of objects and asking individuals to determine which of the two was presented more recently. Performance by patients with PFC damage did not differ from performance by control subjects on this test. However, the patients exhibited significant impairment on a control task in which they were

presented the objects but did not manipulate them. This benefit appeared to be rather selective to patients with PFC damage because performance by amnesic patients with temporal lobe lesions was not facilitated by the manipulation condition.

A Board of Executives

How can one interpret the role of the PFC in memory processes? As described here, the PFC monitors and controls information processing thus enabling executive or 'top-down' control. Top-down control refers to the manner in which thoughts and knowledge control lower levels of analysis. In one view of top-down processing, called metacognitive control, basic processes – such as object recognition, speech analysis, and semantic memory access – are defined as 'object-level' processes, which are controlled by 'meta-level' processes. Meta-level processes monitor object-level processes, and – as a result of this monitoring – initiate control (see Figure 1). The PFC fits well in this model as it can serve as the meta-level processor to basic processors. It is presumed that top-down control is implemented by reciprocal neural pathways between PFC and posterior regions. Control occurs as a result of selecting and maintaining task-relevant activity (activation) and by filtering irrelevant activity (inhibition).

As suggested by findings presented above, different PFC regions serve different control functions, such as selecting information from the environment, maintaining information in working memory, accessing semantic knowledge, and retrieval. Thus, rather than one executive controller, there appear to be numerous controllers that monitor and control different aspects of information processing. By analogy, one could view the brain as having a board of executives, with each one assigned to a specific function. Executives interact with each other, though each one is responsible for monitoring and controlling a particular part of a business. It is known that different PFC regions are connected to distinct regions in the posterior cortex. By way of these reciprocal interconnections, PFC has the capability of influencing many object-level processes in posterior cortex.

Figure 1 Metacognitive model of executive control. Monitoring of object-level processes is achieved by bottom-up pathways from posterior cortex to PFC. Meta-level processors in the PFC initiate control by top-down pathways to object-level processes. Control of memory is enabled in this model by the role of the PFC in selecting, maintaining, accessing, and retrieving object-level processes for efficient learning and memory.

Physiological evidence exists for the role of the PFC in metacognitive control of neural activity. Studies using electroencephalogram (EEG) scalp recordings assess neural activity in response to stimulus presentations. Patients with PFC lesions exhibit abnormal increases in neural response in posterior cortex. Thus, as a result of PFC damage, bottom-up neural signals are disinhibited due to a failure to modulate or control posterior cortical activity. In PET and fMRI studies of normal individuals, increased activity in the dlPFC is often correlated with decreased activity in posterior cortical regions, as if PFC can not only select posterior activity, but it can also suppress irrelevant activity.

In summary, the frontal lobes play a significant role in human memory. Rather than being the storehouse of semantic knowledge or autobiographical memories, the PFC monitors and controls processes associated with accessing, encoding, and retrieving memories. PFC initiates and channels information so that it can be held in working memory and efficiently manipulated or updated. PFC facilitates encoding and organization during learning, and access and recall during retrieval. Without it, thoughts are disorganized, and memories are poorly learned and retrieved. Executive control, top-down processing, and metacognitive control are terms used to describe how PFC monitors and controls information processing. In the service of memory processes, PFC is critical for efficient access to and retrieving from our storehouse of knowledge, as well as adding new knowledge to it. It is as critical for memory as an efficient librarian is for a library.

Huntington's Disease

J F Gusella and M E MacDonald, Massachusetts General Hospital, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

In 1872, George Huntington, a Long Island physician, drew on his own experience and that of his father and grandfather to provide a graphic description of the neurodegenerative genetic disease that now bears his name. Originally known as 'Huntington's chorea,' this autosomal disorder is inherited in a completely dominant fashion and has a prevalence of about 1 in 10 000. Huntington's disease (HD) is characterized by progressive involuntary choreiform (dancelike) movements, psychologic disturbance, cognitive decline, and a distinctive neuropathology. The onset of symptoms can occur at any time in life but most commonly begins during the fourth to fifth decade (mean ~38 to 40 years). In a small percentage of cases, termed juvenile onset HD and usually inherited paternally, the first symptoms occur before age 15. In typical adult-onset HD, the initial signs of motor disturbance are slight, such as awkwardness of gait, clumsiness, facial twitching, or subtle involuntary movements of the fingers. Progression of the disorder makes the involuntary movements more frequent and exaggerated, impairing and eventually climinating normal day-to-day activity by interfering with the ability to walk, stand, write, speak, and swallow. In some cases, particularly those of juvenile onset, extreme rigidity is seen rather than chorea. Emotional and behavioral changes often accompany or precede the onset of movement disorder and similarly can have a profound impact on ability to function and on interaction with family members. Impulsive, erratic behavior, impaired memory, poor concentration, and moodiness can all be early signs of HD. In particular, chronic depression occasionally precedes motor symptoms by several years. The distinctive symptoms of HD are caused by the loss of neurons that is most prominent in the striatum but is seen also in the globus pallidus and more diffusely in the cortex. Medium spiny neurons appear to be the first target of the genetic defect, and their loss follows a characteristic gradient proceeding along posteroanterior, dorsoventral, and mediolateral axes of the striatum. There is no effective treatment for preventing the onset or delaying the progression of HD. After a course of 10 to 20 years that leads to severe emaciation and complete incapacitation, the afflicted individual usually succumbs to heart disease, choking, or pneumonia secondary to aspiration.

In 1983, the Huntington's disease gene (*HD*) was mapped to chromosome 4 by tracking the segregation of polymorphic DNA markers in families with the disorder. This landmark study was the first successful application of this nascent technology, and it set off a torrent of similar investigations that has led to the mapping of dozens of other human disease genes. It also acted as the foundation for a decade-long quest to isolate and characterize the genetic defect based on its chromosomal location. This location-cloning strategy passed through a number of stages as the technologies available for human genome analysis evolved rapidly. Somatic cell hybrid mapping panels that dissected 4p 16.3 supported the isolation of large numbers of restriction fragment length polymorphism (RFLP), variable number of tandem repeat (VNTR), and simple sequence repeat (SSR) markers. These were used to create detailed genetic linkage maps and to anchor the construction of physical maps and overlapping clone sets. A progressive refinement of the location for the HD defect was provided by recombination analysis in disease pedigrees and by linkage disequilibrium between the disorder and individual markers. Ultimately, through a novel strategy employing haplotypes of multiallele markers, a small region shared by one-third of disease chromosomes with a common ancestral mutation was identified. Detailed inspection of candidate genes merged with continued search for informative polymorphisms to reveal a polymorphic CAG trinucleotide repeat in the 5′ end of a long, novel gene (*ITI5*), which was given the locus name *HD*. The recognition that this CAG repeat is expanded and unstable on HD chromosomes signaled that the marathon search for the defect was over and a new quest for understanding of mode of action had begun.

On normal chromosomes, the *HD* gene's CAG repeat varies from 6 to 34 trinucleotide units and is inherited in a Mendelian fashion. On HD chromosomes, the repeat is expanded, with 35 to more than 100 units, and is unstable, changing in length in most meiotic transmissions. Usually, the repeat increases or decreases in length by only a few units, but occasionally the increase are larger, sometimes more than doubling the number of CAGs. These larger jumps occur preferentially in male gametogenesis. About 50% of the variability in disease severity is explained by the inherited CAG repeat, the length of which is inversely correlated with age at onset of motor and psychiatric symptoms and age at death. The remaining variability is not accounted for by somatic variation in CAG repeat length, which is extremely limited in magnitude and may be due to modifying genes,

environmental factors, or stochastic processes. The inverse correlation of repeat length and age at onset, combined with the occurrence of occasional large repeat length increases in male transmissions, explains the bias for paternal inheritance of juvenile onset disease.

All cases of HD share the same mechanism of disease, expansion of the CAG segment, although haplotype analysis indicates that there have been multiple independent origins of this HD defect. New mutations to HD have been identified as cases in which expansion of a CAG repeat occurs into the HD size range in a family with no history of the disorder. In such families, the allele subject to expansion typically possesses a repeat length intermediate between the normal and HD size ranges. In some cases, CAG alleles in the intermediate range of 34 to 39 units may be nonpenetrant, with the carrier not displaying HD symptoms in a normal lifespan, again presumably due to modifying genes that moderate the effects of the expanded CAG allele.

The genetic linkage study that mapped *HD* to chromosome 4 introduced the potential for presymptomatic diagnosis of 'at risk' individuals. The linkage test was necessarily cumbersome, expensive, and of limited applicability, because it required the participation of several affected and unaffected family members. However, its advent prompted a cautious, careful assessment of the difficulties inherent in delivering potentially disastrous genetic information many years before any sign of disease in an untreatable disorder with a strong psychiatric component. This experience led to formal guidelines for presymptomatic testing that should be applicable to other late-onset disorders and that are now being applied in HD with increased frequency, because the discovery of the genetic defect has produced a direct test to replace the linkage assay. Assay of CAG repeat length by polymerase chain reaction amplification represents a less costly, more accurate alternative that is applicable to any at risk individual. It can also be used to confirm HD in cases difficult to diagnose or in individuals with no family history.

The question in HD of how the expanded CAG repeat triggers the characteristic pattern of neuronal death remains open. The CAG repeat is located in the 5′ end of the coding sequence of a ~348 kDa protein of unknown function that has been named *huntingtin*. The HD mutation does not simply eliminate the normal function of huntingtin, because individuals with one copy of the gene inactivated by deletion or translocation do not display HD-like symptoms. Indeed, the effect of the expanded CAG stretch must be dominant to explain the similar clinical picture of HD heterozygotes and HD homozygotes. Huntingtin is expressed in the cytoplasm of a wide variety of cells in both the nervous system and peripheral tissues, in contrast to the specific pattern of cell death in HD. The expanded CAG stretch of the disease allele does not eliminate huntingtin expression but alters its structure by extending a stretch of polyglutamine near the N-terminus of the protein. The absence of any obvious effects on the pattern of expression of huntingtin early in the disease suggests that the defect probably acts via this polyglutamine segment as a gain-of-function mutation by conferring a new property on huntingtin that is peculiarly detrimental to striatal neurons. Several other neurodegenerative disorders with different patterns of neuronal loss, including spinobulbar muscular atrophy, spinocerebellar ataxias 1, 2, 3, 6, 7, and 17, and dentatorubropallidoluysian atrophy, have all been found to be caused by expanded, translated CAG trinucleotide repeats. Thus, all of these disorders and HD may share a common mechanism of neuronal toxicity, in which the susceptibility of particular neuronal populations is determined by the context in which the lengthened polyglutamine segment is presented.

Investigations of HD and the other polyglutamine disorders have led to a number of criteria for the mechanism that triggers the pathogenic pathway leading to disease onset: (1) a threshold polyglutamine length below which the disease does not occur in a normal lifespan, (2) progressive severity with increasing polyglutamine length, (3) dominance over the normal copy of the gene present in most heterozygous HD patients, (4) relatively greater sensitivity to increasing polyglutamine length than to the increased disease protein concentration produced from two disease alleles in homozygotes, and (5) specificity of neuronal loss that is influenced by the nature (structure, function, or localization) of the protein containing the polyglutamine tract. These criteria have provided a means for judging potential mechanisms and have led to the notion that the deleterious property of the polyglutamine tract may involve an altered conformation of huntingtin's N-terminal region. This alteration is demonstrated most easily by the capacity of an expanded polyglutamine tract, in the context of a small N-terminal huntingtin fragment, to promote aggregation and conversion to an amyloid structure. Expression of truncated mutant huntingtin also leads to aggregates *in vivo*. For example, the first HD mouse model involved the expression of such an N-terminal fragment of mutant huntingtin producing large intranuclear aggregates in neurons and other cells. Similar aggregated material has been detected in affected brain postmortem, leading to the suggestion that aggregate toxicity might be the

cause of pathogenesis. However, the overexpression of mutant N-terminal fragments of huntingtin are not universally toxic to cells. Moreover, expression of full-length mutant huntingtin does not lead directly to aggregate formation, which occurs only after activation of proteolytic enzymes such as caspases, calpain, and others leads to huntingtin cleavage.

While aggregate formation is a clear phenomenon late in disease pathogenesis, the question remains as to how the cascade of pathogenesis is first triggered by the expanded polyglutamine tract. Generation of mouse models that express mutant huntingtin at physiologic levels suggest that the deleterious conformational property has its first physiologic consequences due to the polyglutamine tract in huntingtin when it is still full length, many months before the appearance of truncated fragments or aggregates. The nature of the effects of mutant huntingtin early in pathogenesis remain the subject of intensive investigation, with early results suggesting that altered intracellular signaling and energy metabolism indicate subtle neuronal dysfunction that progresses only much later to neuronal loss. The full-length mutant huntingtin mouse models also suggest that the late onset of HD results from a pathogenic pathway that begins early in life and progresses in a time-dependent and polyglutamine length-dependent manner, rather than beginning in midlife shortly before the onset of symptoms.

The application of recombinant DNA techniques during the past 20 years has moved our understanding of HD from descriptive knowledge of the clinical and pathologic features of the disorder to identification of the molecular trigger for neuronal cell loss. It has also acted as a model for applying similar approaches in other disorders. Investigations of HD are now targeted at delineating the pathway that leads from the expression of the CAG repeat to the eventual death of specific neurons. As each step is identified, it may present an opportunity to develop a rational treatment that effectively derails initiation of the disorder or halts the currently inescapable progression of pathologic changes that bring about the patient's decline and demise. Consequently, altered properties of mutant huntingtin and the alterations that these cause in biochemical, cellular, and animal models are all being used as assays to screen chemical libraries for small compounds worthy of testing in clinical trials as potentially effective drugs to prevent the onset or delay the progression of HD.

Huntington's Disease

Huntington's disease (HD) is characterized by progressive motor dysfunction, cognitive decline, and psychiatric disturbances. The mutation causing the disease is an unstable expansion in the number of CAG repeats in exon 1 of the gene that encodes huntingtin (Figure 1). Whereas the normal number of CAG repeats varies from 6 to 35, repeat lengths of 36–41 lead to an increased risk for the disease, and greater lengths cause HD with full penetrance. Although there is a direct correlation between repeat length and age of onset, with juvenile forms being usually caused by repeat lengths of over 60, there is considerable variation in age at onset for the same number of CAG repeats in the mid-range of the expansions.

Neurodegeneration in HD

Neuronal degeneration is the pathological signature of HD. Progressive striatal and cortical atrophy can be detected by brain imaging *in vivo* and is striking at autopsy (Figure 2). The most clearly affected neuronal population is the medium-sized spiny GABAergic efferent neurons of the striatum, which comprise 95% of neurons in this region. Neuronal loss in the striatum proceeds in a medial to lateral gradient that led to the classification of the disease progression into four stages or grades. In contrast to efferent neurons, striatal interneurons are relatively spared, although whether this extends to all classes of interneurons remains a matter of debate. Although pathology is mostly restricted to the striatum and cortex at early stages, other brain areas such as the globus pallidus, hippocampus, thalamus, and cerebellum may be affected by grades 3 and 4. The involvement of the hippocampus and the cerebellum is particularly noticeable in cases of juvenile HD. Thus, an important point about neurodegeneration in HD is that although striatal efferent neurons are clearly more vulnerable than other neuronal types, this 'selective vulnerability' is not absolute, and greater CAG repeat burden seems to lead to the involvement of a wider range of neurons.

Ultrastructural studies in postmortem human brains, although notoriously difficult, revealed a loss of dendrites, dendritic spines, and synaptic connections in surviving neurons, with indentations of the nuclear membrane, disorganization of the nucleolus, and depletion of the ribosomes of the rough endoplasmic reticulum. Increased spine density and curved, elongated dendrites have also been observed, suggesting proliferative changes in spared neurons. These observations indicate that even surviving neurons are affected by the disease process, and these morphological changes may be related to neuronal dysfunction which occurs in humans long before evidence for neuronal degeneration. Similarly, decreases in neurotransmitter peptides in the axons of striatal efferent neurons have been detected in the few cases of presymptomatic carriers examined at autopsy. Finally, recent imaging studies revealed that alterations in white matter tracts could precede neuronal loss, as assessed by brain atrophy. It is striking, however, that surviving neurons even in advanced grades have high levels of the corresponding mRNA and that degenerating neurons appear to be intermingled with spared ones.

Neuropathological studies in humans have not fully resolved the mechanisms of neuronal cell death occurring. It has been suggested that apoptosis is the primary mechanism of cell death in HD. Evidence, however, remains inconclusive. Indeed, although there is no doubt that DNA nick labeling techniques revealed DNA damage in HD tissue, examination of these DNA fragments by gel electrophoresis did not reveal the characteristic apoptosis profile. This is not incompatible with the histological data as TUNEL or other DNA damage stains are by no means specific for apoptotic cell death. Nevertheless, a number of factors may hinder the detection of apoptotic cell death in postmortem brain, such as postmortem delay, the transient nature of apoptosis, or a low quantity of DNA fragments being present in tissue. Morphological changes are the most reliable method of detecting apoptosis, but they are difficult to assess in postmortem human tissue. Interestingly, caspase and calpain family members are increased in HD tissue. However, the extensive and early astrocytosis observed in HD brains argues against an apoptotic mechanism.

In conclusion, neurodegeneration is a critical aspect of HD but its mechanism remains uncertain. It affects primarily but not exclusively the striatum, and proceeds according to a well-characterized gradient

Figure 1 Cartoon of the gene encoding human huntingtin. In the normal population, the CAG repeats in exon 1 range from 6 to 35. CAG repeat lengths of 42 and above cause HD while repeat lengths between 36 and 41 increase the risk of the disease.

Figure 2 Representation of degeneration in a human HD brain (left) compared with a normal brain (right). Representations are of coronal sections at the level of frontal lobe. Karger AG, Basel.

in this region, where it mostly affects efferent neurons. Neuronal loss can be followed during the patient's life by assessing regional atrophy with structural brain imaging techniques but a period of neuronal dysfunction is likely to precede cell death, which appears to be stochastic even in the most affected regions. These observations point to the importance of understanding the early mechanisms of neuronal dysfunction caused by the HD mutation, rather than cell death, in order to identify most effective therapeutic targets.

Neurodegeneration in *In Vitro* Models of HD

Since the identification of the HD-causing mutation in 1993, much effort has been devoted to reproducing HD in cellular and animal models. Expression of mutated huntingtin in yeast and mammalian cells leads to neurodegeneration under certain experimental conditions. In general, neurodegeneration is promoted by smaller fragments of mutated huntingtin compared to the full-length protein, suggesting that protein cleavage is an essential step in the pathophysiology of the disease. *In vitro* studies have revealed an association between cell death and the interaction of mutated huntingtin with transcriptional coactivators and transcriptional dysregulation. They also challenged the idea that neurodegeneration is directly linked to the formation of insoluble aggregates of mutated huntingtin. Indeed, aggregates can be neuroprotective despite frequent correlative evidence that neurodegeneration parallels the formation of aggregates. Several *in vitro* studies have suggested that mutated huntingtin can induce cell death by triggering apoptotic mechanisms, with evidence of DNA fragmentation, caspase activity, and cytochrome *c* release. However, the relevance of these mechanisms to the disease situation remains unclear, due to the usually high levels of mutant protein in cell lines.

Neurodegeneration in *In Vivo* Models of HD

The first example of neurodegeneration in an animal model of HD was obtained in *Drosophila*. Expression of mutated huntingtin (exons 1–3 and part of 4) under the eye-specific expression construct pGMR led to progressive degeneration of ommatidia with reduced age of onset of degeneration and increased nuclear accumulation with increased polyglutamine length. Similarly, neurodegeneration was observed in *Caenorhabditis elegans*. These models were instrumental in demonstrating the ability of the chaperones to prevent HD-induced neurodegeneration. They also played a key role in furthering our understanding of mutation-induced mechanisms of neurodegeneration (see below).

Paradoxically, neurodegeneration has proved to be challenging to demonstrate in genetic mammalian

models of HD. Prior to the identification of the HD mutation, neurodegeneration was created in the rodent or monkey striatum by local or peripheral injections of the neurotoxins quinolinic acid or 3-nitropropionic acid. The relevance of these models to HD was inferred from the similarity of their effects to the pattern of neuronal death observed in HD, with preferential loss of efferent neurons and relative sparing of interneurons. These models pointed to the potential role of excitotoxicity for inducing neurodegeneration in HD, an idea that remains timely (see below). Since the discovery of the HD-causing mutation, genetic mammalian models are a more direct route to understand HD pathophysiology, and many different mouse and even rat models have been created.

The first published transgenic mouse model of HD, the R6 line generated by the laboratory of Gillian Bates, remains the best characterized. The R6/2 line expresses exon 1 of the HD gene with approximately 145 CAG repeats. These mice have severe motor anomalies, cognitive decline, weight loss, and seizures; they die around 4 months of age. Levels of mRNA and protein for neuronal molecules present in striatal medium-sized spiny neurons are decreased in a 4-week-old mice, but evidence of neurodegeneration is only obtained late in disease development (Figure 3). This observation indicates that, similar to humans, neurological symptoms precede neurodegeneration in mice, indicating a protracted period of neuronal dysfunction before cell death occurs. Similar observations were made in a number of other mouse models of HD, including both transgenics, and mice with extended CAG repeats inserted in their own HD gene (knock-in mice). Most of these mice show brain atrophy at least at late stages of the disease, and some present evidence of 'dark cells' that are interpreted as degenerating neurons. Few models, however, show a decrease in the number of neurons in the striatum when examined with stereological methods.

Contrary to expectation, work in mice did not unequivocally clarify the mechanism of cell death induced by the HD mutation. In R6/2 mice, 'dark' neurons were found in the striatum and had dense nuclear condensation but no evidence of apoptotic bodies. The absence of DNA fragmentation with either TUNEL staining or *in situ* nick translation does not support an apoptotic mechanism, but some authors did report DNA fragmentation at the very late stages of disease. Also arguing against an apoptotic mechanism, the levels of proteins involved in apoptotic pathways were not changed in R6/2 mice, although increases in these proteins were reported in another R6 line, R6/1, which also showed 'dark' neurons. Increases in apoptotic proteins, TUNEL staining, and apoptotic profiles were reported in another full-length transgenic line, which is no longer in existence. It should be noted that these differences among transgenic models parallel the severity of the phenotype, with the mice that exhibit a more prolonged life and milder phenotype showing more evidence for apoptosis than mice with a more severe course of disease. A recent study proposed that mutated huntingtin causes neurodegeneration through a novel mechanism of cell death related to reduction in Pol II-dependent transcription. The cell death was prolonged, morphologically unlike apoptosis, necrosis or autophagy, and modulated by isoforms of yes-associated protein (YAP), and these isoforms reduced degeneration in an HD *Drosophila* model.

Although most knock-in and transgenic models show little cell loss, viral vectors encoding long

CAG repeats induce apoptotic cell death *in vivo* when introduced into the striatum. This may be due to the very high expression levels of the abnormal polyglutamine tract in this model.

Pathophysiological Mechanisms of Neurodegeneration in HD

As indicated earlier, the precise mechanism of cell death in HD remains unclear. However, much information has accumulated in the last 13 years on the various ways mutated huntingin alters cellular function. Evidence that the lack of huntingtin is embryonic lethal and that mutated huntingtin can rescue this phenotype suggests that the mutation causes an abnormal gain of function. What is not excluded, however, is that the detrimental effects of this gain of function are compounded by a loss of function of the normal protein, in particular its role in stimulating the production of brain-derived neurotrophic factor (BDNF), an essential growth factor for striatal medium-sized spiny neurons.

A compelling abnormal property of mutated huntingtin is its ability to form insoluble aggregates both in the cytoplasm and in the nucleus. These aggregates are usually detected with antibodies against the N-terminal portion of the protein (which contains the polyglutamine expansion), but they can also contain full-length huntingtin. Aggregates, which range in size from microaggregates to large nuclear inclusions, were described in human brain and later found to contain huntingtin. After their detection in the R6/2 line, they were described in all animal models of HD (Figure 4), as well as in many cellular models. Normal huntingtin does not form aggregates, although it can be recruited into aggregates of mutated protein. Aggregates are present in all diseases of CAG repeat expansion and can be formed by long polyglutamine repeats, either isolated or inserted in a nonrelevant gene.

Despite their obvious association with pathology, aggregates may not be pathological themselves. *In vitro* studies have shown that they do not always cause cell death or they can even be neuroprotective. A lack of causal relationship between aggregates and neuronal dysfunction has been demonstrated in several mouse models where a careful analysis has shown that behavioral deficits precede detectable aggregates, and in a recent description, mice expressing exon 1 and 2 of mutant huntingtin show widespread aggregate development, but no atrophy or motor impairments. Even in postmortem human brains, aggregate location does not correlate with neurodegeneration. Finally, several compounds have beneficial effects in models of HD without causing a parallel decrease in aggregates.

Figure 4 Photomicrograph of aggregated huntingtin in striatal neurons in knock-in (CAG 140) mouse brain at 13 months of age (Zhu and Chesselet, unpublished). Mutant huntingtin forms nuclear inclusions (arrowhead) and neuropil aggregates (arrows) in striatal neurons. Immunohistochemistry with polyclonal EM48 (Gift from Dr. X.-J. Li, Emory University). Scale bar = 20 μm.

Although huntingtin aggregates do not appear to directly cause neurodegeneration, they could contribute to pathology in different ways. Aggregated huntingtin may interfere with axonal transport, block proteasomal degradation of other proteins, and sequester proteins that are important for cell functioning. Indeed, transcriptional dysregulation appears to be a critical pathophysiological mechanism in HD and histone deacetylase inhibitors, which reverse this deficit, have beneficial effects in cellular and animal models. Interactions with transcription coactivators, however, may depend on huntingtin misfolding and/or truncation and do not always parallel aggregate formation.

The form of huntingtin that initiates the aggregation process (or is pathological in itself) is not fully identified. As indicated earlier, truncated huntingtin is more toxic than the full-length protein, suggesting that protein cleavage is important. Critical proteases that have come to light include several caspases and calpains. Indeed, recent data show that preventing cleavage of mutant huntingtin at the caspase 6 cleavage site (as opposed to the caspase 3 site) protects transgenic mice from neurodegeneration and motor impairments.

Whatever the pathophysiological mechanisms leading to neurodegeneration in HD, a main question that remains is the relative selective vulnerability of certain cell types despite the widespread expression of huntingtin. Recent studies in mice with restricted expression of the mutated protein suggest that the

process may be initiated not in the striatum but in cortical interneurons, which in turn affect corticostriatal projections and ultimately result in the death of striatal neurons. A role for glutamatergic cortical inputs in HD was suspected since the experiments with quinolinic acid mentioned earlier. For example, cellular pathology caused by mutant huntingtin in presynaptic corticostriatal terminals might result in an increased release of glutamate. Alternatively, impaired clearance of glutamate from the synaptic cleft might increase glutamatergic neurotransmission. In both cases, striatal excitotoxicity could occur. Intracerebral microdialysis has shown that depolarizing concentrations of potassium chloride increase the extracellular concentrations of glutamate substantially more in HD mutant than in control mice, and, in particular, the glial glutamate transporter is downregulated before any evidence of neurodegeneration. This indicates that there is an impairment in glutamate transport and glutamate–glutamine cycling, and suggests that a defect in astrocytic glutamate uptake could contribute to the phenotype.

One of the first indications of electrophysiological changes in the corticostriatal pathway was the observation that the stimulus intensity necessary to evoke an excitatory postsynaptic potential (EPSP) in medium-sized spiny neurons was significantly increased in symptomatic HD transgenic mice. Another observation was that synaptic responses in transgenic mice displayed slower rise and incomplete decay of the EPSP. This phenomenon was hypothesized to indicate a larger contribution of a slower kinetic current, such as the one mediated by activation of *N*-methyl-D-aspartate (NMDA) receptors. This idea is supported by the occurrence of enhanced NMDA receptor-mediated responses. In addition to alterations in evoked synaptic responses, both transient and progressive changes in spontaneous synaptic currents occur. Spontaneous excitatory postsynaptic currents show a progressive reduction in frequency that becomes more evident as the HD phenotype becomes more severe. This effect was interpreted as a progressive disconnection between the striatum and its cortical inputs. There is also a transient expression of complex, large amplitude synaptic currents that coincide temporally with the onset of the behavioral phenotype. These large currents probably reflect dysregulation of glutamate release and/or an increase in cortical synchronization.

Changes in the corticostriatal pathway and glutamate receptors alone are probably insufficient to produce neurodegeneration. However, numerous membrane properties of striatal medium-sized spiny neurons are also altered. One of the earliest and most consistent alterations in the basic membrane properties is an increase in input resistance. This increase probably reflects loss of conductive membrane channels due to morphological changes such as reduced membrane area, possibly as a consequence of the loss of spines. Consistent with this observation, cell capacitance is significantly reduced in symptomatic animals. The increase in membrane input resistance could also be due to alterations in the number and/or properties of K^+ channels. As a consequence, many medium-sized spiny neurons have a depolarized resting membrane potential and are less able to repolarize. These alterations are particularly relevant because membrane depolarization can remove the Mg^{2+} block of the NMDA receptor, causing neurons to become more depolarized when glutamatergic inputs are activated. These neurons will stay in a depolarized state for longer periods of time, thus predisposing them to excitotoxicity. Other voltage-gated conductances may also be affected as alterations in firing patterns occur. For example, there is a reduction in high voltage-activated Ca^{2+} conductances in symptomatic HD mice but an increase in these currents in presymptomatic mice. Taken together, the complex set of alterations in voltage-gated conductances of medium-sized spiny neurons will produce dysfunctional cells that have altered responses to inputs. Early increases in Ca^{2+} conductances will predispose cells to become more easily depolarized while subsequent decreases might be protective. Early increases in input resistance will decrease electrotonic decay of conductances allowing peripheral inputs to depolarize over longer distances while specific changes in K^+ channel function can also predispose neurons to remain depolarized and more excitable. In particular, decreased inward rectification could amplify excitatory inputs. These alterations emphasize that striatal medium-sized spiny neurons are dysfunctional and may be primed to be affected by abnormal cortical inputs. Thus, selective vulnerability in HD may result from a combination of changes in intrinsic properties of neurons and extrinsic inputs.

Conclusion

Thirteen years after the identification of the mutation that causes HD, much has been learned about the disease but the exact mechanisms leading to neurodegeneration remain unclear. Although cell loss remains a hallmark of advanced HD, extensive evidence that neuronal dysfunction precedes cell death has shifted emphasis from preventing neurodegeneration to maintaining neuronal health. Even apoptotic mechanisms may contribute to pathology by cleaving the mutant protein into more toxic forms rather than

leading directly to cell death. Current data point to a number of avenues for therapeutic development that are being actively pursued. Some successes have been obtained in animal models but the challenge remains to develop compounds that are safe enough for long-term use and target the most critical mechanisms rather than peripheral or secondary effects of the mutation.

Hyperacuity

Acuity

Acuity as a term in a sensory system is traditionally used to describe the limit of the capacity to resolve two stimuli as separate. In vision it has long been of interest in connection with distinguishing between single and binary stars. The notion has full underpinning from studies in physics, anatomy, and physiology.

Microscopy of the retina reveals that individual receptors are packed in the fovea in a tight hexagonal mosaic. Each acts as a discrete unit, indivisible, with a unique position label within its matrix, called local sign. Although they can be singled out nowadays in ophthalmoscopic view, under ordinary visual conditions receptors are not stimulated just one at a time because the eye's optics cannot generate an image sufficiently compact. Even an ideal optical system cannot recreate a point or infinitely narrow slit; these become diffraction patterns, whose diameter is at a minimum of the order of λ/a in angular measure (radians), where λ is the wavelength of light and a the aperture of the pupil, both in the same units. When inevitable aberrations are factored in, the narrowest possible light spread on the retina of a light point or star covers at least a dozen receptors (see Figure 1).

When two such objects are placed close together in object space (unless both arise from the same laser source), light in their images will intermingle indistinguishably. For them to be resolved, their joint light distribution needs to have a detectable dip that enables the segregation into two components (Figure 1). In practice, this is the case when the objects are separated by about half the width of the distribution. This distance is called the Rayleigh limit after the nineteenth-century British physicist who first used this approach to analyze the fine structure of lines in spectroscopes. Moreover, because of compartmentalization of light processing in receptors, the three salient features of the distribution (viz., the two peaks and the intervening trough) have to be captured each by a separate receptor. Finally, the light intensity incident on these receptors has to be such that their output to the next neural stage is distinguishably different. For large fields, signal summation yields signal-to-noise ratios good enough to enable intensity differences of 1% or less to be detected, but when it comes to adjoining individual receptors it requires a difference of approximately 20%, and this is just about the peak/trough ratio of an optical image at the Rayleigh limit.

In the human eye, there is a satisfactory match between this Rayleigh limit, the spacing of the retinal receptor elements, and the experimentally determined resolution limit of good human observers in sharp focus. This, then, is the widely accepted teaching of visual acuity: three separate lines of enquiry – optics, anatomy and psychophysics – converge in a single limit, which is about 1 arcmin of visual angle (2 mm at a viewing distance of 6 m or 20 ft). Optometric acuity charts using letters with a 2 mm stroke width to be seen at 20 ft embody this standard (20/20).

The anatomical projection from the retina preserves and conveys to the brain the responses from individual foveal cones separately, even in the presence of abundant neural interconnectivity in the retina and later stages of the visual stream. The large number of neurons in the primary visual cortex, in relation to the number of incoming optic nerve fibers, would seem to ensure that no information loss is incurred in this juncture, although difficulties of recording have so far prevented the demonstration of a cortical spatial grain matching that of the retina.

Better Than Acuity

The solidity of the teaching of visual acuity, which has served so well as a clinical tool and as a showcase example of how behavior ultimately must obey the limits set by physics and anatomy, deflected attention from findings, just as valid and venerable, that appear to be at variance on their face. Soon after Weber enunciated his rule about the constancy of the ratio between the detectable difference and the intensity of a sensory stimulus, $\Delta I/I = \text{constant}$, experiments were performed to document it for an observer's judgment of the distance between two points in visual space. In general, no disagreement was found, but a careful analysis of the situation for very short separations revealed that the detectable difference in separation has values lower than the resolution limit. This, together with the observation that a movement was detectable when an object was shifted through a distance smaller than the separation needed to tell the endpoints as separate when they were shown simultaneously, at first was regarded as throwing doubt on the idea of a discrete receptor mosaic in the retina. But by the end of the nineteenth century, retinal histology and careful measurements of the precision with which two abutting lines could be aligned had sharpened the issue. This vernier procedure, which

Figure 1 Schematic diagram illustrating the factors operating when two stars can just be detected as separate in the human fovea. Each of the two sources gives rise to a light distribution that spreads over several foveal cones (solid curves). Optical quality of the eye, grain of the retinal mosaic, and the sensitivity to light differences in the visual system all have converged to a limit at a critical separation, where the two peaks and the intervening trough in the summed distribution (dashed curve) each covers a single receptor and the peak/trough light ratio is just detectable. This is the basis of the eye's resolving power to which the term acuity is applied.

had had practical utility for centuries, was measured by Wülfing in 1892 to have a thresholds in the human fovea to be of the order of 10 arcsec, at least one-third of the diameter of a foveal cone and of the half width of the eye's diffraction image. This observation prompted Hering to formulate the concept that, whereas each cone had its own unique and indivisible local sign (as needed for visual acuity), a more precise spatial value could be arrived at by averaging the local signs of all the cones along the image of a line.

Hering's notion appeared to constitute a compelling bridge between two important research directions: on the one side, strong psychophysical findings based in the traditional views of retinal image width and in cone local sign and spacing, and on the other, averaging, an acceptable kind of neural processing. A challenge by Ludvigh in 1953, who claimed that alignment can be just as good when points were substituted for lines, was laid aside because his experiment was performed on only one observer with methods that were questioned at the time. Moreover, his 2-arcsec thresholds are almost impossibly low, even by present standards.

Because of the very small distances and laborious experimental procedures, new investigations had to await the advent of computer-driven visual displays and research apparatus. With these, it quickly became apparent not only that the earlier suggestions of visual spatial thresholds below the resolution limits were well founded but also that Hering's proposition had to be dropped. Alignment thresholds with point targets can be just as good and sometimes even better than with lines, and many other spatial visual thresholds have values smaller than the elements of the retinal mosaic and are of a kind for which averaging of signals along image contours cannot be invoked as a plausible explanation.

Clearly, room had to be made for a class of sensory discriminations in which the performance limit is not set by the element size of the receptor grain. The task requires more sophisticated neural processing than reliance on the detection of a differentiable signal in the middle one of three adjoining individual receptors. The word visual acuity had been preempted for over 100 years by its identification with a concept centered on the eye's resolving power, diffraction limit, dimensions of the elements of the receptor mosaic, and letter eye charts based on form discrimination and two-line resolution. Thus a new word, hyperacuity, was coined, implying that ordinary acuity is being transcended. Superresolution (in German, *Überauflösungsvermögen*) had already been used in radar in an entirely different connection, and, in any case, it still has the connotation of detecting separability.

The nomenclature helps to emphasize that two fundamentally different tasks are involved. In one task, ordinary acuity such as tested in the Snellen Letter Chart, one is dealing with the ability to detect feature components as separate, requiring differentiable retinal image components such as separable peaks and troughs. In the other, the task is to identify the location of a feature, the exact nature of whose retinal image is not at issue. Acuity and hyperacuity are now used as the terms applied to the limits, respectively, of resolution and localization (**Figure 2**). Although the resolution limit must perforce conform, at a minimum, with the diffraction equations, no laws of physics are disobeyed when the location of an object is specified to a much smaller value. The detection of a single photon from a point object will, to be sure, have location uncertainty given by the diffraction pattern (an expression of the uncertainty principle). But if stability is retained between source and receiver, the accumulation of enough photon events will enable the identification of the source location with arbitrary precision.

If the optical stimulation and the subsequent processing were entirely punctate (i.e., if all information were directed to, accepted by, and subsequently handled entirely in discrete units without overlap), the tiling of the visual space by these units would indeed constitute the inescapable lower bound of spatial differentiation. The information flow from each

Figure 2 Acuity (bottom row) and hyperacuity (top rows). The relative location of two light sources (top rows) can be detected when the shift is much smaller than the one required to resolve them as separate (bottom row). Adapted from Whitaker D and Buckingham T (1987) Theory and evidence for a clinical hyperacuity test. *Ophthalmic and Physiological Optics* 7: 431–435.

Figure 3 Discrimination thresholds in the hyperacuity range: (a) detection of the misalignment in the direction orthogonal to the line joining two features (typical example: vernier acuity); (b) discrimination of the separation of two or more features (typical example: bisection); (c) form discrimination (typical example: detection of curvature). Thresholds are generally robust to the nature of the features but critically depend on distance factors.

receptor would be independent of that from the others. But this is far from the case. As is apparent in Figure 1, the spread of light from a point source covers to varying degrees many receptors. There is considerable convergence and overlap of signals within the retina, so that the impulses carried by the optic nerve from individual ganglion cells, although their number in the fovea exceeds that of receptors, is a composite of the light from a wider spatial region and the output of many receptors. Subtle processing can then tease out location parameters enabling exceedingly fine discriminations (Figure 3).

The neural mechanism by which this is achieved still needs detailed elucidation. It has been convincingly demonstrated that responses of single neurons in the cat and primate retina can differentiate between target locations just a hyperacuity distance apart. This provides a necessary, but not sufficient, neural substrate because such response differences can also arise from light intensity differences. For single small sources, it seems clear that there is an apparatus which arrives at the position of the centroid of the retinal light distribution as it emerges after passage through the individual receptors and their retinal connections, probably by way of a population vector. The equivalent concept in statistics is the calculation of the mean of a histogram. Edge location, which is just as good as points', is thought to involve a mechanism of fixing the position of the inflexion points of the light distribution, which mathematically is defined as zero-crossing of their second derivative.

Even though all the physical preconditions have been met and there is the physiological apparatus for it, localizing a single target in isolation is difficult for an observer because eye position is neither maintained with the requisite stability nor can it be read out with sufficient precision. However, if the task is relative localization, then long-term stability is not required. This view of the situation is accentuated by the fact that for good visual alignment and separation acuity, exposure of the whole pattern needs to be simultaneous; onset asynchronies of as little as 20–50 ms of configuration components leads to a reduction of performance (Figure 4).

A critical experiment was the demonstration that the relative localization of two visual targets in the hyperacuity range is robust to movements imposed on them jointly, up to a velocity of several degrees per second. In practice, this means that the distance between two lines or edges, or the degree of their alignment, can be judged with a precision of a small fraction of the diameter of the elements of the retinal

Figure 4 Performance is impaired when there is asynchrony of the presentation of the two components of a vernier alignment task, an indication of the processing mechanism for hyperacuity.

Figure 5 Laterally placed flanks interfere with the ability to detect the misalignment of a vernier configuration. The effect is maximal when the flanks are a few arcminutes distant and are clearly seen as separate, and it persists when the target and flanks are presented to different eyes (dichoptic presentation). This and other contextual effects implicate cortical processing.

mosaic when the whole configuration sweeps across the retina at the rate of 100 receptors in 200 ms. A sophisticated cortical apparatus is clearly at play.

Some information is available to narrow down the parameters of its operation. For one thing, it can operate on target components of a variety of shapes and in directions both along the line joining target components and orthogonal to it (Figure 3). Although it is better for the vertical and horizontal meridians, performance is still commendable in the obliques. This suggests that it is not simply a matter of using the known receptive field properties of neurons in the primary visual cortex.

As distinct from ordinary visual acuity, which needs exposures of more than 100 ms duration for optimal values, hyperacuity can be quite good at very short durations. Further information about the processing apparatus is provided by the fact that hyperacuity thresholds are very susceptible to interference by neighboring stimuli, a phenomenon called masking (Figure 5). It seems that, to arrive at local signs of feature elements, or the difference between their local signs, signals are used that cover a larger spatial territory than the area of the individual targets, something that might be expected if the very precise location value arises from processing of a population of neurons.

Again, as might be inferred from the more central processing that is involved, hyperacuity thresholds can be improved by practice, a phenomenon that goes under the rubric of perceptual learning. Two regimes can be distinguished here. Because the measurement requires some familiarity with the targets and the registration of responses, threshold values improve, often by a factor of two, in the first few sessions or the first few hundred responses in

psychophysical procedures. This fast perceptual learning should be distinguished from true perceptual learning, which takes place over several thousand responses extending over several days and represents long-lasting modification of circuitry in the cortex. This phenomenon can also serve to illuminate the processing apparatus by estimating the transfer of training to neighboring location and to related tasks.

Lest it be thought that even within the category of spatial visual abilities all hyperacuities are similar, it should be pointed out that stereoacuity, the facility to determine location differences in the third dimension, does not share some of its important characteristics with, say, vernier acuity, to which it is closely related. Its distance and temporal summation properties are different, although its amazingly low thresholds, depending on the detection of binocular disparity, are tiny compared with the size of retinal receptors even in the fovea.

General Considerations

Hyperacuity refers to sensory abilities in which the whole organism's performance transcends the grain imposed by the anatomical structure and physiological organization of the sensory apparatus. It has been most closely studied in spatial vision, in which the size of the retinal receptors and the indivisibility of their local sign had been used previously to lay the foundation for a highly successful interpretation of visual acuity, a major functional attribute of clinical and scientific import.

The understanding of neural processing derived from the distinction between visual acuity and hyperacuity are of more general value in the study of neural circuitry. The perception of the orientation of contours in visual space – for example, whether a picture frame is hung accurately – is usually thought to arise at the level of orientation-selective neurons in the primary visual cortex, associated with their discoverers Hubel and Wiesel, and concentrated in cortical columns of shared orientation. For a while, the question about the minimum orientation difference between adjoining cortical columns was asked, with the implication that there was need to seek a tiling of visual space into a set of discrete orientations. The analogy with visual acuity becomes helpful here. Most observer can quickly learn to distinguish between orientations 0.5° apart. Yet the orientation tuning of the cortical cells (i.e., the range of contour orientations to which they will respond) is many degrees, even many tens of degrees, wide. The domain of contour orientation is covered by neural elements with widely overlapping acceptance lobes, and it is patent that the sharply defined orientation of a seen contour must emerge from or, if this concept is preferred, be computed by, a circuit using the output of a range of such elements. Such a notion can then progress effortlessly to the study and understanding of masking phenomena, due to activation by adjoining contours of inhibitory connections, and of contour grouping, due to potentiating influences from collinear or even top-down connections.

For the chromatic rather than spatial attribute of visual perception, the physical basis is the wavelength acceptance of the three visual pigments which overlap widely. The highly refined discrimination of very small chromaticity steps is, in a way, a hyperacuity. We do not see just three basic hues, one for each of the pigment types, but many thousand of shades, responding in a nuanced manner to differential patterns of output from the three classes of cones.

Auditory, Tactile and Other Senses

These considerations and observations in the visual sense have found resonance in other sense modalities. In the tactile sense, Loomis has shown that cutaneous patterns can be distinguished in a hyperacuity range, as in reading Braille, and the underlying peripheral neural mechanism has been explored. Similarly, it has been demonstrated that many auditory responses, when analyzed psychophysically and in the firing pattern of cortical neurons, fit the classification of hyperacuity.

Finally, the concept of discrimination of only a fraction of the size of the elementary unit of a particular dimension has been applied also in the temporal domain, to the discharge pattern of neurons. Refractory periods set an upper limit of a few hundred hertz to the firing frequency of neurons, yet meaningful temporal information has been assigned to epochs of only a very few milliseconds and, in the case of echolocation of bats and jamming avoidance of electric fish, even much less.

Hypocretin/Orexin and MCH and Receptors

A Adamantidis and L de Lecea, Stanford University School of Medicine, Palo Alto, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Discovery

The hypocretins (Hcrts) were discovered as part of a subtractive hybridization study to identify messenger RNAs restricted to discrete nuclei within the rat hypothalamus. Among these was a species, named prepro-hypocretin, whose expression was restricted to a few thousand neurons that were bilaterally distributed within the dorsolateral hypothalamus. The sequence of preprohypocretin suggested that it encoded two putative neuropeptides, named hypocretin-1 (Hcrt1) and Hcrt2, with significant similarity to the incretin peptide family.

A large collaborative study to identify endogenous ligands for orphan G-protein-coupled receptors (GPCRs) discovered the peptides independently. This group referred to the peptides as orexins because they stimulated acute food intake when administered to rats during the daytime. In this article, we refer to the peptides by their first-used name, hypocretins (from the sequence similarities with various members of the incretin family and its hypothalamic localization), but both names have been used extensively in the large literature that has grown up around the peptides.

Melanin-concentrating hormone (MCH) was originally discovered in salmon pituitaries, in which it acts as a circulating hormone and lightens skin in response to the background color change or during stress reaction. MCH acts antagonistically to α- and β-melanocyte-stimulating hormone (MSH) and induces pigment aggregation of melanin granules in skin melanophores *in vitro* and *in vivo*. In fish, MCH is a cyclic neuropeptide of 17 amino acids which is generated along with other peptide (neuropeptide EI (NEI)) by cleavage of a preprohormone. Subsequent to its identification in fish, MCH immunoreactive-like labeling in rat brains led to the identification of this peptide, its gene, and its tissue localization in this species. In vertebrates, MCH-producing neurons are restricted to the lateral hypothalamus (LH) and zona incerta (ZI).

Structure

Both Hcrt and MCH peptides are derivatives of a longer precursor of 130 and 165 residues, respectively, with an apparent signal sequence.

The C-terminal 19 residues of these two putative peptides – Hcrt2 (28 residues; RPGPPGLQG RLQRL-LQANGNHAAGILTM-amide) and Hcrt1 (33 residues; EPLPDCCRQKTCSCRLYELLHGAGNHAAGILTL-amide) – share 13 amino acid identities, suggesting that the peptides have related structures and functions. This region of Hcrt2 contains a seven-amino-acid match with secretin. Hcrt1 contains two intrachain disulfide bonds. Human Hcrt1 is identical to the rodent peptide, whereas human Hcrt2 differs from rodent Hcrt2 at two residues. The nonamidated forms of the peptides are not electrophysiologically active.

The MCH intrachain disulfide bond leads to a cyclic peptide (19 residues; DFDMLRCMLGRVY RPCWQV). Strong sequence similarity has been found with the somatostatin peptide family.

Distribution

Hcrt and MCH neurons are morphologically very similar, multipolar or fusiform in shape, with two to five primary dendrites that are either smooth or sparsely invested with dendritic spines. In rats (3000 neurons) and humans (50 000–80 000 neurons), cells highly positive for Hcrt mRNA and immunoreactivity are located between the rat fornix and the mammillothalamic tracts (Figure 1). In addition to their close localization to the Hcrt neurons, MCH-producing neurons are also found in the ZI. Transcripts and immunostaining for MCH in a small set of neurons of the olfactory tubercules and pontine tegmentum have also been reported.

The projections of Hcrt and MCH cells are widely distributed within the central nervous system (CNS) in accordance with their respective receptors' transcripts distribution. Sparse anatomical and physiological evidence supports the existence of subpopulations of Hcrt or MCH neurons. Based on c-fos profile expression, Harris and colleagues proposed two subpopulations of Hcrt neurons related to arousal and consummatory behaviors. Subpopulations of MCH neurons have been identified with the presence of the cocaine- and amphetamine-regulated transcript (CART) peptide immunoreactivity and neuroanatomical projections.

There are several reports of Hcrt, MCH, and receptors expression in the periphery, including in the enteric nervous system, pancreas, kidney, stomach, and ileum. Hcrt expression has also been detected in the human retina, anterior pituitary, and adrenal gland.

Figure 1 Neuroanatomy of the hypocretin (Hcrt) and melanin-concentrating hormone (MCH) systems. Schematic drawing of a saggital section through the rat brain showing the organization of the MCH and Hcrt systems. Dots indicate the relative location and abundance of MCH (green)- and Hcrt (red)-expressing cell bodies. Arrows point out some of the more prominent terminal fields. *In situ* hybridization of both precursor mRNA (ppMCH and ppHcrt) in mice is shown below in a coronal brain section made at the level of the vertical black line. Receptors and Signaling Cascades

The initial orphan GPCR, Hcrt receptor 1 (Hcrtr1) (also referred to as OX1R), binds Hcrt1 with high affinity, but binds Hcrt2 with 100- to 1000-fold lower affinity. A related GPCR, Hcrtr2 (OX2R), sharing 64% identity with Hcrtr1, was identified by searching database entries with the Hcrtr1 sequence and has a high affinity for both Hcrt2 and Hcrt1. These two receptors are highly conserved (95%) across species. Radioligand-binding studies and Ca^{2+} flux measurements have shown Hcrt1 to have an equal affinity for Hcrtr1 and Hcrtr2, whereas Hcrt2 has ~10-fold greater affinity for Hcrtr2 than Hcrtr1.

The mRNAs that encode the two hypocretin receptors and the receptor proteins themselves, detected by immunohistochemistry, are both enriched in the brain and moderately abundant in the hypothalamus. But they have different distributions within the brain.

The distribution of Hcrt receptors is largely consistent with Hcrt axon innervation patterns. The composite distribution of the two Hcrt receptors strongly resembles the distribution of MCH receptor 1 (MCHR1). In the locus coeruleus (LC), amygdala, and other brain stem noradrenergic groups, MCHR1 mRNA distribution is similar to that of the Hcrtr1. In regions such as the septum, hypothalamus, and much of the brain stem, the distribution of MCHR1 mRNA resembles that of the Hcrtr2.

Interestingly, *in silico* analysis of the human genome sequences revealed a second MCH receptor (MCHR2), which shares 38% identity with MCHR1. However, the MCHR2 is only functional or encoded in the dog, ferret, monkey, and human, whereas it is absent or encoding a nonfunctional truncated protein (pseudogene) in the mouse, hamster, rat, guinea pig, and rabbit. In addition to a different gene structure (five exons instead of the two in MCHR1) MCHR2 expression is restricted to the cortex, hippocampus, amygdala, and hypothalamus in the CNS. The Hcrt and MCH receptors are also widely expressed in the periphery, especially in endocrine tissues, including the pituitary, adrenal gland, testis, gastrointestinal tract, pancreas, and pineal gland.

Both Hcrt1 and Hcrt2 act through a family of guanosine triphosphate (GTP)-binding proteins (G_q) that activate protein kinase C (PKC) and the mobilization of intracellular Ca^{2+}. G_q-activated signaling cascades result in phosphorylation of Ca^{2+} channels, which can increase Ca^{2+} conductance and neuronal excitability.

Probably depending on the tissue considered, the MCHR1 GPCR could be coupled to $G_{i/o}$, G_α, G_s, or G_q via different intracellular cascade including mitogen-activated protein kinase (MAPK) and extracellular signal-regulated kinase ERK(1/2). In contrast, the MCHR2 receptor has been reported to act only through G_q.

Activation of specific intracellular pathways by the MCH may rely on the modification of MCHR1 (or MCHR2) binding properties through interactions with cytosolic or membrane protein. Recently, using a yeast two-hybrid approach, the group of Bachner identified several proteins (MCHR1-interacting zinc-finger protein (MIZIP), periplakin, and neurochondrin), which interact with the C-terminus of the MCHR1 receptor. They may be involved in the regulation of MCHR1 signaling and may play a role in modulating MCH-mediated physiological functions *in vivo*.

Input/Output

Hcrt and MCH neurons in the LH are highly interconnected with a network of glutamatergic, GABAergic, dopaminergic, and cholinergic neurons (Figure 2).

Glutamate, excitatory amino acid transporter (EAAT)3, and the vesicular glutamate transporters VGLUT1 and VGLUT2 are expressed by Hcrt neurons; thus, Hcrt neurons are likely to be glutamatergic. Other proteins detected in Hcrt neurons include dynorphin; $GABA_A$ receptor epsilon subunit; serotonin receptor (5-HT-1A); μ-opioid receptor; pancreatic polypeptide Y4 receptor; adenosine A1 receptor; leptin receptor; signal transducer and activator of transcription (STAT-)3; and the neuronal pentraxin Narp, implicated in clustering of ionotropic glutamate receptors.

In the rat, CART has been show to be coexpressed mainly in the MCH neuron of the rostro-median ZI. Moreover, part of these CART-expressing MCH neurons also express the glutamate decarboxylase enzyme, confirming that part of the MCH neurons are GABAergic. Recently, substance P has been co-localized with few MCH neurons.

Part of the MCH neuronal population expresses several membrane proteins, including neurokinin receptor (NK)3, the receptor to the chemokine stromal cell-derived factor-1α (CXCR4), leptin receptor (Ob-R, undefined subtype), glutamate and GABA receptors, adrenoreceptor (α2), muscarinic and serotoninergic receptors, and HcrtR1 and/or -2. Interestingly, neuropeptide Y (NPY) has been shown to inhibit MCH neurons by pre- and postsynaptic mechanisms, whereas the melanocortin agonist MTII and melanocortin antagonist SHU9119 were without effect.

Biological Actions within the Brain

Experimental administration of MCH and Hcrt peptides to animals stimulates food intake, affects motivation and rewarding behavior and modifies arousal. It is noteworthy that in mammals MCH and Hcrt follow a diurnal pattern of gene expression and probably peptide release. *In vivo* recordings of Hcrt neurons revealed that these cells do not fire tonically but, rather, show bursts of activity at the transitions between sleep and wakefulness and during exploratory or consummatory behavior.

Feeding and Metabolism

Sakurai and colleagues found that intracerebroventricular (ICV) administration of either Hcrt1 or Hcrt2 increased short-term food consumption in rats. Furthermore, rats that had been deprived of food for 48 h showed increased concentrations of Hcrt mRNA and peptides in the hypothalamus. Feeding responses can be elicited by the local administration of Hcrt1 to the paraventricular nucleus, the dorsomedial nucleus, the LH, or the perifornical area. ICV administration of Hcrt2 also increases food intake in sheep and goldfish. Many observations leave little doubt that the Hcrt system influences and is influenced by primary nutritional homeostasis circuits. For instance, Hcrt neurons are sensitive to glucose, leptin, and triglyceride concentrations. Hcrt neurons are contacted by NPY-containing neurons in the arcuate nucleus, and much of the food intake increase elicited by Hcrt1 seems to be mediated by NPY.

Other findings suggest that the Hcrts are not critical players in feeding activities but, rather, play roles in increasing arousal and motivation levels so that feeding can take place. Continuous administration of Hcrt1 for 7 days in rats does not significantly alter daily food intake, body weight, blood glucose, total cholesterol, or free fatty acid levels, suggesting that many of Hcrt's effects may be limited to the short-term immediate stimulation of feeding behavior consequent to the increased wakefulness. If Hcrt has a direct role on food intake, we expect a lean phenotype in Hcrt-deficient mice, as has been described for MCH. Hcrt knockout mice show very modest, if significant, differences in food intake. Hcrt ataxin-3 mice, which are genetically depleted of Hcrt neurons and would be expected to be lean, show obesity and hypolocomotion, and this effect appears to be dependent on diet and genetic background. During fasting, Hcrt1 accumulation in the cerebrospinal fluid (CSF) does not exceed concentrations normal for the waking period. Also, Hcrt ataxin-3 mice, unlike wild-type animals, do not show an increase in locomotor activity after fasting. All these data suggest that some of the food-uptake effect may result from arousal rather than direct feeding pressure.

Among the putative roles of MCH neurons, their involvement in feeding behavior, energy homeostasis, and body weight are by far the best documented. Chronic intracerebral injection increased food intake

Figure 2 Inputs to hypocretin (Hcrt) and melanin-concentrating hormone (MCH) neurons. Schematic showing electrophysiologically demonstrated excitatory (green) and inhibitory (red) inputs on Hcrt and MCH neurons. Note that some transmitters have pre- and postsynaptic mechanisms on glutamatergic and GABAergic interneurons, and therefore they can be excitatory and inhibitory. Hcrt neurons are known to contact and excite MCH cells, and in the reciprocal connection it is likely that MCH project back onto Hcrt neurons. Hcrt1 excites Hcrt neurons via glutamatergic interneurons; direct changes in membrane potential have not been observed.

during the hours following injections without modifying the ingested food amount in 24 h or the body weight. Also, both ppMCH mRNA and MCH peptide increase after fasting, as does the MCHR1 mRNA. Mice overexpressing MCH develop mild obesity and hyperphagia and MCH knockout mice are lean but hyperphagic, probably because of their increased nocturnal locomotor activity and consequent increased metabolic rate. Accordingly, transgenic mice depleted of MCH neurons also develop late-onset leanness. Finally, leptin has been shown to depress MCH gene expression in a series of obese leptin-deficient animal models (ob/ob knockout mouse, fa/fa rat, and yellow agouti mice, in which animals develop overfeeding). At the cellular level, glucose dose-dependently enhances the electrical excitability of MCH neurons by inducing depolarization and increasing membrane resistance, but it has the opposite effect on the electrical activity of Hcrt cells. As a result of this participation in food intake behavior and energy homeostasis, a plethora of anorexigenic MCHR1 antagonists has been developed in recent years.

Motivation and Addiction

Intracranial self-stimulation (ICSS) is a well-characterized paradigm for quantifying brain reward. Infusion of Hcrt1 in the brain ventricles elevates ICSS thresholds, indicating that the peptide decreases brain reward function in a way that is similar to stress.

Hcrt neurons are highly responsive to morphine, and their activation is linked to preferences for cues associated with drug and food reward and also naltrexone-precipitated withdrawal. Moreover, Hcrt reinstates extinguished drug-seeking behavior, an effect blocked by an Hcrt1 antagonist. Hcrt1 infusion into the ventricle or the ventral tegmental area leads to a dose-dependent reinstatement of drug-seeking behavior, and it also increases ICSS threshold. Hcrt-induced reinstatement of cocaine seeking was prevented by the blockade of noradrenergic and corticotropin-releasing hormone systems. Accordingly, Hcrtr1 antagonist blocks footshock-induced reinstatement of previously extinguished cocaine-seeking behavior, leading to the conclusion that Hcrts are a major gate in driving stress-mediated drug-seeking behavior. Hcrt knockout mice exhibit dramatically attenuated morphine-withdrawal symptoms.

However, the response of these neurons is heterogeneous, suggesting that there might be different subpopulations of Hcrt cells. Expression of pepro-Hcrt increases after precipitated withdrawal. Hcrt neurons express the μ-opioid receptor; hence their response may be directly related to morphine and naltrexone. These observations might explain why animals self-administer heroin to the LH. Hcrt neurons have extensive projections to the mesolimbic dopamine and noradrenergic (LC) pathways, regions well studied for their roles in drug addiction. These neurons also project to and inhibit nucleus accumbens neurons, resulting in a negative regulation of the activity of brain reward circuitries.

In contrast, MCH neurons are not activated during acute and chronic morphine treatment or following naltrexone-induced withdrawal. Interestingly, MCH injection in the nucelus accumbens has been shown to induce food intake, whereas an MCHR1 antagonist has the opposite effect. Theses data support the idea that, like Hcrt peptide function, the feeding response relies at least partly on activation of brain reward mechanisms.

Furthermore, MCHR1 knockout mice fail to develop behavioral (locomotor) sensitization to cocaine and do not exhibit any sign of cocaine conditioning during a saline challenge. It is speculated that MCHR1 may contribute to the neurobiological mechanisms of conditioned cocaine-induced psychomotor effects, possibly to these underpinning sensitizations, and to a lesser extent to those subserving acute pharmacological cocaine action.

Arousal

Rodent models Continuous recording of the behavior of Hcrt gene-deleted mice (Hcrt knockout mice) revealed periods of ataxia, which were especially frequent during the dark period. Electroencephalograph (EEG) recordings showed that these episodes were not related to epilepsy, and that the mice suffered from cataplectic attacks and their EEGs showed episodes of direct transition from wakefulness to rapid-eye movement (REM) sleep, the hallmarks of narcolepsy. Similar observations were made in rats in which the Hcrt neurons of the LH were inactivated by saporin targeting, although in this model, cataplexy was not observed. Mice with an inactivated Hcrtr2 gene had a milder narcoleptic phenotype than the Hcrt knockouts; Hcrtr1 knockouts exhibited only a sleep-fragmentation phenotype, whereas double Hcrtr1/Hcrtr2 mutants recapitulated the full Hcrt knockout phenotype, suggesting that signaling through both receptors contributes to normal arousal, although the role of Hcrtr2 is greater than that of Hcrtr1.

Transgenic rats and mice depleted of Hcrt neurons have been generated by expressing a mutant form of ataxin 3 in Hcrt neurons. These animals show a narcolepsy-like phenotype as well as reduced locomotor activity on fasting, strongly suggesting a key role of Hcrt neurons in linking metabolic needs with arousal.

Human narcolepsy Nishino and colleagues studied Hcrt concentrations in the CSF of normal controls

and patients with narcolepsy by radioimmunoassay. In control CSF, Hcrt concentrations were highly clustered, suggesting that tight regulation of the substance is important. However, of nine patients with narcolepsy, only one had a Hcrt concentration within the normal range. One patient had a greatly elevated concentration, and seven patients had no detectable circulating Hcrt. In an expanded study, Hcrt was undetectable in 37 of 42 narcoleptics and in a few cases of Guillain–Barré syndrome. CSF Hcrt was in the normal range for most neurological diseases, but was low, although detectable, in some cases of CNS infections, brain trauma, and brain tumors.

Peyron, Thannikal, and their teams of collaborators found that, in the brains of narcolepsy patients, they could detect few or no Hcrt-producing neurons. Whether the Hcrt neurons are selectively depleted, as is most likely, or only no longer expressing Hcrt is not yet known, although one report showed some indications of gliosis. The codistributed MCH neurons were unaffected. Furthermore, a single patient with a non-human leukocyte antigen (HLA)-linked narcolepsy carries a mutation within the hypocretin gene itself. The mutation results in a dominant negative amino acid substitution in the secretion signal sequence that sequesters both the mutant and heterozygous wild-type Hcrt nonproductively to the smooth endoplasmic reticulum. These findings leave no doubt as to the central role of the Hcrt system in narcolepsy. Because most cases are sporadic, mutations in the Hcrt gene or those for its receptors can account for no more than a small subset of the human narcolepsies. The HLA association, loss of neurons with signs of gliosis, and age of disease onset are consistent with autoimmune destruction of the Hcrt neurons accounting for the majority of narcolepsy, although a non-immune-mediated degenerative process has not been ruled out.

As mentioned previously, the MCH cell population is still intact in narcoleptic patients, and no mutation in the ppMCH or MCHR1/2 genes has been found or linked to arousal pathology. MCHR1 antibody has been found in vitiligo patients, an autoimmune pathology causing skin depigmentation. On the other hand, it has been proposed that MCH neurons act as the counterpart of Hcrt cells. In this way, Verret and collaborators showed in rats that, during a REM sleep rebound induced by specific REM sleep deprivation, a large population of MCH neurons were immunoreactive for the c-FOS protein, a marker of neuronal activity. In addition, after ICV infusion of the peptide in rats, REM sleep and non-REM sleep amounts were increased, leading the authors to propose a hypnogenic role for MCH neurons.

Concluding Remarks

The anatomical and electrophysiological data suggest that Hcrt neurons integrate complex information about circadian, limbic, and metabolic variables. This information is transmitted into a coherent output that excites arousal centers depending on the physiological demand. *In vivo* recordings of Hcrt neurons have revealed that these cells are active in anticipation of wakefulness and during consummatory behaviors but are mostly silent. Together the data gathered thus far indicate that the Hcrts provide an alarm signal and stability to arousal centers. In contrast, MCH neurons, which strongly innervate Hcrt cells and regulate Hcrt activity, appear to be modulated mostly by energy demand. The cross-talk between these two peptidergic neurons in the LH provides a balance system to modulate complex behaviors dependent on metabolic needs.

Introduction

The mammalian hypothalamus is integral to regulatory systems essential for survival of organisms and their species. The influences of this small subdivision of the diencephalon upon physiology and behavior are far-reaching and emerge directly from the unique functional properties of its constituent neurons, its extensive interconnections with other regions of the neuraxis, and structural specializations that permit it to exert regulatory control over peripheral organ systems through the pituitary gland. The goal of this article is to place these essential functions within a structural framework that illustrates how the hypothalamus accomplishes its many and varied responsibilities. Rather than being comprehensive, the discussion focuses upon three aspects of hypothalamic function that are representative of its diverse functional capacity. These include (1) the unique timekeeping capabilities that allow it to impose temporal organization upon behavior and hormone secretion, (2) the means through which it orchestrates reproduction of the species, and (3) the neural systems that are involved in the control of feeding. These discussions are introduced with a short consideration of fundamental organizational principles that enable hypothalamic functions.

Functional Organization of the Hypothalamus

The limits of the hypothalamus are clearly defined by distinctive landmarks on the medial and ventral surfaces of the brain (Figures 1 and 2). These include the optic chiasm, the tuberal eminence and its associated pituitary stalk, and the mammillary bodies. In classical literature these landmarks were used to divide the overlying hypothalamus into chiasmatic, tuberal, and mammillary subdivisions. Although this nomenclature is still commonly used as a reference frame to localize hypothalamic cell groups, contemporary scientific literature has advanced organizational principles that are functionally based. Particularly influential in this regard are studies that have defined hypothalamic phenotype, circuit organization, and patterns of neuronal activation that occur in response to homeostatic challenges. Collectively, this literature suggests that hypothalamic nuclei are organized into three columns that extend through the longitudinal axis of this subdivision of diencephalon (Figure 3). Important to this organizational framework is the recognition that major neural inputs to the hypothalamus project onto these columns. This arrangement is central to hypothalamic organization in that it allows cell groups mediating similar functions to share relevant sensory input. In this regard it is useful to note that the control of motivated behavior is common to a number of hypothalamic functions (e.g., foraging, defensive responses, reproduction) and that, while these functions are localized to different hypothalamic cell groups, they often draw upon the same sensory input. Thus, there is functional utility for the distribution of sensory information among the functionally distinct cell groups that form hypothalamic columns. This is a fundamental tenet upon which contemporary hypotheses of the functional organization of the hypothalamus are based.

The hypothalamus imposes profound influences upon physiology and behavior through classical synaptic mechanisms and through hormonal regulation. The synaptology of neural systems that mediate these effects is complex and often involves synaptic relays that have not been fully defined. For example, although much is known of the identity of hypothalamic cell groups that impose temporal organization upon behavior, the neural circuitry through which this is accomplished is only understood in general terms. Similarly, multiple cell groups participate in the control of the autonomic nervous system through descending projections that often involve brain stem relays that serve as integrative centers. The use of relays to impose regulatory influence upon other systems, which is a characteristic feature of hypothalamic projection systems, serves the important purpose of allowing the hypothalamus to orchestrate integrated control of homeostasis and behavior.

A much broader influence upon peripheral physiology derives from neuroendocrine regulation of the pituitary gland. The pituitary controls peripheral organ systems through the release of hormones into the vascular circulation, and this release is similarly regulated by hormone release from neurons that reside in the hypothalamus (Figure 4). This 'neuroendocrine regulation' is achieved through a dedicated portal vasculature that transports bioactive molecules released from the hypothalamus to the pituitary. The absence of a blood–brain barrier at the contact zone where neural processes of hypothalamic origin terminate upon the fenestrated vasculature is an essential component of this system. The access to the vasculature afforded by these 'circumventricular organs' also

Figure 1 The position of the hypothalamus is illustrated in sagittal (a, b) and ventral (d) exposures of the human brain. The boxed area in panel (a) is shown at higher magnification in panel (b). (c) A schematic illustrating the relationship of the pituitary gland to ventral hypothalamus. This relationship is mapped onto the sagittal exposure of the hypothalamus in panel (b), which also defines the rostral, dorsal, and caudal boundaries of the hypothalamus.

allows circulating molecules to influence the activity of hypothalamic systems. This capacity for 'feedback regulation' is integral to the tightly regulated function of the hypothalamus. Thus, the hypothalamus exerts regulatory influence over disseminated systems, both central and peripheral, and is in turn regulated by the output of those systems.

Hypothalamic Influences upon the Temporal Organization of Behavior

The hypothalamus has long been implicated in the control of rhythmic aspects of behavior and hormone secretion. The early evidence in this regard derived from alterations in behavioral state documented in clinical and experimental studies that involved damage to the hypothalamus. Baron Constantin von Economo provided one of the more interesting and historically significant observations through his studies of the neural basis of encephalitis lethargica. The pandemic that gave rise to this disease occurred in the early 1900s and was characterized by high fever, double vision, headache, and lethargy. The most serious cases caused persistent coma, and postmortem analysis of the brains of these individuals by von Economo revealed lesions that involved the posterior hypothalamus. This observation took on added significance in the 1950s with the experimental demonstration that hypothalamic lesions produced either coma or insomnia, depending upon the location of the damage. These findings led Walle Nauta to postulate that the hypothalamus contains 'sleep centers' responsible for the control of the sleep–wake cycle. Contemporary studies have validated the role of the hypothalamus in behavioral state regulation and identified four functionally distinct cell groups that participate in this control.

The neurons of the hypothalamic suprachiasmatic nuclei (SCN) (Figure 3) provide one of the most prominent influences upon behavioral state. This small population of neurons overlying the optic chiasm plays a fundamental role in generating the daily oscillatory pattern of activity and rest. The SCN was initially

Figure 2 Landmarks defining the position of the human hypothalamus in coronal sections through the pituitary (infundibular) stalk are illustrated. The boxed area in panel (a) is illustrated at higher magnification in panels (b). Panel (c) illustrates a section through the same approximate area stained for myelin (blue-black). The rostral limit of the hypothalamus (lamina terminalis) is visible at the rostral extent of the third ventricle (V3). The columns of the fornix are also prominent at the dorsal extent of the diencephalon. This projection pathway is an important source of sensory information essential to the ability of the hypothalamus to orchestrate motivated behaviors. AC, anterior commissure; OT, optic tract; IS infundibular stalk; F, fornix.

implicated in behavioral state regulation on the basis of anatomical studies that demonstrated that it received a direct projection from the retina (subsequently coined the 'retinohypothalamic tract (RHT)') and on the basis of lesion experiments that eliminated the rhythmic aspects of the sleep–wake cycle and hormone secretion. Subsequently it was established that the activity of SCN neurons oscillates over a period approximating 24 h and that this circadian (*circa*, 'about'; *diem*, 'day') rhythm is genetically determined rather than being the emergent property of a network. That is, each SCN neuron is a circadian oscillator and the synchronous activity of the population is achieved through local circuit connections among the constituent neurons. Additionally, the rhythmic activity of the pacemaker is entrained to the environmental cycle of light and dark through the RHT, an observation with functional implications for the treatment of jet lag and some sleep disorders. Interestingly, the retinal ganglion cells that give rise to this projection are functionally distinct from those involved in visual perception and contain light-sensitive opsins. Thus, these retinal neurons represent a component of the visual system dedicated to the temporal organization of behavior rather than to visual perception.

Lesion studies in rodents have proven to be particularly illuminating in establishing the role of the SCN in the sleep–activity rhythm. Following destruction of the SCN, activity and sleep are distributed in small bouts across the 24 h period rather than being consolidated in periods of activity and rest. Importantly, the sum total of these bouts of activity and rest over a 24 h period in animals with complete SCN lesions approximates that observed in animals with an intact SCN. Thus, it is apparent that the SCN imposes temporal organization upon rest and activity rather than generating the behavior. Available evidence supports the conclusion that the temporal influences of the SCN are exerted through relays that wire the pacemaker into a larger polysynaptic circuit of neurons responsible for generating rest and activity. Support for this hypothesis can be found in studies demonstrating that caudal hypothalamic neurons that receive SCN input project to the locus coeruleus, a brain stem nucleus with activity that is correlated with arousal and vigilance. Functional studies indicate that the SCN functions through pathways such as this to promote arousal, which opposes the homeostatic drive for sleep.

The larger circuit of neurons devoted to the control of behavioral state includes other hypothalamic cell groups with activity that is associated with either arousal or somnolence. An interesting set of studies has demonstrated that neurons in the ventrolateral preoptic nuclei (VLPO) become active at the onset of sleep. In addition, it is known that these inhibitory neurons synapse upon caudal hypothalamic cell groups that are known to promote arousal. The latter include histaminergic neurons in the tuberomammillary

Figure 3 The locations of internal structures of the hypothalamus in the rat brain are shown in this figure. The locations of circumventricular organs lacking a blood–brain barrier are shown in red on the midsagittal schematic at the top of the figure. The cytoarchitecture of the hypothalamus and the positions of hypothalamic cell groups discussed in the text are illustrated in Nissl-stained sections in the middle of the figure. These sections illustrate half of the brain, presented in coronal section. The lower figure illustrates a coronal section through the portion of the hypothalamus that is connected to the pituitary gland (not shown); the heavy black outline defines the boundaries of the hypothalamus on either side of the third ventricle. The thin black outline on the left defines the boundaries of hypothalamic columns that are distinguished by cytoarchitecture, phenotype, and connections. These columns (Pi, periventricular; M, medial; L, lateral) extend through the rostrocaudal extent of the hypothalamus and are recipient of topographically organized sensory hippocampal input that is relayed through the septum. nuclei (Figure 3) and hypocretin-containing neurons in the lateral hypothalamic area that project diffusely to the cortical mantle and other subcortical cell groups known to promote arousal (e.g., locus coeruleus). These observations illuminate the neural circuitry underlying the 'sleep centers' advanced by Nauta in the 1950s, and indicate that the rostral and caudal hypothalamic cells groups function cooperatively to alter behavioral state. That is, the consequence of the increasing activity of VLPO neurons at the onset of sleep is to inhibit the hypocretin and histaminergic neurons that are known to produce arousal. While it is important to emphasize that these cell groups function within a larger circuit of neurons outside of the hypothalamus, this literature makes the important point that the hypothalamus is an essential component of this system.

The cooperative interaction of these functionally distinct hypothalamic cell groups, with one another and with the larger system of central nervous system (CNS) neurons that control behavioral state, is apparent in studies of the neural basis for narcolepsy. Narcolepsy is a neurological disorder characterized by excessive daytime sleepiness, abnormal rapid eye

Figure 4 The means through which the hypothalamus imposes regulatory influences over the secretory activity of the pituitary gland is illustrated. The gland is connected to the hypothalamus via a stalk that serves both as a conduit for axons that terminate with a vascular plexus in the anterior caudal portion of the pituitary and as a conduit for long portal vessels that connect a fenestrated vascular plexus in the median eminence with vascular plexus in the anterior pituitary that surrounds hormone-producing cells. Magnocellular neurons provide the only direct neural connection between the hypothalamus and pituitary. The axons of these neurons release vasopressin or oxytocin into the vasculature, to influence the activity of peripheral targets. For example, vasopressin release (antidiuretic hormone) into the circulation acts on the kidneys to reduce fluid excretion. Control over the hormone secretion of cells in the anterior pituitary is achieved through the portal plexus connecting the median eminence to this portion of the gland. Bioactive molecules released into the portal vasculature either stimulate or inhibit the secretion of hormones from cells in the anterior lobe. The role of luteinizing hormone (LH) releasing hormone (LHRH) in the production of gametes provides a good example of this neuroendocrine regulation (FSH, follicle-stimulating hormone; see the text for a more detailed description).

movement (REM), or 'dream' sleep, and cataplexy. Narcoleptic patients typically exhibit multiple unregulated episodes of REM sleep during the waking hours but do not sleep more than normal individuals. In this respect their behavior is similar to experimental animals with complete SCN lesions. However, available evidence, derived from experimental studies of animal models and postmortem clinical analysis, indicates that the pathology underlying narcolepsy involves hypocretin neurons rather than neurons in the SCN. Cerebrospinal fluid levels of hypocretin are considerably reduced in patients with narcolepsy, and postmortem analysis reveals substantial reductions in the number of hypocretin cells as well as their terminal fields in areas such as the locus coeruleus. These observations are in accord with animal models in which alterations in behavioral state regulation similar to the symptoms of narcolepsy result from interference with hypocretin signaling. Considered collectively, these data demonstrate the importance of hypothalamic neurons to the CNS systems responsible for the control of behavioral state.

Hypothalamic Regulation of Reproductive Function

The hypothalamus contains the neural systems essential for reproduction. These systems exert regulatory control over the production of gametes (gameteogenesis; generation of ova and sperm) as well as the gender-specific motivated behaviors associated with successful mating. Separate populations of hypothalamic neurons, the activity of which must be coordinated for successful fertilization to occur, administer these interdependent components of reproduction. Thus, there is adaptive significance to these functionally distinct cell groups being located in close proximity to one another so that they can efficiently integrate sensory information relevant to reproductive function.

Hypothalamic cell groups responsible for the control of ovulation and spermatogenesis do so through control over the secretory activity of the anterior lobe of the pituitary gland (Figure 4). The pituitary exerts its control over peripheral targets such as the ovaries and testes through the regulated secretion of hormones, and this regulation is controlled by the hypothalamus through the release of bioactive molecules (peptides and neurotransmitters) into the fenestrated portal vasculature. These peptides and neurotransmitters stimulate or inhibit the release of hormones from the pituitary gland and are therefore more commonly known as release factors or inhibiting factors. In the case of gametogenesis, release of luteinizing hormone releasing hormone (LHRH) into the portal vasculature elicits the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary (Figures 4 and 5). In males, these hormones act upon different cells in the testes in support of spermatogenesis. In addition, LH and FSH also stimulate the production of hormones (testosterone and inhibin, respectively) that provide negative feedback control over the release of LH and FSH from the pituitary. In females, FSH stimulates the growth of follicles in the early stages of ovulation and also is integral to the production of the hormone

Figure 5 Illustration of the organization of phenotypically defined rat median eminence neural systems that participate in the control of the pituitary gland. The top diagram is a sagittal schematic (OVLT, organum vasculosum of lamina terminalis; P, pineal; ME, median eminence; PG, pituitary gland; AP, area postrema). (a) Vasopressin-immunoreactive cells and processes in a sagittal section through the hypothalamus, corresponding to the boxed area in the sagittal schematic diagram. Vasopressin-containing magnocellular neurons in the upper left of the micrograph are the source of axons that pass through the intermediate layer of the median eminence into the pituitary stalk, to gain access to the posterior lobe of the pituitary. (b) The position of these axons in the intermediate zone of the median eminence is shown in the coronal plane. (c, d) The dense distribution of hypothalamic parvicellular axons in the external 'contact' zone of the median eminence is seen. These axons release their peptides into the fenestrated portal vessels for transport to the anterior pituitary. The distributions of somatostatin (growth hormone inhibiting factor)-containing axons (c) and of LHRH-containing axons (d) are illustrated. Note that these axons are differentially distributed within the external zone. Schematic diagram adapted from Swanson LW (1998) *Brain Maps: Structure of the Rat brain*, 2nd edn. New York: Elsevier.

estradiol. Levels of estradiol are further enhanced through LH-stimulated secretion of testosterone in the ovary, which is converted to estradiol. Elevated levels of estradiol in the circulation increase the sensitivity of the pituitary to LHRH (positive feedback), which ultimately produces a surge in LH release from the pituitary that results in ovulation. This simplified overview of neuroendocrine regulation of gameteogenesis illustrates the general mechanisms through which the hypothalamus exerts hormonal control over peripheral target organs, emphasizing the preeminent role of hypothalamus in the control of body homeostasis.

Successful reproduction depends upon coordinating reproductive physiology (gametogenesis) with the behaviors that give rise to copulation and fertilization. Reproductive behaviors are under the control of hypothalamic cell groups that exhibit sexual

dimorphism in their structure and connectivity. The experimental demonstration that the cytoarchitecture and synaptology of hypothalamic nuclei involved in reproductive behaviors can be modified through manipulation of sex steroid exposure during different developmental stages was very influential in establishing this dimorphism. Thus, a defining feature of these cell groups is the fact that they express receptors that render them responsive to circulating sex steroids. It is also important to note that brain circuitry involved in reproductive behavior includes cell groups outside of the hypothalamus that are steroid sensitive and project upon the hypothalamus. Chief among the hypothalamic nuclei implicated in the control of sexual behavior are the medial preoptic nuclei and the ventromedial hypothalamic nuclei. These cell groups reside within the same hypothalamic columns that control gameteogenesis, providing a neural substrate for sharing sensory information necessary for coordination of reproductive physiology and behavior. Among the neural pathways that exert a prominent influence upon the activity of these nuclei are relayed projections from the hippocampal formation conveying multimodal sensory information, components of the olfactory system carrying pheromonal information, and projections from the amygdala. While details concerning the organization and dimorphism of this circuitry continue to evolve, it is clear that the hypothalamus is an essential regulatory component of this system.

Hypothalamic Regulation of Feeding

The historical literature on the neural control of food intake is remarkably similar to that of the neural control of behavioral state, in that lesion studies were influential in identifying the hypothalamus as an important regulator of energy homeostasis. In this regard, investigations conducted in the 1940s documented substantial increases in food intake and obesity following medial hypothalamic lesions, and reductions in food intake and weight loss after lesions of the lateral hypothalamus. Contemporary literature has confirmed a preeminent role for the hypothalamus in the control of feeding and has identified a complex circuitry that is responsive to sensory measures of nutrient state. In fact, many of the recent advances in understanding of this system can be traced to the identification of circulating molecules linked to nutritional status that act upon the nervous system to produce compensatory alterations in food intake. This circuitry consists of neurons with opposing influences upon food intake and is a component of a larger regulatory network responsible for reinforcement of behavior. The system is also heavily dependent upon sensory feedback conveying environmental information that supports successful foraging. While the details of how the components of these systems function in a cooperative fashion continue to evolve, much has been learned regarding the identity of hypothalamic systems that participate in this regulation and how they sample the nutritional state of the parent organism.

Given that survival is dependent upon adequate ingestion of nutrients, it is not at all surprising that food and fluid intake is tightly regulated and involves redundant systems. The hypothalamus contains at least four phenotypically distinct populations of neurons that provide regulatory control over nutrient intake through dedicated systems that stimulate or inhibit ingestion of food and fluids. Sensory measures of gastrointestinal function, circulating nutrients, and nutrient stores determine the activation state of components of this system. These sensory measures of nutritional state reach the hypothalamus through neural circuits relayed from the viscera as well as through blood-borne signals. Thus, the access to the vasculature afforded by circumventricular organs in the hypothalamus and brain stem is an essential component of the modulation of hypothalamic feeding circuits.

The arcuate nucleus (**Figure 3**) contains two groups of neurons that are particularly influential in the control of feeding. This became apparent in early studies of rodents in which chemically induced lesions of the arcuate nucleus were shown to produce obesity. The basis for this lesion-induced obesity became apparent in the 1990s following identification of a blood-borne signal, the protein leptin, which acts upon the hypothalamus to modify feeding behavior. It is now firmly established that this protein is secreted into the circulation by white adipose tissue and that levels of leptin provide a relative measure of body fat stores. Circulating leptin acts upon arcuate neurons that express neuropeptide Y (NPY) and agouti-related peptide (AgRP), to stimulate feeding, and inhibits feeding through arcuate neurons that express proopiomelanocortin (POMC) and the cocaine and amphetamine-related transcript (CART). Both of these populations of arcuate neurons exert their influence through projection targets that have not been fully defined, but include neurons in the paraventricular hypothalamic nucleus and neurons in the lateral hypothalamic nucleus. The latter includes neurons that express hypocretin (also known as orexin) and melanin-concentrating hormone (MCH). Both of these cell groups give rise to widespread projection patterns and induce feeding. POMC/CART neurons are thought to exert their inhibitory influence through CNS neurons expressing melanocortin receptors. Investigations of the synaptology of these systems continue to reveal how they function to modify

appetite and feeding and have also raised the possibility that these circuits reorganize in response to changes in metabolic demand. Clearly, much has been learned about the identity of neural systems that control feeding, and this has made it abundantly clear that the hypothalamus is central to this regulation. Identification of these systems has also created many opportunities for exploring how they function in the control of energy balance.

As noted previously, blood-borne leptin plays an important role in modulating the activity of central circuitry controlling food intake. However, leptin is not the only circulating molecule that modulates this circuitry. The gastrointestinal tract is the source of other important signaling molecules that can modulate these circuits either directly, at the level of the hypothalamus, or indirectly, by acting upon brain stem neurons that project to the hypothalamus. All of these molecules exert their influence through circumventricular neurons that are lacking a blood–brain-barrier. Ghrelin, a hormone secreted by the stomach, is one such molecule that increases feeding. Increased circulating levels of ghrelin occur in response to fasting and NPY/AgRP arcuate neurons are among those in the CNS that express ghrelin receptors. Circulating molecules secreted by the viscera also act upon neurons outside of the blood–brain-barrier in the area postrema of the caudal brain stem. These include the hormones glucagon-like peptide-1 (GLP-1) and cholecystokinin (CCK). CCK and GLP-1 activate area postrema neurons, which, in turn, activate neurons in the adjacent nucleus of the solitary tract (NTS) that project to the hypothalamus. Interestingly, GLP-1 is also produced in a subset of the NTS neurons that project to the hypothalamus. The central effects of CCK and GLP-1 function to reduce food intake. Experimental evidence has also implicated GLP-1 signaling in conditioned taste avoidance as well as nausea. These observations are in accord with the important role of the NTS in taste.

The aforementioned hypothalamic cell groups interact with a larger constellation of neural circuits that contribute to the maintenance of adequate nutritional state. These include systems involved in control of behavioral state, feeding behavior (foraging), and the rewarding aspects of nutrient intake. Again, the way in which these systems interact is only understood in general terms, and defining these organizational principles remains an important goal.

Summary and Conclusions

There can be little debate over the assertion that the hypothalamus exerts essential regulatory control over the maintenance of homeostasis and behavioral state. This control is dependent upon structural specializations that enable circulating molecules to influence the activity of hypothalamic neurons. Structural specializations that permit the hypothalamus to exert neuroendocrine control over pituitary secretion are also fundamental to the regulatory capacity of this small but influential subdivision of the diencephalon. The use of relays to distribute information from hypothalamic cell groups is also a fundamental feature of the means through which hypothalamic neurons exert their control. This use of relays suggests that the output of functionally defined hypothalamic neurons is often integrated with that of other systems. This hypothesis is parsimonious, with the conclusion that physiology and behaviors orchestrated by the hypothalamus are relevant to a variety of systems and must be integrated with their outputs. Collectively, these observations reveal the hypothalamus to be a dynamic regulatory unit with integrated activity that is essential to an organism's abilities to function productively in their environment.

Hypothalamic–Pituitary–Adrenal (HPA) Axis

N Pecoraro and M F Dallman, University of California at San Francisco, San Francisco, CA, USA

© 2009 Published by Elsevier Ltd.

The Hypothalamic–Pituitary–Adrenal Axis

The hypothalamic–pituitary–adrenal (HPA) axis keys reactive and predictive physiological and mental adjustments to environmental demand. Understanding HPA axis complexity requires viewing it as the final common output pathway of diverse inputs – including circadian pattern generators; systems sensitive to metabolic, immune, and nociceptive stimuli; cognitive assessments; and intrahypothalamic networks coordinating neuroendocrine and other motor outflows – and recognizing HPA axis feedback and feed-forward effects on brain.

Motor neurons in the paraventricular nucleus (PVN) of the hypothalamus project to the median eminence and release corticotropin-releasing factor (CRF) into a portal vasculature perfusing anterior pituitary glandular corticotropes that release adrenocorticotropic hormone (ACTH) into the systemic circulation. Systemic ACTH stimulates adrenal cortex to release glucocorticoids (GCs) into the systemic circulation to act on peripheral tissues and organs, and brain regions involved in cognition, memory, motivation, and primary motor outflows, including HPA axis outflow (see Figure 1).

The Paraventricular Nucleus of the Hypothalamus

The PVN integrates diverse inputs and contains distinctive neuroendocrine, behavioral, and autonomic cell groups. Neurosecretory regions include parvicellular neurons containing CRF/arginine vasopressin (AVP) peptides that are co-packaged in vesicles, and co-secreted. Synthesis is drive dependent. CRF neurons arc through perifornical hypothalamus exhibiting boutons of passage, sweeping ventrally to the median eminence and anterior pituitary. Magnocellular cells containing oxytocin (OXY) or AVP reside laterally to CRF neurons and project to the neural lobe of the pituitary.

Nonneuroendocrine, descending PVN divisions control behavioral and autonomic outflows. Preautonomic cell groups include the 'dorsal cap,' and a group at the caudolateral tip of the PVN extending caudally into zona incerta. A related retrochiasmatic group participates in a putative pattern generation network (described later).

Pituitary Corticotropes

Proopiomelanocortin (POMC) molecule cleavage products (e.g., ACTH) are stored in intracellular corticotrope vesicles and secreted in response to CRF associating with CRF receptor (CRF_1R) via G-protein/cyclic adenosine monophosphate (c-AMP)-mediated mechanisms. AVP weakly stimulates ACTH secretion, via a receptor ($AVP_{1b}R$)-mediated mechanism, but synergizes with CRF, dramatically increasing ACTH secretion. Corticotropes contain glucocorticoid receptors (GRs) and corticosteroid-binding globulin (CBG, or transcortin). GR activation inhibits synthesis and secretion of ACTH through a negative glucocorticoid recognition element (GRE) on POMC DNA, but CBG binds GCs with high affinity. Tonic inhibitory action of GCs on corticotropes requires high concentrations, exceeding CBG capacity, making ACTH secretion vulnerable to high doses of exogenous GCs – for example, during treatment of autoimmune diseases, in patients with pituitary ACTH-secreting adenomas (Cushing's disease), or when warding off transplant rejection.

Adrenal Zona Fasciculata

Unlike pituitary corticotropes that store hormone, the adrenal cortex zones synthesize and secrete hormones on ACTH demand. ACTH acts via c-AMP at the rate-limiting step of cholesterol transfer from cytosolic esters to mitochondria, where steroid synthesis begins. ACTH increases other enzymes involved in GC synthesis. All three zones of cortex (zona glomerulosa, zona fasciculata, and, in primates, zona reticularis) respond to ACTH, acting through melanocortin receptors (MCR2). In primates, injection of ACTH stimulates secretion, within minutes, of aldosterone (glomerulosa), cortisol (fasciculata), and dehydroepiandrosterone sulfate (reticularis). The major steroids (cortisol in primates; corticosterone in most rodents) synthesized in the zona fasciculata are most important in HPA function. ACTH transiently stimulates zona glomerulosa cells, but the major role of ACTH is sustained stimulation of GCs.

CBG (Transcortin) Binding

CBG (transcortin), synthesized and secreted from liver, is a high-affinity binding protein for GCs, and, under basal conditions, when adrenal secretion is low, 95–99% of the secreted steroid is bound to CBG without diffusion to targets. CBG–GC is in reversible equilibrium with free GCs. CBG is a saturable reservoir and buffer for biologically active GCs, so that considerable free steroid is able to diffuse to target

Figure 1 The hypothalamic–pituitary–adrenal axis. The paraventricular nucleus of the hypothalamus is depicted as a bilateral coronal section in an oblique view, with the third ventricle (V3) indicating the midline. The periventricular region (light gray) contains parvicellular neuroendocrine cells with corticotropin-releasing factor (CRF)/arginine vasopressin-containing neurons in the dorsolateral region; these project to the median eminence (ME) and portal vasculature to the anterior pituitary. The magnocellular neuronal division (medium gray) consists of cells containing oxytocin (OXY) and vasopressin (VP); these project directly to the posterior, neural lobe of the pituitary. The descending division of the paraventricular nucleus (black) contains preautonomic neurons projecting to lower brain stem areas and spinal cord, involved in both behavioral and autonomic regulation. CRF/arginine vasopressin release into the portal vasculature of the anterior pituitary stimulates glandular corticotropes to release adrenocorticotropin hormone (ACTH) into the systemic circulation. Plasma ACTH then stimulates adrenocortical cells to synthesize and release glucocorticoids (GC) into the systemic circulation to act on peripheral tissues and organs and the central nervous system.

cells during stress. Because GCs inhibit hepatic CBG synthesis, when tonic GC concentrations are low, circulating CBG is high, and vice versa. Because total GC concentrations in plasma (bound and free) are usually measured, it is worth knowing the history of GC secretion when collecting acute samples.

Inhibition of the HPA Axis by GC

GC elevations inhibit activity in PVN CRF cells and pituitary corticotropes, first by membrane GR-mediated effects, then by GC-associated GR protein–protein interactions altering gene expression. Feedback ensures controlled neuroendocrine responses. Longer term feedback effects exist in both brain and pituitary (e.g., through GC–GR complexes interacting with a negative GRE on POMC in corticotropes). Chronic GCs diminish HPA axis outflow in proportion to exposure, provided no concurrent stress exists, making the axis unresponsive to new stressors and thus explaining the requirement for extra GC coverage during major surgery in patients on chronic GC therapy.

There is rapid inhibitory GC feedback on both CRF and ACTH secretion. In hypothalamic slices *in vitro*, GC alters neuronal activity, including CRF-synthesizing cells, within 3 min. GC stimulates endocannabinoid secretion, presynaptically inhibiting glutamate-stimulated miniature excitatory postsynaptic currents (mEPSCs) via endocannabinoid EC-1 receptors. GCs infused directly into neurons does not have this effect, and rapid GCs actions on pituitary ACTH secretion *in vitro* are not inhibited by exposure to protein or by RNA synthesis inhibitors, suggesting membrane-mediated feedback.

Distinctive HPA Axis Drivers

Distinctive brain systems impinge on HPA axis outflow (Figure 2), including two circadian oscillators, brain stem, vasculature, and circumventricular organ systemic networks, cortico-striato-pallidal-brain stem cognitive networks, and an intrahypothalamic network that coordinates other drivers and motor outflows.

Periodic/Circadian Drivers of the HPA Axis

In constant darkness, HPA axis activation exhibits free-running circadian oscillations that entrain to light/dark cycles. Plasma GC concentrations increase at least tenfold around the time of waking. GCs decline throughout the activity phase, propped up by postprandial elevations, before they reach a nadir in early rest. When restricted feeding time is pitted against a light/dark cycle, a separate food-entrainable oscillator allows the HPA axis to separately track mealtimes.

The suprachiasmatic nuclei The suprachiasmatic nuclei (SCN) sit atop the optic chiasm in the basal hypothalamus, serving as the master, light-entrainable oscillator (LEO) in mammals. The SCN receive transduced light stimuli via the retinohypothalamic tract to entrain endogenous pacemaker activities of the SCN, driving the HPA axis and PVN preautonomic neurons. The SCN indirectly influence PVN CRF neurons via substantial projections to the subparaventricular zone, which targets the PVN with γ-aminobutyric acid (GABA)ergic inputs. The SCN project substantially to the dorsomedial hypothalamus (DMH), which

Figure 2 This highly simplified schematic depicts the major drivers of the hypothalamic–pituitary–adrenal (HPA) axis, with some indications of their coordinated drive on the autonomic outflow (pre-ANS; preautonomic nervous system) and on one another. For simplicity, paraventricular nucleus (PVN) corticotropin-releasing factor (CRF)-containing cells are grouped with the heavily interconnected subparaventricular zone (sPVZ). The suprachiasmatic nuclei, the master, light-entrainable oscillator (LEO), provide endogenous circadian drive to the PVN CRF-containing cells, the PVN preautonomics, and the hypothalamic visceromotor pattern generator (HVPG). During restricted, scheduled feedings a second food-entrainable oscillator swings into motion to track mealtimes and entrain food anticipatory rhythms. Systemic threats to homeostasis are signaled through circumventricular organs (CVO), the melanocortin system (NPY/POMC; neuropeptide Y/proopiomelanocortin) in the arcuate nucleus of the hypothalamus, and the ascending medullary catecholaminergic neurons (NPY and NE/E; norepinephrine, epinephrine). Psychogenic drive on the HPA axis is represented by multilayered cortico-striato-pallido-hypothalamic networks, in this case showing the visceromotor medial prefrontal cortex (mPFC) projecting to the lateral septum (LS) and amygdala (AMYG), bed nucleus of the stria terminalis (BNST), and HVPG. Virtually all HPA axis drivers also project to the 'neuroendocrine' paraventricular thalamus (PVT). Also indicated is the food-entrainable oscillator (FEO).

also projects to neuroendocrine and preautonomic divisions. AVP levels in and around the PVN vary on a circadian basis, being highest at rest, during basal HPA axis activity. AVP infusions into brain cause rapid decreases in GCs, and lesser decreases in ACTH. The DMH is the most effective infusion site, providing substantial GABAergic inhibitory fibers to CRF neurons. Disinhibition of HPA axis activity by AVP antagonists occurs only in SCN-intact animals, suggesting origination in the SCN. The SCN project to the medial preoptic (MPO) hypothalamus, an area involved in coordination of outflows. Outside hypothalamus, SCN project to the paraventricular thalamus (PVT), a PVN target involved in both acute and chronic stress networks. Pseudorabies virus injected into the adrenals is retrogradely propagated transsynaptically via the intermediolateral column to PVN preautonomics in the SCN. This pathway controls adrenocortical sensitivity to ACTH. In early darkness, bright light inhibits GCs, but not ACTH, secretion, only in SCN-intact rats. Thus, the SCN influence HPA axis output through CRF motor neurons and by neuronally controlling adrenal sensitivity to ACTH.

The food-entrainable oscillator A separate, food-entrainable circadian oscillator (FEO) prevails during restricted, scheduled feedings to entrain activity, feeding, drinking, body temperature, HPA axis activity, and peripheral metabolic rhythms. Entrainment is robust in SCN-lesioned animals that would otherwise be arrhythmic under a light/dark cycle when freely feeding. In intact rats, SCN-coupled rhythms free-run (e.g., 26 h period) in constant dark, but animals can independently and simultaneously anticipate scheduled meals at different periods (e.g., every 24 h) from the free-running rhythms. It takes 3–13 days for anticipatory activity to precede scheduled meals, but evidence suggests that single meals can reset food-entrainable rhythms. Food anticipatory activity continues for several days in the absence of the food zeitgeber prior to damping.

The anatomical locus of the FEO is unknown. Ascending medullary norepinephrine/neuropeptide Y (NE/NPY) systems entrained by scheduled meals drive prefeeding peaks in HPA axis output and feeding rhythms. Lesions of the ascending ventral noradrenergic bundle (VNAB) prevent food-anticipatory

elevations in plasma GCs. Striatal and pallidal inputs to the HPA axis – namely, the central nucleus of the amygdala (CeA) and bed nucleus of the stria terminalis (BNST) – exhibit phase shifts in clock gene expression during food entrainment. Like SCN, both the CeA and the BNST oval (BNST-ov) nucleus exhibit circadian rhythms in the clock gene period2 (per2) that peak at activity onset under *ad libitum* feeding. Restricted feeding forces per2 rhythms in CeA and BNST-ov out of phase relative to SCN. Constant light and free feeding abolish per2 rhythms in all three areas; these are reestablished by restricted feeding, such that peak per2 is in antiphase to feeding. Adrenalectomy (ADX) also abolishes per2 rhythms in limbic regions in a GC-reversible fashion. Lesions of the DMH (or insular cortex) prevent preprandial temperature elevations, and severely damp locomotor activity, pointing to integrated output from the DMH. Both systemic and limbic networks are candidate mediators of HPA axis entrainment by food.

Homeostatic Inflow: Systemically Responsive Networks Driving the HPA Axis

The HPA axis is highly sensitive to energy balance and other systemic threats, such as nociception and immune challenge, which have distinct and shared pathways to the HPA axis.

The arcuate NPY/melanocortin system The melanocortin system (Figure 2) includes cell groups in the arcuate nucleus (ARC) of the hypothalamus and the medullary nucleus of the tractus solitarius (NTS) sensitive to energy balance, and expressing POMC (usually co-expressing cocaine and amphetamine-related transcript (CART)) or neuropeptide Y (co-expressing agouti-related peptide (AgRP) in the ARC). POMC neurons mainly reside in the ARC, projecting primarily to stress-sensitive sites, including the PVN, perifornical lateral hypothalamus, NTS, reticular nuclei (RET), lateral parabrachial nucleus, nucleus accumbens (NACC), lateral septal nucleus, BNST, CeA, and medial amygdala (MeA). Tyrosine hydroxylase (TH)-negative POMC-expressing neurons also originate from the NTS. ARC NPY/AgRP neurons have similar projection patterns (e.g., PVN, DMH, PH, PVT, MPO, lateral septal nucleus). Energy balance signals may be transmitted neurally and through proximal circumventricular organs (CVOs).

ARC POMC. ARC POMC cleaves into α-melanocyte-stimulating hormone (α-MSH), a potent agonist at melanocortin-3 and -4 receptors (MCR3 and MCR4). Intracranial administration of leptin activates POMC neurons, suppresses feeding, and increases autonomic outflow. CRF mediates the inhibitory effects of α-MSH on feeding. Like α-MSH, central administration of CART also inhibits feeding, whereas fasting reduces CART mRNA expression. Three populations of CART neurons contribute innervation to the PVN, including medullary and arcuate POMC neurons and a third unknown source.

NPY neurons. NPY neurons directly innervate PVN CRF neurons. Increases in NPY elevate CRF mRNA expression, ACTH and GC secretion, and food intake, and suppress sympathetic outflow to brown fat. In contrast to α-MSH, AgRP is an antagonist at MCRs. Negative energy balance (e.g., low insulin and leptin) activates NPY neurons, including inhibitory GABAergic fibers to POMC neurons. POMC and NPY neurons are 'dueling rheostats' on energy balance.

GC effects on POMC/NPY. POMC/CART and NPY/AgRP neurons in the ARC express GRs. ADX or inhibition of GC synthesis reduces expression of CART mRNA. Though CART appears anorectic, CART-expressing medullary neurons co-express an epinephrine-synthesizing enzyme, phenylethanolamine-*N*-methyltransferase (PNMT), which is involved in feeding responses to glucoprivation. In addition, CART phosphorylation of cAMP response element-binding protein (CREB) in PVN CRF neurons should have additive effects with α-adrenoreceptor activation of CRF expression. Despite opposite signaling functions of CART and GCs, evidence suggests some positive feedback. GCs also stimulate NPY gene expression, peptide synthesis, receptor activity, and NPY-induced feeding. Here, positive feedback biases the system to correct further energetic disturbances. Clear evidence for functional interplay between GC and melanocortin systems exists, but the details require further elucidation.

Systemic threats: The medullary NE/E/NPY system Stimuli signaling actual threats to homeostasis are categorized as systemic stressors; these include including ether, hemorrhage, glucoprivation, and nociception, and are transduced by various lower brain stem NPY/catecholaminergic cell groups, including the dorsomedial medulla (NTS; A2–C2 cell groups) and ventrolateral medulla (A1–C1 cell groups). Ninety percent of all catecholaminergic innervation ascends to the PVN via the ventral noradrenergic bundle (VNAB). Immunostaining for dopamine β-hydroxylase, a marker for epinephrine (E) and norepinephrine (NE), shows extensive innervation of the PVN. NPY immunostaining shows similar, but more extensive, patterns in the PVN. NPY co-localizes in lower brain stem with PNMT in most adrenergic neurons (C1, C2, C3), but shows less co-localization in noradrenergic A1 neurons, about 60% rostrally and many fewer caudally. Some ascending VNAB fibers arrive at the median eminence rather than at the PVN,

possibly controlling exocytosis. Eergic, NEergic, and NPYergic stimulation of the PVN increases HPA axis outflow and feeding. Disrupting ascending inputs through chemical lesions, inhibiting transmitter synthesis in originating neurons, α-1 or β receptor blockade in PVN, or neutralization of CRF neurons, all disrupt HPA axis responses to systemic threats.
